/* INTRINSICS ARE THE LAST RESORT: they are target-specific,
   they do not adapt to a wider vector unit, and they are
   easy to get subtly wrong. Try, in order:
     1. restructure the loop and the data layout
     2. restrict, alignment, pragmas
     3. intrinsics
     4. hand-written assembly
```

```
   and MEASURE at each step - the auto-vectoriser is
   frequently within 10% of hand-written intrinsics on simple
   kernels, and it improves with every compiler release. */
```

Reading vectorised output

```
; float sum(const float *a, int n)
;     { float s = 0; for (int i=0;i<n;i++) s += a[i];
;       return s; }
; aarch64, -O3 -ffast-math

sum:
        cmp     w1, #0
        b.le    .Lzero
        ...
        movi    v0.4s, #0               ; accumulator, 4 lanes
        movi    v1.4s, #0               ; a SECOND accumulator
.Lvector:
        ldp     q2, q3, [x0], #32       ; load 8 floats
        fadd    v0.4s, v0.4s, v2.4s     ; interleaved, to hide
        fadd    v1.4s, v1.4s, v3.4s     ; FP latency
        subs    x8, x8, #8
        b.ne    .Lvector

        fadd    v0.4s, v0.4s, v1.4s     ; combine accumulators
        faddp   v0.4s, v0.4s, v0.4s     ; horizontal reduce
        faddp   s0, v0.2s               ; ...to one scalar
        ...
.Lscalar:                               ; the epilogue, for
        ldr     s1, [x0], #4            ; the remaining
        fadd    s0, s0, s1              ; elements
        subs    w8, w8, #1
        b.ne    .Lscalar
        ret

/* THE SHAPE TO RECOGNISE:
     1. a guard for small n
     2. possibly a runtime alias check
     3. the VECTOR BODY, often unrolled with several
        accumulators to hide latency (ARM chapter 10)
     4. a HORIZONTAL REDUCTION to combine lanes
     5. a SCALAR EPILOGUE for the remainder

   `q0`, `v0.4s`, `faddp` - the presence of these means it
   vectorised. All-scalar `s0`, `w0` means it did not.

   AND NOTE `-ffast-math` was required for this one, because
   the reduction reorders FP additions.                  */
```

How it shows up

Symptom	Cause
Loop not vectorised, no obvious reason	Ask: `-fopt-info-vec-missed`
"unsafe dependent memory operations"	Possible aliasing — try `restrict`
Two copies of the loop in the assembly	Runtime alias check — `restrict` removes it
Vectorises for `float` but not the reduction	FP associativity — needs explicit consent

Symptom	Cause
Vectorised but no faster	Memory bandwidth bound, not compute bound
Slower after `-O3`	Code growth from unrolling; I-cache pressure
Array-of-structs loop will not vectorise	Strided access — restructure to struct-of-arrays
Cache misses dominate	Loop order — interchange so the innermost stride is 1
Hand-written copy loop no faster than `memcpy`	It became `memcpy`
Results differ with `-ffast-math`	Expected — it permits reassociation (CA ch. 03)
Intrinsics beaten by autovectorisation	Common. Measure before hand-writing

Check yourself

- ✓ Name eight loop transformations and what each buys.
- ✓ Explain why loop rotation happens before other loop passes.
- ✓ Explain why loop interchange is often the largest available win.
- ✓ Explain idiom recognition and its consequence for freestanding builds.
- ✓ Describe NEON's element arrangements and how SVE differs.
- ✓ List seven reasons a loop fails to vectorise, with a fix for each.
- ✓ Use `-fopt-info-vec-missed` on a real loop and act on the output.
- ✓ Explain what `restrict` promises and the cost of lying.
- ✓ Convert an array-of-structures layout to structure-of-arrays and explain why it helps.
- ✓ Recognise the five parts of a vectorised loop in assembly.

Instruction selection and scheduling

The back end's first two jobs: choosing which machine instructions implement the IR, and deciding what order to issue them in so the pipeline stays busy. This is where target knowledge finally enters the compiler.

Instruction selection

```
The IR says WHAT to compute. Instruction selection decides
WHICH instructions do it - and there are usually several
answers.

   IR:      %1 = mul i32 %a, 4
            %2 = add i32 %b, %1

   CANDIDATES on AArch64:

     (a)  lsl  w1, w0, #2          ; a * 4
          add  w2, w3, w1
          -> 2 instructions

     (b)  add  w2, w3, w0, lsl #2  ; ONE instruction:
          -> the shifted-register addressing form

   ARM's instruction set has many such fused forms, so
   selection matters more than on a simpler ISA:

     add  x0, x1, x2, lsl #3       shifted operand
     madd w0, w1, w2, w3           multiply-add
     msub w0, w1, w2, w3           multiply-subtract
     ubfx w0, w1, #4, #8           bitfield extract
     bfi  w0, w1, #4, #8           bitfield insert
     csel w0, w1, w2, eq           conditional select
     csinc, csneg, csinv           select-and-modify
     ldp/stp  x0, x1, [x2]         load/store PAIR
     ldr  w0, [x1, w2, sxtw #2]    scaled, sign-extended
                                   index

   RECOGNISING THESE IS THE JOB. A pattern-matching selector
   covers the IR graph with the cheapest set of patterns that
   tile it.
```

Tree tiling

```
/* The classic formulation: the IR is a tree (or DAG); each
   instruction is a PATTERN with a COST; find the cheapest
   cover.                                                    */

   IR TREE for  a[i] = b + 1 :

              store
             /     \
          add       add
         /   \     /   \
       a    shl   b     1
           /   \
          i     2

   PATTERNS available:
      "add reg, reg"                    cost 1
      "add reg, reg, lsl #n"            cost 1   <- covers 3
                                                    nodes
      "str reg, [reg, reg, lsl #n]"     cost 1   <- covers 5
                                                    nodes!
      "lsl reg, reg, #n"                cost 1

   THE GREEDY COVER using the third pattern:
      add  w1, w2, #1              ; b + 1
      str  w1, [x0, x3, lsl #2]    ; a[i] = ...
   TWO instructions for eight IR nodes.

/* THE ALGORITHMS:
     · maximal munch - greedily take the largest matching
       pattern at each node. Simple, near-optimal in practice.
     · dynamic programming (BURG, iburg) - provably optimal
       tiling for a tree, in linear time
     · DAG-based selection (LLVM's SelectionDAG) - handles
       shared subexpressions
     · GlobalISel (LLVM's newer path) - works on the whole
       function, better for cross-block patterns and faster
       to compile

/* IN LLVM you write patterns in TableGen: */
   def : Pat<(add GPR32:$a, (shl GPR32:$b, imm:$c)),
             (ADDWrs GPR32:$a, GPR32:$b, imm:$c)>;
/* and the build generates the matcher. AArch64's target
   description is roughly 40,000 lines of this - which is a
   measure of how much of a compiler is target knowledge. */
```

Peephole optimisation

```
/* After selection, a sliding window over the instruction
   stream replaces short sequences with better ones.       */

        mov  w0, w0                     ->  (delete)
        add  w0, w0, #0                 ->  (delete)

        str  w0, [x1]                   ->  str w0, [x1]
        ldr  w0, [x1]                       (the load is
                                             redundant)

        mov  w1, #0                     ->  str wzr, [x0]
        str  w1, [x0]                       (use the zero
                                             register)

        cmp  w0, #0                     ->  cbz w0, .L1
        b.eq .L1                            (compare-and-
                                             branch)

        sub  w0, w0, #1                 ->  subs w0, w0, #1
        cmp  w0, #0                         b.ne .L1
        b.ne .L1                            (subs sets the
                                             flags)

        ldr  w0, [x1]                   ->  ldp w0, w1, [x1]
        ldr  w1, [x1, #4]                   (paired load)

/* ARM-SPECIFIC ONES worth recognising in output:
     wzr / xzr        the ZERO REGISTER - reading gives 0,
                      writing discards. `mov w0, wzr` is how
                      you zero a register, and `str wzr, [x0]`
                      stores zero with no register needed.
     cbz / cbnz       compare-with-zero and branch, one
                      instruction
     tbz / tbnz       test a single BIT and branch
     ldp / stp        load/store pair - half the instructions
                      for prologues and epilogues
     ret              a specialised `br x30`                */

/* THE PEEPHOLE PASS IS WHY hand-optimised assembly rarely
   beats the compiler on straight-line code: every one of
   these substitutions is applied automatically and
   exhaustively.                                           */
```

Instruction scheduling

```
The processor is pipelined (CA chapter 11). An instruction
that needs a result not yet available STALLS.

   POORLY SCHEDULED:
      ldr  w0, [x1]        ; 4-cycle load latency
      add  w0, w0, #1      ; STALLS 3 cycles waiting for w0
      ldr  w2, [x3]
      add  w2, w2, #1      ; STALLS again
      -> ~14 cycles

   SCHEDULED:
      ldr  w0, [x1]
      ldr  w2, [x3]        ; issue the second load while the
                           ; first is in flight
      add  w0, w0, #1      ; by now w0 is ready
      add  w2, w2, #1
      -> ~8 cycles

  SAME INSTRUCTIONS, same result, fewer stalls.

  THE SCHEDULER NEEDS A MACHINE MODEL:
     each instruction's LATENCY (when its result is ready)
     each instruction's THROUGHPUT (how often it can issue)
     which FUNCTIONAL UNITS it uses, and how many there are
     the issue WIDTH
     forwarding paths

  LLVM's is in the target's TableGen; you can see it:
     llvm-mca -mcpu=cortex-a72 input.s
  which prints a cycle-by-cycle simulation, the bottleneck
  resource, and the achieved IPC. It is the best tool for
  "why is this loop slower than I expect".
```

```
/* LIST SCHEDULING, the standard algorithm:

   1. build a DEPENDENCE DAG for the basic block
        true dependence   (read-after-write) - real
        anti-dependence   (write-after-read) - removable by
                          renaming
        output dependence (write-after-write) - ditto
        memory dependences, where aliasing is unclear

   2. compute each node's PRIORITY - usually the critical
      path length to the end of the block

   3. repeatedly: from the instructions whose operands are
      ready, issue the highest priority one

   THE TENSION WITH REGISTER ALLOCATION (chapter 09):
   spreading instructions apart to hide latency INCREASES the
   number of simultaneously live values, which increases
   register pressure, which may cause spills that cost more
   than the stalls saved. Compilers schedule before and after
   allocation for this reason, and the pre-allocation
   scheduler is deliberately register-pressure-aware.     */

/* WHY IT MATTERS LESS THAN IT USED TO:
   an out-of-order core (CA chapter 12) reorders instructions
   itself, within its window. So scheduling matters most on:
     · in-order cores - Cortex-A53, A55, most microcontrollers
     · very long dependence chains that exceed the window
     · code where the compiler can see further ahead than the
       hardware can

   ON A CORTEX-A53 (in-order) good scheduling can be worth
   20-30%. On a Cortex-X (aggressively out-of-order) it is
   often under 5%. -mtune= tells the compiler which model to
   use, and it is worth setting correctly even when -march
   must stay generic.                                     */
```

`-MARCH` VERSUS `-MTUNE`

`-march` says which instructions may be *emitted* — get it wrong and you get an illegal instruction on older hardware. `-mtune` says which core to *optimise for* — scheduling, inlining thresholds, alignment. Tuning for the wrong core costs performance; targeting the wrong architecture costs correctness. For a product shipping on one SoC, set both: `-mcpu=cortex-a53` sets them together.

Software pipelining

```
/* Overlap iterations, so the loop body issues work from
   several iterations at once and no stage waits.          */

   NAIVE:  for each i:  load a[i] ; compute ; store b[i]

           |load|      |          |
           |    |compute|         |
           |    |      |store|    |
                             |load|      |
   -> the load latency is exposed every iteration.

   PIPELINED:
           |load i+2 | compute i+1 | store i |
           |load i+3 | compute i+2 | store i+1|
   -> each iteration issues a load for a FUTURE element, a
      compute for the previous one, and a store for the one
      before that. The pipeline is always full.

   REQUIRES a PROLOGUE to fill the pipeline and an EPILOGUE to
   drain it, which is why software-pipelined loops look
   complicated in the assembly.

/* GCC: -fmodulo-sched, and it is not on by default at -O2
   because it increases register pressure and code size.
   LLVM does it for some targets via the MachinePipeliner.

/* YOU CAN DO IT BY HAND, and on an in-order DSP-like core it
   is sometimes worth it: */
        t = a[0];
        for (i = 0; i < n - 1; i++) {
                u = a[i + 1];           /* load for NEXT */
                b[i] = f(t);            /* compute for THIS */
                t = u;
        }
        b[n-1] = f(t);
/* But measure first. On an out-of-order core the hardware
   already does this.                                      */
```

Reading the output

```
; int dot(const int *a, const int *b, int n)
; aarch64 -O2 -mcpu=cortex-a53

dot:
        cmp     w2, #0
        b.le    .Lzero
        mov     x3, #0                  ; i
        mov     w4, #0                  ; sum
.Lloop:
        ldr     w5, [x0, x3, lsl #2]    ; a[i] - SCALED INDEX
        ldr     w6, [x1, x3, lsl #2]    ; b[i]
        add     x3, x3, #1              ; i++  - issued while
                                        ; the loads are in
                                        ; flight
        cmp     x3, x2, sxtw
        madd    w4, w5, w6, w4          ; sum += a[i]*b[i]
                                        ; ONE instruction
        b.lt    .Lloop
        mov     w0, w4
        ret
.Lzero:
        mov     w0, #0
        ret

/* WHAT TO NOTICE:

   `[x0, x3, lsl #2]`   the index scaling is FREE, folded
                        into the addressing mode. No separate
                        multiply or shift.
   `madd`               multiply-accumulate in one
                        instruction - selection recognised the
                        pattern.
   `add x3, x3, #1` placed BETWEEN the loads and their use -
                        the scheduler hiding load latency.
   `sxtw`               sign-extend w2 to 64 bits, folded into
                        the compare.
   `cmp` then `b.lt`    the flags are set once and used once.

   FIVE INSTRUCTIONS in the loop body for a load, a load, a
   multiply, an add, an index update and a branch. That is
   what good selection plus scheduling looks like, and it is
   why hand-writing this in assembly is unlikely to help. */

# --- ANALYSE IT ---
    llvm-mca -mcpu=cortex-a53 -timeline dot.s
    ; cycle-by-cycle, with the bottleneck identified

    perf stat -e cycles,instructions,stalled-cycles-frontend ./prog
    perf annotate                ; per-instruction cost
```

How it shows up

Symptom	Cause
Illegal instruction on target	`-march` allowed something the CPU lacks
Slower than expected on an in-order core	Wrong `-mtune`; the schedule targets a different pipeline
Many separate shifts and adds for an index	The addressing mode was not matched — often an unusual element size

Symptom	Cause
Multiply and add not fused	Rounding rules for FP, or the intermediate value is used elsewhere
Long stalls on loads	Dependence chain the scheduler could not break — or a real cache miss
Loop faster with manual reordering	Register pressure prevented the scheduler from doing it
Assembly full of prologue/epilogue code	Software pipelining or vectorisation — normal
Hand-written assembly no faster	Peephole plus selection already found those patterns
IPC far below the issue width	Run `llvm-mca` — it names the bottleneck resource

Check yourself

- ✓ Explain instruction selection and give three ARM fused forms it must recognise.
- ✓ Tile a small IR tree and count the instructions saved.
- ✓ Name four peephole substitutions and the ARM features they exploit.
- ✓ Explain what the zero register buys.
- ✓ Explain why scheduling matters and what a machine model must contain.
- ✓ Describe list scheduling and its tension with register allocation.
- ✓ Say when scheduling matters most and least, and why.
- ✓ Distinguish `-march` from `-mtune` and the failure each wrong choice causes.
- ✓ Explain software pipelining and why it needs a prologue and epilogue.
- ✓ Read a compiled loop and identify selection and scheduling decisions in it.

Register allocation

The IR has unlimited virtual registers; the machine has 31. Deciding which values live in registers and which get pushed to memory is an NP-complete problem the compiler solves thousands of times a second — and it explains why your variable "does not exist" in the debugger.

The problem

```
AFTER instruction selection:

   %1 = ldr [%a]
   %2 = ldr [%b]
   %3 = add %1, %2
   %4 = ldr [%c]
   %5 = mul %3, %4
   str [%d], %5

Six virtual registers. AArch64 has:

   x0–x7     arguments and results     CALLER-saved
   x8        indirect result location
   x9–x15    temporaries               CALLER-saved
   x16, x17  IP0, IP1 – linker veneers
   x18       PLATFORM register (TLS on some ABIs;
             RESERVED – never use it)
   x19–x28   CALLEE-saved
   x29       frame pointer
   x30       link register
   sp/xzr    stack pointer / zero register

   v0–v31    FP/SIMD; v8–v15's LOW 64 BITS are callee-saved

So roughly 29 usable general-purpose registers – generous
by historical standards, and still not unlimited.

THE JOB: map virtual registers to physical ones, such that
two values that are LIVE AT THE SAME TIME never share a
register. When that is impossible, SPILL one to the stack.
```

Liveness

```
/* A value is LIVE from its definition until its LAST USE. */

        a = 1;          /* a live from here            */
        b = 2;          /* b live                      */
        c = a + b;      /* a and b DIE here; c is born */
        d = c * 2;      /* c dies                      */
        return d;       /* d dies                      */

   LIVE RANGES:
        a:  |---|
        b:   |--|
        c:      |--|
        d:         |--|

   MAXIMUM SIMULTANEOUSLY LIVE = 2. Two registers suffice.

/* COMPUTED BY BACKWARD DATAFLOW over the CFG: */

        live_out(B) = union of live_in(S) for successors S
        live_in(B)  = used(B) ∪ (live_out(B) − defined(B))

/* Iterate to a fixed point. In SSA (chapter 05) this is
   cheaper, because each value has exactly one definition and
   the live range is the region dominated by it that reaches a
   use.                                                    */

/* REGISTER PRESSURE at a point = the number of values live
   there. Where pressure exceeds the register count, a spill
   is unavoidable. THAT is what the allocator is measuring,
   and it is why:
     · long-lived variables cost more than short-lived ones
     · a value used once far from its definition is expensive
     · calls are pressure points, because they clobber every
       caller-saved register                              */
```

Graph colouring

```
Chaitin's insight (1981): this is GRAPH COLOURING.

  Build an INTERFERENCE GRAPH: a node per value, an edge
  between any two values live at the same time.

     a --- b
      \   /
       \ /
        c --- d

  Colour the graph with K colours (K = number of registers)
  such that no two adjacent nodes share a colour.

  With K = 2:  a=red, b=blue, c=red, d=blue.  Done.

  THE ALGORITHM (Chaitin-Briggs):

   1. BUILD the interference graph.
   2. SIMPLIFY: repeatedly remove any node with FEWER THAN K
      neighbours, pushing it on a stack. Such a node can
      always be coloured later, whatever its neighbours get.
   3. If only nodes with >= K neighbours remain, SPILL one -
      choose by a heuristic: highest degree, lowest use
      count, not inside a loop.
   4. When the graph is empty, POP the stack and assign each
      node a colour differing from its already-coloured
      neighbours.
   5. If a spill was chosen, rewrite the code with store/load
      around it and START AGAIN - the new loads and stores
      create new, very short live ranges.

  GRAPH COLOURING IS NP-COMPLETE, so this is a heuristic. It
  is also why compilation time can jump on functions with
  enormous basic blocks - the graph gets large.

  THE OTHER ALGORITHM you will meet: LINEAR SCAN. Sort live
  intervals by start point, sweep, assign the first free
  register, spill the interval ending latest. Far faster,
  slightly worse code. LLVM's -O0 uses "fast" allocation;
  -O2 uses a greedy allocator that is closer to colouring in
  quality and closer to linear scan in speed.
```

Spilling

```
/* When a value cannot get a register, it lives on the STACK,
   loaded before each use and stored after each definition. */

/* WITHOUT spilling: */
        add  w0, w1, w2

/* WITH the result spilled: */
        add  w0, w1, w2
        str  w0, [sp, #16]              ; SPILL
        ...
        ldr  w0, [sp, #16]              ; RELOAD
        mul  w3, w0, w4

/* THE COST: two memory accesses. L1 hits, so a few cycles
   each - but in a hot loop, per iteration, it adds up
   quickly.

/* HOW THE ALLOCATOR CHOOSES what to spill:
        spill cost ≈ (loads + stores) × 10^(loop depth)
                     ──────────────────────────────────
                                 degree
   So a value used once outside a loop is cheap to spill; one
   used every iteration of a triple-nested loop is not.

/* SPILL SLOTS live in the stack frame, which is why a
   register-pressured function has a large frame - and why
   -Wframe-larger-than can fire on code with no large locals
   at all (Linux chapter 02).

/* WHAT CAUSES PRESSURE, in order of how often it is the
   cause:
     1. too many live variables - long functions doing many
        things at once
     2. aggressive inlining, which merges several functions'
        pressure into one
     3. unrolling and vectorisation, which multiply the live
        values per iteration
     4. large structs passed or returned by value
     5. many function arguments (more than 8 on AArch64 go on
        the stack anyway)
     6. taking the address of locals, which prevents promotion
        entirely (chapter 05)

/* AND THE FIX, in the same order: split the function. A
   200-line function with 40 live variables will spill; four
   50-line functions will not, and the compiler will inline
   them back if it helps.                                  */
```

> **"OPTIMIZED OUT" IN THE DEBUGGER**
>
> When gdb says `<optimized out>`, the variable has no single location — it lives in a register for part of its range, in a different register later, on the stack briefly, and nowhere at all where the compiler proved it unnecessary. DWARF location lists (chapter 14) can describe this, and modern compilers emit them, but not for values that genuinely no longer exist. Build with `-Og` when you need to inspect everything.

Calling conventions constrain it

```
/* The ABI (chapter 10) divides registers into two classes,
   and the allocator must respect it. */

   CALLER-SAVED (volatile): x0-x18, v0-v7, v16-v31
        A call may destroy them. If a value must survive a
        call, the CALLER saves it - or the allocator puts it
        in a callee-saved register instead.

   CALLEE-SAVED (non-volatile): x19-x28, v8-v15 (low 64 bits)
        A function using one must save and restore it in its
        prologue and epilogue.

/* THE ALLOCATION STRATEGY that follows:

     a value NOT live across any call
          -> prefer a CALLER-saved register: free, no
             prologue cost

     a value live ACROSS a call
          -> prefer a CALLEE-saved register: pay once in the
             prologue rather than at every call site       */

/* WHICH IS WHY a leaf function looks like this: */
        f:
                add   w0, w0, #1
                ret
/* no prologue at all - it uses only caller-saved registers
   and calls nothing.

/* AND A FUNCTION WITH A CALL IN A LOOP looks like this: */
        g:
                stp   x29, x30, [sp, #-32]!    ; FP and LR
                mov   x29, sp
                stp   x19, x20, [sp, #16]      ; callee-saved
                mov   w19, w0                  ; keep the arg
                                               ; across calls
        .Lloop:
                bl    helper                   ; clobbers
                                               ; x0-x18
                add   w19, w19, w0             ; w19 SURVIVED
                ...
                ldp   x19, x20, [sp, #16]
                ldp   x29, x30, [sp], #32
                ret

/* THE `stp`/`ldp` PAIRS are the prologue and epilogue, and
   their size tells you immediately how many callee-saved
   registers the function needed - which is a proxy for how
   much simultaneous state it carries.                  */
```

Coalescing and rematerialisation

```
/* --- COALESCING: eliminate copies ----------------------- */

/* Phi elimination (chapter 05) inserts copies: */
        mov  w1, w0
        ...uses of w1...

/* If w0 and w1 do NOT interfere, give them the same register
   and delete the move. That is coalescing, and it is why
   phi nodes usually cost nothing.

   THE TENSION: coalescing MERGES two nodes in the
   interference graph, and the merged node has the union of
   both neighbour sets - a higher degree, which may make the
   graph uncolourable and force a spill. So aggressive
   coalescing can be worse than none.

   CONSERVATIVE COALESCING (Briggs): only merge if the result
   has fewer than K neighbours of significant degree. This is
   what production allocators use.                          */

/* --- REMATERIALISATION: recompute instead of reload ----- */

/* Spilling a constant is silly: */
        mov  w0, #42
        str  w0, [sp, #8]       ; spill
        ...
        ldr  w0, [sp, #8]       ; reload

/* Just recompute it: */
        mov  w0, #42
        ...
        mov  w0, #42            ; REMATERIALISED - one
                                ; instruction, no memory

/* REMATERIALISABLE VALUES: constants, addresses of globals,
   the frame pointer plus an offset, and anything computed
   from values that are still live. The allocator prefers
   rematerialisation to spilling whenever it applies, which
   is why constants almost never occupy a register across a
   call.                                                    */

/* --- LIVE RANGE SPLITTING ------------------------------ */
/* Instead of spilling a value for its whole range, split the
   range at the pressure point:                             */
        v is live from A to Z
        pressure is high only between M and N
   ->   keep v in a register A..M
        spill it M..N
        reload into a (possibly different) register N..Z
/* This is what LLVM's greedy allocator does, and it is the
   main reason its output beats a naive colouring
   allocator.                                               */
```

Seeing the pressure

```
# --- How big is the frame? Spills live there. ---
    objdump -d prog | grep -A2 '<myfunc>:'
    ; look at the first `sub sp, sp, #N` or `stp ... [sp,#-N]!`

    gcc -fstack-usage prog.c
    ; writes prog.su:  prog.c:10:5:myfunc  128  static

    gcc -Wstack-usage=256
    gcc -Wframe-larger-than=1024      ; the kernel sets this

# --- Count the spills directly ---
    llvm: -mllvm -stats 2>&1 | grep -i spill
      12 regalloc - Number of spill slots allocated
      34 regalloc - Number of spills inserted
      41 regalloc - Number of reloads inserted

    gcc: -fdump-rtl-ira -fdump-rtl-reload

# --- In the assembly, look for str/ldr to [sp, #N] ---
# that are not obviously part of the ABI. A loop body with
# stack traffic in it is spilling.

# --- Reduce pressure, in order of effectiveness ---
#   1. split the function
#   2. shorten variable lifetimes - declare at first use,
#      not at the top
#   3. avoid taking the address of locals
#   4. pass large structs by pointer, not by value
#   5. reduce unrolling: #pragma clang loop unroll(disable)
#   6. reduce inlining: __attribute__((noinline)) on the
#      callee, or -finline-limit=
#   7. on FP-heavy code, check whether v8-v15 spilling is the
#      issue - those are callee-saved and expensive

# THE FIRST ONE IS ALMOST ALWAYS THE ANSWER. Register
# pressure is a symptom of a function doing too much.
```

How it shows up

Symptom	Cause
`<optimized out>` in gdb	The value has no single home — use `-Og`
Loop body contains `str` / `ldr` to the stack	Spilling — reduce pressure
Large stack frame with no large locals	Spill slots
`-Wframe-larger-than` fires unexpectedly	Same
Performance drops after inlining	Merged pressure caused spills
Performance drops after unrolling	More live values per iteration
A function got much slower after adding one variable	It crossed the pressure threshold
Compile time spikes on one function	A huge basic block; the interference graph is large
Long prologue with many `stp` pairs	Many callee-saved registers needed

Symptom	Cause
Constants reloaded from the stack	Rematerialisation did not apply — often an address that is not statically known
Code uses `x18` and crashes on some platforms	It is reserved — never allocate it by hand

Check yourself

- ✓ State AArch64's register classes and which are callee-saved.
- ✓ Compute live ranges for a straight-line sequence and the maximum pressure.
- ✓ Explain graph colouring allocation and the simplify/spill/select loop.
- ✓ Explain why the algorithm restarts after inserting spill code.
- ✓ Contrast graph colouring with linear scan.
- ✓ Give the spill cost heuristic and say why loop depth dominates it.
- ✓ List six causes of register pressure and the fix for each.
- ✓ Explain why a value live across a call prefers a callee-saved register.
- ✓ Explain coalescing and why aggressive coalescing can hurt.
- ✓ Explain rematerialisation and when it applies.
- ✓ Measure spills in a real function and reduce them.

Calling conventions and the ABI

The contract that lets separately compiled code work together: where arguments go, who saves what, how the stack is laid out. Violate it and you get corruption that looks like a hardware fault — and every language's foreign function interface is built on it.

What an ABI covers

```
An API is a source-level contract: function names, types,
semantics. An ABI is a BINARY contract:

  · sizes and alignments of every type
  · struct layout and padding rules
  · where arguments are passed, and in what order
  · where return values come back
  · which registers are preserved across a call
  · stack frame layout, alignment, and direction
  · the stack unwinding format, for exceptions
  · name mangling (C++)
  · object file format, relocations, symbol visibility
  · dynamic linking: PLT, GOT, TLS model
  · system call numbering and convention

THE RELEVANT DOCUMENT for ARM 64-bit is:
  "Procedure Call Standard for the Arm 64-bit Architecture"
  (AAPCS64), plus the ELF ABI supplement.

TWO OBJECT FILES AGREE ON AN ABI OR THEY DO NOT WORK. This
is why you cannot link an armhf library into an aarch64
binary, why C++ objects from different compilers may not
link, and why the kernel's syscall interface is frozen
forever (Linux chapter 02).
```

AAPCS64: the register map

Register	Role	Preserved?
`x0` – `x7`	Arguments 1–8; `x0` (– `x1`) returns the result	No
`x8`	Indirect result location (for large returns)	No
`x9` – `x15`	Temporaries	No
`x16`, `x17`	IP0/IP1 — the linker may clobber these in veneers	No
`x18`	**Platform register** — reserved. TLS on Windows/Darwin, shadow call stack on some Linux configs	Do not touch
`x19` – `x28`	General purpose	**Yes**
`x29`	Frame pointer	**Yes**
`x30`	Link register — the return address	**Yes**
`sp`	Stack pointer, **16-byte aligned**	Yes
`v0` – `v7`	FP/SIMD arguments and results	No
`v8` – `v15`	FP/SIMD	**Low 64 bits only**
`v16` – `v31`	FP/SIMD temporaries	No

```
/* THE v8-v15 RULE IS A REAL TRAP: only the LOW 64 BITS are
   callee-saved. A function that uses the full 128-bit v8 and
   restores only the low half has corrupted its caller's
   upper half. Hand-written SIMD assembly must save the whole
   register if it uses the whole register.               */

/* AND x18: on Linux it is usually free, but on Windows on
   ARM and on Darwin it holds the TEB/TLS pointer, and with
   -fsanitize=shadow-call-stack it holds the shadow stack
   pointer. Compile with -ffixed-x18 if you are writing code
   that must be portable across those. Never allocate it in
   hand-written assembly.                                 */
```

Argument passing

```
/* THE ALGORITHM, simplified but accurate for the common
   cases:

   NGRN = next general register number (starts at 0)
   NSRN = next SIMD register number (starts at 0)
   NSAA = next stacked argument address

   For each argument, in order:
     · integer or pointer, fits in 8 bytes
           -> x[NGRN++], if NGRN < 8; else stack
     · 16-byte integer (__int128)
           -> an even-numbered register PAIR
     · float, double, or a short vector
           -> v[NSRN++], if NSRN < 8; else stack
     · HFA/HVA - a struct of 1-4 identical float/vector
       members
           -> consecutive v registers, one per member
     · other struct, <= 16 bytes
           -> passed in 1 or 2 general registers, by value
     · other struct, > 16 bytes
           -> a COPY is made, and its ADDRESS is passed in a
              register. The callee may modify the copy.
     · variadic arguments after the named ones
           -> on the stack, on most platforms (Darwin differs)
*/

/* WORKED EXAMPLE: */
        struct Small { int a, b; };            /* 8 bytes  */
        struct Big   { int a[10]; };           /* 40 bytes */
        struct Vec3  { float x, y, z; };       /* an HFA    */

        void f(int a, double b, struct Small c,
               struct Big d, struct Vec3 e, int f);

/*      a -> w0
        b -> d0
        c -> x1              (8 bytes, packed into one reg)
        d -> x2 = &copy_of_d (too large - by reference)
        e -> s1, s2, s3      (HFA - one register per member)
        f -> w3                                          */

/* THE HFA RULE IS WHY a 3-float vector type is efficient on
   ARM and a 3-int one is not: floats get three registers,
   ints get packed and spilled. It is also why graphics and
   DSP code on ARM tends to use float structs.           */

/* VARIADIC FUNCTIONS: the named arguments follow the normal
   rules, everything after goes on the stack in a defined
   layout, and va_arg walks it. THIS IS WHY:
     · printf("%d", someFloat) is UB - the float was passed in
       a v register or promoted to double on the stack, and
       %d reads an integer slot
     · a function must have a prototype in scope: without it,
       the compiler cannot know whether an argument is named
       or variadic                                        */
```

Return values

```
        int f(void);                    -> w0
        long f(void);                   -> x0
        void *f(void);                  -> x0
        float f(void);                  -> s0
        double f(void);                 -> d0
        __int128 f(void);               -> x0, x1
        struct Small f(void);           -> x0 (and x1 if 9–16
                                           bytes)
        struct Vec3 f(void);            -> s0, s1, s2 (HFA)

        struct Big f(void);
/* THE CALLER allocates space, passes its address in x8, and
   the callee writes the result there. So:            */

        struct Big result = f();
   compiles to:
        add   x8, sp, #16          ; where to put it
        bl    f
        ; f writes 40 bytes at [x8]

/* WHICH IS WHY returning a large struct by value is not as
   expensive as people assume — there is one copy, into a
   destination the caller chose, not two. And why NAMED RETURN
   VALUE OPTIMISATION matters in C++ (C++ chapter 05): if the
   callee builds the result directly at [x8], there is no copy
   at all.                                                */
```

The stack frame

```
higher addresses
+---------------------------+
|  caller's frame           |
+---------------------------+  <- sp on entry, 16-aligned
|  stacked arguments        |     (arguments 9+)
+---------------------------+
|  x29 (saved FP)           |  <- x29 points HERE
|  x30 (saved LR)           |
+---------------------------+
|  other callee-saved regs  |
|  x19-x28, v8-v15          |
+---------------------------+
|  local variables          |
|  spill slots (chapter 09) |
+---------------------------+
|  outgoing arguments for   |
|  calls this function makes|
+---------------------------+  <- sp, always 16-aligned
lower addresses

THE STANDARD PROLOGUE:
     stp   x29, x30, [sp, #-48]!   ; push FP and LR,
                                   ; allocate 48 bytes
     mov   x29, sp                 ; establish the frame
     stp   x19, x20, [sp, #16]     ; save callee-saved
     str   x21, [sp, #32]

THE EPILOGUE, exactly reversed:
     ldr   x21, [sp, #32]
     ldp   x19, x20, [sp, #16]
     ldp   x29, x30, [sp], #48     ; pop and deallocate
     ret                           ; = br x30

THE FRAME POINTER CHAIN: each x29 points at the previous
x29, forming a linked list. That is how a backtrace works
without debug information - walk the chain, read the saved
x30 at each level. -fomit-frame-pointer breaks it, which is
why profilers and the kernel build with
-fno-omit-frame-pointer.

16-BYTE ALIGNMENT IS MANDATORY at every public interface.
Misalign the stack and you get a fault the first time
something executes a 128-bit SIMD load/store relative to
sp - typically deep inside memcpy, far from the cause.
```

Type layout

```
/* SIZES AND ALIGNMENTS on AArch64 Linux (LP64): */

        char            1    align 1
        short           2    align 2
        int             4    align 4
        long            8    align 8      <- 4 on Windows!
        long long       8    align 8
        pointer         8    align 8
        float           4    align 4
        double          8    align 8
        long double    16    align 16     <- 8 on some ABIs
        bool            1    align 1

/* THE `long` DIFFERENCE is the classic portability bug:
     LP64  (Linux, macOS):  long = 8
     LLP64 (Windows):       long = 4
   Use int64_t/uint64_t/intptr_t and the question does not
   arise.                                                  */

/* STRUCT LAYOUT: members in declaration order, each at the
   next offset satisfying its alignment; the struct's
   alignment is the maximum of its members'; the size is
   rounded up to that.                                     */

        struct A {              /* 24 bytes */
                char  a;        /* offset 0            */
                                /* 7 bytes PADDING     */
                long  b;        /* offset 8            */
                char  c;        /* offset 16           */
                                /* 7 bytes TAIL PADDING*/
        };

        struct B {              /* 16 bytes - REORDERED */
                long  b;        /* offset 0            */
                char  a;        /* offset 8            */
                char  c;        /* offset 9            */
                                /* 6 bytes padding     */
        };

/* SORTING MEMBERS LARGEST-FIRST is the simplest layout
   optimisation available, and it costs nothing. On an array
   of a million elements, 24 versus 16 bytes is 8 MB and a
   third more cache lines (CA chapter 14).

   SEE THE LAYOUT:
        pahole -C A prog.o
        clang -Xclang -fdump-record-layouts -c prog.c        */

/* PACKING, and why it is dangerous: */
        struct __attribute__((packed)) Wire {
                uint8_t  type;
                uint32_t value;         /* offset 1 -
                                           MISALIGNED */
        };
/* On ARM, an unaligned access to Normal memory works but may
   be slower; to DEVICE memory it FAULTS (ARM chapter 11).
   And taking a POINTER to a packed member and dereferencing
   it is undefined behaviour - the compiler warns with
   -Waddress-of-packed-member for exactly this reason.
```

```
   FOR WIRE FORMATS, prefer explicit serialisation:      */
        static void encode(uint8_t *buf, const struct Msg *m)
        {
                buf[0] = m->type;
                put_le32(buf + 1, m->value);
        }
/* Slower to write, correct everywhere, and endian-explicit. */
```

THE C++ ADDITIONS

C++ layers name mangling (so overloads and templates get distinct symbols), vtable layout, RTTI representation, exception unwinding tables, and the rules for empty base optimisation on top of the C ABI. The Itanium C++ ABI is what GCC and Clang both implement on Linux and ARM, which is why their objects interoperate — and MSVC's differs entirely, which is why they do not on Windows.

Inline assembly and the ABI

```
/* Writing assembly means obeying the ABI yourself. */

static inline uint64_t read_cntvct(void)
{
        uint64_t val;

        __asm__ volatile("mrs %0, cntvct_el0"
                         : "=r" (val)     /* output */
                         :                /* no inputs */
                         : "memory");     /* clobbers */
        return val;
}

/* THE CONSTRAINT LETTERS you need on AArch64:
     "r"    a general register
     "w"    a SIMD/FP register
     "m"    a memory operand
     "i"    an immediate constant
     "I"    a 12-bit immediate valid for add/sub
     "0"    same as operand 0 (tied)
     "+r"   read AND written
     "=r"   write only

/* THE CLOBBER LIST is where mistakes happen:
     · list EVERY register you modify that is not an output
     · "memory" means "this may read or write memory the
       compiler does not know about" - it prevents the
       compiler from caching loads across the asm and from
       reordering memory operations around it
     · "cc" means the condition flags are modified

/* FORGETTING A CLOBBER produces the worst class of bug: the
   compiler keeps a value in a register you overwrote, and the
   corruption appears somewhere unrelated, only at -O2, only
   sometimes.

/* AND `volatile` on the asm means "do not delete this even if
   its outputs are unused, and do not move it". Required for
   anything with a side effect - an MMIO access, a barrier, a
   system register write.                                  */

/* A COMPLETE EXAMPLE with input, output and clobbers: */
static inline void write_ttbr0(uint64_t val)
{
        __asm__ volatile("msr ttbr0_el1, %0\n"
                         "isb"
                         :
                         : "r" (val)
                         : "memory");
}

/* FOR A WHOLE FUNCTION IN ASSEMBLY, the ABI is entirely
   yours: save x19-x28 if you use them, keep sp 16-aligned,
   return through x30, put the result in x0. Get any of it
   wrong and the failure appears in the CALLER.          */
```

How it shows up

Symptom	Cause
Corruption in the caller after a call	Callee-saved register not restored — often hand-written assembly
Corruption only in SIMD code	Only the low 64 bits of `v8`–`v15` are preserved
Fault inside `memcpy` with a sane pointer	Stack not 16-byte aligned
Works at `-O0`, corrupts at `-O2`	Missing clobber in inline assembly
Wrong value from `printf`	Argument type does not match the format — variadic slots
Struct different size on two platforms	`long`, or different alignment rules
Struct larger than the sum of its members	Padding — reorder largest first
Unaligned access fault	A packed struct member, or a cast to a wider type
Backtrace stops after one frame	`-fomit-frame-pointer`, or hand-written assembly with no frame
C++ objects will not link across compilers	Different C++ ABI
Crash only on Windows/Darwin ARM	Used `x18`
Passing a 3-float struct is fast, 3-int is not	The HFA rule

Check yourself

- ✓ List what an ABI specifies beyond an API.
- ✓ State AArch64's register roles from memory, including `x8` and `x18`.
- ✓ Explain the `v8`–`v15` partial-preservation rule and the bug it causes.
- ✓ Work out where each argument of a mixed-type function is passed.
- ✓ Explain HFAs and why they favour float structs on ARM.
- ✓ Explain how a large struct is returned and why NRVO matters.
- ✓ Draw a stack frame and write a correct prologue and epilogue.
- ✓ Explain the frame pointer chain and what breaks it.
- ✓ Lay out a struct by hand and reorder it to save space.
- ✓ Explain why packed structs are dangerous on ARM.
- ✓ Write inline assembly with correct constraints and clobbers, and say what `"memory"` prevents.

Object files, symbols and relocation

What the assembler produces: machine code with holes in it, a list of the names it defines, a list of the names it needs, and instructions for filling the holes. Understanding this makes linker errors readable and explains where every byte of your binary comes from.

ELF structure

```
 +-----------------------------+
 |  ELF HEADER                 |  magic, class (32/64),
 |                             |  endianness, type, machine,
 |                             |  entry point, offsets to
 |                             |  the two tables below
 +-----------------------------+
 |  PROGRAM HEADERS            |  for the LOADER: which
 |  (segments)                 |  chunks to map, where, with
 |                             |  what permissions.
 |                             |  Absent in a .o file.
 +-----------------------------+

 +-----------------------------+
 |  SECTION HEADERS            |  for the LINKER: name,
 |                             |  type, flags, size, offset
 +-----------------------------+

TWO VIEWS OF THE SAME BYTES:
   SECTIONS  are what the LINKER manipulates
   SEGMENTS  are what the LOADER maps

A relocatable object (.o) has sections and no segments.
An executable has both. The linker's job is largely to
combine sections into segments.

INSPECT:
   readelf -h prog.o        ; header
   readelf -S prog.o        ; sections
   readelf -l prog          ; segments
   readelf -s prog.o        ; symbols
   readelf -r prog.o        ; relocations
   objdump -d prog.o        ; disassembly
   size prog.o              ; text/data/bss totals
```

Sections

```
/* WHERE EACH DECLARATION LANDS: */

        int   global_init  = 42;        /* .data           */
        int   global_zero;              /* .bss            */
        const int global_ro = 7;        /* .rodata         */
        static int file_static = 1;     /* .data, local    */
        char *s = "hello";              /* the POINTER in
                                           .data, the STRING
                                           in .rodata      */

        void f(void) { }                /* .text           */

        void g(void) {
                static int counter;     /* .bss - a static
                                           local is a global
                                           with local scope */
                int local;              /* the STACK - not in
                                           the object file  */
        }

/* .bss COSTS NO FILE SPACE. It records "reserve N zeroed
   bytes at this address"; the loader provides zeroed pages.
   Which is why a program with a 1 GB zero array is a small
   file, and why moving a large zero-initialised array into
   .data by writing `= {0}`... does nothing, because the
   compiler recognises all-zero initialisers and puts it in
   .bss anyway.                                              */

/* SECTION FLAGS - what readelf -S shows: */
        A   ALLOC      occupies memory at run time
        X   EXECINSTR  executable
        W   WRITE      writable
        M   MERGE      identical entries may be merged
        S   STRINGS    contains NUL-terminated strings

        .text    AX     read + execute, not writable (W^X)
        .rodata  A      read only
        .data    WA     read + write
        .bss     WA     read + write, NOBITS type
        .symtab  (none) not loaded at run time

/* CUSTOM SECTIONS, which embedded code uses constantly: */
        __attribute__((section(".isr_vector")))
        const void *vectors[] = { &stack_top, reset_handler };

        __attribute__((section(".fastcode")))
        void hot_function(void) { ... }

/* and the linker script places them (chapter 12).

/* THE PATTERN FOR REGISTRATION TABLES, used by the kernel's
   initcalls (Linux chapter 04) and by test frameworks: */

        #define REGISTER(fn) \
            static void (*const _reg_##fn)(void) \
                __attribute__((section("my_table"), used)) = fn;

/* The linker gathers every entry into one contiguous section
   and defines __start_my_table and __stop_my_table
```

```
    automatically, so you can iterate the table without
    maintaining a list.                                    */
```

Symbols

```
$ readelf -s prog.o

Num: Value  Size Type    Bind   Vis      Ndx Name
  0: 0         0 NOTYPE  LOCAL  DEFAULT  UND
  5: 0         4 OBJECT  LOCAL  DEFAULT    3 file_static
  8: 0        24 FUNC    GLOBAL DEFAULT    1 main
  9: 0         4 OBJECT  GLOBAL DEFAULT    3 global_init
 10: 0         0 NOTYPE  GLOBAL DEFAULT  UND printf
 11: 0         4 OBJECT  WEAK   DEFAULT  COM global_zero

/* THE FIELDS THAT MATTER:

   TYPE     FUNC, OBJECT (data), SECTION, FILE, NOTYPE
   BIND     LOCAL   - not visible outside this object
                      (`static`)
            GLOBAL  - visible; duplicate definitions are an
                      error
            WEAK    - may be overridden by a GLOBAL of the
                      same name; if never defined, resolves
                      to 0
   NDX      the section it lives in, or:
            UND     - UNDEFINED. This object NEEDS it.
            ABS     - an absolute value
            COM     - a COMMON symbol (see below)
   VIS      DEFAULT, HIDDEN, PROTECTED, INTERNAL

/* UND SYMBOLS ARE THE UNRESOLVED REFERENCES. Every
   "undefined reference to X" from the linker means: some
   object had X as UND, and nothing supplied a definition
   (chapter 12).

/* WEAK SYMBOLS, and why embedded code uses them: */
        __attribute__((weak)) void board_init(void) { }
        /* a default that a board file may override */

        __attribute__((weak)) extern int optional_feature;
        if (&optional_feature)          /* NULL if absent */
                use_it();

/* This is exactly how a vendor SDK provides overridable
   default handlers, and how the kernel provides
   architecture-overridable functions.

/* COMMON SYMBOLS - a historical C wart: */
        int x;          /* at file scope, in TWO .c files */
/* Traditionally this was legal: both become COMMON, and the
   linker merges them into one object. That silently merges
   what were meant to be two separate variables.
   -fno-common is now the DEFAULT (GCC 10+), making it an
   error. Do not turn it off.                              */

/* VISIBILITY, for shared libraries: */
        __attribute__((visibility("hidden")))
        void internal_helper(void);
/* Not exported from the .so: faster calls (no PLT), smaller
   dynamic symbol table, and a real API boundary. Build with
   -fvisibility=hidden and mark exports explicitly - this is
   what well-behaved libraries do.                         */
```

Relocations

```
/* The assembler does not know where anything will end up. So
   it leaves HOLES and records how to fill them.          */

        extern int counter;
        void inc(void) { counter++; }

$ objdump -d inc.o
0000000000000000 <inc>:

/* THE ADRP + ADD PAIR is the standard AArch64 idiom for
   forming an address:
        adrp x0, symbol          ; the 4 KB PAGE containing it
        add  x0, x0, :lo12:symbol ; plus the offset within
   Two instructions, +/-4 GB range, position independent.
   You will see it constantly in ARM64 disassembly.      */

/* THE 128 MB LIMIT ON `bl` matters in large binaries: if a
   call is further than that, the linker inserts a VENEER - a
   small stub that does a full 64-bit indirect branch, using
   x16/x17 (chapter 10). That is what those registers are
   reserved for, and it is why a huge kernel or browser binary
   contains thousands of tiny thunks.                    */
```

> **READING A RELOCATION TELLS YOU WHAT THE LINKER WILL DO**
> When a symbol resolves to the wrong thing, or a call goes to address zero, `readelf -r` on the object shows exactly which reference the linker was asked to patch and with what. That is usually faster than reasoning about link order, and it distinguishes "the reference is wrong" from "the definition is missing".

What the assembler does

```
/* Two passes, conceptually:

   PASS 1: read the source, build the symbol table, assign
           offsets. Every instruction's size must be known -
           which is why ARM's fixed 32-bit instructions make
           this trivial and x86's variable-length ones do not.

   PASS 2: emit the encodings. For anything whose value is not
           yet known, emit zero and record a relocation.

/* ASSEMBLER DIRECTIVES - not instructions, but commands to
   the assembler: */

         .text                   ; switch to the .text section
         .section .rodata
         .globl  main            ; make `main` GLOBAL
         .type   main, %function
         .size   main, .-main    ; current position minus start
         .align  3               ; align to 2^3 = 8 bytes
         .p2align 4,,15
         .word   0x12345678      ; emit 4 bytes
         .quad   symbol          ; emit 8 bytes + a relocation
         .byte   1, 2, 3
         .asciz  "hello"         ; string with a NUL
         .space  100             ; 100 zero bytes
         .equ    CONST, 42       ; a symbolic constant
         .macro  / .endm         ; assembler macros
         .cfi_startproc          ; unwind information
         .cfi_def_cfa_offset 32  ; (chapter 14)
         .cfi_offset 29, -32
         .cfi_endproc

/* THE .cfi_* DIRECTIVES generate .eh_frame, which is how
   backtraces and C++ exceptions work without frame pointers.
   Hand-written assembly that omits them is invisible to
   unwinders - which is why kernel assembly routines carry
   them, and why a missing one breaks perf's call graphs. */

/* THE LOCAL LABEL CONVENTION:
         .L...      a local label, NOT in the symbol table
         1:  2:     numeric labels, referenced as 1b (back)
                    or 1f (forward) - reusable, and the usual
                    choice inside macros                    */
```

The toolchain

```
# --- What is in this object? ---
    readelf -a prog.o | less
    objdump -x prog.o
    nm prog.o                   ; symbols, compactly
      0000000000000000 T main       T = text, global
      0000000000000000 D global      D = data, global
      0000000000000004 B counter     B = bss
      0000000000000000 R constant    R = rodata
                       U printf      U = UNDEFINED
      0000000000000000 t helper      lowercase = LOCAL
      0000000000000000 W weak_fn     W = weak

    nm -C prog.o                ; DEMANGLE C++ names
    nm --defined-only prog.o
    nm -u prog.o                ; undefined only - "what does
                                ; this object need?"

# --- Disassemble ---
    objdump -d prog.o           ; code only
    objdump -D prog.o           ; ALL sections, including data
    objdump -dS prog.o          ; interleaved with SOURCE
                                ; (needs -g)
    objdump -drwC prog.o        ; with relocations, demangled

    llvm-objdump -d --mcpu=cortex-a53 prog.o

# --- Where did the size go? ---
    size prog.o
       text    data     bss     dec     hex filename
       1234     100     256    1590     636 prog.o

    size -A prog                ; PER SECTION
    nm --size-sort -S prog | tail -20      ; the biggest
                                           ; symbols
    bloaty prog                 ; the best tool - attributes
                                ; every byte to a source file

# --- Manipulate ---
    strip prog                  ; remove symbols
    strip --strip-debug prog    ; keep the symbol table
    objcopy -O binary prog.elf prog.bin      ; for flashing
    objcopy --only-keep-debug prog prog.debug
    objcopy --add-gnu-debuglink=prog.debug prog
    ; ship a stripped binary plus separate debug info

    ar rcs libfoo.a a.o b.o     ; a static library is just an
    ar t libfoo.a               ; archive of object files
    ranlib libfoo.a             ; build the symbol index
```

How it shows up

Symptom	Cause
"undefined reference to X"	X is UND in some object and defined nowhere — `nm -u` finds who needs it
"multiple definition of X"	Two objects define it — likely a definition in a header
Two variables silently became one	Common symbols — build with `-fno-common`

Symptom	Cause
A weak default is not overridden	The strong definition is in a library the linker did not pull in (ch. 12)
Binary far larger than expected	Debug info, or no `--gc-sections`. Run `bloaty`
A 1 GB array makes a small file	It is in `.bss` — correct
"relocation truncated to fit"	Target out of range — usually a large binary or a wrong memory model
Thousands of tiny stubs in the disassembly	Linker veneers for out-of-range calls
Backtrace stops in assembly code	Missing `.cfi_*` directives
A symbol is exported that should not be	Default visibility — use `-fvisibility=hidden`
C++ symbol names are unreadable	Mangled — use `nm -C` or `c++filt`
A custom section is dropped	Missing `used` attribute, or `--gc-sections` removed it

Check yourself

- ✓ Describe ELF's structure and the difference between sections and segments.
- ✓ Say which section each kind of declaration lands in, and why `.bss` is free.
- ✓ Use a custom section plus `__start_` / `__stop_` to build a registration table.
- ✓ Read a symbol table and explain TYPE, BIND and NDX.
- ✓ Explain weak symbols and give two embedded uses.
- ✓ Explain common symbols and why `-fno-common` is now the default.
- ✓ Explain what a relocation contains and read one with `readelf -r`.
- ✓ Explain the `adrp` + `add` idiom and the 128 MB branch limit.
- ✓ Say what `.cfi_*` directives produce and what breaks without them.
- ✓ Use `nm`, `objdump`, `size` and `bloaty` to account for a binary's contents.

Static and dynamic linking

Combining object files into a program: symbol resolution, the archive rules that make link order matter, linker scripts for bare metal, and the shared-library machinery that resolves calls at run time.

What the linker does

```
INPUT:   a.o  b.o  libc.a  libfoo.so
OUTPUT:  a.out

1. READ every input, collecting sections and symbols.

2. RESOLVE symbols: for every UND reference, find a
   definition.

3. For ARCHIVES (.a), pull in ONLY the members that
   resolve a currently-undefined symbol. This is where
   link order comes from.

4. LAYOUT: assign an address to every output section,
   merging like-named input sections.
      .text  = a.o(.text) + b.o(.text) + ...
      .data  = a.o(.data) + b.o(.data) + ...

5. RELOCATE: now that every address is known, patch every
   hole (chapter 11).

6. Emit PROGRAM HEADERS describing what the loader should
   map, with what permissions.

THE ORDER OF STEPS 2 AND 3 IS THE WHOLE STORY behind the
most confusing linker errors, so it is worth being precise:
the linker processes inputs LEFT TO RIGHT, maintaining a
set of currently-undefined symbols. An archive is scanned
ONCE, at the position where it appears.
```

Link order

```
# THE RULE: a library must appear AFTER the objects that need
# it.

    gcc main.o -lfoo            # WORKS
    gcc -lfoo main.o            # "undefined reference to
                                #  foo_init"

/* WHY: when the linker reaches -lfoo in the second case,
   nothing is undefined yet, so it takes NOTHING from the
   archive. Then main.o introduces undefined symbols, and the
   archive is already behind it.                          */

# CIRCULAR DEPENDENCIES between two libraries:
    gcc main.o -lfoo -lbar -lfoo      # repeat it
    gcc main.o -Wl,--start-group -lfoo -lbar -Wl,--end-group
    ; the group is rescanned until no new symbols are resolved

# THE GRANULARITY IS THE ARCHIVE MEMBER (one .o), not the
# function. Pulling in one function from a member drags in the
# whole member - and everything IT references. This is why:
#   · a static library should have one function per source
#     file if size matters
#   · linking a "small" helper can pull in printf, and with it
#     the entire formatted-output machinery and locale support

# FORCE INCLUSION, when a member is needed for its side
# effects (a constructor, a registration table):
    -Wl,--whole-archive -lfoo -Wl,--no-whole-archive
    -u symbol_name              ; pretend this symbol is
                                ; undefined, forcing the
                                ; member in

# THIS IS A REAL EMBEDDED PROBLEM: a driver registered by a
# constructor in a static library is silently absent, because
# nothing referenced it. --whole-archive or an explicit -u is
# the fix.
```

Static libraries

```
# A .a is just an ar archive of .o files, plus an index.

    ar rcs libmath.a add.o sub.o mul.o
    ar t libmath.a              ; list members
    ar x libmath.a add.o        ; extract one
    nm libmath.a                ; symbols, per member
    ranlib libmath.a            ; rebuild the symbol index

    gcc main.c -L. -lmath -o prog
    gcc -static main.c -o prog  ; link EVERYTHING statically

# PROPERTIES:
#   + no runtime dependencies; one file to deploy
#   + no dynamic loader cost at startup
#   + the linker can do whole-program optimisation
#     (--gc-sections, LTO)
#   + no symbol interposition, so calls are direct
#   - larger binaries if many programs share the library
#   - a library fix requires relinking every program
#   - glibc's static linking has caveats: getaddrinfo, NSS
#     and dlopen still need the matching shared libraries at
#     run time, which defeats the point

# FOR FULLY STATIC BINARIES, use musl:
    musl-gcc -static main.c -o prog
    ; or a musl-based cross toolchain. This is what most
    ; container and embedded images do.

# EMBEDDED PRACTICE: static linking is the norm. There is no
# dynamic loader on bare metal, the memory saving of sharing
# does not apply with one program, and the determinism is
# worth a great deal.
```

Dead code elimination at link time

```
# By default the linker keeps whole SECTIONS. Put each
# function and variable in its own section and it can drop
# the unused ones.

    gcc -ffunction-sections -fdata-sections -c *.c
    gcc -Wl,--gc-sections *.o -o prog

    # see what was dropped:
    gcc -Wl,--gc-sections -Wl,--print-gc-sections ...

# TYPICAL SAVING on embedded code: 20-50%. On a
# flash-constrained part this is the single highest-value
# linker flag.

# KEEP something the linker would drop:
    __attribute__((used))              /* in the source */
    KEEP(*(.isr_vector))               /* in the linker
                                          script - REQUIRED
                                          for vector tables */
    -Wl,--undefined=symbol

# AND THE OTHER SIZE TOOLS:
    -Wl,--icf=all              ; identical code folding: merge
                               ; byte-identical functions
                               ; (lld and gold)
    -flto                      ; whole-program optimisation
                               ; (chapter 06)
    -Os / -Oz
    strip / --strip-debug

# MEASURE, do not guess:
    size -A prog
    bloaty prog -d compileunits,symbols
    ; bloaty attributes every byte to a source file and
    ; symbol, which turns "the binary is too big" into a
    ; ranked list.
```

Linker scripts

```
/* On bare metal you must tell the linker where memory IS.
   This is a realistic script for a Cortex-M or an ARM64
   firmware image.                                          */

ENTRY(Reset_Handler)

MEMORY
{

        while (1) ;
}

/* USEFUL SCRIPT CONSTRUCTS:
     .           the current location counter
     ALIGN(n)
     ADDR(sec), LOADADDR(sec), SIZEOF(sec)
     PROVIDE(sym = value)    define only if not already
     ASSERT(cond, "message") FAIL THE LINK on a condition -
                             e.g. ASSERT(_ebss < _stack_top,
                             "RAM overflow")
     NOLOAD                  reserve space, emit no data

/* THE ASSERT IS UNDERUSED and worth adopting: a link that
   fails with "RAM overflow" is far better than a firmware
   image that overwrites its own stack at run time.      */

# See the default script:
    ld --verbose
    gcc -Wl,--verbose ...
# and the final layout:
    gcc -Wl,-Map=out.map ...
    ; the map file shows every section's address and size, and
    ; WHY each object was included. Read it when something is
    ; unexpectedly present.
```

Shared libraries

```
# Build one:
    gcc -fPIC -c foo.c bar.c
    gcc -shared -Wl,-soname,libfoo.so.1 \
        -o libfoo.so.1.2.3 foo.o bar.o
    ln -s libfoo.so.1.2.3 libfoo.so.1
    ln -s libfoo.so.1 libfoo.so

# THE THREE NAMES:
#   libfoo.so           the LINKER name - what -lfoo finds
#   libfoo.so.1         the SONAME - what the loader records
#                       in the executable and searches for
#   libfoo.so.1.2.3     the real file
#
# THE SONAME IS THE ABI VERSION. Change the ABI
# incompatibly -> bump it to .so.2, and old binaries keep
# using .so.1. Get this wrong and you break every program on
# the system.

# -fPIC IS REQUIRED for shared library code: the library may
# be mapped at any address, so it must not contain absolute
# addresses (chapter 13).

# --- Inspecting ---
    ldd prog                    ; what it needs
    readelf -d prog             ; the DYNAMIC section:
                                ; NEEDED, SONAME, RPATH
    readelf --dyn-syms libfoo.so
    objdump -T libfoo.so        ; the dynamic symbol table

# --- Finding libraries at run time, in order ---
#   1. DT_RPATH in the executable (deprecated)
#   2. LD_LIBRARY_PATH
#   3. DT_RUNPATH
#   4. /etc/ld.so.cache        (built by ldconfig)
#   5. /lib, /usr/lib
#
    LD_LIBRARY_PATH=/opt/lib ./prog
    LD_DEBUG=libs ./prog        ; trace the search
    LD_DEBUG=all ./prog
    ldconfig -p | grep foo

# --- $ORIGIN, for relocatable installs ---
    gcc -Wl,-rpath,'$ORIGIN/../lib' ...
    ; resolves relative to the EXECUTABLE's location, so the
    ; whole tree can be moved. This is how self-contained
    ; application bundles work.
```

Symbol interposition

```
/* In a dynamic link, the FIRST definition found wins - across
   the whole process. That is interposition, and it is both a
   feature and a hazard.                                      */

# LD_PRELOAD: insert a library before all others
    LD_PRELOAD=./mymalloc.so ./prog
    ; every call to malloc now goes to yours

/* WRITING ONE: */
#define _GNU_SOURCE
#include <dlfcn.h>

void *malloc(size_t size)
{
        static void *(*real_malloc)(size_t);

        if (!real_malloc)
                real_malloc = dlsym(RTLD_NEXT, "malloc");

        void *p = real_malloc(size);
        log_allocation(p, size);
        return p;
}

/* USES: profiling, leak tracking, fault injection, sandboxing,
   and - the reason security people care - hijacking.

/* THE COST OF ALLOWING IT: every call to a global function
   from within a shared library must go through the PLT, in
   case someone interposed. That is why:
        -fvisibility=hidden          hide internals
        -Bsymbolic                   bind internal references
                                     directly
        __attribute__((visibility("hidden")))
   are worth using: they make intra-library calls direct, and
   they stop your internals becoming part of your ABI.

/* VERSION SCRIPTS - the disciplined way: */
        {
          global:
            foo_init;
            foo_process;
            foo_shutdown;
          local:
            *;                  /* everything else hidden */
        };
    gcc -shared -Wl,--version-script=foo.map ...

/* This is what a well-maintained library ships. It makes the
   exported set explicit and reviewable, rather than
   "whatever happened not to be static".                */
```

> **STATIC OR SHARED, FOR EMBEDDED WORK**
> On bare metal there is no choice: static. On embedded Linux, the trade is real — shared libraries save flash and RAM when several programs use them, and static linking gives determinism, faster startup, no version skew, and lets LTO and `--gc-sections` see the whole program. Most modern embedded images static-link the application against musl and keep only a handful of shared libraries. Measure both for your image; the answer depends on how many binaries you ship.

The linkers

Linker	Notes
`ld.bfd`	The classic GNU linker. Most features, most target support, slowest.
`ld.gold`	Faster, ELF only. Now deprecated and unmaintained.
`lld`	LLVM's. Very fast, good diagnostics, ICF, ThinLTO. `-fuse-ld=lld`
`mold`	The fastest available; a drop-in for most uses. `-fuse-ld=mold`

```
# Switching is usually one flag and worth trying on a large
# project — link time can drop by 5–10x:
    gcc -fuse-ld=lld ...
    gcc -fuse-ld=mold ...
    ld --version

# WHEN IT MATTERS: an incremental build's wall time is often
# dominated by the link, not the compile. On a kernel or a
# large C++ application the difference between bfd and mold is
# minutes per build.
```

How it shows up

Symptom	Cause
"undefined reference" despite the library being listed	Library before the object that needs it — put `-l` last
"undefined reference" only in a static build	Circular archive dependency — use `--start-group`
A constructor in a static library never runs	Nothing referenced that member — `--whole-archive` or `-u`
Vector table missing from the image	Garbage collected — needs `KEEP()`
Firmware runs from flash but variables are wrong	`.data` not copied from LMA to VMA by the startup code
Silent stack/heap collision at run time	No `ASSERT` in the linker script
"cannot find -lfoo"	Missing `-L`, or no `libfoo.so` symlink
Runs on the build host, "cannot open shared object" on target	Library not deployed, or the SONAME differs
Program picks up the wrong library version	Search order — check with `LD_DEBUG=libs`
Upgrading a library breaks every binary	SONAME not bumped on an incompatible change
Internal function called through the PLT	Default visibility — use a version script
Binary much bigger than expected	No `--gc-sections`; run `bloaty`

Check yourself

- ✓ List the linker's six steps in order.
- ✓ Explain why link order matters and give three ways to handle circularity.
- ✓ Explain archive-member granularity and its size consequence.
- ✓ Say why a constructor in a static library may never run, and two fixes.
- ✓ Enable section-level garbage collection and measure the saving.
- ✓ Write a linker script with MEMORY, SECTIONS and an ASSERT.
- ✓ Explain LMA versus VMA and write the startup code that bridges them.
- ✓ Explain the three shared-library names and what the SONAME governs.
- ✓ Trace the runtime library search with `LD_DEBUG`.
- ✓ Explain symbol interposition, its cost, and how a version script controls it.
- ✓ Compare static and shared linking for an embedded image.

Loaders, PIE and address space layout

From an executable file to a running process: what the kernel maps, what the dynamic loader does before `main`, and how position-independent code makes address space randomisation possible.

What happens on exec

```
execve("./prog", argv, envp)
     |
KERNEL:
  · parse the ELF header, check the magic and machine
  · tear down the old address space
  · MAP the PT_LOAD segments at their requested addresses,
    with the requested permissions
  · set up the stack: argv, envp, and the AUXILIARY VECTOR
  · if there is a PT_INTERP segment, ALSO map the
    interpreter named in it - normally
    /lib/ld-linux-aarch64.so.1
  · set PC to the INTERPRETER's entry point, not the
    program's
     |
DYNAMIC LOADER (ld.so):
  · relocate ITSELF first
  · read DT_NEEDED from the executable: which libraries
  · find and map each one, recursively
  · perform RELOCATIONS across all of them
  · initialise TLS
  · run each library's initialisers, then the
    executable's
  · jump to the executable's entry point
     |
_start  (in crt1.o)
  · set up the frame, align the stack
  · call __libc_start_main(main, argc, argv, ...)
     |
__libc_start_main
  · initialise libc: stdio, locale, the heap
  · register the atexit handler for destructors
  · call the .init_array constructors
  · call main(argc, argv, envp)
  · call exit(main's return value)

FOR A STATIC BINARY there is no PT_INTERP, so the kernel
jumps straight to _start and the whole loader phase does
not exist. That is most of the startup-time difference.

WATCH IT:  LD_DEBUG=all ./prog 2>&1 | less
           strace ./prog
```

Position independence and ASLR

```
/* THREE KINDS OF BINARY: */

   ET_EXEC       fixed load address, baked into the file.
                 Cannot be randomised. Historical default.

   ET_DYN + PIE  POSITION INDEPENDENT EXECUTABLE. Can be
                 loaded anywhere. The default on every modern
                 distribution.

   ET_DYN        a shared library. Always position
                 independent.

/* BUILD THEM: */
        gcc -fPIE -pie prog.c -o prog       ; PIE (default)
        gcc -fno-pie -no-pie prog.c -o prog ; fixed
        gcc -fPIC -shared foo.c -o libfoo.so

/* WHY PIE MATTERS: ADDRESS SPACE LAYOUT RANDOMISATION. If the
   attacker does not know where your code is, return-oriented
   programming becomes far harder - they cannot construct a
   chain of gadget addresses without an information leak
   first.

   WHAT GETS RANDOMISED on Linux:
        the executable itself   (only if PIE)
        every shared library
        the heap (brk)
        mmap regions
        the stack
        vdso

   CHECK:
        cat /proc/sys/kernel/randomize_va_space
             0 = off, 1 = partial, 2 = full (the default)
        cat /proc/self/maps          ; twice - the addresses
                                     ; differ
        setarch -R ./prog            ; run with ASLR disabled,
                                     ; for reproducible
                                     ; debugging

/* THE COST: PIE code must reach its own globals without
   absolute addresses. On AArch64 that costs almost nothing -
   `adrp`+`add` is PC-relative and already the normal idiom
   (chapter 11). On 32-bit x86 it cost a dedicated register
   and 5-10% performance, which is why the transition took so
   long there and was trivial on ARM.                    */
```

The GOT and the PLT

```
A call to a function in another shared object cannot be a
direct branch: the address is unknown until load time, and the
code page must stay read-only and shared between processes.

  THE SOLUTION: indirection through two tables.

   GOT   Global Offset Table - in .data, WRITABLE. Holds
         resolved ADDRESSES.
   PLT   Procedure Linkage Table - in .text, executable. A
         small stub per external function.

  CALLING printf:

     your code:
         bl   printf@plt

     printf@plt:                    (in .plt)
         adrp x16, :got:printf
         ldr  x17, [x16, :got_lo12:printf]   ; load from GOT
         br   x17                            ; jump there

     GOT entry for printf:
         initially -> the PLT resolver stub
         after the first call -> the real address of printf

  LAZY BINDING: the first call goes to the resolver, which
  finds printf, WRITES its address into the GOT, and jumps to
  it. Every later call loads the now-correct address and goes
  straight there.

  WHY LAZY: a program using 5,000 library functions but
  calling 200 of them resolves only 200. Startup is faster.

  WHY YOU MIGHT NOT WANT IT:
        LD_BIND_NOW=1 ./prog
        gcc -Wl,-z,now -Wl,-z,relro
  Resolve everything at startup, then make the GOT READ-ONLY
  (RELRO). This closes "GOT overwrite" attacks, in which an
  attacker with an arbitrary write redirects a library call.
  FULL RELRO is standard hardening and costs a little startup
  time.

  CHECK IT:
        readelf -d prog | grep -E 'BIND_NOW|FLAGS'
        checksec --file=prog
```

Thread-local storage

```
        __thread int counter;           /* GNU */
        _Thread_local int counter;      /* C11 */
        thread_local int counter;       /* C++11 */

/* Each thread gets its own instance. The implementation
   depends on how much the compiler knows at compile time -
   there are four MODELS, from fastest to most general: */

   LOCAL-EXEC       the variable is in the main executable.
                    Its offset from the thread pointer is
                    known at LINK time.
                        mrs  x0, tpidr_el0
                        add  x0, x0, #:tprel_hi12:counter
                        add  x0, x0, #:tprel_lo12_nc:counter
                    TWO instructions. The fastest.

   INITIAL-EXEC     in a library loaded at startup. The offset
                    comes from the GOT.
                        mrs  x0, tpidr_el0
                        adrp x1, :gottprel:counter
                        ldr  x1, [x1, :gottprel_lo12:counter]
                        add  x0, x0, x1

   LOCAL-DYNAMIC    several variables in a dlopen'd library.
   GENERAL-DYNAMIC  the fully general case. Calls
                    __tls_get_addr - a FUNCTION CALL for every
                    access.

/* SELECT ONE: */
        gcc -ftls-model=initial-exec ...
        __attribute__((tls_model("initial-exec")))

/* THE PRACTICAL POINT: a `__thread` variable in a library
   that might be dlopen'd uses general-dynamic and costs a
   function call per access. In a hot path that is
   significant, and forcing initial-exec is the fix - at the
   cost of the library no longer being dlopen-able.

   ON AARCH64 the thread pointer is TPIDR_EL0, readable from
   user mode with one instruction, which is why local-exec TLS
   is nearly free.                                          */
```

Constructors and destructors

```
/* Code that runs before main and after it returns. */

        __attribute__((constructor))
        static void my_init(void) { ... }

        __attribute__((destructor))
        static void my_fini(void) { ... }

        __attribute__((constructor(101)))   /* priority:
                                               lower runs
                                               first          */
        static void very_early(void) { ... }

/* HOW: pointers are placed in .init_array / .fini_array, and
   the loader (or __libc_csu_init for a static binary) walks
   the array.

        readelf -x .init_array prog

/* C++ STATIC INITIALISATION uses the same mechanism: a
   constructor for every namespace-scope object with a
   non-constant initialiser.

/* THE STATIC INITIALISATION ORDER FIASCO: the order of
   constructors ACROSS translation units is UNSPECIFIED. So: */

        /* a.cpp */  Logger logger;
        /* b.cpp */  Config config{logger};   /* MAY run first,
                                                   using an
                                                   unconstructed
                                                   logger        */

/* THE FIX - construct on first use, which is guaranteed to be
   ordered by the dependency itself: */
        Logger &get_logger(void)
        {
                static Logger instance;   /* constructed on the
                                             first call, and
                                             thread-safe since
                                             C++11             */
                return instance;
        }

/* AND IN A SHARED LIBRARY, constructors run at dlopen and
   destructors at dlclose - so a library that registers itself
   with a constructor works, and one that assumes main() has
   already run does not.                                      */
```

The process address space

```
$ cat /proc/self/maps

aaaab2340000-aaaab2341000 r-xp 00000000 fe:01 12345 /bin/cat
aaaab2350000-aaaab2351000 r--p 00000000 fe:01 12345 /bin/cat
aaaab2351000-aaaab2352000 rw-p 00001000 fe:01 12345 /bin/cat
aaaad4f60000-aaaad4f81000 rw-p 00000000 00:00 0     [heap]
ffff8a100000-ffff8a280000 r-xp 00000000 fe:01 23456 /lib/libc.so.6
ffff8a280000-ffff8a290000 r--p 00180000 fe:01 23456 /lib/libc.so.6
ffff8a290000-ffff8a292000 rw-p 00190000 fe:01 23456 /lib/libc.so.6
ffff8a2a0000-ffff8a2c0000 r-xp 00000000 fe:01 34567 /lib/ld-linux-aarch64.so.1
ffffc4d20000-ffffc4d41000 rw-p 00000000 00:00 0     [stack]
ffffa3b40000-ffffa3b41000 r-xp 00000000 00:00 0     [vdso]

/* READ THE PERMISSIONS COLUMN:
     r-xp   code: readable, executable, NOT writable
     r--p   read-only data, including relocated-then-RELRO
     rw-p   writable data
     p      private (copy-on-write); s would be shared

   NO SEGMENT IS BOTH `w` AND `x`. That is W^X, and it is
   what makes injected shellcode unusable without a further
   step. A binary that needs writable-executable memory - a
   JIT - must mprotect explicitly, and hardened systems
   forbid it.

/* [vdso] - a page the kernel maps into every process
   containing fast implementations of gettimeofday,
   clock_gettime and getcpu, which read the clock directly
   without a syscall. That is why clock_gettime costs about
   25 ns rather than 500 (ARM chapter 32).

/* THE FILE OFFSETS reveal the segment structure: libc appears
   three times, at offsets 0, 0x180000 and 0x190000 - the
   same file mapped three times with different permissions,
   which is exactly the PT_LOAD segments from chapter 11. */
```

HARDENING FLAGS, AND WHAT EACH STOPS

```
-fstack-protector-strong    stack smashing
-D_FORTIFY_SOURCE=2         buffer overflows in libc calls
-fPIE -pie                  enables ASLR of the executable
-Wl,-z,relro,-z,now         GOT overwrite
-Wl,-z,noexecstack          executable stack
-fstack-clash-protection    stack-guard-page jumping
-fcf-protection / -mbranch-protection=standard
                            ROP/JOP, via BTI and PAC on ARMv8.3+
```

Check what a binary actually has with `checksec --file=prog`. On ARMv8.3 and later, `-mbranch-protection=standard` enables pointer authentication and branch target identification, which are the strongest of these and cost very little.

Loading at run time

```
#include <dlfcn.h>

        void *h = dlopen("libplugin.so", RTLD_NOW | RTLD_LOCAL);
        if (!h) {
                fprintf(stderr, "%s\n", dlerror());
                return -1;
        }

        /* the cast is ugly and POSIX-required */
        void (*fn)(int) = (void (*)(int))dlsym(h, "plugin_run");
        if (!fn) { ... }

        fn(42);
        dlclose(h);

/* THE FLAGS:
     RTLD_NOW     resolve everything at dlopen. Fails
                  immediately on a missing symbol.
     RTLD_LAZY    resolve on first use. Fails LATER, at the
                  call - much harder to diagnose.
     RTLD_GLOBAL  the library's symbols become available to
                  subsequently loaded libraries
     RTLD_LOCAL   they do not. The safe default.
     RTLD_NODELETE  never unload

/* PREFER RTLD_NOW | RTLD_LOCAL. Lazy binding in a plugin
   means a typo in an exported name crashes in production
   rather than failing at load.

/* THE C++ PROBLEM: dlsym takes a mangled name. Export plugin
   entry points as extern "C", or provide a single registration
   function.

/* AND THE UNLOAD HAZARD: after dlclose, every pointer into
   the library - function pointers, vtables, static data,
   string literals - is dangling. A callback registered with
   another subsystem and never unregistered becomes a crash
   at an arbitrary later moment. Plugin systems commonly use
   RTLD_NODELETE for exactly this reason.              */
```

How it shows up

Symptom	Cause
"cannot open shared object file"	Not on the search path — `LD_DEBUG=libs` shows where it looked
Wrong library version loaded	Search order; check `ldd` and `LD_LIBRARY_PATH`
Addresses differ every run	ASLR — use `setarch -R` for reproducible debugging
Crash at a call, long after a successful `dlopen`	`RTLD_LAZY` hid a missing symbol
Crash after `dlclose`	A dangling pointer into the unloaded library
`dlsym` returns NULL for a C++ function	Name mangling — use `extern "C"`
Static object used before construction	Static initialisation order fiasco — construct on first use
Thread-local access is slow	General-dynamic TLS model — try `initial-exec`
Startup is slow	Many libraries and relocations; consider static linking or prelinking

Symptom	Cause
Exploit mitigations absent	Check with `checksec`; the flags are not all on by default
JIT fails with a permission error	W^X — the page must be `mprotect`ed, and hardened systems may refuse

Check yourself

- ✓ Trace execution from `execve` to `main`, naming each participant.
- ✓ Explain what changes for a statically linked binary.
- ✓ Distinguish ET_EXEC, PIE and shared objects, and say why PIE enables ASLR.
- ✓ Explain the GOT and PLT and how lazy binding works.
- ✓ Explain RELRO and the attack it prevents.
- ✓ Name the four TLS models and the cost of each.
- ✓ Explain how constructors are implemented and the static initialisation order fiasco.
- ✓ Read `/proc/self/maps` and explain the permissions and repeated file mappings.
- ✓ Explain what the vdso is for.
- ✓ List six hardening flags and what each stops.
- ✓ Use `dlopen` safely and name three hazards.

Debug information and how debuggers work

How a debugger maps machine addresses back to source lines, finds variables that live in registers, and walks a stack. DWARF is the format, and understanding it explains both what debuggers can do and why optimised code is harder to inspect.

DWARF

```
Debug information lives in ELF sections that are NOT
loaded at run time:

  .debug_info     the DIE tree: types, variables,
                  functions, scopes
  .debug_abbrev   the abbreviation table it is encoded
                  against
  .debug_line     the LINE TABLE: address -> file:line
  .debug_str      strings
  .debug_loclists variable LOCATIONS, per address range
  .debug_ranges   non-contiguous address ranges
  .debug_frame    stack unwinding
  .eh_frame       unwinding, LOADED (used by C++
                  exceptions, so it must exist at run
                  time)

THE CENTRAL STRUCTURE is a tree of DIEs - Debugging
Information Entries. Each has a TAG and ATTRIBUTES:

  DW_TAG_compile_unit
    DW_AT_name       "prog.c"
    DW_AT_comp_dir   "/home/me/src"
    DW_AT_producer   "GNU C17 13.2.0 -O2 -g"
    |
    +- DW_TAG_base_type
    |    DW_AT_name "int"  DW_AT_byte_size 4
    |    DW_AT_encoding DW_ATE_signed
    |
    +- DW_TAG_structure_type
    |    DW_AT_name "point"  DW_AT_byte_size 8
    |    +- DW_TAG_member  "x"  DW_AT_data_member_location 0
    |    +- DW_TAG_member  "y"  DW_AT_data_member_location 4
    |
    +- DW_TAG_subprogram
         DW_AT_name "main"
         DW_AT_low_pc  0x1000
         DW_AT_high_pc 0x1080
         DW_AT_frame_base  DW_OP_call_frame_cfa
         +- DW_TAG_formal_parameter "argc"
         |    DW_AT_location  ...
         +- DW_TAG_variable "sum"
              DW_AT_location  ...

READ IT:
   readelf --debug-dump=info prog | less
   llvm-dwarfdump prog
   objdump --dwarf=info prog
   dwarfdump prog
```

The line table

```
/* .debug_line maps ADDRESSES to source positions. It is
   encoded as a bytecode program for a state machine -
   because a naive table would be enormous.               */

$ readelf --debug-dump=decodedline prog

File name  Line number  Starting address
prog.c              10             0x1000
prog.c              11             0x1008
prog.c              12             0x1010
prog.c              11             0x1020    <- back to 11!
prog.c              14             0x1030

/* THE OUT-OF-ORDER ENTRY at 0x1020 is the optimiser: code
   from line 11 was scheduled after code from line 12. That is
   why single-stepping optimised code jumps around, and it is
   not a bug in the debugger.

/* EACH ROW ALSO CARRIES FLAGS:
     is_stmt          a good place for a breakpoint
     basic_block
     end_sequence
     prologue_end     <-- where a `break func` actually lands
     epilogue_begin

   `prologue_end` is why a breakpoint on a function stops
   AFTER the prologue, so the arguments are already in their
   final locations. Without it the debugger would show
   garbage for every parameter.

/* WITH INLINING, one address may map to SEVERAL source
   positions - the inlined line and the call site. DWARF
   expresses this with DW_TAG_inlined_subroutine, and it is
   how a backtrace can show:

       #0  helper (x=5) at helper.c:12
       #1  caller () at main.c:30
   even though `helper` was inlined and there is no stack
   frame for it. gdb calls these "inline frames".        */
```

Where variables live

```
/* At -O0 a variable has one home: a stack slot. Simple.

   At -O2 it moves: a register here, a different register
   there, spilled briefly, and gone entirely where the
   compiler proved it unnecessary. DWARF describes this with a
   LOCATION LIST - an expression per address range.       */

$ llvm-dwarfdump --debug-loclists prog

0x0000000c:
  [0x1000, 0x1018): DW_OP_reg0 W0
  [0x1018, 0x1030): DW_OP_reg19 W19
  [0x1030, 0x1040): DW_OP_fbreg -20
  [0x1040, 0x1050): <empty>

/* READS AS: between 0x1000 and 0x1018 the variable is in w0;
   then in w19; then at frame base minus 20; then NOWHERE -
   which is what gdb reports as `<optimized out>`.

/* THE EXPRESSIONS are a small stack language, DWARF
   expressions:
        DW_OP_reg3           it IS register 3
        DW_OP_breg3 -16      at [register 3 - 16]
        DW_OP_fbreg -20      at [frame base - 20]
        DW_OP_addr 0x4000    at a fixed address
        DW_OP_piece          the value is SPLIT across
                             several locations
        DW_OP_stack_value    the value is computed, and does
                             not exist in memory at all

   `DW_OP_stack_value` is how a debugger can show a variable
   that was optimised into an expression - "x is y*2" - even
   though nothing stores x.

/* THIS IS WHY -Og EXISTS: it optimises, but avoids
   transformations that destroy variable locations. For
   debugging code that must run at speed, -Og -g is the right
   answer, not -O0.                                       */
```

> **WHY `<OPTIMIZED OUT>` IS NOT A COMPILER BUG**
>
> If the compiler proved a variable's value is never needed at a point, it does not exist there. There is no location to report because there is no value. DWARF can describe registers, memory, split values and even computed values — but not values that were never computed. That is the honest answer, and the fix is `-Og`, not distrust of the debugger.

Stack unwinding

```
/* To produce a backtrace, a debugger must find each caller's
   frame. Two ways:

   1. THE FRAME POINTER CHAIN (chapter 10). x29 points at the
      saved x29, forming a linked list; x30 is beside it.
      Simple, fast, and REQUIRES -fno-omit-frame-pointer.

   2. CFI - CALL FRAME INFORMATION. A table describing, for
      every address, how to compute the CANONICAL FRAME
      ADDRESS and where each saved register is. No frame
      pointer needed, and it works mid-prologue.        */

$ readelf --debug-dump=frames-interp prog

   LOC     CFA      x19 x29 x30 ra
0000001000 sp+0                  u   (nothing saved yet)
0000001004 sp+32    c-32 c-24  c-8     (after the stp)
0000001008 x29+32   c-32 c-24  c-8     (after mov x29,sp)
...
0000001040 sp+0                  u   (after the epilogue)

/* READS AS: at 0x1004 the canonical frame address is sp+32,
   x19 is saved at CFA-32, and the return address at CFA-8.
   An unwinder reads that row and steps to the caller.

/* THE ASSEMBLER DIRECTIVES that generate it (chapter 11): */
        .cfi_startproc
        stp     x29, x30, [sp, #-32]!
        .cfi_def_cfa_offset 32
        .cfi_offset 29, -32
        .cfi_offset 30, -24
        mov     x29, sp
        .cfi_def_cfa_register 29
        ...
        .cfi_endproc

/* HAND-WRITTEN ASSEMBLY WITHOUT THESE IS INVISIBLE to
   unwinders: the backtrace stops there, C++ exceptions
   cannot propagate through it, and perf's call graphs are
   truncated. Every kernel and libc assembly routine carries
   them for this reason.

/* .eh_frame VERSUS .debug_frame: identical in structure, but
   .eh_frame is ALLOCATED - it is present in a stripped
   binary, because C++ exception handling needs it at run
   time. Which is why a stripped C++ binary can still produce
   a backtrace, and a stripped C binary compiled with
   -fno-asynchronous-unwind-tables cannot.              */
```

How a debugger works

```
/* --- BREAKPOINTS --- */
/* Replace the instruction at the target with a trap. On
   AArch64 that is BRK #0 (0xd4200000).                    */

        1. read and SAVE the original 4 bytes
        2. write BRK #0 there
        3. continue
        4. the CPU traps; the kernel sends SIGTRAP; the
           debugger is notified via waitpid
        5. to continue: restore the original instruction,
           single-step over it, re-insert the trap, resume

/* HARDWARE BREAKPOINTS use the debug registers instead - no
   memory modification, so they work on read-only or flash
   memory. AArch64 provides a handful (typically 6 breakpoint
   and 4 watchpoint registers), which is why gdb limits you.

/* --- WATCHPOINTS --- */
        watch myvar
/* Hardware watchpoints use the same debug registers and trap
   on ACCESS. SOFTWARE watchpoints single-step the entire
   program and compare after each instruction - correct, and
   thousands of times slower. gdb tells you which it used.

/* --- SINGLE STEPPING --- */
        PSTATE.SS, or ptrace(PTRACE_SINGLESTEP)
/* `step` (source line) is implemented as: repeatedly
   single-step until the line table says we left the current
   line. Which is why stepping optimised code jumps around -
   the line table genuinely does.

/* --- THE PTRACE INTERFACE --- */
        ptrace(PTRACE_ATTACH, pid, 0, 0);
        waitpid(pid, &status, 0);
        ptrace(PTRACE_PEEKDATA, pid, addr, 0);
        ptrace(PTRACE_POKEDATA, pid, addr, value);
        ptrace(PTRACE_GETREGSET, pid, NT_PRSTATUS, &iov);
        ptrace(PTRACE_CONT, pid, 0, signal);
        ptrace(PTRACE_DETACH, pid, 0, 0);

/* THE WHOLE DEBUGGER is ptrace plus DWARF plus a great deal
   of careful bookkeeping. A minimal one is a few hundred
   lines, and writing one is the fastest way to understand
   what gdb is doing.

/* WHY YOU MAY NOT BE ABLE TO ATTACH: */
        cat /proc/sys/kernel/yama/ptrace_scope
        # 0 = any process may attach to any of its own
        # 1 = only to descendants (the default) - which is why
        #     `gdb -p` on an unrelated process fails
        # 2 = admin only,  3 = nobody                      */
```

Managing debug info

```
# Debug info is LARGE - often several times the code size.

# --- SPLIT IT OUT, ship the binary, keep the symbols ---
    objcopy --only-keep-debug prog prog.debug
    objcopy --strip-debug prog
    objcopy --add-gnu-debuglink=prog.debug prog
    ; gdb finds prog.debug automatically via the debuglink,
    ; or via a build-id path in /usr/lib/debug

    readelf -n prog | grep -A1 'Build ID'
    ; the build-id is how distributions match a binary to its
    ; separately-packaged debug symbols

# --- SPLIT DWARF: keep it out of the .o files entirely ---
    gcc -g -gsplit-dwarf -c prog.c
    ; produces prog.dwo alongside prog.o. The linker never
    ; reads it, so LINK TIME DROPS SUBSTANTIALLY on large
    ; projects - often the single biggest build-time win for
    ; a debug build of a large C++ codebase.

# --- COMPRESS ---
    gcc -gz              ; compressed debug sections
    -Wl,--compress-debug-sections=zlib

# --- DWARF VERSION ---
    -gdwarf-4  -gdwarf-5
    ; DWARF 5 is smaller and better, but old tools may not
    ; read it. Check what your target's gdb supports.

# --- LEVELS ---
    -g0    none
    -g1    line tables and function names only - enough for
           BACKTRACES, a fraction of the size. Good for
           production builds.
    -g     (= -g2) the normal level
    -g3    plus MACRO definitions, so gdb can expand macros

# THE PRODUCTION RECOMMENDATION: build with -g, split the
# debug info out, ship the stripped binary, and archive the
# .debug file with the build. Then a crash dump from the
# field is analysable, and the shipped image is small.
```

Beyond gdb

```
# DWARF is a general format, and many tools consume it:

    pahole -C mystruct prog.o    ; STRUCT LAYOUT with holes
                                 ; marked - the best tool for
                                 ; finding padding
                                 ; (chapter 10)
    pahole --reorganize          ; suggests a better order

    perf report --call-graph dwarf
    ; unwinds using CFI rather than frame pointers, so it
    ; works on binaries built with -fomit-frame-pointer

    bpftrace, systemtap
    ; use DWARF to attach probes to source lines and read
    ; local variables in a running kernel

    addr2line -e prog -f -i 0x1234
    ; -i shows INLINE frames too - essential for making sense
    ; of an optimised backtrace

    llvm-symbolizer < addresses.txt
    ; what the sanitizers use to turn addresses into
    ; file:line

    eu-stack, gcore, coredumpctl
    ; post-mortem analysis

# AND THE KERNEL:
    CONFIG_DEBUG_INFO_DWARF5=y
    CONFIG_GDB_SCRIPTS=y         ; lx-dmesg, lx-symbols
    CONFIG_DEBUG_INFO_BTF=y      ; BTF - a compact type format
                                 ; derived from DWARF, used by
                                 ; BPF and by kernel tooling.
                                 ; A fraction of DWARF's size,
                                 ; enough for type
                                 ; introspection.
```

How it shows up

Symptom	Cause
"No symbol table is loaded"	Built without `-g`, or stripped and the debuglink is missing
`<optimized out>`	The value does not exist there — use `-Og`
Stepping jumps around	The line table genuinely is out of order after scheduling
A breakpoint lands in the wrong place	Line-table granularity; try an address breakpoint
Backtrace stops in assembly	Missing `.cfi_*` directives
Backtrace stops after one frame	`-fomit-frame-pointer` and no CFI, or a corrupted stack
Inlined function missing from a backtrace	Use `addr2line -i`, or a debugger that shows inline frames
Cannot set more than a few watchpoints	Hardware debug register limit
Watchpoint makes the program crawl	Fell back to a software watchpoint
`gdb -p` refuses to attach	`ptrace_scope` — check the yama setting
Debug build links very slowly	Debug info volume — use `-gsplit-dwarf`

Symptom	Cause
Symbols do not match the binary	Different build — check the build-id

Check yourself

- ✓ Name DWARF's main sections and what each holds.
- ✓ Read a DIE tree and identify a function, its parameters and its types.
- ✓ Explain the line table and why `prologue_end` exists.
- ✓ Explain location lists and what `<optimized out>` really means.
- ✓ Explain the two unwinding mechanisms and when each is available.
- ✓ Say what `.cfi_*` directives produce and what breaks without them.
- ✓ Explain how a software breakpoint is implemented, step by step.
- ✓ Explain when hardware breakpoints are required and why they are limited.
- ✓ Split debug info out of a binary and have gdb find it again.
- ✓ Use `pahole` and `addr2line -i` on a real binary.

Undefined behaviour and the optimiser

Why a compiler deletes your bounds check, why a bug appears only at `-O2`, and why "it worked before" is not evidence. Undefined behaviour is not a bug in the compiler — it is a licence you granted it, and this chapter is about what it does with that licence.

The contract

```
THE C STANDARD says: if a program executes undefined
behaviour, the standard imposes NO REQUIREMENTS on what
happens.

THE OPTIMISER READS THAT CONTRAPOSITIVELY:

  "The programmer promised this program has no UB.
   Therefore I may ASSUME the conditions that would cause
   UB never occur, and optimise on that assumption."

That is not aggressive interpretation - it is the only
interpretation that makes optimisation possible at all.
Every optimisation is "this transformation preserves
behaviour for all DEFINED executions".

THE CONSEQUENCES that surprise people:

  · UB is not "does something unpredictable at that line".
    It can affect code BEFORE it, because the compiler
    reasons backwards.

  · UB in a branch that is never taken can still change
    your program, because the compiler used it to conclude
    the branch is unreachable.

  · "It works" is not evidence of correctness. It is
    evidence that this compiler, at this optimisation
    level, this week, happened to choose an outcome you
    liked.

FOUR CATEGORIES, and the difference matters:
  UNDEFINED         anything may happen
  UNSPECIFIED       one of several behaviours, no record
                    (argument evaluation order)
  IMPLEMENTATION-DEFINED   one of several, DOCUMENTED
                    (whether char is signed)
  LOCALE-SPECIFIC
```

The ones that bite

```
/* --- 1. SIGNED INTEGER OVERFLOW ------------------------- */
        int f(int x) { return x + 1 > x; }
   ->   mov w0, #1
        ret
/* ALWAYS TRUE. Signed overflow is UB, so the compiler may
   assume x + 1 > x. For UNSIGNED it must emit a real
   comparison, because unsigned wrapping is DEFINED.

        for (int i = 0; i <= n; i++)
/* With int i, the compiler may assume i never wraps, which is
   what lets it prove the loop terminates and unroll it. With
   `unsigned i` and n == UINT_MAX, the loop is infinite and
   the compiler must preserve that.

   THE FLAG: -fwrapv makes signed overflow wrap (defined),
   at some optimisation cost. -ftrapv traps. The kernel uses
   -fno-strict-overflow.

/* --- 2. NULL DEREFERENCE IMPLIES NON-NULL --------------- */
        void f(int *p) {
                int x = *p;             /* dereference */
                if (p == NULL)          /* DELETED - if p were
                        return;            NULL we already had
                *p = x + 1;                UB               */
        }
/* The check is removed. This exact pattern caused
   CVE-2009-1897 in the Linux kernel: a dereference before a
   NULL check let the compiler delete the check, and the
   dereference of a mapped NULL page became exploitable.

/* --- 3. STRICT ALIASING --------------------------------- */
        float bits_to_float(uint32_t u)
        {
                return *(float *)&u;    /* UB */
        }
/* Objects of different types may not alias, so the compiler
   may assume the float load does not see the uint32_t store,
   and reorder or elide them.

   THE CORRECT WAYS: */
        memcpy(&f, &u, sizeof f);       /* always correct, and
                                           compiles to zero
                                           instructions      */
        f = __builtin_bit_cast(float, u);   /* C++20 / clang */
        union { uint32_t u; float f; } c = { .u = u };
        return c.f;                     /* legal in C, NOT in
                                           C++               */

/* char, unsigned char and std::byte may alias ANYTHING - that
   is the exception that makes memcpy work.

   THE KERNEL BUILDS WITH -fno-strict-aliasing because it
   type-puns deliberately in many places. Application code
   should NOT rely on that flag.

/* --- 4. OUT-OF-BOUNDS ACCESS ---------------------------- */
        int a[10];
        a[10] = 0;              /* UB, and the compiler may
                                   assume it does not happen */
/* Which is why a bounds check AFTER the access is deleted,
```

```
   and why `if (i < 10 || i > 10)` can be simplified in
   surprising ways once the compiler knows an access at a[i]
   already happened.

/* --- 5. UNINITIALISED VALUES ---------------------------- */
        int x;
        if (x) ...              /* UB - and `x` is not merely
                                   a random number: it may
                                   behave INCONSISTENTLY,
                                   because it is "poison" in
                                   the IR and may be folded
                                   differently at each use  */

/* --- 6. SHIFT COUNT ------------------------------------- */
        1 << 32                 /* UB for 32-bit int */
        x >> -1                 /* UB */
        1 << 31                 /* UB in C99 for signed int;
                                   use 1u << 31            */
/* And note the HARDWARE differs: ARM masks the shift count to
   the register width, x86 masks to 5 or 6 bits. So the same
   UB gives different answers on different targets.

/* --- 7. INFINITE LOOPS WITHOUT SIDE EFFECTS ------------- */
        while (1) { }           /* UB in C++; in C, UB only if
                                   the condition is not a
                                   constant                */
/* The compiler may assume any loop terminates, and delete or
   fall through it. This has produced genuinely astonishing
   output when someone wrote an empty spin loop.

/* --- 8. DATA RACES -------------------------------------- */
        /* two threads, no synchronisation, one writes */
/* UB. Not "you get one value or the other" - the compiler may
   split a store into two, invent a store, or cache the value
   in a register indefinitely. Use _Atomic, or a lock.

/* --- 9. UNSEQUENCED MODIFICATION ------------------------ */
        i = i++ + 1;            /* UB */
        f(i++, i++);            /* UB */
        a[i] = i++;             /* UB */
/* Not merely "unspecified order" - genuinely undefined.

/* --- 10. FUNCTION POINTER TYPE MISMATCH ----------------- */
        void (*f)(void) = (void (*)(void))some_int_fn;
        f();                    /* UB */
/* And with control-flow integrity enabled, it now TRAPS -
   which is how a long-latent bug becomes a crash after a
   toolchain upgrade.                                      */
```

THE PATTERN BEHIND ALL OF THEM

The compiler is not looking for your UB and punishing it. It is doing ordinary reasoning — "this pointer was dereferenced, so it is non-null"; "this loop counter is `int`, so it does not wrap" — and propagating the conclusion. The transformation is correct for every program without UB. Yours has UB, so it is outside the set the compiler promised anything about.

Finding it

```
# --- UBSAN: the single most valuable tool here ---
    gcc -fsanitize=undefined -fno-sanitize-recover=all -g
    clang -fsanitize=undefined,integer,nullability -g

# It instruments the program and reports at RUN TIME:
    prog.c:10:12: runtime error: signed integer overflow:
    2147483647 + 1 cannot be represented in type 'int'

# WHAT IT CHECKS:
    signed integer overflow      shift out of range
    null dereference             misaligned access
    array bounds (with known sizes)
    division by zero             invalid enum/bool values
    float-to-int overflow        unreachable code reached
    object size violations       vptr misuse (C++)
    function pointer type mismatch

# COST: roughly 20% slower. Cheap enough to run all your tests
# under. THE MINIMAL PRODUCTION SUBSET:
    -fsanitize=undefined -fsanitize-minimal-runtime \
    -fno-sanitize-recover=all
# which traps rather than printing, and costs very little.

# --- ASAN: memory errors ---
    -fsanitize=address -fno-omit-frame-pointer
# use-after-free, buffer overflow, double free, leaks.
# ~2x slower, 3x memory. Reports with the allocation and free
# stacks.

# --- TSAN: data races ---
    -fsanitize=thread
# ~10x slower, but it finds races that no amount of testing
# will.

# --- MSAN: uninitialised reads (clang) ---
    -fsanitize=memory
# Requires ALL code including libraries to be instrumented,
# which is the practical obstacle.

# --- STATIC ANALYSIS ---
    gcc -fanalyzer             ; GCC 10+, genuinely good
    clang --analyze
    clang-tidy
    cppcheck
    scan-build make

# --- COMPILER WARNINGS THAT SPECIFICALLY CATCH UB ---
    -Wall -Wextra
    -Wstrict-aliasing=2
    -Warray-bounds=2
    -Wnull-dereference
    -Wshift-overflow=2
    -Wsequence-point
    -Wuninitialized -Wmaybe-uninitialized

# THE COMBINATION THAT FINDS THE MOST, in practice:
#   -Wall -Wextra -Werror in CI
#   + all tests under UBSan and ASan
#   + a nightly TSan run if threaded
```

```
# That catches the overwhelming majority of what this chapter
# describes.
```

Writing code that has none

```
/* --- CHECK BEFORE, NOT AFTER --- */
        if (p == NULL) return;
        int x = *p;                     /* right order */

/* --- CHECK OVERFLOW WITHOUT CAUSING IT --- */
        /* WRONG: */
        if (a + b < a) overflow();      /* the add is already
                                           UB               */
        /* RIGHT: */
        if (a > INT_MAX - b) overflow();
        /* OR, best: */
        int result;
        if (__builtin_add_overflow(a, b, &result))
                overflow();
        /* which compiles to one add plus a branch on the
           carry flag - no cost at all on ARM             */

/* --- USE UNSIGNED FOR BIT MANIPULATION --- */
        uint32_t mask = 1u << 31;       /* defined */
        int32_t  bad  = 1 << 31;        /* UB */

/* --- TYPE-PUN WITH memcpy --- */
        uint32_t u;
        memcpy(&u, &f, sizeof u);
        /* every compiler recognises this and emits ZERO
           instructions for it when the types are
           register-sized                                 */

/* --- PASS SIZES, ALWAYS --- */
        void f(int *a, size_t n);       /* not `int a[]` and
                                           a guess          */

/* --- USE THE SAFE STRING FUNCTIONS --- */
        strscpy(dst, src, sizeof dst);      /* kernel */
        snprintf(buf, sizeof buf, ...);
        /* never strcpy, strcat, sprintf, gets */

/* --- ENABLE THE FLAGS THAT NARROW UB --- */
        -fwrapv                 signed overflow wraps
        -fno-strict-aliasing    type punning permitted
        -fno-delete-null-pointer-checks
        -ftrivial-auto-var-init=zero     initialise locals
/* THE KERNEL USES ALL FOUR. They cost some optimisation and
   remove whole bug classes, which for a codebase of that size
   and lifetime is clearly the right trade. For your code,
   decide deliberately rather than by default.

/* --- AND THE STRUCTURAL ONES --- */
/*   · prefer array indices to pointer arithmetic
     · keep buffer sizes next to buffers, or use a struct
     · make invalid states unrepresentable where you can
     · initialise at declaration
     · one exit point for resources (C ch. 26 / cmp ch. 06) */
```

The language design answer

Language	Approach to UB
C, C++	Extensive UB, for optimisation freedom and to accommodate every historical machine
Java, C#	Almost none: bounds checked, integers wrap, null throws. Pays runtime cost
Go	Almost none; bounds checked, but data races are still UB
Rust	None in *safe* code — the compiler proves it away. UB is confined to `unsafe` blocks, which are auditable and rare (Rust ch. 02)
Zig	UB is checked in debug builds, assumed in release — an explicit, per-build choice
Ada/SPARK	Checked by default; provably absent with formal verification

This is the strongest single argument for Rust in systems programming, and it is worth stating precisely: Rust does not eliminate the hardware realities — it moves the burden of proving the absence of UB from the programmer's discipline to the compiler's type system, and confines the cases it cannot prove to blocks you must write `unsafe` on. The bugs in this chapter do not become easier to find; they become impossible to write outside a marked region.

How it shows up

Symptom	Likely UB
Works at `-O0`, fails at `-O2`	Almost certainly UB somewhere
A NULL check is missing from the assembly	A dereference before it
A bounds check disappears	An out-of-bounds access elsewhere let the compiler conclude the index range
A loop is deleted or becomes infinite	Signed overflow, or a loop with no side effects
A comparison folds to a constant	Signed overflow assumption
Type punning gives stale values	Strict aliasing
Different results on ARM and x86	Shift count, or signedness of `char`
Breaks after a compiler upgrade	A new optimisation exploited existing UB
Breaks when LTO is enabled	The optimiser can finally see the contradiction
Crashes only under load, in threads	A data race
Traps after enabling CFI	Function pointer type mismatch
Value differs between two uses	Uninitialised — it is poison, not a fixed random number

Check yourself

- ✓ State the contract and explain why the optimiser's reading is the only workable one.
- ✓ Distinguish undefined, unspecified and implementation-defined behaviour.
- ✓ Explain why `x + 1 > x` folds to true for `int` and not `unsigned`.
- ✓ Explain the deleted-null-check pattern and the kernel CVE it caused.
- ✓ Explain strict aliasing and give three correct ways to type-pun.
- ✓ Explain why UB can affect code before it in the source.
- ✓ List ten kinds of UB in C and recognise each in code.

- ✓ Enable UBSan and ASan and run a test suite under them.
- ✓ Rewrite an overflow check so it does not itself overflow.
- ✓ Name four flags that narrow UB and say what each costs.
- ✓ Explain how Rust changes the situation, precisely.

Reading compiler output like a professional

The practical skill this whole track exists to give you: look at generated AArch64 assembly and understand what the compiler did and why. It is the only way to settle a performance argument, and it is faster than you expect once you know the patterns.

The workflow

```
# --- godbolt.org, for anything small ---
# Source left, assembly right, colour-matched by line. Set the
# compiler to "ARM64 gcc" or "armv8-a clang", flags to -O2.
# Nothing else comes close for exploring a question.

# --- Locally, for real code ---
    gcc -S -O2 -fverbose-asm prog.c -o prog.s
    ; -fverbose-asm annotates each instruction with the
    ; variable names involved

    objdump -dS --demangle prog.o | less
    ; disassembly INTERLEAVED with source (needs -g)

    objdump -d --no-show-raw-insn --demangle prog.o

# --- One function only ---
    objdump -d prog | awk '/<myfunc>:/,/^$/'
    gdb -batch -ex 'disassemble /s myfunc' prog

# --- With performance data attached ---
    perf record ./prog
    perf annotate myfunc
    ; shows the percentage of samples on each instruction -
    ; which turns "this function is slow" into "this load is
    ; slow"

# --- Cycle-level analysis ---
    llvm-mca -mcpu=cortex-a53 -timeline prog.s
    ; a pipeline simulation with the bottleneck named

# --- ALWAYS COMPILE WITH THE FLAGS YOU SHIP. Reading -O0
# output tells you nothing about your release build, and
# reading -O2 output while shipping -Os tells you almost as
# little.
```

Recognising the skeleton

```
; int add(int a, int b) { return a + b; }
add:
        add     w0, w0, w1              ; args in w0,w1;
        ret                             ; result in w0

; A LEAF FUNCTION: no prologue, no stack, no calls. If you see
; this shape, the function is as cheap as it can be.

; ------------------------------------------------------------
; int call_it(int x) { return helper(x) + 1; }
call_it:
        stp     x29, x30, [sp, #-16]!   ; PROLOGUE: save FP,LR
        mov     x29, sp
        bl      helper                  ; the call
        add     w0, w0, #1
        ldp     x29, x30, [sp], #16     ; EPILOGUE
        ret

; A NON-LEAF FUNCTION. The stp/ldp pair is the giveaway.
; ------------------------------------------------------------
; A function needing callee-saved registers:
big:
        stp     x29, x30, [sp, #-64]!
        mov     x29, sp
        stp     x19, x20, [sp, #16]     ; more saves ->
        stp     x21, x22, [sp, #32]     ; more simultaneous
        str     x23, [sp, #48]          ; live state
        ...
; THE PROLOGUE SIZE IS A PRESSURE GAUGE (chapter 09). Five
; saved registers and a 64-byte frame means the function is
; carrying a lot at once - a candidate for splitting.
```

The patterns worth knowing

You see	It means
`ldr w0, [x1, x2, lsl #2]`	Array index, scaling folded in — free
`adrp x0, sym` + `add x0, x0, :lo12:sym`	Forming a global's address — PC-relative
`madd`, `msub`	Multiply-accumulate fused into one instruction
`csel`, `csinc`, `cinc`	A branch was if-converted — no misprediction
`ubfx`, `sbfx`, `bfi`	Bitfield extract/insert in one instruction
`ldp` / `stp`	Paired access — two loads for the price of one
`cbz`, `tbz`	Compare-with-zero or test-bit and branch
`wzr`, `xzr`	The zero register — no register needed to store 0
`v0.4s`, `q0`, `faddp`	**Vectorised** (ch. 07)
`bl memcpy` where you wrote a loop	Idiom recognition
`str` / `ldr` to `[sp, #n]` in a loop	**Spilling** (ch. 09)
`dmb ish`, `dsb`, `isb`	A memory barrier (ARM ch. 21)
`ldaxr` / `stlxr` loop	An atomic read-modify-write (ARM ch. 22)

You see	It means
`paciasp` / `autiasp`	Pointer authentication — return-address signing
`bti c`	Branch target identification — an indirect-branch landing pad
`brk #0x3e8` / `udf`	A trap the compiler inserted — UBSan, or unreachable code

A worked example

```
/* SOURCE: */
int count_set_bits(const uint32_t *data, int n)
{
        int count = 0;

        for (int i = 0; i < n; i++)
                count += __builtin_popcount(data[i]);

        return count;
}

; aarch64 gcc -O2 -mcpu=cortex-a72
count_set_bits:
        cmp     w1, #0
        b.le    .Lreturn_zero           ; guard: n <= 0
        mov     x2, #0                  ; i
        mov     w3, #0                  ; count
.Lloop:
        ldr     w4, [x0, x2, lsl #2]    ; data[i] - scaled
        fmov    s0, w4                  ; move to a SIMD reg
        cnt     v0.8b, v0.8b            ; popcount per BYTE
        addv    b0, v0.8b               ; sum the bytes
        fmov    w4, s0                  ; back to a GP reg
        add     x2, x2, #1
        add     w3, w3, w4
        cmp     x2, x1, sxtw
        b.lt    .Lloop
        mov     w0, w3
        ret
.Lreturn_zero:
        mov     w0, #0
        ret

/* WHAT THIS TELLS YOU:

   1. __builtin_popcount became `cnt` + `addv` on the SIMD
      unit, because AArch64 has no scalar population count.
      Four instructions including the register moves.

   2. THE fmov PAIR IS THE COST. Moving between general and
      SIMD registers has real latency (typically 3-5 cycles
      each way on an A72), and it happens EVERY iteration.

   3. IT DID NOT VECTORISE. Processing four words at once
      would amortise the moves, and it did not - because the
      reduction plus the per-element move confused the
      vectoriser.

   4. THE FIX, and this is the point of reading the output:
      restructure so the popcount stays in the vector domain: */

int count_set_bits_v2(const uint32_t *data, int n)
{
        uint32x4_t acc = vdupq_n_u32(0);
        int i;

        for (i = 0; i <= n - 4; i += 4) {
                uint8x16_t v = vreinterpretq_u8_u32(
                                        vld1q_u32(data + i));
                uint8x16_t c = vcntq_u8(v);
```

```
                acc = vaddq_u32(acc,
                        vpaddlq_u16(vpaddlq_u8(c)));
        }

        int count = vaddvq_u32(acc);

        for (; i < n; i++)              /* the tail */
                count += __builtin_popcount(data[i]);

        return count;
}
/* Four words per iteration, no domain crossing in the loop,
   one horizontal reduction at the end. Typically 3–4x faster.

   YOU WOULD NOT HAVE KNOWN TO DO THIS without reading the
   assembly. The source looked fine.                       */
```

WHAT READING ASSEMBLY IS ACTUALLY FOR

Not to hand-optimise — the compiler usually wins at that. It is to answer three questions no other tool answers: *did the optimisation I expected happen?*, *what is this loop actually doing per iteration?*, and *is the cost where I think it is?* Every performance investigation that gets past guesswork goes through this step.

The questions to ask

```
/* Work down this list on any hot function: */

1. IS IT A LEAF? No stp/ldp prologue means no calls, no
   frame. Good.

2. HOW BIG IS THE FRAME? `sub sp, sp, #N` or the stp
   immediate. Large frames mean spilling or large locals.

3. WHAT IS IN THE LOOP BODY? Count the instructions between
   the label and the backward branch. That is your per-
   iteration cost, roughly.

4. ANY STACK TRAFFIC IN THE LOOP? str/ldr to [sp, #n] means
   spilling. Reduce pressure (chapter 09).

5. ANY CALLS IN THE LOOP? `bl` prevents most optimisation
   across it and clobbers the caller-saved registers.

6. DID IT VECTORISE? Look for v registers and q loads. If not,
   ask why with -fopt-info-vec-missed (chapter 07).

7. ARE THE ADDRESSING MODES BEING USED? `[x0, x1, lsl #2]`
   good; a separate lsl then add means something prevented
   folding.

8. ARE THERE REDUNDANT MOVES? A `mov` between two registers
   that could have been the same one suggests a coalescing
   failure or a domain crossing.

9. ANY BARRIERS OR ATOMICS? dmb/ldaxr are expensive and often
   unintended - a stray volatile or an atomic where a plain
   variable would do.

10. IS THE HOT PATH THE FALL-THROUGH? A taken branch on the
    common path costs more than a not-taken one. PGO fixes
    this (chapter 06); __builtin_expect hints it.

11. WHAT DOES perf annotate SAY? The instruction with the
    samples on it is often a load - i.e. the problem is
    memory, not code (CA chapter 14), and no amount of
    instruction tuning will help.
```

Comparing two versions

```
# The most productive use of all: does my change help?

    gcc -O2 -S before.c -o before.s
    gcc -O2 -S after.c  -o after.s
    diff -u before.s after.s

# Or count instructions in the hot loop:
    objdump -d prog | awk '/\.Lloop/,/b\.lt/' | wc -l

# Or measure sizes:
    size -A before.o after.o
    nm --size-sort -S prog | tail

# AND THEN MEASURE THE ACTUAL PROGRAM, because instruction
# count is a proxy, not the answer:
    perf stat -r 10 ./prog
      cycles, instructions, IPC, branch-misses,
      cache-misses, stalled-cycles

# THE THREE NUMBERS THAT DIAGNOSE MOST THINGS:
#   IPC low + high cache-misses    -> memory bound
#   IPC low + high branch-misses   -> branchy code
#   IPC high but slow              -> genuinely doing too much
#                                     work; look at the
#                                     algorithm

# A CHANGE THAT REMOVES INSTRUCTIONS AND DOES NOT REMOVE TIME
# means the bottleneck is elsewhere. That is worth
# discovering before spending a day on it.
```

Traps when reading

```
/* --- 1. THE FUNCTION IS NOT THERE --- */
/* It was inlined. Look at the caller, or build with
   -fno-inline to see it in isolation - accepting that you are
   now looking at different code.

/* --- 2. THE LOOP IS NOT THERE --- */
/* Constant-folded, deleted as dead, or turned into a closed
   form. If you wrote a benchmark whose result is unused, the
   compiler deleted the whole thing. Defeat it: */
        __asm__ volatile("" : : "r"(result) : "memory");
        /* or use a benchmark framework's DoNotOptimize() */

/* --- 3. THE CODE IS DUPLICATED --- */
/* Loop unswitching, vectorisation with a scalar epilogue,
   runtime alias checks (chapter 07) - all produce several
   copies. Find the one that runs.

/* --- 4. YOU ARE READING -O0 --- */
/* Every variable in memory, every expression separate. It
   tells you nothing about your release build.

/* --- 5. LINE ATTRIBUTION IS APPROXIMATE --- */
/* After scheduling, an instruction's source line is where it
   CAME FROM, not where it runs. objdump -S interleaving looks
   scrambled for this reason (chapter 14).

/* --- 6. THE STATIC FUNCTION VANISHED --- */
/* If a `static` function has one caller it is usually inlined
   and the out-of-line copy deleted. Add
   __attribute__((noinline)) temporarily to study it.

/* --- 7. YOU ARE ON THE WRONG TARGET --- */
/* godbolt defaults to x86-64. Check the compiler selection.
   Half of all "the compiler did something strange" reports
   are this.                                              */
```

A practice routine

```
# Twenty minutes, and it teaches more than reading about it.

# 1. Open godbolt.org, set ARM64 gcc, -O2.

# 2. Type each of these and read the output:
    int f(int x) { return x * 2; }          ; lsl
    int f(int x) { return x / 2; }          ; the signed
                                            ; correction
    unsigned f(unsigned x) { return x / 2; } ; one lsr
    int f(int x) { return x % 7; }          ; magic-number
                                            ; division
    int f(int a, int b) { return a > b ? a : b; }  ; csel
    int f(int *p) { return p ? *p : 0; }
    int f(void) { int a[4] = {1,2,3,4};
                  return a[0]+a[1]+a[2]+a[3]; }    ; folded?

# 3. Then a loop, and check whether it vectorises:
    void f(float *a, float *b, int n) {
            for (int i = 0; i < n; i++) a[i] += b[i];
    }
    ; add `restrict` and watch the alias check disappear

# 4. Then something from your own codebase.

# THE HABIT TO BUILD: whenever you wonder "is this fast?" or
# "did that help?", spend two minutes looking rather than
# reasoning. It is almost always faster than the argument,
# and it is always more reliable.
```

How it shows up

Symptom	What to look for
Function slower than expected	Stack traffic in the loop; calls; missing vectorisation
Your optimisation changed nothing	The compiler was already doing it — diff the assembly
Benchmark shows zero time	The loop was deleted; the result is unused
Cannot find the function	Inlined
Several copies of the loop	Unswitching, vectorisation epilogue, or alias-check versioning
Unexpected `bl` to a libc function	Idiom recognition, or a division/modulo helper
Unexpected barriers	A stray `volatile`, or an atomic type
Register moves everywhere	Domain crossing (GP↔SIMD), or coalescing failure
Assembly looks fine but it is still slow	Memory bound — check `perf stat` cache misses
x86 instructions in the output	Wrong target selected

Check yourself

- ✓ Get from a source file to annotated assembly three different ways.
- ✓ Recognise a leaf function, a non-leaf, and a register-pressured one at a glance.
- ✓ Identify fifteen AArch64 patterns and say what each implies.

- ✓ Work the eleven diagnostic questions on a real hot function.
- ✓ Spot spilling, vectorisation and idiom recognition in output.
- ✓ Diff two versions of a function and quantify the change.
- ✓ Use `perf stat` to decide whether you are memory or compute bound.
- ✓ Name seven traps that make assembly misleading, and how to avoid each.
- ✓ Find a real optimisation opportunity in your own code by reading its output.
- ✓ Explain what reading assembly is for, and what it is not for.

> **END OF THE COMPILERS TRACK**
>
> Sixteen chapters, from preprocessing to reading the result. You now know what happens to your source, which phase to blame for a given behaviour, and how to check rather than guess. Next: C++, where the same machinery has to cope with a far larger language.

TRACK

ARM architecture

The A-profile architecture concept by concept: registers, translation, caches, ordering, interrupts and the exception model.

35 chapters

What ARM is: architecture versus microarchitecture

Arm Ltd does not make chips. It writes a specification and licenses core designs that implement it. Keeping those two things apart is the first thing to get right, because it tells you which of your bugs are portable and which are specific to the silicon in front of you.

Two products, often confused

	Architecture	Microarchitecture
Is	A specification — a contract about behaviour	An implementation — actual logic gates
Defines	Instructions, registers, memory model, exception behaviour	Pipeline depth, cache sizes, prefetchers, branch predictors
Document	The *Arm Architecture Reference Manual* ("the ARM ARM")	A core's Technical Reference Manual, plus its errata
Determines	**Correctness**	**Performance**
Examples	ARMv8-A, ARMv9-A, ARMv8-M	Cortex-A78, Neoverse N2, Apple Firestorm, Qualcomm Oryon

WHY THIS MATTERS WHEN YOU ARE DEBUGGING

Ask which one you are fighting.

Architectural problems are portable: if your code violates the memory model, it is wrong on every ARM implementation, and the fix is in your code. **Microarchitectural** surprises — timing, cache line effects, an erratum — are specific to one core, and the fix may be a workaround, a different compiler flag, or a kernel quirk.

A useful test: *would this still be a bug on a hypothetical, perfectly simple in-order implementation of the same architecture?* If yes, it is architectural and it is your problem to fix properly.

The licensing model, and why it shapes the ecosystem

Licence type	Buys	Licensees
Core licence	A ready-made core design (Cortex-A78) to drop into your SoC	Most SoC vendors: NXP, ST, TI, Rockchip, MediaTek
Architecture licence	The right to design your *own* core implementing the ARM architecture	Apple, Qualcomm, Nvidia, Ampere, Fujitsu
Subsystem / CSS	A pre-integrated cluster, interconnect and memory system	Vendors wanting a shorter path to silicon

The architecture licence is why Apple's cores are dramatically faster than a Cortex core of the same generation while running identical binaries: same contract, very different implementation. It is also why "ARM performance" is a meaningless phrase — you must name the core.

```
One architecture, many implementations, all running your binary:

   ARMv8-A specification
        │
        ├── Cortex-A53   in-order, 8-stage, tiny, power-efficient
        ├── Cortex-A78   out-of-order, 4-wide, deep, fast
        ├── Neoverse V2  server-class, wide vectors, huge caches
        ├── Apple M-series  very wide, very large reorder buffer
        └── Qualcomm Oryon  custom, architecture-licensed

Same instructions. Same page table format. Same barriers.
10-50x difference in single-thread performance, and completely
different cache hierarchies.
```

What the architecture actually specifies

- **The instruction set** — encodings and precise semantics.
- **The register file** — what exists and what each register means.
- **The memory model** — what reorderings are permitted, and what barriers guarantee (ch. 20).
- **The exception model** — exception levels, vectors, what hardware saves (ch. 26).
- **Address translation** — page table formats, descriptor bits, TLB maintenance (ch. 13).
- **System registers** — names, fields, and which level may access them.
- **Required behaviour on reset**, and what is *IMPLEMENTATION DEFINED*.

> **IMPLEMENTATION DEFINED IS A FORMAL TERM**
>
> The ARM ARM uses precise vocabulary that is worth learning, because it tells you exactly how much you may rely on something:
>
> - **IMPLEMENTATION DEFINED** — the implementer chooses and must document it. Cache size, number of breakpoints, whether a feature exists.
> - **UNPREDICTABLE** — behaviour is not specified, but must not be a security hole or hang the machine. Never write code that relies on it.
> - **CONSTRAINED UNPREDICTABLE** — one of a specified, enumerated set of behaviours. Still do not rely on it.
> - **RES0 / RES1** — reserved bits you must write as zero or one respectively, so that future architecture versions can use them without breaking your code. Ignoring this is why some old firmware fails on new silicon.

Never assume — ask the CPU

```
/* The architecture provides ID registers describing exactly which
   optional features this implementation has. Software must query
   them rather than assume, because the SAME architecture version
   allows different feature sets.                                  */

MIDR_EL1          /* implementer, part number, revision — "who am I" */
MPIDR_EL1         /* affinity: which core in which cluster           */
ID_AA64ISAR0_EL1  /* atomics (LSE), CRC32, crypto, SHA               */
ID_AA64ISAR1_EL1  /* pointer authentication, JSCVT, DPB              */
ID_AA64MMFR0_EL1  /* physical address size, granule sizes supported  */
ID_AA64MMFR1_EL1  /* VHE, hardware access/dirty bit management       */
ID_AA64PFR0_EL1   /* which exception levels exist, SVE, FP           */
CTR_EL0           /* cache line sizes — readable from EL0            */

/* Example: does this core have the Large System Extensions? */
static bool has_lse(void)
{
        uint64_t isar0;
        asm volatile("mrs %0, id_aa64isar0_el1" : "=r"(isar0));
        return ((isar0 >> 20) & 0xF) >= 2;   /* Atomic field */
}
/* Linux and Windows both do exactly this at boot and PATCH the
   binary — replacing an LDXR/STXR loop with a single LDADD where
   the hardware supports it. One kernel image, optimal on each. */
```

```
# see what your machine reports
cat /proc/cpuinfo
#   CPU implementer : 0x41        (0x41 = 'A' = Arm Ltd; 0x61 = Apple)
#   CPU architecture: 8
#   CPU variant     : 0x1
#   CPU part        : 0xd0b       (0xd0b = Cortex-A76)
#   Features        : fp asimd atomics crc32 sha1 sha2 ...
#                     ^^^^^^^ "atomics" means LSE is present

lscpu
cat /sys/devices/system/cpu/cpu0/regs/identification/midr_el1
```

Errata

> **READ THE ERRATA DOCUMENT. ALWAYS.**
> Every core has documented hardware bugs, published as an errata notice, each with a software workaround. They are not rare and they are not theoretical — the Linux kernel contains hundreds of them, gated by `MIDR` checks so the workaround applies only on affected revisions.

```
grep -rn "ARM64_WORKAROUND" arch/arm64/kernel/cpu_errata.c | head
cat /sys/devices/system/cpu/vulnerabilities/*

/* A real example: Cortex-A53 erratum 843419 — a specific sequence
   of ADRP plus a load can compute the wrong address. The fix is a
   LINKER workaround (--fix-cortex-a53-843419), which is why some
   toolchains pass it by default for that core.

   The lesson: when hardware behaves impossibly, check the errata
   before assuming your code is at fault. And when bringing up new
   silicon, read the whole document once, up front.          */
```

Why ARM ended up everywhere

Property	Consequence
Licensable IP	Any company can build a custom SoC without designing a CPU. This, more than any technical property, is why ARM won mobile and embedded.
Power efficiency	Simple decode, load/store design, and a culture of performance-per-watt
Scalability	The same architecture family spans a coin-cell sensor and a 128-core server
Clean 64-bit ISA	AArch64 was designed fresh in 2011, without decades of compatibility baggage
Ecosystem	Linux, Windows, Android, every RTOS, every toolchain

Using the ARM ARM

```
It is over 12,000 pages. It is a REFERENCE, not a textbook, and
reading it linearly is a mistake beginners make once.

  How to use it:
    · start from a QUESTION ("what does ESR_EL1 bit 24 mean?")
    · search the PDF, or use developer.arm.com's HTML version
    · the register descriptions (section D) are the most-used part
    · pseudocode in the manual is NORMATIVE — when prose and
      pseudocode disagree, the pseudocode wins

  Start instead with:
    "Arm Cortex-A Series Programmer's Guide for ARMv8-A"
      — a few hundred readable pages, written as a tutorial
    "Learn the architecture" guides on developer.arm.com
      — short, topic-focused, and genuinely good

  Then use the ARM ARM to answer the questions those raise.
```

How it shows up

Symptom	Cause
Code works on one ARM board, fails on another	Architectural violation exposed by a different implementation, or a missing feature check
Illegal instruction on some cores only	Used an optional feature without querying the ID registers
Timing-dependent bug appears only on the big cores	Microarchitectural: deeper out-of-order window widens the race
Hardware behaves impossibly	Check the errata before doubting yourself
Firmware fails on newer silicon	RES0 bits written as non-zero
Benchmark differs 10× between two "ARM" chips	Different microarchitectures — the name of the core matters
Atomics are slow under contention	Exclusive-based path; the core lacks LSE, or the kernel did not patch

Check yourself

- ✓ State the difference between architecture and microarchitecture, and give an example bug of each kind.
- ✓ Explain what an architecture licence permits that a core licence does not.
- ✓ Define IMPLEMENTATION DEFINED, UNPREDICTABLE and RES0, and say how much you may rely on each.
- ✓ Name three ID registers and what they tell you.
- ✓ Explain why a kernel patches its own code at boot after reading ID registers.
- ✓ Say why errata documents matter and give one example of a linker-level workaround.
- ✓ Explain the right way to use the ARM ARM.

Profiles and architecture versions

"ARM" names a family, not a thing. A Cortex-M0 and a Neoverse V2 share a vendor and very little else. This chapter maps the territory so that when someone says "ARMv8" you know which of several very different machines they mean.

The three profiles

	A — Application	R — Real-time	M — Microcontroller
Optimised for	Throughput, rich OS	Deterministic latency	Cost, power, small code
Memory protection	**Full MMU**, virtual memory	MPU, sometimes MMU	Optional MPU, **no MMU**
Privilege model	EL0–EL3	EL0–EL2 (v8-R)	Thread / Handler mode, optional Secure
Instruction set	A64 (and A32/T32)	A32/T32, A64 in v8-R	**Thumb-2 only**
Interrupt controller	GIC	GIC	**NVIC** — vectored, in-core
Typical software	Linux, Android, Windows	RTOS, bare metal, safety islands	Bare metal, FreeRTOS, Zephyr
Examples	Cortex-A53/A78, Neoverse	Cortex-R5/R52/R82	Cortex-M0+/M4/M33/M55

THE SINGLE DISTINCTION THAT MATTERS MOST

MMU or no MMU. With one, you get virtual memory, process isolation, demand paging and everything in the OS track. Without one, every address is physical, a wild pointer can corrupt anything, and "protection" means an MPU checking region permissions with no translation. Almost every other difference follows from this one.

M-profile: different enough to surprise you

```
Cortex-M is not "a small Cortex-A". Concretely different:

  EXCEPTIONS       the hardware stacks R0-R3, R12, LR, PC, xPSR
                   automatically, so an ISR is a PLAIN C FUNCTION.
                   No vector table of code — a table of ADDRESSES.

  VECTOR TABLE     entry 0 is the initial STACK POINTER, entry 1 is
                   the reset handler. The CPU loads SP from memory
                   before executing anything.

  NVIC             priorities, tail-chaining (skip the unstack/stack
                   between back-to-back interrupts), late arrival.
                   Interrupt latency ~12 cycles, deterministic.

  TWO STACKS       MSP (main, used by handlers) and PSP (process).
                   An RTOS gives each task a PSP and keeps MSP for
                   exceptions.

  BIT-BANDING      (v7-M) an alias region where each word maps to
                   one bit — atomic single-bit access without
                   read-modify-write.

  TRUSTZONE-M      a function CALL across the boundary, not an SMC.
                   Tens of cycles, not thousands (ch. 15 of the
                   security track).

  NO A64           Thumb-2 only: mixed 16- and 32-bit encodings,
                   chosen for code density.
```

Architecture versions

Version	Year	Brought
ARMv7-A	2005	32-bit only. Processor *modes* (User, FIQ, IRQ, SVC, Abort, Undef, System, Monitor, Hyp) with banked registers. CP15 coprocessor for system control. NEON, TrustZone, LPAE.
ARMv8-A	2011	**AArch64.** A clean 64-bit ISA, 31 general registers, exception levels replacing modes, system registers replacing CP15, a formally specified memory model.
ARMv8.1	2014	**LSE atomics**, VHE (host OS runs at EL2), hardware access/dirty bit management
ARMv8.2	2016	SVE, half-precision FP, RAS extensions, 52-bit addresses
ARMv8.3	2016	**Pointer Authentication** (PAC), nested virtualisation, JavaScript FP conversion
ARMv8.4	2017	**Secure EL2**, memory partitioning and monitoring (MPAM)
ARMv8.5	2018	**BTI** (Branch Target Identification), **MTE** (Memory Tagging), speculation barriers
ARMv9-A	2021	SVE2 mandatory, **CCA / Realm Management Extension** (a fourth security state), BTI and MTE promoted to baseline

> **VERSIONS ARE CUMULATIVE AND MOSTLY OPTIONAL**
> ARMv8.5 includes everything from 8.1 to 8.4. But many individual features remain *optional* even within a version, which is why software must query the ID registers rather than infer capability from a version number (chapter 01). "This is an ARMv8.2 core" does not tell you whether it has SVE.

Execution states

```
ARMv8-A defines TWO execution states, and a core may implement
one or both:

  AArch64                        AArch32
    A64 instruction set            A32 (ARM) + T32 (Thumb)
    31 x 64-bit registers          16 x 32-bit registers
    fixed 32-bit encodings         mixed 16/32-bit (T32)
    EL0-EL3                        modes mapped onto ELs
    no conditional execution       full predication (IT blocks)
    system registers               CP15 coprocessor

  Switching states happens ONLY on an exception boundary:
    · taking an exception can move AArch32 → AArch64
    · ERET can move AArch64 → AArch32
    · a HIGHER EL may be AArch64 while a lower one is AArch32,
      never the reverse

  So a 64-bit kernel can run 32-bit userspace, but a 32-bit kernel
  cannot run 64-bit applications.

  AArch32 support is now commonly OMITTED at EL0 in new cores
  (Cortex-A510 onward, Apple silicon). 32-bit ARM Linux binaries
  simply will not run there — a real migration issue for
  long-lived embedded products.
```

The security features, briefly

Feature	Defends against	How
PAC (v8.3)	ROP/JOP — corrupting return addresses and function pointers	A cryptographic signature in the unused top bits of a pointer, checked before use
BTI (v8.5)	Jump-oriented programming	An indirect branch may only land on a `BTI` instruction
MTE (v8.5)	Buffer overflow and use-after-free	A 4-bit tag on each 16-byte granule and in each pointer; hardware compares them
PAN (v8.1)	Kernel accidentally dereferencing a user pointer	Kernel access to user memory faults unless explicitly enabled
CCA / RME (v9)	An untrusted hypervisor or host	A fourth world ("Realm") isolated from both Normal and Secure

```
# build with the hardening on
gcc -mbranch-protection=standard    # PAC on returns + BTI
gcc -march=armv8.5-a+memtag         # MTE

# MTE is the most interesting of these: it makes ASan-class
# detection cheap enough to run in PRODUCTION. Android ships it.
cat /proc/cpuinfo | grep -o 'paca\|bti\|mte'
```

Decoding the names

```
Cortex-A78AE
|      | | └── AE = Automotive Enhanced (lockstep, safety)
|      | └──── generation number: higher is newer/bigger
|      └─────── profile: A, R or M
└──────────────── Arm's own core family

Neoverse N2 / V2 / E2
  N = balanced (scale-out cloud)
  V = maximum performance (HPC, high-end server)
  E = efficiency (edge, networking)

Cortex-M33 / M55 / M85
  M23, M33  → ARMv8-M with TrustZone-M
  M55, M85  → ARMv8.1-M with Helium (M-profile vector extension)

DynamIQ Shared Unit (DSU)
  the cluster that ties heterogeneous cores together with a
  shared L3 — the successor to big.LITTLE's separate clusters

Suffixes worth recognising:
  -AE   automotive, functional safety
  -AP   with parity/ECC for safety
  +crypto / +sve / +simd  in compiler -march strings
```

Telling the compiler what to target

```
# architecture version — what INSTRUCTIONS may be emitted
-march=armv8-a
-march=armv8.2-a+crypto+fp16
-march=armv9-a+sve2

# tune for a specific microarchitecture — SAME instructions,
# different scheduling and cost model
-mtune=cortex-a76

# both at once
-mcpu=cortex-a76           # implies -march and -mtune
-mcpu=cortex-a55+crypto

# big.LITTLE: build for the LEAST capable core you must run on,
# tune for the one that matters
-mcpu=cortex-a55 -mtune=cortex-a76

# M-profile
-mcpu=cortex-m4 -mfpu=fpv4-sp-d16 -mfloat-abi=hard -mthumb

# runtime dispatch instead: build a baseline binary and select
# optimised routines after reading the ID registers. This is what
# glibc's ifunc mechanism and every crypto library do.
gcc -march=armv8-a ... ; if (has_crypto()) use_aes_instructions();
```

> **`-MARCH=NATIVE` IS A TRAP IN EMBEDDED WORK**
>
> It targets the build machine, not the deployment target — and on a big.LITTLE system it may target whichever core the compiler happened to run on. The result runs until it is scheduled onto a LITTLE core lacking a feature, then takes an illegal-instruction fault. Always name the target explicitly.

Which profile for which job

Requirement	Profile	Why
Run Linux or Android	**A**	Needs an MMU
Hard real-time, microsecond deadlines	**R** or **M**	Deterministic interrupt latency, no paging
Battery-powered sensor, years of life	**M**	Microamp sleep currents
Motor control beside a rich UI	**A** + **M/R** on one SoC	Asymmetric multiprocessing (OS ch. 19)
Functional safety certification	**R** (-AE parts)	Lockstep cores, ECC, safety documentation
Server or cloud	**Neoverse**	Core count, memory bandwidth, RAS

How it shows up

Symptom	Cause
Illegal instruction on some cores, not others	Optional feature used without an ID-register check
32-bit binary will not run on a new ARM64 chip	AArch32 at EL0 not implemented
Code built with `-march=native` faults in the field	Targeted the build machine, or the big core only
Cortex-M interrupt handler needs no special attribute	Hardware stacks the caller-saved registers
MMU-based isolation unavailable on a Cortex-M	M-profile has no MMU — MPU only
Atomics are slow on an older core	No LSE; falls back to exclusive loops
Two "ARMv8" chips differ 10× in performance	Different microarchitectures entirely
Security hardening flags do nothing	The core predates PAC/BTI/MTE

Check yourself

- ✓ Give the three profiles, their memory-protection model, and typical software for each.
- ✓ Name four concrete ways M-profile differs from A-profile.
- ✓ Say what ARMv8-A changed relative to ARMv7-A, in four points.
- ✓ Explain why a version number does not tell you which features are present.
- ✓ State the rule about which exception levels may be AArch32 versus AArch64.
- ✓ Explain what PAC, BTI and MTE each defend against.
- ✓ Give the difference between `-march`, `-mtune` and `-mcpu`.
- ✓ Explain why `-march=native` is dangerous for embedded targets.

Load/store architecture and the RISC philosophy

One design rule shapes everything else about ARM: only load and store instructions touch memory. Everything else operates on registers. This chapter draws out the consequences, several of which are the direct cause of bug classes you will meet for the rest of your career.

The rule

LOAD/STORE ARCHITECTURE

Memory is accessed *only* by the `LDR` and `STR` instruction families. Every arithmetic, logical and comparison instruction reads its operands from registers and writes its result to a register. There is no `ADD [address], #1`.

```
/* C source */
counter++;

/* AArch64 — three separate instructions, plus address formation */
        adrp    x0, counter               // page address of the symbol
        add     x0, x0, :lo12:counter     // + low 12 bits = full address
        ldr     w1, [x0]                  // LOAD    memory → register
        add     w1, w1, #1                // MODIFY  register only
        str     w1, [x0]                  // STORE   register → memory

/* x86, by contrast, can do it in one instruction: */
        incl    counter(%rip)             // read-modify-write in one op
/* — but note that even on x86 this is NOT atomic without a LOCK
   prefix. The hardware still performs three steps internally.  */
```

What follows from it

1. Read-modify-write is never atomic

```
   Core 0                    Core 1
   ldr  w1, [x0]   → 5
                             ldr  w1, [x0]   → 5
   add  w1, w1, #1 → 6
                             add  w1, w1, #1 → 6
   str  w1, [x0]   → 6
                             str  w1, [x0]   → 6

   Two increments, one result. This is not an ARM quirk — it is
   the direct, visible consequence of the load/store rule, and it
   is why the atomics of chapter 22 exist as separate instructions
   rather than as a property of ADD.
```

2. Address formation is explicit

```
/* A 64-bit address does not fit in a 32-bit instruction, so ARM
   builds addresses from pieces. Three common idioms:          */

/* PC-relative, ±4 GB — how globals are reached in position-
   independent code. ADRP gives the 4 KB PAGE address; the low
   bits come from an ADD or the load's own offset.            */
        adrp    x0, symbol
        add     x0, x0, :lo12:symbol

/* Small immediate offset, folded into the load */
        ldr     x1, [x0, #16]

/* Large constants are built 16 bits at a time */
        movz    x0, #0x1234, lsl #16
        movk    x0, #0x5678

/* This is why disassembly shows ADRP/ADD pairs everywhere, and
   why the linker has relocation types specifically for splitting
   an address across two instructions.                         */
```

3. Fixed 32-bit instruction width

Consequence	Effect
Decode is trivial	Several instructions can be decoded in parallel with no serial dependency — a major reason ARM cores go wide cheaply
Disassembly is unambiguous	You can start disassembling at any 4-byte-aligned address and be correct. On x86, you cannot.
No unaligned instructions	Every instruction address is 4-byte aligned; the low two bits of the PC are always zero
Immediates are limited	Only 12 bits for arithmetic, so large constants need several instructions or a literal pool
Code density is worse than x86	Which is exactly why Thumb-2 exists for M-profile, mixing 16- and 32-bit encodings

4. Memory access is visible and countable

```
/* Because every access is an explicit instruction, you can SEE the
   memory traffic in the disassembly. This makes ARM assembly
   unusually readable for performance work.                    */

objdump -d prog | grep -cE '\b(ldr|ldp|str|stp)'   /* count accesses */

/* And it makes the compiler's decisions visible: if a variable
   stays in a register across a loop, there are no LDRs inside
   the loop. If `volatile` forces a reload, you see one per
   iteration. This is the fastest way to confirm what volatile
   and restrict actually did (C chapters 10 and 18).         */
```

RISC in practice, not in slogans

Classic RISC claim	Reality on modern ARM
"Reduced instruction *set*"	AArch64 has well over a thousand instructions. The set is not small.
"One instruction per cycle"	Wide superscalar cores retire several per cycle; some instructions take many
"Simple instructions only"	`FJCVTZS` (JavaScript float-to-int), `AESE`, `SHA256H`, `LD64B` — these are not simple

Classic RISC claim	Reality on modern ARM
"No microcode"	Largely true, and it does matter: decode stays cheap
"Load/store architecture"	**True, and the one that actually matters**
"Fixed-width instructions"	True for A64; false for Thumb-2
"Many general-purpose registers"	True — 31, versus x86-64's 16

> **THE RISC/CISC DISTINCTION HAS LARGELY DISSOLVED**
>
> Modern x86 cores decode complex instructions into RISC-like micro-operations and execute those. Modern ARM cores have complex instructions. What remains genuinely different is the *front end*: fixed-width, regularly encoded instructions are much cheaper to decode in parallel, which lets ARM cores go wide with less power. That, plus load/store discipline, is the real substance behind the label.

Why 31 registers changes how code looks

```
/* With 16 registers (x86-64), the compiler spills to the stack
   constantly. With 31, most functions keep everything in
   registers. Compare a small function:                          */

/* AArch64 — no memory traffic at all inside the function */
sum4:   add     w0, w0, w1
        add     w0, w0, w2
        add     w0, w0, w3
        ret

/* And the calling convention passes EIGHT arguments in registers
   (chapter 09), so most calls involve no stack traffic either.

   Practical consequence: on AArch64, seeing LDR/STR of stack
   slots inside a hot loop usually means something is wrong —
   an address was taken, aliasing blocked an optimisation, or
   the function is genuinely register-starved.                */
```

Orthogonality and its limits

```
/* Most instructions accept any register in any operand position —
   which makes the ISA easy to generate code for. But there are
   real exceptions worth knowing:                                */

/* XZR/WZR — register 31 reads as zero and discards writes.
   This gives you several idioms for free:                       */
        mov     x0, xzr          // x0 = 0
        subs    xzr, x1, x2      // compare, discard the result
                                 //   (this IS how CMP is encoded)
        str     xzr, [x0]        // store zero, no register needed

/* But in SOME encodings, register 31 means the STACK POINTER
   instead of the zero register. Which one depends on the
   instruction:                                                  */
        add     x0, sp, #16      // here 31 = SP
        add     x0, x1, xzr      // here 31 = XZR

/* This is a genuine trap when hand-writing or reading assembly,
   and the reason disassemblers print SP and XZR explicitly.  */
```

No predication — and what replaced it

```
/* ARMv7 could predicate almost ANY instruction:
        ADDEQ r0, r1, r2      @ execute only if Z is set
   This saved branches, but cost 4 encoding bits on every single
   instruction and complicated out-of-order execution.

   A64 dropped it. Instead there are conditional SELECT
   instructions, which are branchless without needing predication
   everywhere:                                                  */

        cmp     w0, w1
        csel    w2, w3, w4, gt      // w2 = (w0 > w1) ? w3 : w4
        cset    w2, eq              // w2 = (Z) ? 1 : 0
        csinc   w2, w3, w4, ne      // w2 = ne ? w3 : w4 + 1
        csinv, csneg, cinc, cneg

/* This is how the compiler turns a small if/else into branchless
   code — and why the branchless idioms in CA chapter 12 and C
   chapter 08 compile so well on AArch64.                       */

int max(int a, int b) { return a > b ? a : b; }
/*      cmp     w0, w1
        csel    w0, w0, w1, gt
        ret                    — no branch, no mispredict      */
```

Flags are set explicitly

```
/* Most instructions do NOT touch the condition flags. You opt in
   with an S suffix. This is the opposite of x86, where nearly
   everything clobbers EFLAGS.                                  */

        add     w0, w1, w2       // flags unchanged
        adds    w0, w1, w2       // sets N, Z, C, V
        subs    xzr, x1, x2      // == cmp x1, x2
        ands    wzr, w1, w2      // == tst w1, w2

/* Why it matters: because flags survive across unrelated
   instructions, the compiler can compute a condition early,
   do other work, and branch on it later — which schedules
   better on a deep pipeline. It also means an overflow check
   needs an explicit ADDS, which is exactly what
   __builtin_add_overflow generates (C chapter 02).          */
```

Reading AArch64 disassembly

```
# the fastest way to learn: compile and look
gcc -O2 -S -o - test.c              # assembly source
gcc -O2 -c test.c && objdump -d test.o
objdump -d --source prog            # interleaved with C (needs -g)

# godbolt.org is the fastest iteration loop for this

# what to look for, in order:
#   1. LDR/STR inside loops  → memory traffic; is it necessary?
#   2. B / B.cond            → branches; predictable?
#   3. CSEL / CSET           → the compiler went branchless
#   4. ADRP/ADD pairs        → global variable access
#   5. STP/LDP at entry/exit → the prologue and epilogue
#   6. BL                    → calls that were not inlined
#   7. LD1/ST1/V registers   → it vectorised
```

> **THE HABIT WORTH BUILDING**
> When a performance question comes up, look at the assembly before theorising. AArch64 output is regular enough to read without being an assembly programmer, and it answers questions — did it vectorise, did `restrict` help, is that load hoisted out of the loop — that no amount of reasoning about the source will settle.

How it shows up

Symptom	Cause
A shared counter loses increments	Read-modify-write is three instructions; needs an atomic
Disassembly is full of ADRP/ADD pairs	Normal — that is how PC-relative addresses are built
A loop reloads a variable every iteration	`volatile`, or possible aliasing the compiler cannot rule out
Hand-written assembly corrupts the stack	Confused XZR with SP in an encoding where register 31 means SP
An overflow check compiles away	No `ADDS` emitted because signed overflow is UB (C ch. 15)
Branchless code on x86 becomes branches on ARM	Or the reverse — check for `CSEL` in the output
Code size larger than the x86 equivalent	Fixed 32-bit encodings; use Thumb-2 on M-profile
Stack traffic in a small hot function	Address taken, or register pressure — look for the spill

Check yourself

- ✓ State the load/store rule and show `counter++` as instructions.
- ✓ Explain why atomicity requires dedicated instructions, from that rule.
- ✓ Explain what an `ADRP` / `ADD` pair does and why it takes two instructions.
- ✓ Give three consequences of fixed 32-bit instruction width.
- ✓ Explain the dual meaning of register 31 and when each applies.
- ✓ Say what replaced ARMv7's predication and why the change was made.
- ✓ Explain why the `S` suffix exists and one place it matters.
- ✓ List five things to look for when reading AArch64 disassembly.

The AArch64 register file

Thirty-one general-purpose registers, a stack pointer per exception level, a zero register that is also sometimes the stack pointer, and a vector file that may be 128 or 2048 bits wide. This chapter is the map you will refer back to constantly.

General-purpose registers

```
X0 — X30      31 registers, 64 bits each
W0 — W30      the LOW 32 BITS of the same registers

┌──────────────────────────────────────────────────┐
│                    X0  (64 bits)                 │
│                ┌──────────────────────────────┐  │
│  upper 32      │        W0  (32 bits)         │  │
└────────────────┴──────────────────────────────┘──┘

CRITICAL RULE: writing Wn ZEROES the upper 32 bits of Xn.
               There is no way to write only the low half.

     mov     x0, #0xFFFFFFFFFFFFFFFF
     mov     w0, #1                    // x0 is now 0x1, NOT
                                       // 0xFFFFFFFF00000001

This is a deliberate design choice: it removes the partial-
register dependency stalls that plague x86, where writing EAX
must merge with the old RAX. It also means 32-bit arithmetic is
free — no sign or zero extension needed afterwards.
```

Roles assigned by the ABI

Register	Role	Preserved across a call?
`X0` – `X7`	Arguments 1–8, and return value in `X0` (`X0` / `X1` for 128-bit)	No — caller-saved
`X8`	Indirect result location (large struct return). On Linux, also the **syscall number**.	No
`X9` – `X15`	Temporaries	No — caller-saved
`X16`, `X17`	IP0, IP1 — intra-procedure-call scratch, used by linker veneers and PLT stubs	No; may be clobbered by the linker
`X18`	Platform register. Reserved on some OSes; TLS on Windows; kernel shadow-call-stack pointer on Android.	Platform-defined
`X19` – `X28`	General use	**Yes — callee-saved**
`X29`	FP — frame pointer	Yes
`X30`	LR — link register, written by `BL`	Yes, by convention (saved in the prologue)

> **`X18` IS A PORTABILITY TRAP**
>
> The ABI says "platform register" and each OS decides. Windows uses it for TLS; Android's kernel uses it for the shadow call stack; some RTOSes leave it general. Hand-written assembly or a compiler configured with the wrong `-ffixed-x18` setting produces corruption that only appears on one platform. If you write assembly that must be portable, do not touch `X18`.

The special registers

```
/* XZR / WZR — register encoding 31, in most contexts */
        mov     x0, xzr           // x0 = 0, no immediate needed
        str     xzr, [x1]         // store 64 bits of zero
        subs    xzr, x1, x2       // compare: this IS how CMP encodes
        ands    wzr, w1, w2       // test:    this IS how TST encodes

/* SP — register encoding 31, in OTHER contexts */
        add     x0, sp, #16       // 31 here means SP
        mov     x0, sp            // encoded as `add x0, sp, #0`
        sub     sp, sp, #64       // allocate stack

/* The SAME encoding means two different things depending on the
   instruction. This is why disassemblers print them explicitly,
   and why hand-written assembly gets it wrong.               */

/* PC — the program counter is NOT a general register in AArch64.
   You cannot write it directly (unlike ARMv7, where R15 was the
   PC and `mov pc, lr` was a return). It changes only via
   branches, and it can be READ only PC-relatively:          */
        adr     x0, .              // address of this instruction
        adrp    x0, symbol         // page address, ±4 GB range
```

Stack pointers per exception level

```
   SP_EL0    used by EL0, and optionally by higher ELs
   SP_EL1    the kernel's stack
   SP_EL2    the hypervisor's stack
   SP_EL3    the secure monitor's stack

   PSTATE.SPSel selects which one "SP" refers to at the current EL:
        SPSel = 0  →  always SP_EL0        (called "t", thread)
        SPSel = 1  →  SP_ELx for this EL   (called "h", handler)

   This is why exception return states are written EL1t and EL1h,
   and why the vector table has separate entries for exceptions
   taken with SP_EL0 versus SP_ELx (chapter 27).

   WHY IT EXISTS: on exception entry the hardware switches to the
   handler's own stack automatically. Without this, a user process
   with a corrupt SP would take the kernel down with it — the
   kernel would try to save state onto an invalid stack.

   Linux reads `current` from SP_EL0 while running at EL1, using
   the otherwise-unused register as a per-CPU pointer to the
   current task_struct. That is why `current` is one register
   read rather than a lookup (OS chapter 04).
```

SIMD and floating-point registers

```
   V0 — V31      32 registers, 128 bits each

   The SAME register, named by the width you are using:

   ┌──────────────────────────────────────────┐
   │               Q0   (128 bits)            │
   │                    ┌──────────────────────┤
   │                    │    D0  (64 bits)     │
   │                    │           ┌──────────┤
   │                    │           │ S0 (32)  │
   │                    │           │     ┌────┤
   │                    │           │     │H0  │ (16)
   │                    │           │     │  ┌─┤
   │                    │           │     │  │B0│ (8)
   └────────────────────┴───────────┴─────┴──┴─┘

   Bn  8-bit    Hn 16-bit    Sn 32-bit (float)
   Dn 64-bit (double)        Qn 128-bit (full vector)

   Or as VECTORS with a lane specifier:
        V0.16B   16 bytes        V0.8H   8 half-words
        V0.4S    4 words         V0.2D   2 double-words

   Writing Sn or Dn ZEROES the upper bits of Vn — the same rule
   as W registers.

   FPCR / FPSR   control and status: rounding mode, exception
                 flags, flush-to-zero. Note these are NOT in
                 PSTATE and are saved separately.
```

SVE: registers whose width is unknown at compile time

```
/* The Scalable Vector Extension changes the model fundamentally: */

   Z0 – Z31     vector registers, 128 to 2048 bits — the width is
                an IMPLEMENTATION CHOICE, not known when you compile
   P0 – P15     predicate registers, one bit per vector byte
   FFR          first-fault register, for speculative loads

/* Vector-length-agnostic code: the same binary runs optimally on
   any width, because the loop asks the hardware how wide it is:  */

        whilelo p0.s, x0, x1        // predicate = lanes still in range
1:      ld1w    z0.s, p0/z, [x2, x0, lsl #2]
        ld1w    z1.s, p0/z, [x3, x0, lsl #2]
        fadd    z0.s, z0.s, z1.s
        st1w    z0.s, p0,   [x4, x0, lsl #2]
        incw    x0                  // advance by the ACTUAL width
        whilelo p0.s, x0, x1         // recompute the predicate
        b.first 1b

/* No scalar tail loop is needed — the predicate handles the
   remainder. Compare with NEON, which needs an epilogue for
   elements that do not fill a full 128-bit vector.          */

/* Z0–Z31 ALIAS V0–V31: the low 128 bits of Zn IS Vn. */
```

System registers are not general registers

```
/* Configuration lives in SYSTEM registers, which are a separate
   namespace and are accessed only with MRS and MSR (chapter 06). */

        mrs     x0, sctlr_el1        // System register → general
        msr     sctlr_el1, x0        // General → System register

/* They are named REG_ELx where x is the LOWEST exception level
   that may access them. SCTLR_EL1 is accessible at EL1, EL2 and
   EL3 — but not EL0.

   You cannot use a system register as an operand to ADD. You must
   move it to a general register first. This is a common early
   mistake when hand-writing boot code.                       */
```

No banked general registers

> **THE MOST CONSEQUENTIAL DIFFERENCE FROM ARMV7**
>
> ARMv7 banked several registers per processor mode: entering IRQ mode gave you a private `R13` and `R14` automatically. **AArch64 does not bank `X0`–`X30` at all.**
>
> When an exception is taken, the handler begins executing with the interrupted code's register values still live. Nothing is saved for you except `ELR`, `SPSR` and the syndrome registers. Saving and restoring the general registers is *entirely* software's job — and that saved set is `struct pt_regs` in Linux, the trap frame in Windows.
>
> This is why every AArch64 exception vector begins with thirty-odd store instructions (chapter 28), and why getting that stub wrong corrupts the interrupted program in ways that are extremely hard to diagnose.

Register conventions in practice

```
/* A standard prologue and epilogue — read this until it is
   instantly recognisable in any disassembly.               */

my_func:
        stp     x29, x30, [sp, #-32]!   // push FP,LR; pre-decrement SP
        mov     x29, sp                 // establish the frame pointer
        stp     x19, x20, [sp, #16]     // save the callee-saved regs
                                        //   this function will use
        ...
        ldp     x19, x20, [sp, #16]     // restore
        ldp     x29, x30, [sp], #32     // pop FP,LR; post-increment SP
        ret                             // == BR X30, with a hint

/* STP/LDP move TWO registers in one instruction — which is why
   prologues save in pairs, and why the stack is always adjusted
   in multiples of 16 (chapter 09 covers the alignment rule). */

/* A LEAF function — one that calls nothing — needs no prologue
   at all, because LR is not clobbered:                        */
square: mul     w0, w0, w0
        ret
```

Inspecting registers

```
# gdb
info registers                # X0–X30, SP, PC, PSTATE
info registers x0 x1 sp
info all-registers            # including V0–V31 and system regs
p/x $x0                       # one register, in hex
p $sp
info frame                    # the current frame's saved registers

# vector registers
p $v0.d                       # as two doubles
p $v0.s                       # as four floats
p/x $v0.b                     # as sixteen bytes

# system registers, where the target exposes them
p/x $SCTLR_EL1
p/x $CPSR                     # PSTATE, on some gdb versions

# in a core dump or an oops, Linux prints them all:
dmesg | grep -A20 'pc :'
#   pc : ffff800008123456
#   lr : ffff8000081234ab
#   sp : ffff800009abc000
#   x29: ...  x28: ...  x27: ...
```

How it shows up

Symptom	Cause
Upper 32 bits of a value unexpectedly zero	A `W`-register write zeroed them — by design
Hand-written assembly corrupts the caller	Clobbered a callee-saved register (`X19`–`X28`) without saving it
Assembly works on Linux, breaks on Windows	Used `X18`, which is the platform register
Stack corruption in an exception handler	Confused XZR with SP in an encoding where 31 means SP
Interrupted program corrupted after an ISR	Vector stub failed to save all general registers — nothing is banked
Alignment fault on a function call	SP not 16-byte aligned
FP values wrong after a context switch	FPCR/FPSR not saved; they are not part of PSTATE
SVE code faults on a narrower machine	Assumed a fixed vector length instead of being length-agnostic
Cannot use a system register in an ADD	Must `MRS` it into a general register first

Check yourself

- ✓ State what happens to the upper 32 bits when you write a `W` register, and why that design was chosen.
- ✓ Name the argument registers, the callee-saved set, and what `X30` holds.
- ✓ Explain the dual meaning of register encoding 31.
- ✓ Explain why there is a stack pointer per exception level.
- ✓ Give the `t` / `h` distinction in EL1t and EL1h.
- ✓ Explain how `V0`, `D0` and `S0` relate.
- ✓ Say what SVE changes about writing vector code.

✓ Explain why AArch64 exception handlers begin with many store instructions.

PSTATE and the condition flags

ARMv7 had one CPSR register holding all processor state. AArch64 broke it into independently accessible fields called PSTATE. Understanding those fields — especially the interrupt masks — is what lets you read an exception handler, a critical section, or a crash dump.

What PSTATE is

> **NOT A REGISTER**
> PSTATE is an *abstraction*: a collection of processor state bits, each accessed through its own system-register name. There is no instruction that reads all of PSTATE at once during normal execution. It is only gathered into a single value when an exception is taken, at which point the hardware writes it into `SPSR_ELx` — and `ERET` restores it from there.

Field	Meaning	Accessed via
`N Z C V`	Condition flags	`NZCV`
`D A I F`	Exception masks: Debug, SError, IRQ, FIQ	`DAIF`, `DAIFSet`, `DAIFClr`
`EL`	Current exception level, 0–3	`CurrentEL`
`SPSel`	Which stack pointer is in use	`SPSel`
`nRW`	Execution state: AArch64 or AArch32	Only in SPSR
`PAN`	Privileged Access Never	`PAN` (v8.1)
`UAO`	User Access Override	`UAO` (v8.2)
`SSBS`	Speculative Store Bypass Safe	`SSBS` (v8.5)
`BTYPE`	Branch Target type, for BTI	Set by hardware (v8.5)
`TCO`	Tag Check Override, for MTE	`TCO` (v8.5)
`IL`, `SS`	Illegal execution state, software step	Debug

The condition flags

```
  N  Negative   the result's sign bit was 1
  Z  Zero       the result was zero
  C  Carry      unsigned overflow (add) / NO borrow (subtract)
  V  oVerflow   SIGNED overflow

Set only by instructions with the S suffix, or by CMP/CMN/TST/TEQ
(which are themselves encoded as SUBS/ADDS/ANDS with XZR as the
destination — see chapter 03).

THE POINT of having both C and V: one comparison sets both, so
the same CMP serves signed and unsigned tests. The condition code
you branch on decides which interpretation applies.
```

Code	Meaning	Flags	Use for
`EQ` / `NE`	Equal / not equal	Z=1 / Z=0	Either signedness

Code	Meaning	Flags	Use for
`HS` (`CS`) / `LO` (`CC`)	≥ / <	C=1 / C=0	**Unsigned**
`HI` / `LS`	> / ≤	C=1&Z=0 / C=0|Z=1	**Unsigned**
`GE` / `LT`	≥ / <	N=V / N≠V	**Signed**
`GT` / `LE`	> / ≤	Z=0&N=V / Z=1|N≠V	**Signed**
`MI` / `PL`	Negative / positive-or-zero	N=1 / N=0	Sign test
`VS` / `VC`	Overflow set / clear	V=1 / V=0	Signed overflow detection
`AL` / `NV`	Always / never	—	Unconditional

```
/* Why the signed/unsigned distinction is not academic: */

        mov     w0, #-1             // 0xFFFFFFFF
        mov     w1, #1
        cmp     w0, w1

        b.lt    signed_less         // TAKEN:   -1 < 1        ✓
        b.lo    unsigned_less       // NOT taken: 0xFFFFFFFF > 1 ✓

/* Both are correct — for their respective interpretations. Using
   the wrong condition is the assembly equivalent of the signed/
   unsigned comparison bug in C chapter 02, and it is exactly as
   easy to get wrong.                                          */

/* Detecting signed overflow explicitly: */
        adds    w0, w1, w2
        b.vs    overflow_handler    // V set = signed overflow
/* This is what __builtin_add_overflow compiles to (C ch. 02). */
```

```
/* Flags survive across unrelated instructions, because most
   instructions do NOT set them. That enables useful scheduling: */

        cmp     x0, x1              // compute the condition EARLY
        ldr     x2, [x3]            // ...do a long-latency load...
        add     x4, x5, x6          // ...and other work...
        b.eq    equal               // ...then branch. The load has
                                    //    had time to complete.
/* On x86 nearly every instruction clobbers EFLAGS, so this
   separation is not possible. It is a small but real advantage
   of the explicit-S design.                                   */
```

The interrupt masks

```
   D  Debug     mask debug exceptions
   A  SError    mask System Errors (imprecise external aborts)
   I  IRQ       mask normal interrupts
   F  FIQ       mask fast interrupts

   1 = MASKED (disabled).  0 = enabled.

   In DAIF, the bits sit at:   D=9  A=8  I=7  F=6

        msr     daifset, #2      // set I  → DISABLE IRQ
        msr     daifclr, #2      // clear I → ENABLE IRQ
        msr     daifset, #3      // set I and F
        msr     daifset, #0xF    // mask everything

   The immediate is a 4-bit mask over {D,A,I,F} = bits {3,2,1,0}
   of the immediate. So #2 = 0b0010 = the I bit.
```

```
/* Save-and-restore is the ONLY correct pattern for a critical
   section. Unconditionally re-enabling is a serious bug.     */

static inline unsigned long irq_save(void)
{
        unsigned long flags;
        asm volatile("mrs %0, daif\n\t"
                     "msr daifset, #2"
                     : "=r"(flags) :: "memory");
        return flags;
}

static inline void irq_restore(unsigned long flags)
{
        asm volatile("msr daif, %0" :: "r"(flags) : "memory");
}

/* Why unconditional enable is wrong:

        outer_lock();          // disables IRQs
            inner_lock();      // disables IRQs
            inner_unlock();    // ENABLES IRQs  ← WRONG
        ...                    // now running unprotected inside
                               //    the OUTER critical section
        outer_unlock();

   With save/restore, the inner unlock restores "already disabled"
   and nesting works. This is exactly why Linux has
   spin_lock_irqsave() and not just spin_lock_irq()
   (OS chapter 09).                                          */
```

HARDWARE MASKS D, A, I AND F ON EVERY EXCEPTION ENTRY

This is not optional and not configurable. The reason is that `ELR_ELx` and `SPSR_ELx` are single registers, not a stack: a second exception arriving before your handler saved them would overwrite the return address, and you could never get back. Your handler saves them to the kernel stack first, and only *then* may unmask to allow nesting. Getting this order wrong destroys the interrupted context (chapter 28).

IRQ versus FIQ

	IRQ	FIQ
ARMv7	Standard interrupt	"Fast": extra banked registers, last vector entry, higher priority
AArch64	Standard interrupt	**No banked registers, no speed advantage** — just a second, separately maskable signal
Conventional use	Non-secure world	**Secure world**: Group 0 GIC interrupts
Routing	`SCR_EL3.IRQ`, `HCR_EL2.IMO`	`SCR_EL3.FIQ`, `HCR_EL2.FMO`

The practical consequence: on a TrustZone system, a Non-secure OS cannot mask secure interrupts by clearing `I`, because they arrive as FIQ and are configured to be taken to EL3. That separation is what lets the secure world preempt the normal world reliably (security track).

PAN, UAO and the kernel/user boundary

```
/* PAN (Privileged Access Never, ARMv8.1) — when set, EL1 and EL2
   accesses to memory marked user-accessible FAULT.

   Why: it turns "kernel accidentally dereferenced a user pointer"
   from a silent, exploitable bug into an immediate fault. It is
   the ARM equivalent of x86's SMAP.                          */

        msr     pan, #1              // enable PAN

/* Legitimate access to user memory then requires explicitly
   lifting it, which is exactly what copy_to_user does:      */
        msr     pan, #0
        // ... the actual copy, with an exception fixup installed
        msr     pan, #1

/* UAO (User Access Override, ARMv8.2) makes the unprivileged
   load/store instructions (LDTR/STTR) behave as privileged,
   which lets the kernel use ONE code path for both cases.  */

/* This is why you must never dereference a __user pointer
   directly (OS chapter 03) — on a PAN-enabled system it does not
   silently work, it faults.                                  */
```

Reading PSTATE in a crash dump

```
/* A Linux arm64 oops prints the saved PSTATE: */

pstate: 60400009 (nZCv daif +PAN -UAO -TCO -DIT -SSBS BTYPE=--)
        ^^^^^^^^  ^^^^ ^^^^  ^^^^
        raw value |    |     features
                  |    └── masks: lowercase = CLEAR (enabled)
                  |                UPPERCASE = SET (masked)
                  └─────── flags:  lowercase = clear, upper = set

/* Reading it:
     nZCv   → N=0, Z=1, C=1, V=0   (the last comparison was equal)
     daif   → all lowercase = interrupts were ENABLED
     DAIF   → all uppercase = all masked (typical inside a handler)
     +PAN   → PAN was active, so this was NOT a user-memory access

   The low bits of the raw value encode the EL and SPSel:
     0x...09 = 0b1001 → EL2h    0x...05 = 0b0101 → EL1h
     0x...04 = 0b0100 → EL1t    0x...00 = 0b0000 → EL0t

   So `pstate: ...09` means the fault happened at EL2 using
   SP_EL2 — which immediately tells you it was hypervisor code,
   not the guest.                                          */
```

```
# in gdb
p/x $cpsr                    # PSTATE, on targets that expose it
p $pstate

# in Linux, at runtime
cat /proc/cpuinfo | grep Features       # pan, uao, ssbs, bti...

# check what the kernel enabled
dmesg | grep -iE 'PAN|SSBS|BTI|MTE'
```

SPSR: PSTATE, frozen

```
On exception entry the hardware packs PSTATE into SPSR_ELx:

   31 30 29 28        21 20    12 11 10  9  8  7  6  5  4  3   0
  ┌──┬──┬──┬──┬─────────┬──┬─────┬─────┬──┬──┬──┬──┬──┬──┬───────┐
  │ N│ Z│ C│ V│  ...    │IL│ ... │ ... │ D│ A│ I│ F│ 0│nRW│ M[3:0]│
  └──┴──┴──┴──┴─────────┴──┴─────┴─────┴──┴──┴──┴──┴──┴──┴───────┘

   M[3:0] encodes the EL and stack selection to return to:
        0b0000  EL0t        0b0100  EL1t        0b1000  EL2t
                            0b0101  EL1h        0b1001  EL2h
        0b1100  EL3t        0b1101  EL3h

   ERET restores PSTATE from SPSR_ELx and PC from ELR_ELx, both
   ATOMICALLY. That atomicity is the whole point: there is no
   window in which the privilege has changed but the PC has not.

   Firmware uses this to DROP to a lower EL during boot: write the
   target state into SPSR_EL3, the entry point into ELR_EL3, then
   ERET (chapter 28).
```

How it shows up

Symptom	Cause
Comparison behaves oddly at the sign boundary	Used a signed condition for unsigned values, or the reverse
Interrupts stay disabled after a critical section	Unconditional enable instead of save/restore
Nested critical sections lose protection	Same — the inner unlock re-enabled prematurely
Corrupted return address in a nested exception	Unmasked interrupts before saving ELR/SPSR
Kernel faults dereferencing a user pointer	PAN is doing its job — use `copy_from_user`
Secure interrupt not maskable by the normal OS	Delivered as FIQ, routed to EL3 — by design
Overflow check never fires	No `S` suffix, so V was never set
Crash dump shows `pstate: ...09`	The fault was at EL2h — hypervisor, not guest
`ERET` returns to the wrong level	Wrong `M[3:0]` encoding in SPSR

Check yourself

- ✓ Explain why PSTATE is not a single register and when it becomes one.
- ✓ Give the four condition flags and say why both C and V are needed.
- ✓ Choose the right condition code for a signed and an unsigned "less than".
- ✓ Write a nesting-safe critical section and explain why unconditional enable is wrong.
- ✓ Explain why hardware masks DAIF on exception entry.
- ✓ State how FIQ differs from IRQ on AArch64 and what it is used for.
- ✓ Explain what PAN prevents and how `copy_to_user` works with it.
- ✓ Decode `pstate: 60400009 (nZCv daif +PAN)` into plain English.

System registers, MRS and MSR

Every piece of processor configuration — the MMU, caches, exception vectors, timers, security state — lives in a system register. There are hundreds. This chapter covers the naming scheme, the access rules, and the one instruction sequence you must get right or your configuration will not take effect.

The naming scheme

> `NAME_ELX`
>
> The suffix names the **lowest exception level that may access the register** — not the level it applies to. `SCTLR_EL1` is accessible from EL1, EL2 and EL3; it is *not* accessible from EL0. A register with no suffix, or `_EL0`, is accessible from user space.

```
   TTBR0_EL1        translation table base, accessible from EL1+
   TTBR0_EL2        the EL2 equivalent — a SEPARATE register
   VTTBR_EL2        stage-2 table base; only meaningful at EL2
   CNTPCT_EL0       physical counter — readable from USER SPACE
   SCTLR_EL3        secure monitor's system control

   Registers ending _EL1 often have _EL2 and _EL3 counterparts.
   They are DIFFERENT REGISTERS with independent contents, not
   different views of one register. Writing SCTLR_EL1 does not
   affect SCTLR_EL2.

   Special forms:
     _EL12, _EL02    accessed from EL2 with VHE enabled, these
                     alias the EL1/EL0 registers — how a host
                     kernel running at EL2 manipulates guest state
     ICC_*_EL1       GIC CPU interface (chapter 23)
     ID_*_EL1        read-only feature identification (chapter 01)
```

MRS and MSR

```
        mrs     Xt, <systemreg>      // System register → general
        msr     <systemreg>, Xt      // General → System register

/* Mnemonic: MRS = "Move Register from System"
             MSR = "Move System Register"                    */

/* A read-modify-write is three instructions, because system
   registers cannot be ALU operands (chapter 04):            */
        mrs     x0, sctlr_el1
        orr     x0, x0, #(1 << 0)      // set the M bit
        msr     sctlr_el1, x0
        isb                             // ← see below

/* There is also an immediate form for PSTATE fields only: */
        msr     daifset, #2
        msr     spsel, #1
        msr     pan, #1
```

The rule that catches everyone

> **A SYSTEM REGISTER WRITE NEEDS AN `ISB` TO TAKE EFFECT**
>
> Instructions already in the pipeline were fetched, decoded and possibly executed under the *old* configuration. Writing `SCTLR_EL1` to enable the MMU does not retroactively change how the next few instructions were translated.
>
> **ISB** — Instruction Synchronization Barrier — flushes the pipeline so that everything after it is re-fetched and re-decoded under the new context. Without it, behaviour depends on pipeline depth and varies between cores, which is exactly the kind of bug that appears on one board and not another.

```
/* The canonical sequence, and why each part is there: */

        /* 1. make sure prior memory writes (e.g. the page tables
              you just built) are visible to the table walker  */
        dsb     ish

        /* 2. change the configuration */
        msr     ttbr0_el1, x0
        msr     tcr_el1, x1
        msr     sctlr_el1, x2

        /* 3. flush the pipeline so it takes effect NOW */
        isb

/* Which registers need it? Anything that changes how instructions
   are FETCHED, TRANSLATED or PERMITTED:
     SCTLR, TTBR, TCR, MAIR, VBAR, SCR, HCR, CPACR, CPTR, TPIDR

   Registers that only affect a later explicit read - CNTFRQ,
   most ID registers - do not.

   When in doubt, add the ISB. It costs a pipeline flush; the bug
   costs a week.                                              */
```

The registers you will actually use

Register	Controls	Chapter
`SCTLR_EL1`	System Control: `M` MMU enable, `C` data cache, `I` instruction cache, `A` alignment check, `WXN` write-implies-execute-never, `SA` stack alignment	12
`TTBR0_EL1` / `TTBR1_EL1`	Translation table base — low and high address ranges. The ASID lives in `TTBR0[63:48]`.	13
`TCR_EL1`	Translation Control: VA size (`T0SZ` / `T1SZ`), granule size, walk cacheability and shareability, top-byte-ignore	13
`MAIR_EL1`	Memory Attribute Indirection — eight 8-bit slots that descriptors index by number	11
`VBAR_EL1`	Vector Base Address — where the exception vector table lives	27
`ESR_EL1`	Exception Syndrome — *why* the last exception happened	29
`FAR_EL1`	Fault Address — *which address* faulted	29
`ELR_EL1` / `SPSR_EL1`	Saved return address and saved PSTATE	28

Register	Controls	Chapter
`MPIDR_EL1`	Which core am I? Affinity levels, used by SMP startup	33
`CurrentEL`	The exception level right now, in bits [3:2]	26
`CNTFRQ_EL0`, `CNTPCT_EL0`	Generic timer frequency and count	32
`CTR_EL0`	Cache line sizes — readable from EL0 so userspace can do cache maintenance correctly	18
`TPIDR_EL0`	Thread pointer — this is where TLS lives	OS 05
`SCR_EL3`	Secure Configuration: the `NS` bit, interrupt routing, `SMD`	security
`HCR_EL2`	Hypervisor Configuration: stage-2 enable, trap control, virtual interrupts	31

SCTLR_EL1, field by field

```
The single most important register in early boot. The bits you
will actually touch:

   bit  0  M      MMU enable
   bit  1  A      Alignment check — fault on ANY unaligned access
   bit  2  C      Data cache enable
   bit  3  SA     Stack alignment check (SP must be 16-byte aligned)
   bit  4  SA0    Stack alignment check for EL0
   bit 12  I      Instruction cache enable
   bit 19  WXN    Writable implies eXecute-Never — a W^X hardening
   bit 25  EE     Exception endianness
   bit 39  TCF    Tag check fault behaviour (MTE)

  Reset value has M, C and I CLEAR: the MMU and caches are OFF
  when your boot code starts. Turning them on, in the right order
  and with the right barriers, is the job of early boot.

  A common bring-up bug: enabling C (data cache) before the MMU.
  With the MMU off, all memory is treated as Device-nGnRnE and
  the data cache does nothing — so it appears harmless. Then you
  enable the MMU and the previously-uncached writes are suddenly
  cacheable, and stale data appears. Enable M and C together,
  after the tables are built and a DSB has completed.
```

Access can be trapped

```
/* A higher exception level can configure a system register access
   at a LOWER level to trap instead of executing. This is the
   entire basis of virtualisation (chapter 31).              */

/* Example: HCR_EL2.TVM traps guest writes to virtual-memory
   control registers, so the hypervisor sees every TTBR change. */
        mrs     x0, hcr_el2
        orr     x0, x0, #(1 << 26)      // TVM
        msr     hcr_el2, x0
        isb

/* Now a guest at EL1 executing `msr ttbr0_el1, x0` takes a
   synchronous exception to EL2 with ESR_EL2.EC = 0x18
   (trapped MSR/MRS). The hypervisor decodes the syndrome to
   learn which register and which general register were involved,
   emulates the write, advances ELR_EL2 by 4, and ERETs.     */

/* Other common trap controls:
     CPACR_EL1.FPEN     trap FP/SIMD — used for lazy FPU switching
     CPTR_EL2/EL3       the EL2/EL3 equivalents
     HCR_EL2.TGE        route ALL EL0 exceptions to EL2
     MDCR_EL2/EL3       trap debug and performance monitor access
     SCR_EL3.SMD        disable SMC entirely                  */
```

Accessing them from C

```
/* Inline assembly, with the constraints from C chapter 18: */

#define read_sysreg(r) ({                       \
        uint64_t __v;                           \
        asm volatile("mrs %0, " #r : "=r"(__v)); \
        __v;                                    \
})

#define write_sysreg(v, r) do {                 \
        uint64_t __v = (uint64_t)(v);           \
        asm volatile("msr " #r ", %0" :: "r"(__v)); \
} while (0)

uint64_t sctlr = read_sysreg(sctlr_el1);
write_sysreg(sctlr | 1, sctlr_el1);
asm volatile("isb");

/* Linux provides exactly this in arch/arm64/include/asm/sysreg.h,
   plus read_sysreg_s() for registers the assembler does not know
   by name (encoded as S<op0>_<op1>_<CRn>_<CRm>_<op2>).       */

/* Note: `volatile` is REQUIRED here. Without it the compiler may
   delete an MSR whose result is unused, or hoist an MRS out of a
   loop. A register write with a side effect needs it always.  */
```

The encoding, and unnamed registers

```
A system register is identified by five fields:

        S<op0>_<op1>_C<CRn>_C<CRm>_<op2>

Assemblers know the names for architected registers. For newer or
IMPLEMENTATION DEFINED ones, you encode them directly:

        mrs     x0, S3_1_C15_C2_0        // an IMP DEF register

Linux uses this for registers newer than the minimum supported
binutils version:

        #define SYS_ID_AA64ISAR2_EL1  sys_reg(3, 0, 0, 6, 2)
        read_sysreg_s(SYS_ID_AA64ISAR2_EL1);

If you see S3_x_Cy_Cz_w in a disassembly, look it up in the ARM ARM
register index - it is an architected register your disassembler
did not recognise, and it is often the interesting one.
```

System registers and context switching

```
/* Which system registers must be saved on a context switch?
   Only those that are PER-CONTEXT:                          */

   TTBR0_EL1        per address space - this IS the switch
   TPIDR_EL0        thread pointer (TLS)
   TPIDRRO_EL0      read-only thread pointer
   FPCR / FPSR      FP control and status
   (PAC keys, if used)

/* NOT saved, because they are global to the kernel:         */
   SCTLR_EL1, MAIR_EL1, TCR_EL1, VBAR_EL1, TTBR1_EL1

/* This is why a thread switch within one process is cheaper than
   a process switch: TTBR0 does not change, so the TLB entries
   remain valid (OS chapter 07).

   A VM switch is far more expensive: the hypervisor must save and
   restore essentially the entire EL1 system register file, which
   is dozens of registers - one reason VM exits are costly.  */
```

Reading them at runtime

```
# Linux exposes some via sysfs
cat /sys/devices/system/cpu/cpu0/regs/identification/midr_el1
cat /sys/devices/system/cpu/cpu0/regs/identification/revidr_el1

# gdb, on a bare-metal or kernel target
p/x $SCTLR_EL1
p/x $TTBR0_EL1
p/x $ESR_EL1
info all-registers | grep -i el1

# in a kernel oops, the relevant ones are printed for you
dmesg | grep -E 'ESR|FAR|pstate'

# a small kernel module or bare-metal routine to dump the
# configuration is worth having during bring-up:
pr_info("SCTLR=%016llx TCR=%016llx MAIR=%016llx TTBR0=%016llx\n",
        read_sysreg(sctlr_el1), read_sysreg(tcr_el1),
        read_sysreg(mair_el1),  read_sysreg(ttbr0_el1));
```

How it shows up

Symptom	Cause
Configuration change has no effect	Missing `ISB` after the `MSR`
Works on one core, fails on another	Missing barrier; behaviour depends on pipeline depth
Undefined instruction on `MRS`	Accessed a register from too low an exception level
Guest hangs writing a system register	A trap is configured and the hypervisor is not emulating it
Stale data after enabling the MMU	Cache enabled before translation was configured
Alignment faults everywhere after boot	`SCTLR.A` set, enabling strict alignment checking
Compiler removed your `MSR`	Missing `volatile` on the inline assembly
Disassembly shows `S3_0_C0_C6_2`	An architected register the assembler does not know — look it up
TLS broken after a hand-written context switch	`TPIDR_EL0` not saved and restored

Check yourself

- ✓ Explain what the `_ELx` suffix means, and whether `SCTLR_EL1` is one register or several.
- ✓ Write a read-modify-write of a system register and explain why it takes three instructions.
- ✓ Explain why `ISB` is needed and name four registers that require it.
- ✓ Give five `SCTLR_EL1` bits and what each controls.
- ✓ Explain how a hypervisor intercepts a guest's system register write.
- ✓ Say which system registers are per-context and which are global, and why that matters for switch cost.
- ✓ Explain why inline assembly for `MSR` needs `volatile`.
- ✓ Explain what `S3_1_C15_C2_0` is.

The A64 instruction set

You do not need to memorise a thousand instructions. You need to recognise the dozen families, know the idioms the compiler emits constantly, and be able to look up the rest. This chapter is the working subset.

The families

Family	Representative	Notes
Data processing (register)	`ADD` `SUB` `AND` `ORR` `EOR` `MUL` `UDIV` `SDIV`	Suffix `S` sets flags
Data processing (immediate)	`ADD Xd, Xn, #imm12`	12-bit immediate, optionally shifted left 12
Move	`MOV` `MOVZ` `MOVK` `MOVN`	Build 64-bit constants 16 bits at a time
Shift / rotate	`LSL` `LSR` `ASR` `ROR`	Aliases of `UBFM` / `SBFM`
Bitfield	`UBFX` `SBFX` `BFI` `UBFIZ`	Extract and insert in one instruction
Load / store	`LDR` `STR` `LDP` `STP` `LDRB` `LDRSW`	Chapter 08
Branch	`B` `BL` `BR` `BLR` `RET` `CBZ` `TBZ` `B.cond`	See below
Conditional select	`CSEL` `CSET` `CSINC` `CINC` `CSNEG`	Branchless selection
Address formation	`ADR` `ADRP`	PC-relative, ±1 MB and ±4 GB
Atomics	`LDXR` / `STXR`, `LDADD`, `CAS`, `SWP`	Chapter 22
Barriers	`DMB` `DSB` `ISB`	Chapter 21
System	`MRS` `MSR` `SVC` `HVC` `SMC` `ERET` `WFI` `TLBI` `DC` `IC`	The systems programmer's set
SIMD / FP	`FADD` `FMUL` `LD1` `ST1` `DUP` `ADDV`	Operate on `V` registers
Crypto / CRC	`AESE` `SHA256H` `PMULL` `CRC32`	Optional — check the ID registers

Building constants

```
/* A 32-bit instruction cannot hold a 64-bit immediate, so large
   constants are assembled from 16-bit pieces.               */

        movz    x0, #0x1234, lsl #48    // zero the rest, set bits 63:48
        movk    x0, #0x5678, lsl #32    // keep the rest, set bits 47:32
        movk    x0, #0x9abc, lsl #16
        movk    x0, #0xdef0             // x0 = 0x123456789abcdef0

        movn    x0, #0                  // MOVe Negated: x0 = ~0 = -1

/* The assembler's `MOV Xd, #imm` picks whichever of MOVZ, MOVN or
   an ORR-with-bitmask-immediate encodes the value, or emits
   several instructions if none does.                        */

/* BITMASK IMMEDIATES are a genuinely clever encoding: logical
   instructions can take any value that is a repeating pattern of
   set bits. So these are ONE instruction each:              */
        and     x0, x0, #0xFFFFFFFF     // repeating pattern ✓
        orr     x0, x0, #0x0F0F0F0F0F0F0F0F
        and     x0, x0, #0xFFF          // ✓
/* ...but this needs a MOV first, because 0x12345 is not a
   repeating pattern:                                         */
        mov     x1, #0x12345
        and     x0, x0, x1

/* This is why some masks compile to one instruction and visually
   similar ones compile to two. It is not arbitrary.         */
```

Branches

Instruction	Does	Range
`B label`	Unconditional branch	±128 MB
`BL label`	Branch with link — sets `X30`	±128 MB
`BR Xn`	Indirect branch	Anywhere
`BLR Xn`	Indirect call	Anywhere
`RET {Xn}`	Return — `BR X30` plus a predictor hint	Anywhere
`B.cond label`	Conditional on NZCV	±1 MB
`CBZ/CBNZ Xn, label`	Compare with zero and branch — **no flags needed**	±1 MB
`TBZ/TBNZ Xn, #b, label`	Test one bit and branch — no flags needed	±32 KB

```
/* CBZ and TBZ are very common because they need no CMP first: */
        cbz     x0, is_null             // if (p == NULL) goto...
        tbnz    w1, #5, bit_set         // if (flags & (1 << 5)) goto...

/* RET is BR X30 with a hint. The hint matters: it tells the
   return-address stack predictor to POP, which is why using
   BR X30 instead of RET degrades prediction (CA chapter 12). */

/* The ±128 MB limit on B/BL is why LINKER VENEERS exist: if a
   call target is further away, the linker inserts a trampoline
   that loads the full address into X16 and does BR X16. That is
   what X16/X17 are reserved for (chapter 04).               */
```

Conditional select: the branchless workhorse

```
        csel    Xd, Xn, Xm, cond    // Xd = cond ? Xn : Xm
        csinc   Xd, Xn, Xm, cond    // Xd = cond ? Xn : Xm + 1
        csinv   Xd, Xn, Xm, cond    // Xd = cond ? Xn : ~Xm
        csneg   Xd, Xn, Xm, cond    // Xd = cond ? Xn : -Xm

/* And their aliases, which are what you usually see: */
        cset    Xd, cond            // Xd = cond ? 1 : 0
        csetm   Xd, cond            // Xd = cond ? -1 : 0   ← a MASK
        cinc    Xd, Xn, cond        // Xd = cond ? Xn+1 : Xn
        cneg, cinv

/* Source and result: */
int max(int a, int b) { return a > b ? a : b; }
/*      cmp     w0, w1
        csel    w0, w0, w1, gt
        ret                                                 */

int sign(int x) { return (x > 0) - (x < 0); }
/*      cmp     w0, #0
        cset    w1, gt
        csinv   w0, w1, wzr, ge      // clever: -1 when negative
        ret                                                 */

/* CSETM is exactly the mask idiom from C chapter 08:
        mask = -(unsigned)cond;   → csetm
   which is why branchless C compiles so cleanly here.      */
```

Bitfield instructions

```
/* ARM does field extract and insert in ONE instruction, which is
   why the mask-and-shift idioms of C chapter 08 are cheap.  */

        ubfx    w0, w1, #4, #3       // w0 = (w1 >> 4) & 0x7  (unsigned)
        sbfx    w0, w1, #4, #3       // ...sign-extended
        bfi     w0, w1, #4, #3       // insert w1's low 3 bits at 4
        bfxil   w0, w1, #4, #3       // extract and insert low
        ubfiz   w0, w1, #4, #3       // extract, insert, zero the rest

/* Extensions are also bitfield ops: */
        uxtb    w0, w1               // zero-extend byte
        sxtw    x0, w1               // sign-extend word to 64
        lsl     x0, x1, #3           // alias of UBFM

/* Bit counting and reversal, all single instructions: */
        clz     x0, x1               // count leading zeros
        rbit    x0, x1               // reverse bit order
        rev     x0, x1               // reverse BYTE order (endian swap)
        rev16, rev32
        cnt     v0.8b, v1.8b         // popcount, per byte (SIMD)

/* __builtin_clz → CLZ.  __builtin_bswap32 → REV.
   __builtin_ctz → RBIT then CLZ. This is why those builtins are
   free on ARM and you should always prefer them (C ch. 08). */
```

Arithmetic worth knowing

```
/* Multiply-accumulate in one instruction — the basis of every
   DSP and matrix kernel:                                       */
        madd    x0, x1, x2, x3       // x0 = x3 + x1 * x2
        msub    x0, x1, x2, x3       // x0 = x3 - x1 * x2
        mneg    x0, x1, x2           // x0 = -(x1 * x2)

/* Widening multiply: 32x32 → 64, no overflow */
        umull   x0, w1, w2
        smull   x0, w1, w2
        umulh   x0, x1, x2           // HIGH 64 bits of a 64x64 product
        smulh   x0, x1, x2

/* Division is NOT cheap — roughly 10-20 cycles, and there is no
   remainder instruction. `a % b` becomes:                      */
        sdiv    x2, x0, x1
        msub    x2, x2, x1, x0       // x2 = x0 - (x0/x1)*x1

/* Which is why dividing by a constant compiles to a multiply by
   a magic reciprocal plus shifts, and why power-of-two divisors
   become a single shift.                                       */

/* Shifted register operands are free — folded into the ALU: */
        add     x0, x1, x2, lsl #3   // x0 = x1 + (x2 << 3)
        sub     x0, x1, x2, asr #2
/* This is how array indexing compiles: base + index*8 is ONE
   instruction, not two.                                        */
```

System instructions

Instruction	Effect
`SVC #imm`	Supervisor call → exception to EL1. System calls.
`HVC #imm`	Hypervisor call → EL2
`SMC #imm`	Secure monitor call → EL3
`ERET`	Exception return: PC from `ELR`, PSTATE from `SPSR`, atomically
`WFI`	Wait For Interrupt — enter a low-power state until one arrives
`WFE` / `SEV`	Wait For Event / Send Event — used by spinlocks to avoid burning power
`YIELD`	A hint that this thread is spinning; useful on SMT
`NOP`	No operation — also a patch point for runtime code modification
`BRK #imm`	Software breakpoint → debug exception
`HLT #imm`	Halt into the external debugger
`UDF`	Permanently undefined — used to trap deliberately
`TLBI`, `DC`, `IC`, `AT`	TLB, data cache, instruction cache maintenance; address translation

```
/* The WFE/SEV spinlock idiom — spin without burning power: */
1:      ldaxr   w1, [x0]
        cbnz    w1, 2f              // locked? go wait
        stxr    w2, w3, [x0]
        cbnz    w2, 1b
        ...                          // got it
2:      wfe                          // sleep until an event
        b       1b
/* The unlock does SEV (or a store-release, which generates an
   event on the exclusive monitor). This is why ARM spinlocks
   consume far less power than a naive busy loop.            */
```

Compiler idioms you will see constantly

```
Learn to recognise these on sight — they cover most disassembly:

  stp x29, x30, [sp, #-N]!     function prologue
  mov x29, sp
  ldp x29, x30, [sp], #N       epilogue
  ret

  adrp x0, sym                 global variable access
  add  x0, x0, :lo12:sym       (or the offset folded into the LDR)

  cmp  w0, w1                  comparison + branchless select
  csel w0, w0, w1, gt

  ldr  x0, [x1, x2, lsl #3]    array[i] for 8-byte elements

  cbz  x0, .Lnull              null check

  bl   memcpy                  a struct copy the compiler lowered

  ld1 {v0.4s}, [x0], #16       vectorised loop body
  fadd v0.4s, v0.4s, v1.4s
  st1 {v0.4s}, [x1], #16

  nop                          a patch point: static keys, ftrace,
                               or alternative instruction patching
```

Looking things up

```
# the fastest reference loop
#   godbolt.org — paste C, see the assembly, hover for docs
#   developer.arm.com/documentation — searchable A64 ISA guide

# locally
aarch64-linux-gnu-objdump -d prog | less
gcc -O2 -S -o - test.c

# decode a single instruction word
echo '.word 0xd65f03c0' > t.s && as -o t.o t.s && objdump -d t.o
#   d65f03c0  →  ret

# the ARM ARM's index of instructions by encoding is section C6.
# When you meet an unfamiliar mnemonic, search there rather than
# guessing from the name — several are aliases of something else.
```

How it shows up

Symptom	Cause
A simple mask compiles to two instructions	The value is not a valid bitmask immediate
"relocation truncated to fit" at link time	Branch target beyond ±128 MB; the linker needs a veneer
Poor branch prediction on returns	Used `BR X30` instead of `RET`
Modulo is unexpectedly slow	No remainder instruction — it is `SDIV` plus `MSUB`
Compiler emitted `CSEL` where you expected a branch	It went branchless — usually what you want

Symptom	Cause
Illegal instruction on some cores	Optional feature (crypto, LSE, SVE) without an ID check
Spin loop burns power	No `WFE`; use the event-based idiom
Unexplained `NOP`s in the disassembly	Patch points for ftrace, static keys or alternatives

Check yourself

- ✓ Name the instruction families and give one representative of each.
- ✓ Explain how a 64-bit constant is built and why some masks are one instruction.
- ✓ Give three branch instructions that do not need a preceding `CMP`.
- ✓ Explain why `RET` is preferable to `BR X30`.
- ✓ Write branchless `max` and identify the instruction the compiler uses.
- ✓ Explain what `CSETM` produces and which C idiom maps to it.
- ✓ Show how `a % b` is computed and why it costs two instructions.
- ✓ Explain the `WFE`/`SEV` spinlock idiom and what it saves.

Addressing modes

Since only loads and stores touch memory, how they compute an address is where a surprising amount of performance lives. Array indexing, struct access, stack frames and pointer walking each map onto a specific mode, and recognising them makes disassembly readable.

The modes

Syntax	Address used	Side effect on `Xn`	Compiles from
`[Xn]`	Xn	None	`*p`
`[Xn, #imm]`	Xn + imm	None	`p->field`, `a[3]`
`[Xn, Xm]`	Xn + Xm	None	`p[i]` for byte arrays
`[Xn, Xm, LSL #s]`	Xn + (Xm << s)	None	**`a[i]`** — the scaled index
`[Xn, Wm, SXTW #s]`	Xn + (sign-extend Wm << s)	None	`a[i]` with a 32-bit signed index
`[Xn, #imm]!`	Xn + imm	**Xn += imm first**	Push; `*++p`
`[Xn], #imm`	Xn	**Xn += imm after**	Pop; `*p++`
`label` (PC-relative)	PC ± imm19×4	None	Literal pools, `ADR`

```
Pre-index versus post-index — the distinction that trips people up

   PRE-INDEX   [x0, #8]!      "update, then use"
        x0 = x0 + 8
        access [x0]

   POST-INDEX  [x0], #8       "use, then update"
        access [x0]
        x0 = x0 + 8

  Mnemonic: the ! is where the update happens relative to the
  bracket. Inside the bracket → before. After the bracket → after.

  This is exactly *++p versus *p++ in C, and it is why a linked-
  list walk or a memcpy loop needs no separate ADD instruction.
```

The scaled index, and why it matters

```
/* Array indexing is ONE instruction, because the shift is free —
   it happens in the address generation unit, not the ALU.   */

long a[100];
long f(long *a, int i) { return a[i]; }
/*      ldr     x0, [x0, w1, sxtw #3]     // x0 + (sign-ext w1)*8
        ret                                                    */

/* The shift amount matches the element size:
        #0  → 1-byte elements       #2  → 4-byte (int, float)
        #1  → 2-byte                #3  → 8-byte (long, pointer)
        #4  → 16-byte (Q registers)

   Note SXTW: a signed 32-bit index must be sign-extended to 64
   bits. If you index with a size_t (unsigned 64-bit) instead,
   the extension disappears:                                   */

long g(long *a, size_t i) { return a[i]; }
/*      ldr     x0, [x0, x1, lsl #3]      // no extension needed */

/* This is a real, if small, reason to prefer size_t for indices
   in hot loops — and it also removes the signed-overflow UB
   from the index arithmetic (C chapter 15).                */
```

Immediate offset ranges

```
The encodable range depends on the ACCESS SIZE, because the
offset is scaled by it:

   LDRB/STRB    unsigned imm12, scaled by 1   →  0 .. 4095
   LDRH/STRH    unsigned imm12, scaled by 2   →  0 .. 8190,  even
   LDR/STR (W)  unsigned imm12, scaled by 4   →  0 .. 16380, mult of 4
   LDR/STR (X)  unsigned imm12, scaled by 8   →  0 .. 32760, mult of 8

   Unscaled signed form (LDUR/STUR): -256 .. 255, any alignment.
   The assembler picks it automatically when needed.

   LDP/STP      signed imm7, scaled          →  -512 .. 504 for X

WHY THIS MATTERS IN PRACTICE:

  · a struct field at offset 32760 is one instruction; at 32768
    it needs an extra ADD. Very large structs cost more to access.

  · this is why the compiler sometimes rebases a pointer into the
    middle of a large structure — to bring fields into range.

  · stack frames larger than ~32 KB generate extra address
    arithmetic on every local variable access. Another reason
    large stack arrays are a bad idea (C chapter 09).
```

Load and store pair

```
/* LDP/STP move TWO registers in ONE instruction. This is why
   prologues save registers in pairs and why the stack moves in
   multiples of 16 bytes.                                      */

        stp     x29, x30, [sp, #-32]!   // push both, pre-decrement
        stp     x19, x20, [sp, #16]
        ...
        ldp     x19, x20, [sp, #16]
        ldp     x29, x30, [sp], #32     // pop both, post-increment

/* Also used for bulk copies - a 16-byte-at-a-time memcpy: */
1:      ldp     x2, x3, [x1], #16
        stp     x2, x3, [x0], #16
        subs    x4, x4, #16
        b.ne    1b

/* And with Q registers, 32 bytes at a time: */
        ldp     q0, q1, [x1], #32
        stp     q0, q1, [x0], #32

/* Constraint: both registers must be the same size, and the
   offset is a signed 7-bit value scaled by the access size -
   a much narrower range than a single LDR.                  */
```

PC-relative addressing

```
        adr     x0, label        // PC ± 1 MB, byte granular
        adrp    x0, symbol       // PC ± 4 GB, PAGE granular (4 KB)

/* ADRP gives the address of the 4 KB PAGE containing the symbol,
   with the low 12 bits ZEROED. The low bits are supplied
   separately:                                              */

        adrp    x0, my_global
        add     x0, x0, :lo12:my_global     // full address
        ldr     w1, [x0]

/* Or folded into the load's own offset — one instruction fewer: */
        adrp    x0, my_global
        ldr     w1, [x0, :lo12:my_global]

/* Why the split: a single 32-bit instruction cannot encode a
   ±4 GB byte offset. Splitting it into a page offset (21 bits)
   plus a 12-bit low part covers the full range.

   This is also why the LINKER has relocation types specifically
   for the two halves (R_AARCH64_ADR_PREL_PG_HI21 and
   R_AARCH64_ADD_ABS_LO12_NC), and why an ADRP/ADD pair must not
   be separated by the compiler — Cortex-A53 erratum 843419 is
   precisely a bug in that sequence (chapter 01).           */

/* LITERAL POOLS: a PC-relative load of a constant stored in the
   code stream. The assembler's = syntax generates one:      */
        ldr     x0, =0x123456789abcdef0
/*  becomes:
        ldr     x0, .Lpool
        ...
    .Lpool: .quad 0x123456789abcdef0                         */
```

Access sizes and extension

```
        ldrb    w0, [x1]        // load byte,  ZERO-extend to 32
        ldrh    w0, [x1]        // load half,  zero-extend
        ldr     w0, [x1]        // load word   (upper 32 of x0 zeroed)
        ldr     x0, [x1]        // load 64 bits

        ldrsb   w0, [x1]        // load byte,  SIGN-extend to 32
        ldrsb   x0, [x1]        // ...to 64
        ldrsh   x0, [x1]
        ldrsw   x0, [x1]        // load word, sign-extend to 64
                                //   — very common for int → long

        strb    w0, [x1]        // store the low 8 bits
        strh    w0, [x1]
        str     w0, [x1]        // store 32
        str     x0, [x1]        // store 64

/* Note there is no STRSB: sign extension is a property of
   LOADING, not storing. And remember that writing Wn zeroes the
   top half of Xn (chapter 04), so LDR Wn is implicitly a
   zero-extending 64-bit write.                             */
```

Ordered, exclusive and non-temporal

Form	Meaning	Chapter
`LDAR` / `STLR`	Load-acquire / store-release — ordering attached to the access	21
`LDXR` / `STXR`	Exclusive, for atomic sequences	22
`LDAXR` / `STLXR`	Both: exclusive and ordered	22
`LDNP` / `STNP`	Non-temporal pair — a hint not to pollute the cache	17
`LDTR` / `STTR`	Unprivileged — behaves as an EL0 access even when executed at EL1. Used by `copy_to_user`.	05
`PRFM`	Prefetch hint: `PLDL1KEEP`, `PSTL2STRM`...	CA 13

```
/* LDTR/STTR are worth understanding: they let kernel code access
   user memory with USER permissions, so a malicious pointer
   pointing at kernel memory faults rather than succeeding. That
   is how copy_from_user enforces the boundary in hardware
   rather than by checking the address (OS chapter 03).      */

/* Non-temporal, for streaming through data you will not reuse: */
1:      ldnp    q0, q1, [x1], #32
        stnp    q0, q1, [x0], #32
        subs    x2, x2, #32
        b.ne    1b
/* Avoids evicting the working set for a bulk copy — the same
   idea as MADV_DONTNEED at a different level.               */
```

Reading addressing in disassembly

```
/* Each pattern tells you what the source code was doing: */

  ldr  x0, [x1]                 *p
  ldr  x0, [x1, #24]            p->field  (at offset 24)
  ldr  x0, [x1, x2, lsl #3]     a[i]      (8-byte elements)
  ldr  x0, [x1], #8             *p++      (pointer walk)
  ldr  x0, [x1, #8]!            *++p
  ldp  x0, x1, [x2, #16]        two adjacent fields, one instruction
  ldr  x0, [sp, #40]            a local variable, or a spilled reg
  adrp x0, sym / add x0,x0,:lo12: a global
  ldr  w0, [x1, w2, sxtw #2]    a[i] with an int index

/* And the absence of loads inside a loop tells you the compiler
   kept everything in registers — which is the goal.        */
```

THE ADDRESSING MODE REVEALS THE DATA STRUCTURE

When reverse-engineering or reviewing generated code, the addressing mode is the strongest clue about the underlying type. A constant offset means a struct field; a scaled register offset means an array; post-index means a sequential walk; an indirect `BLR` after a load means a function pointer or vtable (C ch. 12). Reading these patterns is a large part of what makes disassembly useful rather than opaque.

How it shows up

Symptom	Cause
Extra `ADD` before every struct access	Field offset beyond the immediate range — the struct is very large
Extra sign-extension in an indexing loop	Index is `int`; use `size_t`
Pointer advances unexpectedly	Post-index side effect — `[Xn], #imm` updates `Xn`
Stack access needs extra arithmetic	Frame larger than the encodable offset range
Alignment fault on a Device-memory access	Unaligned MMIO always faults (ch. 11)
Link error about relocation truncation	Symbol beyond `ADRP`'s ±4 GB, or a branch beyond ±128 MB
Kernel accepts a user pointer into kernel memory	Used a normal load instead of `LDTR` / `copy_from_user`
A bulk copy evicts the working set	Use `LDNP` / `STNP`

Check yourself

- ✓ Name the addressing modes and the C construct each typically compiles from.
- ✓ Explain pre-index versus post-index and the C operators they correspond to.
- ✓ Explain why `a[i]` is one instruction and what the shift amount encodes.
- ✓ Say why the immediate offset range differs between `LDRB` and `LDR X`.
- ✓ Explain what `ADRP` produces and why the low bits are separate.
- ✓ Give three load forms that sign-extend and say why there is no store equivalent.
- ✓ Explain what `LDTR` is for and how it enforces the user/kernel boundary.
- ✓ Given `ldr x0, [x1, x2, lsl #3]`, describe the source construct.

The procedure call standard (AAPCS64)

The ABI is the contract that lets separately compiled code interoperate. You need it to write assembly that C can call, to read stack traces, to debug a corrupted frame, and to understand why a struct passed by value sometimes costs nothing and sometimes costs a memory copy.

Register roles

```
  X0–X7     arguments 1–8, and return value in X0
            (X0:X1 for a 128-bit return)          CALLER-saved
  X8        indirect result location register
            – and, on Linux, the syscall number   CALLER-saved
  X9–X15    temporaries                           CALLER-saved
  X16,X17   IP0/IP1 – linker veneers, PLT stubs   may be clobbered
                                                  by the LINKER
  X18       platform register – OS-specific       don't touch
  X19–X28   general use                           CALLEE-saved
  X29       FP  frame pointer                     CALLEE-saved
  X30       LR  link register                     CALLEE-saved
  SP        stack pointer                         CALLEE-saved

  V0–V7     FP/SIMD arguments and return          CALLER-saved
  V8–V15    LOWER 64 BITS callee-saved            partially saved
  V16–V31   temporaries                           CALLER-saved

Note the oddity in V8–V15: only the low 64 bits are preserved.
Assembly that uses the full 128 bits of V8 must save it itself.
This catches out hand-written SIMD kernels regularly.
```

CALLER-SAVED VERSUS CALLEE-SAVED

Caller-saved (volatile): if you need the value after a call, *you* save it. The callee may destroy it freely.

Callee-saved (non-volatile): if a function uses one, it must restore the original value before returning. The caller may assume it survives.

The split exists so neither side saves more than necessary: values needed across a call go in callee-saved registers, short-lived temporaries go in caller-saved ones, and the compiler allocates accordingly.

The stack

```
   higher addresses
   ┌──────────────────────────┐
   │ caller's frame           │
   ├──────────────────────────┤
   │ arguments 9, 10, ...     │  ← beyond the 8 register arguments
   ├──────────────────────────┤  ← SP on entry, 16-byte aligned
   │ saved X29 (caller's FP)  │  ┐
   │ saved X30 (return addr)  │  │ this frame
   ├──────────────────────────┤  │
   │ saved X19–X28 (as used)  │  │
   ├──────────────────────────┤  │
   │ local variables          │  │
   │ spilled temporaries      │  ┘
   └──────────────────────────┘  ← SP now
   lower addresses            (grows DOWN)

RULES:
  · SP must be 16-BYTE ALIGNED at every public interface.
    Not 8. Sixteen. This is not advisory — instructions that
    assume it will fault, and the fault looks like random
    corruption.
  · SP must always be valid: an exception can occur at any
    instruction and the handler may use it.
  · The RED ZONE that exists on x86-64 does NOT exist here.
    You may not write below SP.
```

```
/* A standard non-leaf function */
func:
        stp     x29, x30, [sp, #-32]!   // allocate 32, save FP and LR
        mov     x29, sp                 // establish the frame pointer
        stp     x19, x20, [sp, #16]     // save what we will use
        ...
        ldp     x19, x20, [sp, #16]
        ldp     x29, x30, [sp], #32     // restore, deallocate
        ret

/* A LEAF function — calls nothing, so LR is untouched and no
   frame is needed at all:                                    */
square: mul     w0, w0, w0
        ret

/* Large frames need an explicit adjustment, because the
   pre-index immediate is limited to ±512 for STP:           */
big:    stp     x29, x30, [sp, #-16]!
        mov     x29, sp
        sub     sp, sp, #4096           // room for locals
        ...
        add     sp, sp, #4096
        ldp     x29, x30, [sp], #16
        ret
```

The frame pointer chain

```
X29 points at a two-word record: {caller's X29, return address}
Each record points to the previous one, forming a linked list:

     X29 ──► ┌─────────────────┐
             │ caller's X29 ├──► ┌─────────────────┐
             │ return addr  │    │ caller's X29 ├──► ...
             └─────────────────┘    │ return addr  │
                                    └─────────────────┘

THIS is how a debugger or profiler walks a stack:
     fp = X29
     while (fp) {
             print_symbol(*(fp + 8));   // return address
             fp = *(fp + 0);            // previous frame
     }

Which is why -fomit-frame-pointer breaks naive stack walking,
and why perf and the kernel want -fno-omit-frame-pointer.
The alternative is DWARF CFI unwinding, which is exact but
requires parsing .eh_frame — far more expensive, and not
usable from an interrupt handler.

Linux arm64 builds with frame pointers ON for this reason.
```

How arguments are assigned

```
/* The rules, applied left to right: */

/* 1. Integers and pointers → the next free X register (X0–X7) */
void f(int a, long b, void *c, char d);
/*     w0      x1       x2      w3                            */

/* 2. Floats and vectors → the next free V register (V0–V7),
      in a SEPARATE sequence from the integer registers        */
void g(int a, double b, int c, float d);
/*     w0      d0        w1      s1
   Note: integers and floats do not compete for slots.        */

/* 3. Small structs (≤ 16 bytes) → passed in up to two registers */
struct pair { long a, b; };
void h(struct pair p);
/*     x0 = p.a, x1 = p.b   — no memory involved              */

/* 4. HFAs/HVAs — a struct of 1–4 identical float members —
      go in consecutive V registers                            */
struct vec3 { float x, y, z; };
void i(struct vec3 v);
/*     s0, s1, s2                                             */

/* 5. Larger structs → COPIED TO THE STACK, and a pointer to
      that copy is passed                                      */
struct big { long a[10]; };
void j(struct big b);
/*     the caller memcpys 80 bytes onto the stack             */

/* 6. Large RETURN values → the caller allocates space and
      passes its address in X8                                 */
struct big k(void);
/*     caller: add x8, sp, #N ; bl k
       callee writes the result through x8                    */

/* 7. Remaining arguments → the stack, right after the frame  */
```

Return type	Returned in
`int`, `long`, pointer	`X0`
128-bit integer	`X0` : `X1`
`float`, `double`	`S0` / `D0`
Struct ≤ 16 bytes	`X0` : `X1`
HFA of ≤ 4 floats	`V0` – `V3`
Anything larger	Memory, via the pointer in `X8`
`void`	Nothing

> **THE PRACTICAL CONSEQUENCE**
>
> A struct of two `long`s costs nothing to pass — it goes in two registers. A struct of three costs a stack copy on every call. That 16-byte boundary is a real, measurable cliff, and it is a good reason to keep small value types genuinely small, or to pass a `const` pointer instead (C ch. 11).

Variadic functions

```
/* Variadic arguments follow the same register rules, but the
   callee must be able to walk them, so va_start saves ALL the
   argument registers into a "register save area" on the stack. */

int printf(const char *fmt, ...);
/*  X0 = fmt, then X1-X7 and V0-V7 hold the variadic args.
    va_start spills X1-X7 and V0-V7 to the stack, then va_arg
    walks that area and then the overflow stack area.        */

/* Which is why:
     · a variadic function has a larger prologue than it looks
     · Apple's arm64 ABI differs here: it passes ALL variadic
       arguments on the STACK, which is a real portability
       difference for hand-written assembly and for JITs
     · default argument promotions apply: float → double,
       narrow ints → int (C chapter 11)                      */

/* The va_list layout is defined by the ABI: */
typedef struct {
        void *__stack;          // next stack argument
        void *__gr_top;         // top of the general register area
        void *__vr_top;         // top of the vector register area
        int   __gr_offs;        // offset into the GP area (negative)
        int   __vr_offs;
} va_list[1];
```

Writing assembly C can call

```
        .text
        .global my_memcpy
        .type   my_memcpy, %function
my_memcpy:
        // x0 = dst, x1 = src, x2 = n   - per the ABI
        // returns dst in x0, so save it
        mov     x3, x0                  // x3 is caller-saved: free

        cbz     x2, 2f
1:      ldrb    w4, [x1], #1            // x4, x5: caller-saved
        strb    w4, [x3], #1
        subs    x2, x2, #1
        b.ne    1b
2:      ret                             // x0 still holds dst
        .size   my_memcpy, . - my_memcpy

/* CHECKLIST for hand-written assembly:
     ☐ arguments read from X0-X7 in order
     ☐ return value placed in X0
     ☐ X19-X28, X29, X30 saved if used
     ☐ low 64 bits of V8-V15 saved if used
     ☐ SP 16-byte aligned at every call you make
     ☐ SP restored exactly before RET
     ☐ X18 untouched
     ☐ .type %function and .size set, so the debugger and
       unwinder recognise it                                 */
```

```
/* Calling assembly from C: declare it with a matching prototype.
   A mismatch is a LINK-time success and a RUNTIME disaster -
   the linker matches by NAME only (C chapter 01).           */

extern void *my_memcpy(void *dst, const void *src, size_t n);

/* And from C++, wrap it: */
extern "C" void *my_memcpy(void *, const void *, size_t);
```

Stack unwinding

```
/* Two mechanisms, with different trade-offs: */

/* 1. FRAME POINTER walking - fast, simple, works anywhere,
      including in an interrupt handler. Requires that every
      frame in the chain has a frame pointer.               */
        -fno-omit-frame-pointer

/* 2. DWARF CFI (.eh_frame) - exact, works without frame
      pointers, but requires parsing unwind tables. Used by
      C++ exceptions, backtrace(), and gdb.                 */
        -funwind-tables
        readelf --debug-dump=frames prog

/* In the kernel, arm64 supports both: frame-pointer unwinding
   for oops traces and ftrace, and now ORC-style tables for
   reliable stacktraces used by live patching.

   The practical rule: if your profiler shows broken or
   truncated stacks, either build with frame pointers or ensure
   the profiler uses DWARF:                                  */
perf record --call-graph=fp   ./prog     # needs frame pointers
perf record --call-graph=dwarf ./prog    # slower, more accurate
```

Pointer authentication and the ABI

```
/* With -mbranch-protection=standard, the prologue and epilogue
   gain two instructions:                                    */

func:   paciasp                         // sign LR using SP as context
        stp     x29, x30, [sp, #-16]!
        ...
        ldp     x29, x30, [sp], #16
        autiasp                         // authenticate LR
        ret                             // faults if it was tampered

/* The signature occupies the unused upper bits of the pointer.
   An attacker who overwrites the saved LR cannot produce a valid
   signature, so the AUT fails and the RET faults.

   Note the interaction with unwinding: a debugger walking the
   stack sees SIGNED return addresses and must strip the
   authentication bits (XPACI) before symbolising them. Older
   tools show garbage addresses on PAC-enabled binaries.    */

/* BTI adds a landing-pad requirement on indirect branches: */
func:   bti     c                       // valid target for BLR
        ...
```

Debugging ABI problems

```
# check the arguments a function actually received
gdb) info args
gdb) info frame
gdb) p $x0
gdb) bt

# the frame pointer chain, by hand
gdb) p/x $x29
gdb) x/2gx $x29          # {caller's fp, return address}

# see what the compiler expects
gcc -O2 -S test.c        # look at the prologue and argument use

# verify alignment at a call site
gdb) p $sp % 16          # must be 0

# a corrupted stack trace, or a return to a garbage address,
# almost always means:
#   · SP misaligned
#   · a callee-saved register clobbered
#   · the frame pointer not established or not restored
#   · a prototype mismatch between caller and callee
```

How it shows up

Symptom	Cause
Caller's local variables corrupted after a call	Callee clobbered a callee-saved register
Return to a garbage address	`X30` not saved, or the stack was corrupted
Alignment fault deep inside libc	SP not 16-byte aligned at the call
Float arguments arrive as garbage	Missing prototype, so they went in the wrong register class
Struct-by-value call is unexpectedly slow	Larger than 16 bytes — a memory copy per call
Assembly works on Linux, fails on Windows or macOS	`X18` use, or Apple's variadic-on-stack rule
SIMD kernel corrupts the caller	Used the full 128 bits of `V8`–`V15`; only the low 64 are preserved
Stack traces truncated in perf	Built with `-fomit-frame-pointer`
Backtrace shows nonsense addresses on a hardened build	PAC-signed return addresses not stripped by the tool

Check yourself

- ✓ Name the argument registers, the return register, and the callee-saved set.
- ✓ Explain caller-saved versus callee-saved and why both exist.
- ✓ State the stack alignment rule and one symptom of violating it.
- ✓ Draw the frame pointer chain and show how a debugger walks it.
- ✓ Explain how a 12-byte struct, a 24-byte struct and a `struct vec3` are each passed.
- ✓ Say what `X8` is for on a large struct return.
- ✓ Give the checklist for hand-written assembly that C will call.
- ✓ Explain what `PACIASP` / `AUTIASP` do and how they interact with unwinding.

How an instruction executes

CA chapter 11 covered pipelining in general. This chapter follows one AArch64 instruction through a real core, showing where the MMU, the caches and the exception machinery each enter the picture — and what can go wrong at each point.

The pipeline, concretely

```
   ┌─────────┐ ┌─────────┐ ┌─────────┐ ┌─────────┐ ┌─────────┐ ┌─────────┐
   │ FETCH   │→│ DECODE  │→│ RENAME  │→│ ISSUE   │→│EXECUTE  │→│ RETIRE  │
   │         │ │         │ │         │ │         │ │ MEMORY  │ │         │
   └─────────┘ └─────────┘ └─────────┘ └─────────┘ └─────────┘ └─────────┘
        ▲           ▲                     ▲           ▲           ▲
        |           |                     |           |           |
   branch       fixed 32-bit          scheduler   MMU + caches  in ORDER,
   predictor    encoding makes        picks ready               architectural
   + I-TLB      this cheap and        instructions              state updates
   + I-cache    parallel                                        HERE ONLY

  Depth varies enormously by core:
     Cortex-A53     8 stages, in-order, 2-wide
     Cortex-A78    13 stages, out-of-order, 4-wide fetch/6-wide issue
     Neoverse V2   deeper still, 8-wide

  Same architecture. Same binary. Very different behaviour — the
  distinction from chapter 01.
```

Fetch: where translation begins

```
/* The PC is a VIRTUAL address. Before any instruction bytes can be
   read, it must be translated.                                    */

   PC → I-TLB lookup
          hit  → physical address in ~1 cycle
          miss → hardware page table walk (chapter 13)
                 walk fails → INSTRUCTION ABORT
                              ESR.EC = 0x20 (lower EL) or 0x21
        → L1 instruction cache
          hit  → up to 4-8 instructions returned
          miss → L2 → interconnect → DRAM

/* In parallel, the branch predictor is already producing the NEXT
   fetch address, so the front end never waits for decode to
   discover that an instruction was a branch (CA chapter 12).  */

/* Three things can go wrong here:
     · translation fault      → instruction abort
     · permission fault       → the page is XN (execute-never)
     · the page is Device     → instruction fetch from Device
                                memory is UNPREDICTABLE. Never
                                execute from an MMIO mapping.  */
```

Decode and rename

```
/* Fixed 32-bit encodings mean the decoder can split N instructions
   simultaneously with no serial dependency - the single biggest
   front-end advantage of the ISA (chapter 03).               */

/* Two things happen that software cannot see but must understand: */

/* 1. CRACKING - some instructions become several micro-operations */
        ldp     x0, x1, [x2]        // may become two loads
        stp     x0, x1, [x2, #16]!  // store + address update

/* 2. REGISTER RENAMING - architectural registers are mapped onto
      a much larger physical register file.                    */

        add     x0, x1, x2      // x0 → physical reg p37
        ldr     x0, [x3]        // x0 → physical reg p52  (a NEW one)
        add     x4, x0, #1      //         reads p52

/* Renaming removes WAR and WAW hazards entirely: the second write
   to x0 does not have to wait for the first, because they are
   different physical registers. Only TRUE dependencies (RAW)
   remain, and those are the ones you can attack in source code
   with multiple accumulators (CA chapter 19).               */
```

The memory stage, in detail

```
This is where most of the interesting failures live.

   effective address computed (base + offset, or base + index<<s)
        |
        ▼
   ① ALIGNMENT CHECK
        Device memory: ANY unaligned access faults
        Normal memory: allowed, unless SCTLR.A is set
        SP-relative:   SP must be 16-byte aligned if SCTLR.SA
        |
        ▼
   ② TRANSLATION — D-TLB, tagged by ASID
        miss → hardware table walk, up to 4 memory accesses
        invalid descriptor → TRANSLATION FAULT
              ESR.EC = 0x24/0x25, FAR = the address
        |
        ▼
   ③ PERMISSION CHECK
        AP bits vs current EL and access type
        PXN/UXN for instruction fetch
        PAN: may EL1 touch this user page right now? (chapter 05)
        fail → PERMISSION FAULT
        |
        ▼
   ④ STAGE 2 — only if a hypervisor is active
        IPA → PA via VTTBR_EL2, second permission check
        fail → exception to EL2, not EL1 (chapter 16)
        |
        ▼
   ⑤ MEMORY TYPE from MAIR, via the descriptor's AttrIndx
        Normal cacheable  → probe the cache
        Device            → bypass the cache, no speculation,
                            no merging (chapter 11)
        |
        ▼
   ⑥ CACHE — L1 hit? L2? L3? interconnect?
        |
        ▼
   ⑦ INTERCONNECT — AXI/CHI transaction carrying
        address, master ID, NS bit, cacheability
        SMMU may translate it (for non-CPU masters)
        XPU may REFUSE it → external abort, DFSC = 0b010000
        |
        ▼
   ⑧ data returned, or the store retires

Every fault code you will decode in chapter 29 corresponds to a
specific step in this list.
```

Out-of-order execution and its limits

```
/* Instructions EXECUTE when their operands are ready, in any
   order. They RETIRE strictly in program order.             */

        ldr     x0, [x1]        // L2 miss: 40 cycles
        add     x2, x3, x4      // independent — executes NOW
        add     x5, x6, x7      // independent — executes NOW
        add     x8, x0, #1      // DEPENDENT on x0 — must wait

/* The reorder buffer holds results until retirement. Two
   properties follow, and both matter:                       */

/* 1. PRECISE EXCEPTIONS. If the load faults, everything after it
      is discarded before retiring, so the architectural state
      looks exactly as if execution stopped at the load. That is
      what makes demand paging possible: the OS fixes the mapping
      and the SAME instruction re-executes (OS chapter 12).  */

/* 2. SPECULATIVE state is NOT rolled back. Caches, TLBs and
      predictor tables were already changed. This is the entire
      basis of Spectre (CA chapter 12), and the reason ARM added
      CSDB, SB and SSBS.                                     */

/* What LIMITS the reordering window:
     · reorder buffer size (~100–500 entries)
     · load/store queue depth
     · physical register file size
     · a full BARRIER, which drains it deliberately (chapter 21) */
```

Where stalls come from

Cause	Cost	Source-level fix
L1 data miss	~12 cycles	Locality, layout (CA 13)
Last-level miss → DRAM	~200 cycles	Blocking, prefetch, smaller working set
TLB miss → page walk	10s–100s of cycles	Huge pages
Branch mispredict	10–20 cycles	Branchless code, predictable branches
True dependency chain	Latency of each link	**Multiple accumulators** (CA 19)
Divide	10–20 cycles, not pipelined	Avoid, or use reciprocal multiply
Store-to-load forwarding failure	10s of cycles	Avoid overlapping partial stores then wide loads
`ISB` / `DSB`	Full drain — expensive	Use the weakest barrier that suffices
Exclusive-loop contention	Unbounded retries	LSE atomics (ch. 22)

```
/* The dependency chain is the one you control most directly: */

/* 4-cycle FP add latency, serialised — 4 cycles per element */
for (i = 0; i < n; i++) sum += a[i];

/* four independent chains — the latencies overlap */
for (i = 0; i < n; i += 4) {
        s0 += a[i];   s1 += a[i+1];
        s2 += a[i+2]; s3 += a[i+3];
}
sum = (s0 + s1) + (s2 + s3);
/* Typically ~4x faster with an UNCHANGED instruction count. The
   compiler will not do this for floats without -ffast-math,
   because it changes the rounding (CA chapter 03).         */
```

Measuring what the pipeline is doing

```
# the top-down view: where are the issue slots going?
perf stat -e cycles,instructions,stall_frontend,stall_backend ./prog

#   stall_frontend high → INSTRUCTION supply
#        I-cache misses, branch mispredicts, ITLB misses
#        fix: code layout, PGO, fewer/predictable branches
#
#   stall_backend high  → DATA supply or execution
#        D-cache misses, dependency chains, divides
#        fix: data layout, more parallelism, better algorithms

# drill down
perf stat -e l1d_cache_refill,l2d_cache_refill,ll_cache_miss_rd \
          -e dtlb_walk,itlb_walk \
          -e br_mis_pred_retired,br_retired \
          -e inst_spec,inst_retired ./prog

#   inst_spec vs inst_retired = how much work was SPECULATED and
#   thrown away. A large gap means heavy mispredict waste.

# which instruction?
perf record -e l1d_cache_refill ./prog && perf annotate

# ARM's own tooling gives a full top-down breakdown
#   topdown-tool (from Arm's telemetry solution)
#   Arm Streamline, Arm MAP
```

> **IPC IS THE FIRST NUMBER TO LOOK AT**
>
> Instructions per cycle tells you immediately which world you are in. Below ~0.5 on a wide core means you are stalled — find out on what. Above ~2 means the core is busy and further gains must come from doing *less work*, i.e. a better algorithm. Between the two, look at the stall counters. This one number saves a great deal of misdirected optimisation.

Where exceptions fit

```
Any stage can raise an exception:

  FETCH    instruction abort — translation or permission
  DECODE   undefined instruction; trapped by a higher EL
  EXECUTE  FP exception, divide-by-zero (where trapped)
  MEMORY   data abort, alignment fault, external abort
  any      IRQ/FIQ arriving asynchronously
  any      SError — an imprecise external abort, often from
           a write posted long ago

SYNCHRONOUS exceptions are precise: the instruction is
identified exactly, and ELR points at it (or past it, for SVC).

ASYNCHRONOUS ones are taken between instructions, at a point
the hardware chooses.

SError is the awkward case: the reported PC has NOTHING to do
with the cause, because the failing transaction retired long
before the error came back. This is why external aborts from a
bus firewall (security chapter 20) are so hard to attribute,
and why an ESB (Error Synchronization Barrier) is used to
contain them at known points.

Chapter 28 covers the entry sequence; chapter 29 covers
decoding what happened.
```

How it shows up

Symptom	Cause
IPC below 0.5 with few cache misses	Long dependency chains, or frontend-bound
Loop 4× faster after manual unrolling	Broke a true dependency chain
Large gap between `inst_spec` and `inst_retired`	Heavy branch misprediction; work thrown away
Unaligned access faults on one region only	That region is mapped as Device memory
Fetching instructions from a peripheral hangs	Execution from Device memory is unpredictable
Fault address unrelated to the reported PC	SError — an imprecise, asynchronous abort
Code faster on a big core than expected	Deeper reorder window hides the latency
Barrier in a hot loop destroys throughput	`DSB` / `ISB` drains the pipeline; use a weaker one
Timing-dependent bug only on out-of-order cores	Reordering the in-order core happened not to perform

Check yourself

- ✓ Name the pipeline stages and say which two involve address translation.
- ✓ Explain what register renaming removes and what it cannot remove.
- ✓ List the eight checks a load passes through in the memory stage.
- ✓ Explain precise exceptions and why demand paging depends on them.
- ✓ Explain why speculative state is not rolled back, and one consequence.
- ✓ Give five sources of pipeline stalls and the source-level fix for each.

- ✓ Say what `stall_frontend` versus `stall_backend` tells you to do.
- ✓ Explain why SError is harder to diagnose than a data abort.

Memory types: Normal versus Device

ARM tags every region of memory with a type that changes what the hardware is permitted to do with accesses to it — reorder them, merge them, speculate them, cache them. Choosing the wrong type is one of the most common and most confusing driver bugs, because the symptom rarely points at the cause.

Why a type is needed at all

RAM AND REGISTERS ARE NOT THE SAME THING

Reading RAM twice gives the same answer and costs nothing. Reading a FIFO register twice *consumes two bytes*. Writing RAM has no effect until someone reads it; writing a control register starts a motor.

The optimisations that make RAM fast — caching, speculation, write merging, reordering — are all *incorrect* for a peripheral. So the architecture provides a type that switches them off, and the page table says which is which.

The two types

	Normal	Device
Used for	RAM, code, data, DMA buffers	Peripheral registers (MMIO)
Reordering	Freely, subject to the memory model	Not reordered relative to other Device accesses
Speculative access	Allowed — the CPU may read addresses you never asked for	**Never**
Merging / splitting	Allowed	Depends on sub-type
Repeating an access	Allowed	Not allowed
Unaligned access	Allowed	**Always faults**
Cacheable	Yes — write-back, write-through, or non-cacheable	Never
Exclusives (`LDXR`)	Supported	**Not supported** — undefined behaviour
Instruction fetch	Yes	Unpredictable — never execute from Device memory

Device sub-types

```
Written Device-<G|nG><R|nR><E|nE>, each letter a permission:

   G / nG   GATHERING - may two accesses be merged into one
                        larger access, or one access split?
   R / nR   REORDERING - may accesses to DIFFERENT addresses in
                        this region be reordered with each other?
   E / nE   EARLY WRITE ACKNOWLEDGEMENT - may a write be
                        acknowledged before it reaches the
                        endpoint (i.e. buffered en route)?

   Device-nGnRnE   nothing allowed. The strictest.
                   Use for: control registers where every write
                   must land, in order, before the next.
                   MAIR encoding 0x00

   Device-nGnRE    early ack permitted, still no gathering or
                   reordering. The common default for most
                   peripherals - noticeably faster than nGnRnE
                   because writes need not stall.
                   MAIR encoding 0x04

   Device-nGRE     reordering permitted
                   MAIR encoding 0x08

   Device-GRE      everything permitted. Use for framebuffers and
                   large streaming windows, where throughput
                   matters and individual accesses have no
                   side effects.
                   MAIR encoding 0x0C

  Ordering of strictness: nGnRnE > nGnRE > nGRE > GRE

  Note that even the most relaxed Device type is NOT cacheable and
  NOT speculatable. Those two properties define "Device".
```

Normal memory cacheability

```
/* Normal memory has independent INNER and OUTER cacheability
   attributes, each one of:                                    */

   Non-cacheable
   Write-Through,  Read-Allocate / Write-Allocate
   Write-Back,     Read-Allocate / Write-Allocate    ← the usual

/* "Inner" and "Outer" are implementation-defined boundaries.
   Typically Inner = the CPU cluster's caches (L1, L2), Outer =
   a system-level cache beyond it. Most software sets them the
   same.                                                       */

/* And a SHAREABILITY attribute, which is separate:           */
   Non-shareable       no coherency maintained
   Inner Shareable     coherent within the inner domain — this is
                       what SMP kernel memory uses
   Outer Shareable     coherent across a wider domain, including
                       some DMA masters

/* Shareability determines how far a barrier or a TLBI
   propagates (chapters 19 and 21). Getting it wrong gives you
   coherency bugs that only appear on multi-core.             */
```

MAIR: how a descriptor names a type

```
A page table descriptor has only 3 bits for attributes (AttrIndx).
Three bits cannot encode all the combinations above, so ARM uses
INDIRECTION:

   MAIR_EL1 holds EIGHT 8-bit attribute values, one per slot.
   The descriptor's AttrIndx selects a slot.

   MAIR_EL1 = 0x00000000_0044FF04
                            || ||
                            || |└─ slot 0 = 0x04 Device-nGnRE
                            || └── slot 1 = 0xFF Normal WB RW-alloc
                            |└──── slot 2 = 0x44 Normal Non-cacheable
                            └───── slot 3 = 0x00 Device-nGnRnE

   Encoding of each byte:
      0x00        Device-nGnRnE
      0x04        Device-nGnRE
      0x08        Device-nGRE
      0x0C        Device-GRE
      0xFF        Normal, Inner+Outer WB, RW-allocate
      0x44        Normal, Inner+Outer Non-cacheable
      high nibble = Outer, low nibble = Inner (for Normal)

   Change MAIR and EVERY page using that slot changes type at
   once — which is convenient, and also a way to break the whole
   system with one register write.
```

```
/* Setting it up, in boot code */
#define MAIR_DEVICE_nGnRnE  0x00
#define MAIR_DEVICE_nGnRE   0x04
#define MAIR_NORMAL_NC      0x44
#define MAIR_NORMAL_WB      0xFF

#define IDX_DEVICE_nGnRnE   0
#define IDX_DEVICE_nGnRE    1
#define IDX_NORMAL_NC       2
#define IDX_NORMAL_WB       3

        uint64_t mair =
                ((uint64_t)MAIR_DEVICE_nGnRnE << (8 * IDX_DEVICE_nGnRnE)) |
                ((uint64_t)MAIR_DEVICE_nGnRE  << (8 * IDX_DEVICE_nGnRE))  |
                ((uint64_t)MAIR_NORMAL_NC     << (8 * IDX_NORMAL_NC))     |
                ((uint64_t)MAIR_NORMAL_WB     << (8 * IDX_NORMAL_WB));

        asm volatile("msr mair_el1, %0" :: "r"(mair));
        asm volatile("isb");            /* chapter 06 */

/* then a descriptor references a slot: */
        pte = pa | PTE_VALID | PTE_AF
                 | PTE_ATTR(IDX_DEVICE_nGnRE)   /* bits [4:2] */
                 | PTE_UXN | PTE_PXN;           /* never execute MMIO */
```

The bugs, and why they are confusing

MMIO MAPPED AS NORMAL CACHEABLE

This is the classic, and it produces four distinct failure modes that look unrelated:

1. **Writes never reach the device.** They sit in a dirty cache line until eviction — which may be never, or may happen minutes later at an unrelated moment.
2. **Reads return stale values forever.** The first read caches the line; every subsequent read hits the cache. A status register appears frozen.
3. **A FIFO drains spontaneously.** Speculative execution reads addresses the program never touched. Reading a FIFO register *pops* it, so data vanishes with no code responsible.
4. **Writes are merged or reordered.** A sequence that must be written in order arrives coalesced, and the device sees an illegal state transition.

The tell: it often works under a debugger (single-stepping defeats the caching and speculation) and fails at speed. If a peripheral "works in debug, fails in release", check the mapping attributes before anything else.

NORMAL MEMORY MAPPED AS DEVICE

The reverse mistake is less dramatic but very costly: correctness is fine, performance collapses. No caching, no speculation, no merging — every access goes to DRAM individually. A memcpy through a Device-mapped buffer can be 50–100× slower than through Normal memory. This is a common cause of "why is my DMA buffer so slow to fill?".

```
/* Two more subtle ones: */

/* 1. Exclusives on Device memory are UNDEFINED. */
        /* A spinlock in a Device-mapped shared region will not
           work — LDXR/STXR need a coherent monitor that Device
           memory does not provide. Shared memory between a CPU
           and a device must be Normal Non-cacheable, not Device,
           if you intend to use atomics on it.                */

/* 2. Unaligned access to Device memory ALWAYS faults, even
      though the same code works on Normal memory.           */
        uint8_t *regs = ioremap(...);
        uint32_t v = *(uint32_t *)(regs + 1);   /* alignment fault */
        /* Which is why casting a byte pointer into a register
           block is a bug, and why register structs must have
           explicit padding (C chapter 07).                   */
```

How the OS picks the type for you

```
/* Linux — the mapping function encodes the choice: */

ioremap(phys, size)          /* Device-nGnRE — the default for MMIO */
ioremap_np(phys, size)       /* Device-nGnRnE — "non-posted", for
                                registers needing strict ordering  */
ioremap_wc(phys, size)       /* Normal Non-cacheable, write-combining
                                — framebuffers, large windows      */
ioremap_cache(phys, size)    /* Normal cacheable — ROM, or memory
                                the device does not modify         */
memremap(phys, size, MEMREMAP_WB)   /* explicitly Normal WB        */

/* And the accessors that go with them: */
readl(addr) / writel(v, addr)               /* with barriers        */
readl_relaxed() / writel_relaxed()          /* without              */

/* Windows */
MmMapIoSpaceEx(pa, len, PAGE_READWRITE | PAGE_NOCACHE);
MmMapIoSpaceEx(pa, len, PAGE_READWRITE | PAGE_WRITECOMBINE);
READ_REGISTER_ULONG / WRITE_REGISTER_ULONG

/* In device tree, a region's cacheability for DMA is expressed
   separately, by whether the device is coherent:              */
        dma-coherent;         /* device participates in coherency  */
        no-map;               /* kernel must not map this at all   */
```

DMA buffers: the third case

```
A DMA buffer is Normal memory, but WHICH Normal memory depends on
whether the device is coherent:

  COHERENT DEVICE (ACE-Lite, CHI, `dma-coherent` in DT)
     map Normal Write-Back Inner-Shareable
     the interconnect keeps the device's view coherent with the
     CPU's caches — no maintenance needed
     dma_alloc_coherent() gives you cacheable memory

  NON-COHERENT DEVICE
     option A: Normal Non-cacheable
               simple and correct, but CPU access is slow
               dma_alloc_coherent() gives you this on such systems
     option B: Normal Write-Back plus explicit cache maintenance
               fast CPU access, but you must clean before the
               device reads and invalidate before you read what
               it wrote (chapter 18, CA chapter 15)
               dma_map_single() / dma_sync_* do this for you

  NEVER map a DMA buffer as Device. It is memory, not registers:
  you want the CPU side to be fast, and the device does not care.

  This is precisely why you must use the DMA API rather than
  choosing yourself — it knows which case applies.
```

Checking what you got

```
# Linux: what is mapped where, and how
cat /proc/vmallocinfo | grep ioremap
#   0xffff800010000000-0xffff800010002000  8192 ioremap ...

cat /proc/iomem                    # physical resource map
cat /proc/self/pagemap             # per-page details (needs root)

# read MAIR and a descriptor from a debug module
pr_info("MAIR_EL1 = %016llx\n", read_sysreg(mair_el1));

# in gdb on a bare-metal target
p/x $MAIR_EL1
p/x $TCR_EL1
# then walk the tables by hand for the address in question
# (chapter 13) and read AttrIndx from bits [4:2]

# the AT instruction asks the hardware to translate for you
        at      s1e1r, x0          // stage-1, EL1, read
        mrs     x1, par_el1        // result: PA plus attributes
/* PAR_EL1 reports the memory attributes actually applied —
   the definitive answer to "how is this address mapped?"   */
```

> **`AT` PLUS `PAR_EL1` IS THE DEBUGGING TOOL TO REMEMBER**
>
> Rather than walking page tables by hand, ask the MMU. `AT S1E1R, Xn` performs a translation and writes the resulting physical address *and its memory attributes* into `PAR_EL1`. If the translation fails, `PAR_EL1.F` is set and the fault status tells you why. This answers "is this address mapped, and as what?" in two instructions, from a live system.

How it shows up

Symptom	Cause
Device works under a debugger, fails at speed	MMIO mapped cacheable; stepping hid it
Status register value never changes	Cached read hitting a stale line
Register writes have no effect	Sitting in a dirty cache line
FIFO loses data with no code reading it	Speculative reads on a cacheable MMIO mapping
Device sees an illegal register sequence	Writes merged or reordered — needs a stricter Device sub-type
Alignment fault on one region only	Device memory always faults on unaligned access
Spinlock in shared memory never acquires	Exclusives on Device memory are undefined
DMA buffer is extremely slow to fill	Mapped Device or Non-cacheable when it need not be
Framebuffer updates are slow	Mapped Device-nGnRnE instead of write-combining
Works on one SoC, fails on another	One is DMA-coherent, the other is not

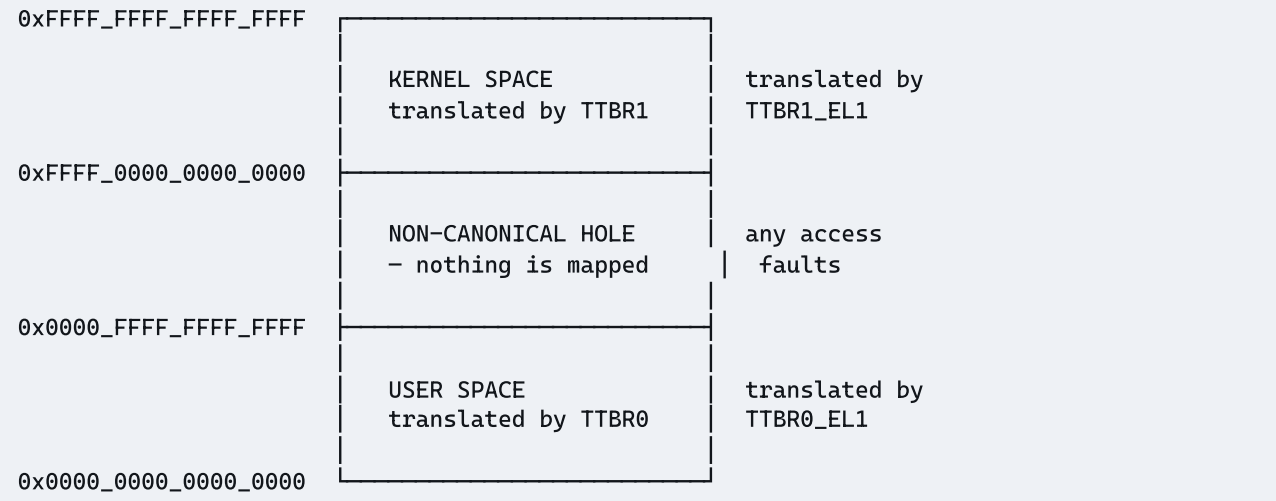
Check yourself

- ✓ Give three optimisations that are correct for RAM and wrong for a peripheral.
- ✓ List five differences between Normal and Device memory.
- ✓ Decode `Device-nGnRE` letter by letter and say when you would use it.
- ✓ Explain what MAIR indirection buys and how a descriptor names a type.
- ✓ Give the four failure modes of mapping MMIO as cacheable.
- ✓ Explain why unaligned access faults on Device memory but not Normal.
- ✓ Say why a DMA buffer should never be Device memory, and what determines its cacheability.
- ✓ Explain how `AT` and `PAR_EL1` answer "how is this address mapped?".

The MMU and the address space split

CA chapter 16 covered virtual memory as an idea. This chapter covers ARM's specific realisation of it: two translation table base registers, a split address space, and the configuration register that ties them together.

Two base registers, one address space



```
The hardware selects the table by the TOP BITS of the address:
   VA[55] (or VA[63], depending on TCR) == 0  →  TTBR0
                                        == 1  →  TTBR1

Bits above the configured VA size must be all-zeros or all-ones
("canonical"). Anything else is a translation fault — which is
why a corrupted pointer with garbage in the top bits produces a
clean fault rather than a wild access.
```

WHY TWO REGISTERS IS THE ELEGANT PART

The kernel mapping lives in `TTBR1_EL1` and never changes. A context switch only rewrites `TTBR0_EL1`. So the kernel stays mapped across every switch, a system call needs no table change at all, and the kernel's TLB entries survive — marked Global so they match under any ASID (chapter 15).

x86-64 has one table root and must place the kernel inside every process's page tables, which is exactly what made Meltdown mitigation (KPTI) so expensive there. ARM's split makes the same isolation nearly free.

TCR_EL1: the configuration register

```
TCR_EL1 controls almost everything about translation. The fields
you will actually set:

   T0SZ  [5:0]     size of the TTBR0 region: VA bits = 64 - T0SZ
                     T0SZ = 16  →  48-bit VA  →  256 TB
                     T0SZ = 25  →  39-bit VA  →  512 GB (3-level)
   T1SZ  [21:16]   the same, for TTBR1

   TG0   [15:14]   TTBR0 granule:  00 = 4KB, 01 = 64KB, 10 = 16KB
   TG1   [31:30]   TTBR1 granule:  10 = 4KB, 11 = 64KB, 01 = 16KB
                     ← note the encodings DIFFER between TG0 and TG1.
                       A classic boot bug.

   IRGN0 [9:8]     cacheability of TTBR0 table WALKS, inner
   ORGN0 [11:10]   ...outer
   SH0   [13:12]   shareability of table walks
   IRGN1/ORGN1/SH1 the same for TTBR1

   IPS   [34:32]   intermediate physical address size
                     000 = 32 bits, 101 = 48 bits, 110 = 52 bits

   TBI0  [37]      Top Byte Ignore — the top 8 bits of a VA are
   TBI1  [38]      not used for translation. This is what makes
                   pointer tagging, HWASAN and MTE possible.

   A1    [22]      which TTBR holds the ASID (0 = TTBR0)
   EPD0  [7]       disable TTBR0 walks entirely
   HA/HD [39:40]   hardware management of Access and Dirty bits
```

```
/* Why walk cacheability matters: a 4-level walk is up to four
   memory accesses. If the tables themselves are uncached, every
   TLB miss costs four DRAM round trips instead of four cache
   hits. Setting IRGN/ORGN to write-back is one of the highest-
   impact single settings in early boot — and forgetting it
   produces a system that boots but is inexplicably slow.    */

#define TCR_T0SZ(x)     ((64 - (x)) << 0)    /* x = VA bits */
#define TCR_T1SZ(x)     ((64 - (x)) << 16)
#define TCR_IRGN_WBWA   ((1UL << 8)  | (1UL << 24))
#define TCR_ORGN_WBWA   ((1UL << 10) | (1UL << 26))
#define TCR_SH_INNER    ((3UL << 12) | (3UL << 28))
#define TCR_TG0_4K      (0UL << 14)
#define TCR_TG1_4K      (2UL << 30)          /* NOT the same value */
#define TCR_IPS_48      (5UL << 32)

        uint64_t tcr = TCR_T0SZ(48) | TCR_T1SZ(48)
                     | TCR_IRGN_WBWA | TCR_ORGN_WBWA | TCR_SH_INNER
                     | TCR_TG0_4K | TCR_TG1_4K | TCR_IPS_48;
        asm volatile("msr tcr_el1, %0" :: "r"(tcr));
```

Granule size

Granule	Levels for 48-bit VA	Block sizes	Notes
4 KB	4 (L0–L3)	1 GB (L1), 2 MB (L2), 4 KB (L3)	Universal. What Linux uses by default.
16 KB	4 (L0–L3)	32 MB (L2), 16 KB (L3)	Apple platforms; good TLB reach with modest waste

Granule	Levels for 48-bit VA	Block sizes	Notes
64 KB	3 (L1–L3)	512 MB (L2), 64 KB (L3)	Fewer levels, best TLB reach, most internal fragmentation

Granule support is optional per implementation — query `ID_AA64MMFR0_EL1` before selecting one. A kernel configured for 64 KB pages will not boot on a core that only implements 4 KB.

Choosing the VA size

```
/* Reducing the VA size removes a whole LEVEL of the page walk. */

   T0SZ = 16  →  48-bit VA  →  L0, L1, L2, L3   (4 levels)
   T0SZ = 25  →  39-bit VA  →  L1, L2, L3       (3 levels)
   T0SZ = 34  →  30-bit VA  →  L2, L3           (2 levels)

/* Trade-off:
     fewer levels  → cheaper TLB miss (fewer memory accesses),
                     smaller tables
     smaller VA    → less address space per process

   Linux offers CONFIG_ARM64_VA_BITS of 39, 42, 47, 48 and 52.
   39 bits (512 GB) is common on embedded systems and saves a
   level; 48 is the desktop/server default.

   Note the kernel and user sizes are configured INDEPENDENTLY
   (T0SZ vs T1SZ), so you can have a large kernel space and a
   small user space, or vice versa.                          */
```

Turning the MMU on

> **THE MOST DELICATE SEQUENCE IN BOOT CODE**
>
> The instruction that enables the MMU is fetched with the MMU *off*, and the instruction after it may be fetched with the MMU *on*. If the currently executing code is not mapped at the same address in the new tables, execution falls off a cliff with no diagnostic whatsoever.
>
> The standard solution is an **identity map**: a temporary mapping where VA equals PA covering the enabling code itself. Enable the MMU, then branch to the final virtual address, then discard the identity map.

```
/* The sequence, with every step justified */

        /* 1. the tables must be VISIBLE to the table walker before
              it is told to use them. The walker reads memory, and
              our writes may still be in a store buffer.        */
        dsb     ish

        /* 2. install the roots and the configuration */
        msr     ttbr0_el1, x0           /* identity map          */
        msr     ttbr1_el1, x1           /* kernel map            */
        msr     tcr_el1, x2
        msr     mair_el1, x3

        /* 3. these must take effect before SCTLR is written    */
        isb

        /* 4. invalidate stale TLB entries from before the MMU
              was configured — there may be entries from a
              previous boot stage                               */
        tlbi    vmalle1
        dsb     nsh
        isb

        /* 5. enable: M (MMU), C (data cache), I (instruction cache) */

```

Top Byte Ignore and pointer tagging

```
/* With TCR.TBI set, bits [63:56] of a virtual address are IGNORED
   for translation. Software may store anything there.       */

   0xFF00_1234_5678_9ABC
     ^^ ignored by the MMU

/* This enables several important features:                  */

/* HWASAN — hardware-assisted AddressSanitizer. A tag in the
   pointer is compared against a shadow-memory tag on each
   access. Far cheaper than classic ASan's redzones.        */

/* MTE — Memory Tagging Extension (ARMv8.5). The comparison moves
   into HARDWARE: each 16-byte granule of memory has a 4-bit tag,
   and the CPU checks it against the pointer's tag on every
   access. Use-after-free and buffer overflow detection at a few
   percent overhead — cheap enough for production. Android
   ships it.                                                */

/* Pointer authentication also lives in these bits when TBI is
   enabled (chapter 09).                                    */

/* The catch: any code that COMPARES pointers or uses them as
   hash keys must strip the tag first, or logically identical
   pointers compare unequal. This is why introducing tagging into
   an existing codebase surfaces latent pointer-arithmetic bugs. */
```

Where the ASID lives

```
/* The ASID is stored in the TOP 16 BITS of TTBR0_EL1 (or TTBR1,
   if TCR.A1 is set — but nobody does that).                */

        ttbr0 = page_table_pa | ((uint64_t)asid << 48);
        msr   ttbr0_el1, x0

/* So a context switch is ONE register write that changes both
   the translation tables and the address-space identity. The
   TLB keeps entries from both processes, tagged by ASID, and
   nothing needs flushing (chapter 15).                     */

/* ASID width is 8 or 16 bits, reported by ID_AA64MMFR0_EL1.ASIDBits.
   Linux uses a generation-rollover scheme: when ASIDs are
   exhausted it bumps a generation counter and flushes, which is
   rare but shows up as a periodic latency blip on systems with
   very many processes.                                     */
```

Translation regimes

```
Each exception level has its OWN translation configuration.
These are entirely separate sets of registers:

   EL1&0 regime     TTBR0_EL1, TTBR1_EL1, TCR_EL1, MAIR_EL1
                    used by EL0 and EL1 — one regime covering both,
                    which is why the split by top bit works

   EL2 regime       TTBR0_EL2, TCR_EL2, MAIR_EL2
                    the hypervisor's own mappings.
                    With VHE (ARMv8.1), EL2 gains TTBR1_EL2 and
                    behaves like EL1&0 — which is what lets a host
                    kernel run at EL2 unmodified.

   EL2 stage 2      VTTBR_EL2, VTCR_EL2
                    translates guest IPAs to PAs (chapter 16)

   EL3 regime       TTBR0_EL3, TCR_EL3, MAIR_EL3
                    single-level, no TTBR1 — the monitor's map

   Secure and Non-secure EL1&0 are also SEPARATE regimes, with
   independent register banks selected by SCR_EL3.NS. So the
   secure world has its own page tables entirely.
```

Inspecting translation

```
/* The AT instruction: ask the hardware to translate an address
   and report the result. The single most useful MMU debugging
   tool.                                                        */

#   — the definitive dump of what the kernel actually mapped

dmesg | grep -i 'Virtual kernel memory layout'
```

How it shows up

Symptom	Cause
Hangs immediately on enabling the MMU	No identity map covering the enabling code
Boots but everything is slow	Table walks configured non-cacheable in TCR
Kernel boots on one core, hangs on another	Missing `ISB` after the `SCTLR` write
Wrong granule accepted at build, faults at run	TG0 and TG1 use different encodings for the same size

Symptom	Cause
Kernel will not boot on a particular SoC	Granule size not implemented — check `ID_AA64MMFR0_EL1`
Pointer comparisons fail after enabling tagging	Tags not stripped before comparison
Access to a high address faults unexpectedly	Non-canonical — bits above the VA size are not all-ones
Periodic latency blip with many processes	ASID rollover forcing a full TLB flush
Guest translation works, host cannot see the mapping	Different translation regimes — separate register banks

Check yourself

- ✓ Explain how the hardware chooses between TTBR0 and TTBR1.
- ✓ Give two advantages of the two-register split over a single root.
- ✓ Name five `TCR_EL1` fields and what each controls.
- ✓ Explain why walk cacheability matters and what happens if you get it wrong.
- ✓ Say how reducing the VA size changes the page walk.
- ✓ Explain why enabling the MMU needs an identity map.
- ✓ Explain what Top Byte Ignore enables and one bug it exposes.
- ✓ Describe what `AT` plus `PAR_EL1` tells you, in both success and failure cases.

Translation tables and the page walk

The single most important mechanism in system software. Trace it by hand once and address translation stops being mysterious — page faults, TLB maintenance, hypervisors and the SMMU all become variations on this one walk.

Decomposing the address

```
48-bit VA, 4 KB granule — the configuration you will meet most

 63       48 47    39 38    30 29    21 20    12 11         0
┌───────────┬────────┬────────┬────────┬────────┬────────────┐
│ sign ext. │ L0 idx │ L1 idx │ L2 idx │ L3 idx │   offset   │
└───────────┴────────┴────────┴────────┴────────┴────────────┘
              9 bits   9 bits   9 bits   9 bits    12 bits

  9 bits = 512 entries per table.
  Each table is 512 × 8 bytes = 4096 bytes = exactly one page.
  That is not a coincidence: the table size is chosen to equal
  the granule so tables can be allocated from the page allocator.

  Coverage per entry:
     L0 entry → 512 GB      L2 entry →   2 MB
     L1 entry →   1 GB      L3 entry →   4 KB

  So one L1 entry can be a 1 GB BLOCK, one L2 entry a 2 MB block,
  or either can point to the next table. That choice is what
  makes huge pages possible.
```

The walk, step by step

THE 0B01 / 0B11 INVERSION AT L3

At levels 0–2, `0b11` means "table" and `0b01` means "block". At level 3 there is no next level, so `0b11` means "page" and `0b01` is **invalid**. Hand-written table code that uses a single "valid leaf" constant across levels produces a translation fault only at L3 — which looks like a random subset of addresses failing. It is one of the two or three most common bugs in bare-metal MMU setup.

A worked example

```
/* Translate VA = 0x0000_0000_4020_1000, 4 KB granule, 48-bit.

   Binary of the relevant bits:
     0x40201000 = 0100 0000 0010 0000 0001 0000 0000 0000

   Extract the indices:
     VA[47:39] = 0            → L0 index 0
     VA[38:30] = 1            → L1 index 1     (0x40000000 / 1 GB)
     VA[29:21] = 1            → L2 index 1     (0x00200000 / 2 MB)
     VA[20:12] = 1            → L3 index 1     (0x00001000 / 4 KB)
     VA[11:0]  = 0            → offset 0

   Walk, with TTBR0 = 0x80000000:

     L0: read  0x80000000 + 0*8  = 0x80000000
         value 0x0000000080001003
               ↑ next table at 0x80001000, bits[1:0]=11 = table

     L1: read  0x80001000 + 1*8  = 0x80001008
         value 0x0000000080002003   → table at 0x80002000

     L2: read  0x80002000 + 1*8  = 0x80002008
         value 0x0000000080003003   → table at 0x80003000

     L3: read  0x80003000 + 1*8  = 0x80003008
         value 0x00600000_9A00_0743
               bits[1:0] = 11 = valid page
               output address bits[47:12] = 0x9A000
               → PA = 0x9A000000 | 0x000 = 0x9A000000

   Do this once with a real dump from your own system. It converts
   the whole subject from abstract to obvious.                 */
```

Blocks: huge pages

```
A BLOCK descriptor terminates the walk early, mapping a large
contiguous region with ONE entry.

   L1 block   1 GB    used for the kernel linear map, and for
                      hugetlbfs 1 GB pages
   L2 block   2 MB    transparent huge pages, most large mappings
   L3 page    4 KB    the normal case

  Requirements: both the VA and the PA must be aligned to the
  block size, and the whole region must have identical
  permissions and attributes.

  BENEFIT — TLB reach. One entry covers 2 MB instead of 4 KB, so
  1024 TLB entries cover 2 GB rather than 4 MB (CA chapter 16).
  Also a shorter walk: 3 levels instead of 4.

  COST — internal fragmentation, and splitting a block later
  (to change permissions on part of it) requires break-before-make
  (below).

  CONTIGUOUS HINT: a descriptor bit saying "this entry and its
  15 neighbours form one contiguous, aligned region with identical
  attributes". The TLB may then use ONE entry for all 16 — a
  64 KB mapping from 4 KB pages, without needing a real block.
  Setting it when the claim is FALSE is a serious error: the TLB
  will happily use one entry for regions that differ.
```

Building tables in code

```
a minimal but correct table builder
```

```
#define PTE_VALID       (1UL << 0)
#define PTE_TABLE       (1UL << 1)   /* L0-L2: points to next table */
#define PTE_PAGE        (1UL << 1)   /* L3:    a 4 KB page          */
#define PTE_BLOCK       (0UL << 1)   /* L1-L2: a block              */
#define PTE_AF          (1UL << 10)  /* access flag - MANDATORY     */
#define PTE_SH_INNER    (3UL << 8)
#define PTE_AP_RW_EL1   (0UL << 6)
#define PTE_AP_RW_ALL   (1UL << 6)
#define PTE_AP_RO_EL1   (2UL << 6)
#define PTE_UXN         (1UL << 54)
#define PTE_PXN         (1UL << 53)
#define PTE_ATTR(i)     ((uint64_t)(i) << 2)

#define IDX(va, level)  (((va) >> (39 - 9 * (level))) & 0x1FF)

static uint64_t *alloc_table(void);   /* returns a zeroed 4 KB page */

static void map_page(uint64_t *l0, uint64_t va, uint64_t pa,
                     uint64_t attrs)
{
        uint64_t *tbl = l0;

        /* walk levels 0..2, creating tables as needed */
        for (int level = 0; level < 3; level++) {
                uint64_t *e = &tbl[IDX(va, level)];

                if (!(*e & PTE_VALID)) {
                        uint64_t *next = alloc_table();
                        /* the ZEROED table must be visible before
                           the descriptor that points at it        */
                        __asm__ volatile("dsb ishst" ::: "memory");
                        *e = (uint64_t)next | PTE_VALID | PTE_TABLE;
                } else if (!(*e & PTE_TABLE)) {
                        return;         /* a block is already here */
                }
                tbl = (uint64_t *)(*e & 0x0000FFFFFFFFF000UL);
        }

        /* level 3: the leaf */
        tbl[IDX(va, 3)] = (pa & 0x0000FFFFFFFFF000UL)
                        | PTE_VALID | PTE_PAGE | PTE_AF | attrs;

        __asm__ volatile("dsb ishst" ::: "memory");
}

/* Note the two DSBs. The table walker is a separate hardware
   observer that reads memory directly; your stores must be
   visible to it before the descriptor referencing them is
   written. Omitting these gives faults that appear only under
   load or only on certain cores.                            */
```

Break-before-make

> **YOU MAY NOT CHANGE A LIVE MAPPING IN PLACE**
> If a TLB holds an entry for a VA and you overwrite the descriptor with a different output address, size or attributes, the architecture permits the TLB to hold *both* old and new translations simultaneously. The result is UNPREDICTABLE — including a possible TLB conflict abort, or accesses going to either address non-deterministically.
>
> The required sequence is **break-before-make**:
>
> ```
> /* 1. BREAK: make the entry invalid */
> *pte = 0;
> dsb     ishst
>
> /* 2. invalidate the TLB entry, everywhere */
> tlbi    vaae1is, x_va
> dsb     ish
> isb
>
> /* 3. MAKE: write the new descriptor */
> *pte = new_descriptor;
> dsb     ishst
> isb
> ```
>
> This applies when changing the output address, the block size (splitting a 2 MB block into 4 KB pages), or the memory type. It is *not* required for a permission-only change from more permissive to less, or for setting the access/dirty bits — the architecture permits those to be atomic.

Hardware access and dirty bit management

```
/* Without hardware management (ARMv8.0):
     · AF starts clear; the first access takes an ACCESS FLAG FAULT
       and software sets it — this is how the OS tracks page usage
     · the dirty state is emulated by mapping the page read-only,
       taking a permission fault on the first write, and recording
       "dirty" in software before making it writable

   Both cost a fault per page. With HA/HD (ARMv8.1), the hardware
   sets AF and clears the DBM-controlled read-only bit itself, and
   the faults disappear.                                          */

        TCR_EL1.HA  = 1        /* hardware Access flag update */
        TCR_EL1.HD  = 1        /* hardware Dirty bit  update  */
        descriptor DBM bit     /* marks a page as dirty-managed */

/* Query support: ID_AA64MMFR1_EL1.HAFDBS
   Linux enables it when present — worth knowing because it
   changes the fault pattern you will see when profiling.    */
```

What can go wrong during a walk

Fault	DFSC	Meaning
Address size fault	`0b0000LL`	Output address exceeds the configured PA size

Fault	DFSC	Meaning
Translation fault	`0b0001LL`	Descriptor invalid at level LL — **not mapped**
Access flag fault	`0b0010LL`	AF was clear
Permission fault	`0b0011LL`	Mapped, but AP/XN forbids this access
Synchronous external abort	`0b010000`	The bus refused it — power, clock, or a firewall
External abort on a table walk	`0b0101LL`	The table memory itself was unreadable
TLB conflict abort	`0b110000`	Overlapping TLB entries — a break-before-make violation

The `LL` field gives the level, which is the most useful diagnostic in the whole set: a level-0 translation fault means the top-level table is wrong or `TTBR` is garbage; a level-3 fault means only the final page is missing. Chapter 29 covers decoding these in full.

Walking tables from a live system

```
# Linux: dump every mapping the kernel installed
mount -t debugfs none /sys/kernel/debug
cat /sys/kernel/debug/kernel_page_tables
#   ---[ Linear Mapping start ]---
#   0xffff000000000000-0xffff000040000000  1G PMD  RW NX SHD AF UXN MEM/NORMAL
#   ---[ vmalloc() area ]---
#   0xffff800008000000-0xffff800008001000  4K PTE  ro x  SHD AF UXN MEM/NORMAL
#         ^ size ^ level ^ perms ^ attrs

# per-process
cat /sys/kernel/debug/page_tables/current   # some configurations

# ask the hardware instead (chapter 12)
        at   s1e1r, x0
        mrs  x1, par_el1

# in a JTAG debugger, most tools have a built-in walker:
#   OpenOCD:  aarch64 mmu / mem2array
#   Trace32:  MMU.List, MMU.DUMP PageTable
#   gdb:      write a small python walker — worth doing once
```

How it shows up

Symptom	Cause
Some addresses translate, others fault at level 3	Used `0b01` for L3 leaves instead of `0b11`
Every access faults at level 0	`TTBR` wrong, or the table is not physically where you think
Access flag faults on every first touch	Normal without HA; set AF yourself in static tables
Mapping works, then fails after a change	Missing TLB invalidate, or missing break-before-make
TLB conflict abort	Overlapping entries from an in-place block split
Faults only under load or only on some cores	Missing `DSB` before the descriptor became visible
External abort during a walk	Table memory itself unmapped, or in a denied region
Huge page mapping silently ignored	VA or PA not aligned to the block size
Random accesses go to the wrong page	Contiguous hint set on a region that is not actually contiguous

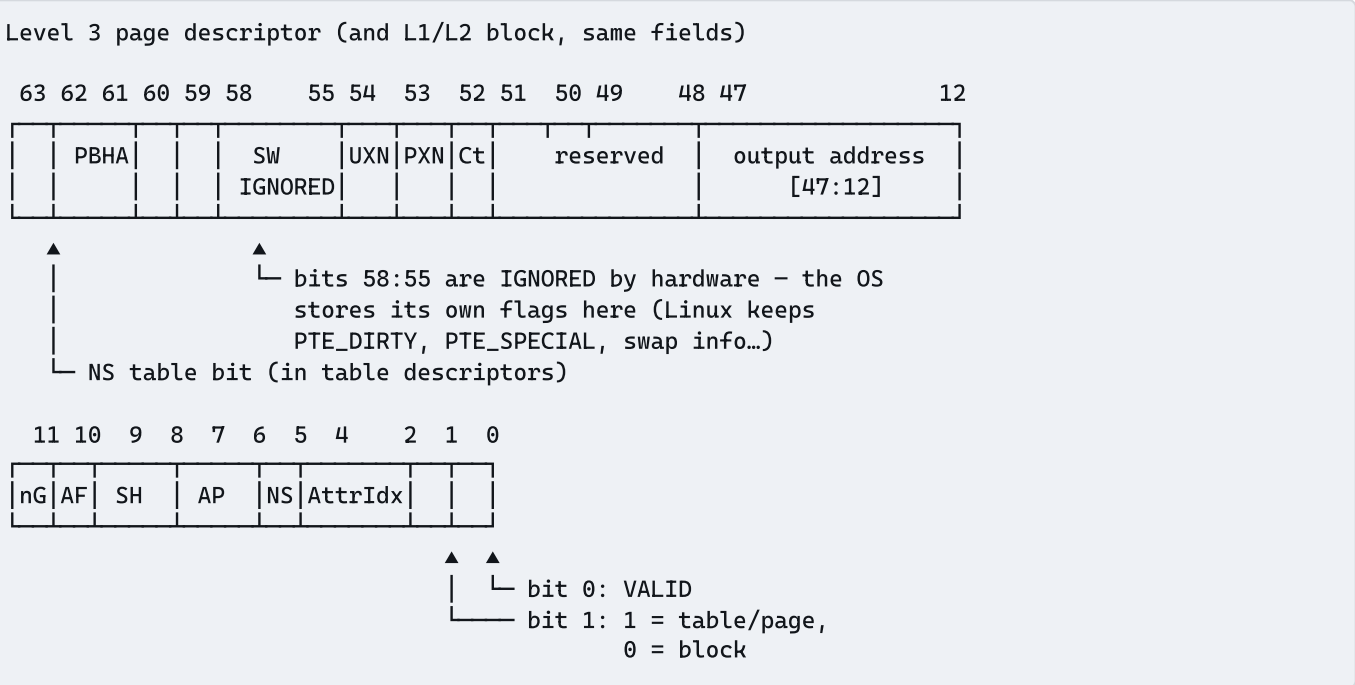
Check yourself

- ✓ Split a 48-bit VA into its four indices and offset, and say how much each level covers.
- ✓ Explain why a table is exactly one page in size.
- ✓ State what `0b01` and `0b11` mean at L2 and at L3, and the bug the difference causes.
- ✓ Walk a real address by hand from a `TTBR` value and four descriptors.
- ✓ Explain what a block descriptor buys and what it costs.
- ✓ State the break-before-make sequence and when it is required.
- ✓ Explain why building tables needs `DSB` instructions.
- ✓ Given a fault with DFSC `0b000101`, say exactly what happened.

Translation table descriptors, decoded

Sixty-four bits per mapped page, and almost every bit does something you can observe. This is the reference chapter — learn to read a descriptor and you can diagnose any permission, attribute or protection question from a raw hex value.

The leaf descriptor



Bits [1:0] — the type

Value	At L0–L2	At L3
`0b00`	Invalid	Invalid
`0b10`	Invalid	Invalid
`0b01`	**Block** — a 1 GB or 2 MB mapping	**Invalid**
`0b11`	**Table** — points to the next level	**Page** — a 4 KB mapping

The L3 inversion is repeated here because it is worth learning twice: it is the most common bare-metal MMU bug (chapter 13).

AP[2:1] — access permissions

```
   AP    EL1 (and above)    EL0        typical use
   ──────────────────────────────────────────────────────
   00    read/write          none       kernel data
   01    read/write          read/write shared with userspace -
                                        rare, and a red flag
   10    read only           none       kernel rodata, code
   11    read only           read only  shared constants, vDSO

  Note what is NOT expressible: "EL0 read/write, EL1 no access".
  Privilege is strictly nested — EL1 can always do at least what
  EL0 can. That is a property of the architecture, not a gap.

  So how does PAN stop the kernel touching user pages? Not through
  AP. PAN is a PSTATE bit that makes any EL1 access to an
  EL0-ACCESSIBLE page fault (chapter 05). It works precisely
  BECAUSE AP cannot express the restriction.
```

Execute-never

```
   UXN  bit 54    Unprivileged eXecute Never — EL0 may not execute
   PXN  bit 53    Privileged   eXecute Never — EL1+ may not execute

/* W^X, the fundamental exploit mitigation, is these two bits: */

   kernel code       AP=10 (RO), PXN=0, UXN=1
   kernel data       AP=00 (RW), PXN=1, UXN=1
   kernel rodata     AP=10 (RO), PXN=1, UXN=1
   user code         AP=11 (RO), PXN=1, UXN=0
   user data         AP=01 (RW), PXN=1, UXN=1

/* Note user data has PXN=1. Without it, an attacker who redirects
   kernel execution into a user-controlled buffer wins — the
   classic ret2usr attack. PXN on all user pages closes it, and
   is the ARM equivalent of x86's SMEP.                       */

/* SCTLR_EL1.WXN makes this automatic: any writable page becomes
   execute-never regardless of the descriptor. A cheap global
   hardening switch.                                          */
```

AttrIndx[2:0] — the memory type

```
/* Three bits selecting one of eight MAIR_EL1 slots
   (chapter 11).                                          */

        pte |= PTE_ATTR(IDX_NORMAL_WB);      /* bits [4:2] */

/* Which slot means what is entirely a software convention —
   whatever you put in MAIR. Linux's arm64 convention:

     0  Device-nGnRnE
     1  Device-nGnRE
     2  Normal Non-cacheable
     3  Normal Write-Back
     4  Normal Write-Through
     5  Normal Tagged (MTE)

   Reading a raw descriptor therefore requires reading MAIR too.
   A descriptor alone does not tell you the memory type.     */
```

SH[1:0] — shareability

SH	Domain	Use for
`00`	Non-shareable	Memory only this core touches; no coherency maintained
`10`	Outer Shareable	Shared with masters beyond the CPU cluster — some DMA
`11`	Inner Shareable	**The normal choice** for all SMP kernel and user memory

Shareability only has meaning for Normal cacheable memory — it is ignored for Device and for Non-cacheable. It determines how far coherency is maintained, and therefore how far a `DMB ISH` or a `TLBI ...IS` propagates (chapter 19). Marking SMP memory Non-shareable produces exactly the coherency bugs of CA chapter 15.

AF — the access flag

THE BIT EVERYONE FORGETS

If `AF` is 0, any access takes an **Access Flag fault** — even though the mapping is otherwise perfect. In hand-written boot tables this presents as "the MMU does not work at all", with a fault code that beginners misread as a translation fault.

Its purpose is page-usage tracking: the OS clears AF, and a later fault tells it the page was touched. That is how LRU approximation works (OS chapter 12). With `TCR.HA` the hardware sets it for you and the fault disappears. In static tables that never move, just set it and forget it.

nG — not global

```
   nG = 0    GLOBAL: the TLB entry matches under ANY ASID
   nG = 1    non-global: tagged with the current ASID

/* Kernel mappings (TTBR1) are Global — they are identical in
   every process, so a context switch need not disturb them.
   User mappings (TTBR0) are non-Global, so several processes'
   entries coexist in the TLB (chapter 15).

   Getting this backwards is a memorable bug: mark a user page
   Global and process B sees process A's memory. Mark a kernel
   page non-Global and it is flushed on every switch, costing
   performance but not correctness.                          */
```

NS — the security bit

```
   NS = 0    this mapping generates SECURE accesses
   NS = 1    this mapping generates NON-SECURE accesses

/* Only meaningful in the Secure translation regime. Secure
   software can create a mapping that issues Non-secure accesses
   — which is how a trusted OS reads a buffer shared with the
   normal world.

   Non-secure software's descriptors have no NS bit that matters:
   its accesses are always NS=1, enforced by hardware.

   In TABLE descriptors there is a separate NSTable bit (bit 63)
   which forces every entry below it to be Non-secure regardless
   of what those entries say — a way to delegate a whole subtree
   safely. Security track, chapter 08.                       */
```

The contiguous hint

```
   Ct  bit 52

/* Asserts: "this entry and its 15 aligned neighbours map a
   contiguous, aligned physical region with identical attributes."
   The TLB may then allocate ONE entry covering all 16 — a 64 KB
   mapping built from 4 KB pages, without needing a block.

   Benefit: 16x the TLB reach for the same table structure.

   Danger: if the claim is FALSE, the TLB uses one translation for
   16 different pages. Accesses silently go to the wrong memory.
   There is no fault. This is the worst kind of bug — silent,
   data-dependent corruption.

   Requirements: all 16 entries valid, physically contiguous,
   16-page aligned in both VA and PA, identical attributes and
   permissions. Changing any one of them requires clearing the
   hint on all 16 first, with break-before-make.            */
```

DBM and hardware dirty tracking

```
   DBM  bit 51    Dirty Bit Modifier

/* With TCR.HD enabled, a descriptor with DBM=1 and AP=read-only
   is upgraded to writable BY HARDWARE on the first write, and
   the hardware records the page as dirty by clearing AP[2].

   Without it, the OS must map the page read-only, take a
   permission fault on the first write, record "dirty" in
   software, and remap writable. One fault per page.

   Reading a descriptor: if DBM is set and AP[2] is CLEAR, the
   page has been written. If AP[2] is SET, it is clean.
   Linux's pte_dirty() checks exactly this.                  */
```

Software-defined bits

```
/* Bits 58:55 (and bits 62:59 in some configurations) are
   IGNORED by hardware. The OS owns them.                    */

/* Linux arm64 uses them for: */
#define PTE_DIRTY       (_AT(pteval_t, 1) << 55)
#define PTE_SPECIAL     (_AT(pteval_t, 1) << 56)
#define PTE_DEVMAP      (_AT(pteval_t, 1) << 57)
#define PTE_PROT_NONE   (_AT(pteval_t, 1) << 58)

/* And for SWAP ENTRIES: when a page is swapped out, the
   descriptor is invalid (bit 0 = 0), so the hardware ignores the
   whole thing — and the OS reuses the other 63 bits to store the
   swap device and offset. That is how the page table doubles as
   the swap map with no extra storage.                       */
```

Decoding a real descriptor

```
/* Given: 0x0060000098765743                                    */

   0x0060000098765743
   = 0000 0000 0110 0000 0000 ... 1001 1000 0111 0110 0101 0111 0100 0011

   bit  0     = 1        VALID
   bit  1     = 1        → at L3: PAGE   (at L1/L2: TABLE)
   bits [4:2] = 0b000    AttrIndx = 0 → MAIR slot 0
   bit  5     = 1        NS — non-secure
   bits [7:6] = 0b01     AP = 01 → RW at EL1 and EL0
   bits [9:8] = 0b11     SH = Inner Shareable
   bit  10    = 1        AF set — accessed
   bit  11    = 0        nG = 0 → GLOBAL
   bits[47:12]= 0x98765  output address → PA base 0x98765000
   bit  53    = 1        PXN — kernel may not execute here
   bit  54    = 1        UXN — user may not execute here

   Conclusion: a global, inner-shareable, read/write,
   non-executable page at PA 0x98765000, memory type = whatever
   MAIR slot 0 holds. Global + user-writable together is unusual
   and worth questioning.

/* A decoder worth keeping in your toolbox: */
static void decode_pte(uint64_t pte, int level)
{
        if (!(pte & 1)) { pr_info("INVALID (%016llx)\n", pte); return; }

        pr_info("PA=%09llx %s %s AP=%llu SH=%llu %s%s%s%s AttrIdx=%llu\n",
                pte & 0x0000FFFFFFFFF000ULL,
                (pte & 2) ? (level == 3 ? "page" : "table") : "block",
                (pte & (1UL << 10)) ? "AF"  : "!AF",
                (pte >> 6) & 3, (pte >> 8) & 3,
                (pte & (1UL << 11)) ? "nG "  : "G ",
                (pte & (1UL << 53)) ? "PXN " : "",
                (pte & (1UL << 54)) ? "UXN " : "",
                (pte & (1UL << 52)) ? "CONT " : "",
                (pte >> 2) & 7);
}
```

Stage-2 descriptors differ

```
Stage-2 (guest IPA → PA, chapter 16) uses a DIFFERENT layout:

   S2AP[7:6]     00 none, 01 read-only, 10 write-only, 11 read/write
                 — absolute permissions, NOT split by EL, because
                   stage 2 applies to the whole guest

   MemAttr[5:2]  the memory type DIRECTLY encoded, with no MAIR
                 indirection — because the guest owns MAIR and
                 the hypervisor cannot rely on it

   XN[54:53]     execute-never, two bits in newer revisions

  The final memory type is the COMBINATION of stage 1 and stage 2,
  and the rule is "the more restrictive wins": if either stage
  says Device, the access is Device; if either says read-only,
  it is read-only. A hypervisor can therefore force a guest's
  mapping to be non-cacheable regardless of what the guest asked
  for — which is how it emulates devices safely.
```

How Linux names these bits

```
/* arch/arm64/include/asm/pgtable-hwdef.h — worth reading once */

#define PTE_VALID       (_AT(pteval_t, 1) << 0)
#define PTE_TYPE_PAGE   (_AT(pteval_t, 3) << 0)
#define PTE_TABLE_BIT   (_AT(pteval_t, 1) << 1)
#define PTE_USER        (_AT(pteval_t, 1) << 6)   /* AP[1] */
#define PTE_RDONLY      (_AT(pteval_t, 1) << 7)   /* AP[2] */
#define PTE_SHARED      (_AT(pteval_t, 3) << 8)   /* SH[1:0] */
#define PTE_AF          (_AT(pteval_t, 1) << 10)
#define PTE_NG          (_AT(pteval_t, 1) << 11)
#define PTE_CONT        (_AT(pteval_t, 1) << 52)
#define PTE_PXN         (_AT(pteval_t, 1) << 53)
#define PTE_UXN         (_AT(pteval_t, 1) << 54)

/* and the composed protections */
#define PAGE_KERNEL       __pgprot(PROT_NORMAL)
#define PAGE_KERNEL_RO    __pgprot(PROT_NORMAL | PTE_RDONLY | PTE_PXN)
#define PAGE_KERNEL_EXEC  __pgprot(PROT_NORMAL & ~PTE_PXN)

/* Reading these definitions is the fastest way to connect the
   architecture to a real kernel's use of it.              */
```

How it shows up

Symptom	Cause
Every access faults despite a correct-looking mapping	`AF` not set
Faults only at level 3	Used `0b01` where L3 needs `0b11`
Kernel executes user-supplied code	`PXN` not set on user pages — ret2usr
Process sees another process's memory	User mapping marked Global instead of non-Global
Performance drops after a context switch	Kernel mapping marked non-Global; flushed every switch
Silent corruption, no fault, data-dependent	Contiguous hint set on a non-contiguous region

Symptom	Cause
Coherency bugs only on multi-core	Shareability set to Non-shareable
Cannot express "user-writable, kernel-inaccessible"	Correct — use PAN, not AP
Guest gets cacheable access to an emulated device	Stage-2 MemAttr too permissive; the stricter stage wins

Check yourself

- ✓ Give the four values of bits [1:0] and their meaning at L2 and at L3.
- ✓ Give the four AP encodings and explain why "EL0-only" cannot be expressed.
- ✓ Explain how PAN achieves what AP cannot.
- ✓ Give the descriptor settings for kernel code, kernel data, user code and user data.
- ✓ Explain why user pages must be PXN.
- ✓ Explain what `AF` is for and why forgetting it looks like a broken MMU.
- ✓ Explain the contiguous hint and why a false claim is worse than a fault.
- ✓ Decode a raw 64-bit descriptor into English.
- ✓ Say how stage-2 descriptors differ and how the two stages combine.

TLBs, ASIDs and invalidation

The TLB is a cache with no coherence protocol. Hardware will never notice that you changed a page table, and the invalidation sequence you must write yourself is exact, order-sensitive, and the source of some of the most confusing bugs in system software.

Why the TLB exists

```
A four-level walk is up to FOUR memory accesses per translation.
Every load and store needs one. Without caching, memory access
would be five times slower.

   L1 TLB      32–128 entries, fully associative, ~1 cycle
               usually SPLIT: separate iTLB and dTLB
   L2 TLB      1024–2048 entries, set-associative, ~10 cycles
               unified, shared between instruction and data
   miss        → hardware table walker → up to 4 memory accesses,
                 each of which may itself hit or miss in the caches

   WALK CACHES are a third structure worth knowing: they cache
   INTERMEDIATE table descriptors (L0/L1/L2), so a miss on a
   nearby address only needs the final level. This is why
   sequential access has far cheaper TLB misses than random.

TLB REACH = entries × page size
     1024 × 4 KB  =    4 MB     ← easily exceeded
     1024 × 2 MB  =    2 GB     ← why huge pages help so much

A TLB miss on a large random working set can cost more than the
cache miss that follows it.
```

What tags an entry

Tag	Distinguishes	Set by
VA	Which address	The access
ASID	Which address space (process)	`TTBR0_EL1[63:48]`
VMID	Which virtual machine	`VTTBR_EL2[63:48]`
Exception level / regime	EL0&1 vs EL2 vs EL3	The current EL
Security state	Secure vs Non-secure	`SCR_EL3.NS`
`nG`	Whether the ASID applies at all	The descriptor (ch. 14)

WHY ASIDS MATTER SO MUCH

Without them, every context switch would have to flush the entire TLB, and the incoming process would take hundreds of misses warming it back up. With them, entries from many processes coexist and a switch is a single `TTBR0` write.

Kernel mappings are marked **Global** (`nG=0`) so they match under any ASID — which is why a system call disturbs the TLB not at all.

```
/* ASID width is 8 or 16 bits — query it, do not assume: */
        ID_AA64MMFR0_EL1.ASIDBits    /* 0 = 8 bits, 2 = 16 bits */
        TCR_EL1.AS                    /* select 8 or 16 bit ASID */

/* A context switch: */
        ttbr0 = next_mm->pgd_pa | ((uint64_t)next_mm->asid << 48);
        asm volatile("msr ttbr0_el1, %0" :: "r"(ttbr0));
        asm volatile("isb");
/* That is the whole switch. No flush.                          */

/* ASID EXHAUSTION: with 16 bits there are 65536; with 8 bits only
   256. When they run out, Linux bumps a GENERATION counter and
   flushes everything, then reassigns. On a system with very many
   short-lived processes this shows up as a periodic latency
   blip — rare, but real, and worth recognising.              */
```

The TLB has no coherence protocol

THE RULE

Caches are kept coherent by hardware (CA ch. 15). **TLBs are not.** If you modify a translation table entry, every TLB in the system may continue using the old translation indefinitely. Nothing will tell you.

Worse, on a multi-core system you must invalidate on *every* core that might hold the entry — which is what the Inner Shareable variants of `TLBI` do, broadcasting the invalidation across the coherency domain.

The TLBI instruction

```
   TLBI <type><level><scope>{, Xt}

   TYPE — what to match
     ALL      everything in this regime
     VMALL    all entries for the current VMID (a whole VM)
     ASID     all entries matching the ASID in Xt
     VA       one VA, matching the ASID in Xt
     VAA      one VA, ALL ASIDs ("VA, All ASID")
     IPAS2    one IPA at stage 2
     RVA      a RANGE of VAs (ARMv8.4+)

   LEVEL — which regime
     E1       EL1&0 regime
     E2       EL2 regime
     E3       EL3 regime
     E1OS     ...outer shareable

   SCOPE
     (none)   this PE only
     IS       Inner Shareable — BROADCAST to all cores in the
              inner domain. This is what SMP needs.
     OS       Outer Shareable — wider still

   Examples:
     tlbi vae1is, x0      one VA, EL1&0, current ASID, broadcast
     tlbi vaae1is, x0     one VA, ALL ASIDs, broadcast
     tlbi aside1is, x0    all entries for one ASID, broadcast
     tlbi vmalle1is       everything in EL1&0, broadcast
     tlbi alle1           everything, this core only
     tlbi vmalls12e1is    both stages, whole VM, broadcast
```

```
/* The Xt operand for VA-based operations is NOT a plain address.
   It packs the ASID and the VA, shifted:                      */

        Xt[63:48] = ASID
        Xt[43:0]  = VA[55:12]        /* the page number */

/* So: */
        addr = (va >> 12) | ((uint64_t)asid << 48);
        asm volatile("tlbi vae1is, %0" :: "r"(addr));

/* Passing a raw byte address is a common error. It invalidates
   the wrong entry, silently, and the stale translation stays.  */
```

The invalidation sequence

> **WRITE → DSB → TLBI → DSB → ISB**
> Every part is load-bearing. Omit any one and you get a bug that appears on one core, under load, or only after an unrelated change.

```
        /* 1. update the descriptor */
        *pte = new_value;

        /* 2. DSB ISHST — ensure the WRITE is visible to the table
              walkers of every core BEFORE we invalidate. Without
              this, a core could refill its TLB from the OLD value
              after our TLBI but before our store lands.       */
        dsb     ishst

        /* 3. TLBI — invalidate, broadcast to the inner domain */
        tlbi    vae1is, x0

        /* 4. DSB ISH — wait for the invalidation to COMPLETE on
              every core. TLBI is issued asynchronously; without
              this, another core may still be using the old entry
              when we proceed.                                 */
        dsb     ish

        /* 5. ISB — flush THIS core's pipeline, so no instruction
              already in flight uses a stale translation.      */
        isb
```

```
/* Linux wraps this. Reading the wrappers is instructive: */

flush_tlb_all()                 /* everything, everywhere      */
flush_tlb_mm(mm)                /* one address space (by ASID) */
flush_tlb_range(vma, start, end) /* a range                    */
flush_tlb_page(vma, addr)       /* one page                    */
flush_tlb_kernel_range(s, e)    /* kernel mappings             */

/* And there is a threshold: below ~32 pages Linux issues
   individual TLBI VA operations; above it, one TLBI ASID, because
   many individual broadcasts cost more than one bulk flush.
   ARMv8.4's TLBI RVA (range) instructions remove that trade-off
   where available.                                            */
```

TLB shootdown

```
Invalidating on OTHER cores is the expensive part.

  ARM: TLBI ...IS BROADCASTS in hardware. The instruction issues,
       the interconnect distributes it, and DSB waits for
       completion. No interrupts, no software involvement.

  x86: NO broadcast instruction. The OS must send an
       inter-processor INTERRUPT to every core that might hold the
       entry, and wait for each to acknowledge. Far more expensive.

  This is a genuine architectural advantage for ARM, and it is why
  munmap-heavy and page-migration-heavy workloads scale better
  there.

  But it is not free. On a large system, a broadcast TLBI must
  reach every core in the domain, and the DSB blocks until it has.
  Workloads that constantly change mappings (JITs, garbage
  collectors, heavy mmap/munmap) can spend measurable time here.

  Mitigations:
    · batch invalidations (Linux's mmu_gather does this: it
      collects the pages freed during an unmap and issues ONE
      flush at the end)
    · use TLBI ASID rather than many TLBI VA
    · TLBI RVA range operations (ARMv8.4)
    · avoid unnecessary permission changes on hot mappings
```

When invalidation is required

Change	Invalidation needed?
Making an invalid entry valid	**No** — nothing could have cached a negative result… *but see below*
Making a valid entry invalid	**Yes**
Changing the output address	**Yes**, with break-before-make
Changing memory attributes	**Yes**, with break-before-make
Making permissions *more* restrictive	**Yes**
Making permissions *less* restrictive	Not architecturally required — the fault handler will re-walk. Linux does it anyway on some paths.
Setting AF or the dirty bit	No
Splitting a block into pages	**Yes**, with break-before-make

> **THE "NO INVALIDATION NEEDED" CASE HAS AN EXCEPTION**
>
> Making an invalid entry valid appears safe — how could a TLB cache "not present"? But some implementations *do* cache negative entries, and more importantly, the walk caches may hold intermediate table descriptors. If you allocate a new L3 table and link it in, a core with a cached L2 entry pointing at the *old* (invalid) state may not see it. Linux issues an invalidation on these paths for exactly this reason. When in doubt, invalidate — it is cheap relative to a stale-translation bug.

Break-before-make, restated

```
/* Changing a LIVE mapping's address, size or attributes in place
   permits the TLB to hold BOTH translations simultaneously.
   The architecture calls the result UNPREDICTABLE, and real
   hardware may raise a TLB conflict abort or use either
   translation non-deterministically.                          */

        /* BREAK */
        *pte = 0;
        dsb     ishst
        tlbi    vaae1is, x_addr
        dsb     ish
        isb

        /* MAKE */
        *pte = new_descriptor;
        dsb     ishst
        isb

/* This is why splitting a 2 MB block into 4 KB pages — which
   Linux does when a partial mprotect() hits a THP — is not a
   simple table edit. It must break the block, invalidate, build
   the L3 table, and only then install the new L2 pointer.   */
```

Stage-2 and VMID

```
/* A guest's TLB entries are tagged with the VMID from
   VTTBR_EL2[63:48], so several VMs coexist in the TLB just as
   several processes do.                                       */

/* Invalidating guest translations from EL2: */
        tlbi    vmalle1is        /* all stage-1 entries, current VMID */
        tlbi    vmalls12e1is     /* both stages, current VMID         */
        tlbi    ipas2e1is, x0    /* one IPA at stage 2                */

/* Note the ordering rule when changing a stage-2 mapping: you
   must invalidate stage 2 BEFORE stage 1, because a stage-1
   entry may have been formed using the old stage-2 translation:

        tlbi    ipas2e1is, x_ipa
        dsb     ish
        tlbi    vmalle1is
        dsb     ish
        isb

   Getting this backwards leaves combined TLB entries built from
   a mixture of old and new — a hypervisor bug class that is
   very hard to reproduce.                                     */
```

Measuring TLB behaviour

```
# is the TLB the bottleneck?
perf stat -e dTLB-load-misses,iTLB-load-misses,\
dtlb_walk,itlb_walk,l1d_tlb_refill,l2d_tlb_refill ./prog

#   dtlb_walk counts actual PAGE WALKS — the expensive event.
#   A high ratio of walks to loads means poor TLB reach.

# does the working set fit?
#   time a pointer chase over increasing sizes; the step changes
#   land at the L1 TLB reach, the L2 TLB reach, and the cache
#   capacities.

# try huge pages and measure the difference
echo always > /sys/kernel/mm/transparent_hugepage/enabled
perf stat -e dtlb_walk ./prog        # before and after

# per-process THP usage
grep -E 'AnonHugePages|ShmemPmdMapped' /proc/PID/smaps_rollup

# TLB shootdown cost, system-wide
perf stat -e tlb:tlb_flush -a sleep 10
cat /proc/interrupts | grep -i tlb    # x86 only; ARM broadcasts
```

How it shows up

Symptom	Cause
Page table change has no effect	Missing `TLBI` entirely
Works on one core, fails on another	Used a non-broadcast `TLBI` instead of the `IS` variant
Works, then fails intermittently under load	Missing `DSB` before or after the `TLBI`
Change visible to other cores but not this one	Missing final `ISB`
TLB conflict abort	Break-before-make violation
Invalidation appears to target the wrong page	Passed a byte address instead of `(va >> 12) | asid<<48`
One process sees another's memory	Mapping marked Global instead of non-Global
Periodic latency blip with many processes	ASID rollover forcing a full flush
Huge pages give a large speedup	TLB reach was the bottleneck
Guest memory corruption after a hypervisor remap	Stage-2 invalidated after stage 1 instead of before
munmap-heavy workload scales badly	Shootdown cost; batch with `mmu_gather`

Check yourself

- ✓ Explain what a TLB caches and why walk caches exist as a separate structure.
- ✓ Name the five things that tag a TLB entry.
- ✓ Explain why ASIDs exist and what Global mappings buy.
- ✓ State the full invalidation sequence and justify each of the five steps.
- ✓ Explain the format of the `TLBI` address operand.
- ✓ Explain what `IS` does and why ARM's approach beats x86's.

- ✓ Say when break-before-make is required and what happens without it.
- ✓ Give the correct ordering for invalidating stage 2 and stage 1, and why.

Two-stage translation

Run the whole translation machinery twice: once under the guest's control, once under the hypervisor's. This is what makes virtualisation efficient rather than emulated — and it is the exact same structure the SMMU uses for devices.

The problem it solves

```
A guest OS believes it owns physical memory starting at 0. So
does every other guest. Three approaches, historically:

  1. PARAVIRTUALISATION — modify the guest to know it is a guest
     and to use real physical addresses. Works, but requires
     changing every OS.

  2. SHADOW PAGE TABLES — the hypervisor maintains its own tables
     mapping guest-VA directly to host-PA, and traps every guest
     page table write to keep them in sync. Correct, and very
     expensive: every guest mmap, fork and page fault becomes a
     trap plus a shadow table update.

  3. TWO-STAGE TRANSLATION — hardware does both mappings.
     The guest edits its own tables freely, with NO traps.

  ARM (and Intel EPT, AMD NPT) all took the third path. It is the
  single feature that made hardware virtualisation practical.
```

The two stages

```
   guest virtual address (VA)
        │
        │  STAGE 1 — the GUEST's page tables
        │  TTBR0_EL1 / TTBR1_EL1, TCR_EL1, MAIR_EL1
        │  the guest writes these; the hypervisor does not touch them
        ▼
   intermediate physical address (IPA)
        │  "what the guest BELIEVES is physical"
        │
        │  STAGE 2 — the HYPERVISOR's tables
        │  VTTBR_EL2, VTCR_EL2
        │  the guest cannot read or write these
        ▼
   physical address (PA)

  Two independent sets of tables, two independent permission
  checks. The guest cannot escape stage 2 because it has no
  access to VTTBR_EL2 — that register is only reachable from EL2.

  HCR_EL2.VM = 1 enables stage 2. With it clear, EL1 accesses go
  straight to PA and the guest is not confined at all.
```

The cost: walks multiply

EVERY STAGE-1 TABLE ACCESS ITSELF NEEDS STAGE-2 TRANSLATION

The stage-1 walker reads descriptors from memory using *IPAs*. Each of those reads must be translated by stage 2. With four levels at each stage:

```
  stage-1 L0 descriptor read → needs a stage-2 walk (4 accesses)
  stage-1 L1 descriptor read → needs a stage-2 walk (4 accesses)
  stage-1 L2 descriptor read → needs a stage-2 walk (4 accesses)
  stage-1 L3 descriptor read → needs a stage-2 walk (4 accesses)
  the final IPA              → needs a stage-2 walk (4 accesses)
  plus the 4 stage-1 descriptor reads themselves       +4
                                                      ──────────

  worst case:  (4 + 1) × 4 + 4  =
24 MEMORY ACCESSES
```

Versus four for a native walk. This is why TLB behaviour matters so much more under virtualisation, why walk caches are critical, and why huge pages at *both* stages are a standard tuning step for VM workloads.

```
/* Mitigations, in order of impact:
     · combined TLB entries — the TLB caches VA → PA directly,
       tagged with both ASID and VMID, so a hit skips both stages
     · walk caches for intermediate descriptors at both stages
     · huge pages at stage 2 (a 1 GB block for the guest's RAM
       is extremely common — one entry covers everything)
     · huge pages inside the guest as well                    */
```

Stage-2 configuration

```
VTTBR_EL2    stage-2 table base, plus the VMID in [63:48]
VTCR_EL2     stage-2 translation control:

   T0SZ    [5:0]    IPA size:  IPA bits = 64 - T0SZ
   SL0     [7:6]    STARTING LEVEL — see below
   IRGN0   [9:8]    walk cacheability
   ORGN0   [11:10]
   SH0     [13:12]
   TG0     [15:14]  granule
   PS      [18:16]  physical address size
   VS      [19]     VMID size: 8 or 16 bits

SL0 is the field unique to stage 2. Because the IPA space is
usually much smaller than 48 bits (a guest with 4 GB of RAM
needs only 32), stage 2 can START at L1 or L2 rather than L0,
removing levels from every walk.

   IPA 40 bits, 4 KB granule → start at L1 (SL0 = 01)
   IPA 32 bits               → start at L2 (SL0 = 00)

CONCATENATED TABLES: stage 2 may also use up to 16 contiguous
tables at the starting level, effectively widening the first
index. A 40-bit IPA can then be covered starting at L1 with
two concatenated tables instead of needing an L0.

Both tricks exist for the same reason: shorten the walk, since
it is already being done up to five times.
```

Stage-2 descriptors

```
/* Stage 2 uses a DIFFERENT descriptor layout from stage 1
   (chapter 14). The important differences:                    */

   S2AP[7:6]      00  no access
                  01  read-only
                  10  write-only
                  11  read/write
      → ABSOLUTE permissions, not split by exception level.
        Stage 2 applies to the whole guest, so "EL0 vs EL1" is
        meaningless here — that distinction belongs to stage 1.

   MemAttr[5:2]   the memory type DIRECTLY encoded, with NO MAIR
                  indirection. The hypervisor cannot use MAIR_EL1,
                  because the guest owns it.

   XN[54:53]      execute-never, two bits in newer revisions

/* COMBINING the two stages — the rule is "more restrictive wins":

     permissions:  the intersection. Read-only at either stage
                   means read-only overall.
     memory type:  the more restrictive. Device at either stage
                   means Device overall. Non-cacheable at either
                   means non-cacheable.
     XN:           execute-never at either stage means no execute.

   So a hypervisor can force a guest's mapping to be non-cacheable
   regardless of what the guest asked for — which is exactly how
   it makes emulated device regions behave correctly even though
   the guest mapped them as ordinary memory.                   */
```

Stage-2 faults

```
A stage-2 fault is taken to EL2, NOT to the guest's EL1. The
guest never sees it — which is the whole point.

   ESR_EL2.EC = 0x24    data abort from a lower EL
   ESR_EL2.EC = 0x20    instruction abort from a lower EL

   HPFAR_EL2            the faulting IPA (bits [47:12] << 4)
   FAR_EL2              the faulting guest VA, when available

   ESR_EL2.ISS for a stage-2 abort:
      DFSC   [5:0]     fault status, with the LEVEL
      WnR    [6]       write (1) or read (0)
      S1PTW  [7]       the fault occurred while the stage-1 WALKER
                       was reading a descriptor — i.e. the guest's
                       PAGE TABLES are in an unmapped IPA
      ISV    [24]      the remaining fields are valid
      SAS    [23:22]   access size: 0=byte, 1=half, 2=word, 3=dword
      SRT    [20:16]   the guest register number involved
      SF     [15]      64-bit register

   ISV/SAS/SRT are the key to MMIO emulation: they tell the
   hypervisor exactly what the guest was trying to do, so it can
   emulate the access without decoding the instruction itself.
```

Emulating a device

```
/* The complete flow — this is how QEMU/KVM presents virtual
   hardware, and it is worth following once end to end.       */

/* GUEST, at EL1: */
        writel(1, uart_base + UART_CR);

/* 1. stage-1 translation: guest VA → IPA. Succeeds — the guest
      mapped its "UART" perfectly well.
   2. stage-2 lookup of that IPA in VTTBR_EL2: the hypervisor
      deliberately left it UNMAPPED.
   3. stage-2 data abort → exception to EL2.                  */

/* HYPERVISOR, at EL2: */
static int handle_mmio(struct kvm_vcpu *v)
{
        u64 esr  = read_sysreg(esr_el2);
        u64 ipa  = (read_sysreg(hpfar_el2) & ~0xFUL) << 8;

        if (!(esr & ESR_ISV))
                return decode_instruction_manually(v);  /* rare, slow */

        bool is_write = esr & ESR_WNR;
        int  size     = 1 << ((esr >> 22) & 3);
        int  reg      = (esr >> 16) & 0x1F;

        if (is_write)
                emulate_device_write(ipa, v->regs[reg], size);
        else
                v->regs[reg] = emulate_device_read(ipa, size);

        /* advance past the faulting instruction */
        write_sysreg(read_sysreg(elr_el2) + 4, elr_el2);
        return 0;               /* then ERET back into the guest */
}

/* The guest resumes with no idea anything happened. Note the
   cost: a full world switch per register access, which is why
   emulated I/O is slow and virtio exists (OS chapter 20).   */
```

VMID and TLB tagging

```
/* Stage-2 TLB entries are tagged with the VMID from
   VTTBR_EL2[63:48], exactly as stage-1 entries are tagged with
   the ASID. Several VMs coexist in the TLB.                  */

        vttbr = stage2_pgd_pa | ((uint64_t)vmid << 48);
        write_sysreg(vttbr, vttbr_el2);
        isb

/* VMID width is 8 or 16 bits (VTCR_EL2.VS). Like ASIDs, they
   are a limited resource with a rollover-and-flush scheme.

/* INVALIDATION ORDER MATTERS (chapter 15): when changing a
   stage-2 mapping, invalidate stage 2 FIRST, because combined
   TLB entries may have been built using the old stage-2
   translation:                                               */
        tlbi    ipas2e1is, x_ipa
        dsb     ish
        tlbi    vmalle1is
        dsb     ish
        isb

/* Reversing these leaves entries built from a mix of old and new
   - a hypervisor bug that is extremely hard to reproduce.   */
```

VHE: running a host kernel at EL2

```
The original design assumed a hypervisor was a small, separate
program at EL2 and the host OS ran at EL1. That is wrong for KVM,
where the "hypervisor" IS the Linux kernel - which would have to
run split across two exception levels, with constant switching.

VHE (Virtualization Host Extensions, ARMv8.1) fixes it:

  HCR_EL2.E2H = 1  makes the EL2 regime behave like EL1&0:
       · EL2 gains TTBR1_EL2 and a two-region address space
       · EL0 can run directly under EL2 (host userspace)
       · the _EL1 system register names, when accessed at EL2,
         are REDIRECTED to their _EL2 equivalents
       · _EL12 accessors let EL2 reach the real guest EL1 state

  Result: an unmodified Linux kernel runs at EL2, host userspace
  runs at EL0 under it, and guests run at EL1. No split, and VM
  entry/exit is far cheaper because the host does not have to
  save and restore its own EL1 state.

  Without VHE, KVM used a small "hyp stub" at EL2 and paid a
  world switch on every exit. With VHE the host never leaves EL2.
  Check: ID_AA64MMFR1_EL1.VH
```

The same structure, for devices

> **THIS IS EXACTLY WHAT THE SMMU DOES**
> An IOMMU applies the identical two-stage scheme to DMA: stage 1 owned by the guest (or the OS) translating device IOVAs to IPAs, stage 2 owned by the hypervisor translating IPAs to PAs. Same descriptor format, same combining rules, same VMID tagging.
>
> That is what makes **device passthrough** safe: a device assigned to a guest is programmed with guest-physical addresses, and stage 2 confines its DMA to that guest's memory exactly as it confines the guest's CPU accesses. Without it, passthrough would let a guest scribble anywhere in host memory. The security track covers this in full.

Debugging two-stage translation

```
/* The AT instruction understands both stages: */
        at      s1e1r,  x0       /* stage 1 only → gives the IPA    */
        at      s12e1r, x0       /* both stages  → gives the PA     */
        at      s1e2r,  x0       /* the EL2 regime's own mapping    */
        isb
        mrs     x1, par_el1

/* PAR_EL1.F = 1 on failure, and bit 8 says WHICH STAGE faulted.
   Running both forms tells you immediately whether the guest's
   tables or the hypervisor's are at fault — the single most
   useful diagnostic here.                                        */

# KVM statistics
perf stat -e kvm:kvm_exit,kvm:kvm_entry -a sleep 10
cat /sys/kernel/debug/kvm/*/vcpu0/*         # per-vCPU exit counts

# which exit reasons dominate?
perf record -e kvm:kvm_exit -a && perf report
#   a high count of MMIO exits means you should be using virtio
#   or passthrough instead of emulation

# stage-2 fault tracing
echo 1 > /sys/kernel/debug/tracing/events/kvm/kvm_mmio/enable
cat /sys/kernel/debug/tracing/trace_pipe
```

Where this goes next

Virtualisation chapter 5 takes stage 2 further: `SL0` and concatenated tables, the descriptor format, the permission and memory-type combining rules, and the invalidation sequence that catches everyone. Chapter 6 covers what happens when a stage-2 walk fails, which is how demand paging, MMIO emulation and live migration all work.

How it shows up

Symptom	Cause
Guest performance far below native on memory-heavy work	Walk multiplication; enable huge pages at both stages
Guest I/O is very slow	Full device emulation — one exit per register access

Symptom	Cause
Guest can access host memory	`HCR_EL2.VM` not set, or stage 2 maps too much
Guest crashes on an address the guest mapped correctly	Stage-2 fault; check `HPFAR_EL2`
Fault with `S1PTW` set	The guest's *page tables* are in an unmapped IPA
Guest memory corruption after a hypervisor remap	Invalidated stage 1 before stage 2
Emulation needs slow instruction decoding	`ESR.ISV` clear — some accesses cannot be decoded from the syndrome
Guest sees cacheable access to an emulated device	Stage-2 `MemAttr` too permissive
VM exits are unexpectedly expensive	No VHE — the host is saving and restoring EL1 state per exit
Passthrough device writes host memory	No IOMMU stage 2 — the exact reason it is mandatory

Check yourself

- ✓ Explain what an IPA is and who owns each stage.
- ✓ Compare shadow page tables with two-stage translation.
- ✓ Compute the worst-case number of memory accesses for a two-stage walk, and explain why.
- ✓ Give three mitigations for walk multiplication.
- ✓ Say how stage-2 descriptors differ from stage-1 and state the combining rule.
- ✓ Explain how `ESR.ISV` / `SAS` / `SRT` make MMIO emulation possible.
- ✓ Give the correct stage-2 then stage-1 invalidation order and why.
- ✓ Explain what VHE changes and why KVM needed it.
- ✓ Explain why device passthrough is unsafe without an IOMMU.

The cache hierarchy

CA chapter 14 covered cache theory. This chapter covers what ARM specifically architects, what it leaves to the implementation, and the terminology — points of coherency and unification — that every cache maintenance operation is defined in terms of.

What the architecture actually guarantees

VERY LITTLE, DELIBERATELY

Cache sizes, associativity, replacement policy, the number of levels, whether they are inclusive — all are **IMPLEMENTATION DEFINED**. The architecture specifies only:

- That caches are *transparent* for Normal memory — correct programs need no maintenance for CPU-to-CPU sharing within a shareability domain.
- The **points** (PoU, PoC, PoP) that maintenance operations target.
- The maintenance instructions themselves and their semantics.
- Discovery registers so software can find out what it is running on.

This is the architecture/microarchitecture split from chapter 01 in its purest form: portable correctness, implementation-specific performance.

Discovering the hierarchy

```
/* Never hardcode a line size. Read it. */

        mrs     x0, ctr_el0            /* Cache Type Register,
                                          readable from EL0        */
/*  CTR_EL0:
       [3:0]    IminLine  log2 of the smallest ICACHE line, in words
       [19:16]  DminLine  log2 of the smallest DCACHE line, in words
       [27:24]  CWG       cache writeback granule
       [23:20]  ERG       exclusives reservation granule
       [31]     DIC       instruction cache is coherent with data
       [29]     IDC       data cache clean not needed for I-fetch  */

static inline unsigned dcache_line_size(void)
{
        uint64_t ctr;
        asm volatile("mrs %0, ctr_el0" : "=r"(ctr));
        return 4U << ((ctr >> 16) & 0xF);
}

/* Enumerating the levels: */
        mrs     x0, clidr_el1          /* how many levels, and their
                                          types (I, D, unified)    */
        msr     csselr_el1, x1         /* select level and type    */
        isb
        mrs     x2, ccsidr_el1         /* size, associativity, sets */

/* CTR_EL0.DIC and .IDC are worth checking: on cores where they
   are set, some cache maintenance around self-modifying code
   becomes unnecessary. Linux uses them to skip work.        */
```

```
# from userspace
lscpu -C
#  NAME ONE-SIZE ALL-SIZE WAYS TYPE        LEVEL SETS
#  L1d       64K     512K    4 Data            1  256
#  L1i      128K       1M    4 Instruction     1  512
#  L2         4M      32M    8 Unified         2 8192
#  L3        16M      16M   16 Unified         3 16384

cat /sys/devices/system/cpu/cpu0/cache/index*/{level,type,size,\
ways_of_associativity,coherency_line_size,shared_cpu_list}

getconf LEVEL1_DCACHE_LINESIZE
```

The points: PoU, PoC, PoP

```
Every cache maintenance operation names a POINT — how far down
the hierarchy the operation must reach. These are the terms the
whole instruction set is defined in.

   PoU — Point of Unification
   ┌──────────────────────────────────────────────────┐
   │ The point where THIS CORE's instruction cache,   │
   │ data cache and table walker see the same copy.   │
   │ Typically the L2 or the unified cache level.     │
   │                                                  │
   │ Used for: making written INSTRUCTIONS visible to │
   │ instruction fetch — JIT, module loading,         │
   │ self-modifying boot code.                        │
   └──────────────────────────────────────────────────┘

   PoC — Point of Coherency
   ┌──────────────────────────────────────────────────┐
   │ The point where ALL observers that can access    │
   │ memory see the same copy — every core, and every │
   │ DMA master. Usually main memory, or a            │
   │ system-level cache that DMA also sees.           │
   │                                                  │
   │ Used for: DMA to and from a non-coherent device. │
   └──────────────────────────────────────────────────┘

   PoP — Point of Persistence   (ARMv8.2, DC CVAP)
   ┌──────────────────────────────────────────────────┐
   │ The point at which data survives power loss —    │
   │ relevant only for persistent memory.             │
   └──────────────────────────────────────────────────┘

   PoU is CLOSER than PoC. Cleaning to PoU is cheaper and is
   sufficient for instruction visibility on the same core;
   cleaning to PoC is required for anything a device will read.

   Choosing PoU where PoC was needed is a classic DMA bug: it
   works on a system where the L2 happens to be coherent with
   the device, and fails on one where it is not.
```

CPU-to-CPU coherency is automatic

```
/* Within a shareability domain, hardware keeps caches coherent
   (MESI/MOESI over ACE or CHI — CA chapter 15). You do NOT need
   cache maintenance between coherent cores.                  */

/* What you DO need is ORDERING — barriers (chapter 21). These are
   different things and confusing them is common:

     COHERENCY  guarantees all cores eventually see the same value
                for one location. Automatic.
     ORDERING   guarantees the RELATIVE order of accesses to
                DIFFERENT locations. NOT automatic — you must ask.

   A missing DMB is not fixed by a cache flush, and a stale DMA
   buffer is not fixed by a barrier. Diagnose which one you have.  */

/* The shareability attribute in the descriptor (chapter 14)
   determines the domain. Marking SMP memory Non-shareable takes
   it OUT of the coherency domain — and then hardware coherency
   genuinely does not apply, which produces exactly the bugs
   people wrongly attribute to missing barriers.             */
```

Where maintenance is genuinely required

Situation	Operation	Point
CPU wrote a buffer, a non-coherent device will read it	**Clean**	PoC
A non-coherent device wrote a buffer, the CPU will read it	**Invalidate**	PoC
Bidirectional DMA buffer	Clean *and* invalidate	PoC
Wrote instructions to memory, about to execute them	Clean D-cache, invalidate I-cache	PoU
Changed page tables	Clean, if the walker is not coherent	PoC or PoU
Powering down a core or a cluster	Clean and invalidate everything	PoC
Before enabling or disabling the MMU	Clean and invalidate	PoC
Writing to persistent memory	Clean	PoP

The instructions themselves are chapter 18. What matters here is recognising *which* of these situations you are in — that determines both the operation and the point.

Inclusion policy

```
  INCLUSIVE      everything in L1 is also in L2
                 + coherency is simple: snoop L2 and you know
                   what the cores hold
                 - wastes capacity: L2 duplicates all of L1

  EXCLUSIVE      a line lives at exactly one level
                 + maximum effective capacity (L1 + L2)
                 - more bookkeeping for coherency

  NON-INCLUSIVE  neither guaranteed
                 the common compromise on ARM designs

Software cannot generally observe which policy is in use, and
should not depend on it. It matters for two things:

1. Reasoning about effective capacity when tuning working-set
   sizes.
2. The "clean and invalidate all levels" sequence used at power
   down, which must walk every level by set and way precisely
   because inclusion cannot be assumed.
```

Set/way operations and why you should not use them

> **`DC CISW` IS ALMOST ALWAYS WRONG**
>
> The set/way operations (`DC ISW`, `DC CSW`, `DC CISW`) iterate over cache *geometry* rather than addresses. They are:
>
> - **Not broadcast.** They affect only the executing core's caches. On SMP they do not do what you want.
> - **Not architecturally reliable for coherency.** A line can migrate between levels or cores while you iterate, and be missed.
> - **Implementation-dependent** in which levels they reach.
>
> Their *only* legitimate use is powering down a core or cluster, where you must flush everything and no other agent is running. For every other purpose — DMA, self-modifying code, MMU changes — use the address-based (`VA`) operations, which *are* broadcast within the shareability domain.
>
> This mistake is common in bare-metal and bootloader code copied from older ARMv7 examples.

```
/* The legitimate set/way use: flush the whole cache before power
   down. Note this is genuinely intricate, which is another
   reason to avoid it unless you must.                          */

flush_all_levels:
        mrs     x0, clidr_el1
        and     w3, w0, #0x07000000     /* LoC: level of coherency */
        lsr     w3, w3, #23
        cbz     w3, finished
        mov     w10, #0                 /* level*2                 */

next_level:
        add     w10, w10, #2
        cmp     w3, w10
        b.gt    loop_level
finished:
        ret

/* Linux does this in __flush_dcache_all(), used only from CPU
   hotplug and suspend paths. Nowhere else.                     */
```

System-level caches

```
Beyond the CPU cluster, many SoCs have a SYSTEM LEVEL CACHE
shared by the CPU, GPU, NPU and display controller.

   ┌────┐ ┌────┐ ┌────┐  ┌─────┐ ┌─────┐
   │CPU0│ │CPU1│ │CPU2│  │ GPU │ │ NPU │
   └──┬─┘ └──┬─┘ └──┬─┘  └──┬──┘ └──┬──┘
      └──────┼──────┘       │       │
         cluster L2         │       │
             │              │       │
   ┌─────────┴──────────────┴───────┴──────┐
   │   System Level Cache / Last Level     │  ← the PoC may be HERE,
   └──────────────────┬────────────────────┘    not at DRAM
                      │
                   ┌──┴──┐
                   │DRAM │
                   └─────┘

  Consequences worth knowing:
   · the Point of Coherency may be the SLC rather than memory,
     which makes DMA to a device behind the SLC coherent without
     any maintenance
   · a device NOT behind the SLC still needs maintenance to PoC
   · whether a given master is coherent is a SoC integration
     property, which is exactly what `dma-coherent` in the device
     tree records
   · MPAM (ARMv8.4) can partition the SLC between agents, which
     is how mixed-criticality systems bound interference
     (OS chapter 19)
```

Performance characteristics

Level	Typical size	Latency	Shared by
L1 I / L1 D	32–128 KB each	3–5 cycles	One core
L2	256 KB – 2 MB	10–20 cycles	One core, or a cluster
L3 / cluster cache	4–32 MB	30–60 cycles	The cluster
SLC	4–64 MB	60–120 cycles	The whole SoC
DRAM	GBs	150–300 cycles	Everything

```
# measure your own machine's steps empirically
perf stat -e l1d_cache,l1d_cache_refill,\
l2d_cache,l2d_cache_refill,\
ll_cache_rd,ll_cache_miss_rd ./prog

# the ratio refill/access at each level is the miss rate there
# a pointer-chase benchmark over increasing working-set sizes
# reveals the capacity of each level as a step in the latency

# non-temporal access, to avoid polluting the hierarchy for a
# streaming copy (CA chapter 14)
        ldnp    q0, q1, [x1], #32
        stnp    q0, q1, [x0], #32
```

How it shows up

Symptom	Cause
Hardcoded 64-byte line size fails on some SoC	Line size is implementation defined — read `CTR_EL0`
DMA works on one board, corrupts on another	One is coherent, the other is not; maintenance missing
Cleaned to PoU, device still reads stale data	Needed PoC — the device is beyond the point of unification
JIT code executes garbage	Missing D-cache clean plus I-cache invalidate to PoU
Set/way flush does not fix an SMP problem	Set/way is not broadcast; use VA operations
Bootloader code from an ARMv7 example misbehaves	Set/way semantics differ; use address-based operations
Coherency bug only on multi-core	Memory marked Non-shareable, so it is outside the domain
Barrier added, stale DMA data persists	An ordering fix applied to a coherency problem
Large copy destroys unrelated performance	Cache pollution; use non-temporal stores

Check yourself

- ✓ Say what the architecture guarantees about caches and what it leaves implementation defined.
- ✓ Explain how to discover the cache line size correctly.
- ✓ Define PoU and PoC, and give a case that needs each.
- ✓ Explain why choosing PoU where PoC was needed is a portable-looking bug.
- ✓ State the difference between coherency and ordering, and give a symptom of each.
- ✓ Give three reasons set/way operations are the wrong tool for DMA.
- ✓ Explain what a system-level cache changes about the Point of Coherency.
- ✓ List the situations that genuinely require cache maintenance.

Cache maintenance operations

Three verbs — clean, invalidate, and both — applied to a point in the hierarchy. Get the verb or the point wrong and you get silent data corruption that appears on one board and not another. This chapter is the operational reference.

The three verbs

CLEAN, INVALIDATE, CLEAN-AND-INVALIDATE

- **Clean** — write dirty lines out to the target point. The line stays in the cache, now clean. Memory now matches the cache. *Use before a device reads your buffer.*
- **Invalidate** — discard the lines without writing them back. Any dirty data is **lost**. The next access re-fetches from memory. *Use before you read what a device wrote.*
- **Clean and invalidate** — write back, then discard. Safe in both directions, slightly more expensive. *Use when unsure, or for bidirectional buffers.*

The asymmetry matters: cleaning is always safe; **invalidating can destroy data** if the line was dirty and you did not mean to discard it.

The instructions

Instruction	Operation	Point	Use for
`DC CVAC, Xn`	Clean by VA	PoC	Before a non-coherent device reads
`DC IVAC, Xn`	Invalidate by VA	PoC	Before reading what a device wrote (EL1+ only)
`DC CIVAC, Xn`	Clean and invalidate	PoC	Bidirectional; the safe default
`DC CVAU, Xn`	Clean by VA	**PoU**	Before executing written instructions
`DC CVAP, Xn`	Clean by VA	PoP	Persistent memory (ARMv8.2)
`DC ZVA, Xn`	Zero a cache line	—	Fast `memset(0)`
`IC IVAU, Xn`	Invalidate I-cache by VA	PoU	After writing instructions
`IC IALLU`	Invalidate all I-cache, this core	PoU	Bulk code modification
`IC IALLUIS`	…broadcast to the inner domain	PoU	SMP code modification
`DC ISW/CSW/CISW`	By set and way	Level	**Power down only** — see chapter 17

```
Decoding the mnemonics — they are systematic:

   DC = Data Cache          IC = Instruction Cache

   C   Clean                I   Invalidate       CI  Clean+Invalidate
   VA  by Virtual Address   SW  by Set/Way       ALL everything
   C   to Point of Coherency
   U   to Point of Unification
   P   to Point of Persistence

   DC CVAC  = Data Cache, Clean by VA to PoC
   DC CIVAC = Data Cache, Clean and Invalidate by VA to PoC
   IC IVAU  = Instruction Cache, Invalidate by VA to PoU

Once you see the pattern the whole set is memorable.
```

VA operations broadcast; set/way do not

```
/* This is the property that makes VA operations the right choice:

   DC CVAC and friends are BROADCAST to every core in the
   shareability domain of the address. One instruction cleans the
   line wherever it lives.

   DC CISW affects only THIS core's caches. On SMP it silently
   does not do what you want.

   So: use VA-based operations for everything except the
   power-down flush.                                          */
```

Writing a maintenance loop

> **OPERATE ON CACHE LINES, NOT ON YOUR BUFFER'S BOUNDS**
>
> Maintenance operates on whole lines. If your buffer starts mid-line, cleaning "from the start of the buffer" still writes back the *entire* line — including the neighbouring data that shares it. Worse, an **invalidate** on a partial line discards the neighbour's dirty data.
>
> This is exactly why you must never DMA to or from a stack buffer, and why the DMA API requires cache-line-aligned allocations.

```
static void dcache_clean_range(void *start, size_t size)
{
        uint64_t ctr;
        asm volatile("mrs %0, ctr_el0" : "=r"(ctr));
        size_t line = 4UL << ((ctr >> 16) & 0xF);   /* never hardcode */

        uintptr_t addr = (uintptr_t)start & ~(line - 1);   /* round DOWN */
        uintptr_t end  = (uintptr_t)start + size;

        for (; addr < end; addr += line)
                asm volatile("dc cvac, %0" :: "r"(addr) : "memory");

        asm volatile("dsb ish" ::: "memory");   /* wait for completion */
}

/* Three things to notice:
     1. the line size comes from CTR_EL0
     2. the start is rounded DOWN to a line boundary
     3. a DSB is REQUIRED afterwards - maintenance operations are
        issued asynchronously, and without the barrier you may
        start the DMA before the writeback has finished     */
```

The DMA sequences

```
CPU → DEVICE  (the device will READ your buffer)

   1. write the data
   2. DC CVAC over the buffer          clean: push it to PoC
   3. DSB ISH                          wait for completion
   4. start the DMA (write a register)

   Without step 2, the device reads DRAM while your data sits
   dirty in L1. It gets garbage - usually the previous contents
   of that buffer, which makes the bug look like stale data
   rather than a coherency problem.

DEVICE → CPU  (the device WROTE your buffer)

   1. start the DMA, wait for completion
   2. DC IVAC over the buffer          invalidate: discard stale
   3. DSB ISH
   4. read the data

   Without step 2, the CPU may still hold a clean copy from
   before the transfer and return it. The symptom is a buffer
   that "never updates" - often mistaken for the device not
   working.

   SUBTLETY: you must ALSO invalidate BEFORE starting the
   transfer, not only after. A speculative read during the DMA
   could pull a stale line into the cache, which then survives
   your post-transfer invalidate window. Linux's dma_map_single
   handles both edges; hand-rolled code frequently does not.

BIDIRECTIONAL

   DC CIVAC before, DC IVAC after. Or just use the DMA API.
```

```
/* Which is why you should never hand-roll this in an OS driver: */

dma_addr_t d = dma_map_single(dev, buf, len, DMA_TO_DEVICE);
/* ...device owns the buffer... */
dma_unmap_single(dev, d, len, DMA_TO_DEVICE);

/* The API knows whether this device is coherent (from
   `dma-coherent` in the device tree), and emits the right
   maintenance — or correctly emits NONE. Hand-written
   maintenance on a coherent system is wasted work; omitted
   maintenance on a non-coherent one is corruption.        */

dma_sync_single_for_cpu(dev, d, len, DMA_FROM_DEVICE);
inspect(buf);
dma_sync_single_for_device(dev, d, len, DMA_FROM_DEVICE);
```

Making written instructions executable

```
The I-cache and D-cache are SEPARATE and NOT coherent with each
other. Writing bytes through the data path does not make them
visible to instruction fetch.

Required sequence, for JITs, module loaders, trampolines and
self-modifying boot code:

   1. write the instructions          (through the D-cache)
   2. DC CVAU  over the range         clean D-cache to PoU
   3. DSB ISH                         wait
   4. IC IVAU  over the range         invalidate I-cache to PoU
   5. DSB ISH                         wait
   6. ISB                             flush THIS core's pipeline

Every step matters:
   · without 2, the instructions are still dirty in the D-cache
     and the I-side cannot see them
   · without 4, the I-cache may hold the OLD bytes at that address
   · without 6, this core may already have PREFETCHED the old
     instructions into the pipeline

On SMP, other cores need the ISB too. Linux sends an IPI
(kick_all_cpus_sync) to force it, because there is no way to
broadcast an ISB.

Shortcut: CTR_EL0.DIC and .IDC tell you when steps can be
skipped on this implementation. Do not assume — read them.
```

```
static void flush_icache_range(void *start, size_t size)
{
        uintptr_t addr, end = (uintptr_t)start + size;
        size_t iline, dline;
        uint64_t ctr;

        asm volatile("mrs %0, ctr_el0" : "=r"(ctr));
        dline = 4UL << ((ctr >> 16) & 0xF);
        iline = 4UL << (ctr & 0xF);          /* I and D can DIFFER */

        if (!(ctr & (1UL << 28))) {          /* IDC clear: need clean */
                for (addr = (uintptr_t)start & ~(dline - 1);
                     addr < end; addr += dline)
                        asm volatile("dc cvau, %0" :: "r"(addr) : "memory");
                asm volatile("dsb ish" ::: "memory");
        }

        if (!(ctr & (1UL << 29))) {          /* DIC clear: need invalidate */
                for (addr = (uintptr_t)start & ~(iline - 1);
                     addr < end; addr += iline)
                        asm volatile("ic ivau, %0" :: "r"(addr) : "memory");
                asm volatile("dsb ish" ::: "memory");
        }

        asm volatile("isb" ::: "memory");
}

/* In userspace, do not write this - call the builtin, which
   emits whatever the platform requires:                     */
        __builtin___clear_cache(start, end);
```

DC ZVA: fast zeroing

```
/* Zeroes a whole cache line without READING it first - avoiding
   the read-for-ownership that a normal store sequence causes.
   This is what memset(0) uses for large blocks.             */

        mrs     x1, dczid_el0
        tbnz    x1, #4, no_dczva        /* DZP: prohibited?        */
        and     w1, w1, #0xF            /* log2 of the block size
                                           in WORDS               */
        mov     x2, #4
        lsl     x2, x2, x1              /* block size in bytes     */

1:      dc      zva, x0                 /* zero one block          */
        add     x0, x0, x2
        subs    x3, x3, x2
        b.gt    1b

/* The block size is NOT necessarily the cache line size - read
   DCZID_EL0. And DZP may be set, meaning the instruction is
   prohibited (it is trapped at EL0 on some configurations).

   Note: DC ZVA on Device memory is UNPREDICTABLE. It is a
   cache operation, and Device memory is not cached.       */
```

Maintenance needs barriers

> **CACHE OPERATIONS COMPLETE ASYNCHRONOUSLY**
> A `DC CVAC` instruction *issues* the operation; it does not wait for the writeback to reach memory. Without a following `DSB`, you can start a DMA transfer before your data has arrived.
>
> The general rule: **maintenance, then `DSB`, then rely on it.** And for instruction cache work, add an `ISB` because the pipeline must also be flushed.

```
/* Choosing the DSB domain:
     dsb ish     inner shareable — SMP within the cluster.
                 The usual choice.
     dsb osh     outer shareable — when a device outside the inner
                 domain is involved
     dsb sy      full system — the safest, and the slowest
     dsb nsh     non-shareable — this core only; used for local
                 TLB and cache work in boot code

   Use the narrowest domain that is correct. `dsb sy` in a hot
   path is a measurable cost.                                  */
```

Maintenance with the MMU off

```
/* Before the MMU is enabled, all memory is treated as
   Device-nGnRnE and the data cache is effectively bypassed. Two
   consequences for boot code:                                  */

/* 1. Data written with the MMU OFF goes straight to memory. Data
      written with the MMU ON may sit in a cache. So if a boot
      stage writes a structure with the MMU off, then enables the
      MMU and reads it, all is well — but the reverse can leave
      stale data. Clean before disabling the MMU.            */

/* 2. Before enabling the MMU, INVALIDATE the caches: they may
      contain lines from a previous boot stage with different
      attributes.                                             */

        /* early boot, before enabling the MMU */
        bl      invalidate_dcache_all       /* set/way — legitimate
                                               here: single core,
                                               nothing else running */
        ic      iallu
        dsb     nsh
        isb
        /* now build tables and enable the MMU (chapter 12) */

/* 3. And when handing off to another stage that will run with
      the MMU off — such as a kernel entered per the boot
      contract (OS chapter 18) — you must CLEAN the image you
      loaded to PoC, or it will not see your writes.        */
```

Decision procedure

```
Is the other observer a COHERENT CPU in the same domain?
     → NO maintenance needed. You may need a BARRIER
       (chapter 21) — a different problem.

Is it a NON-COHERENT DEVICE?
     device will READ  → DC CVAC  + DSB     (clean to PoC)
     device WROTE      → DC IVAC  + DSB     (invalidate to PoC)
                         and invalidate BEFORE the transfer too
     both              → DC CIVAC + DSB
     → or better: use the DMA API and let it decide

Am I about to EXECUTE bytes I just wrote?
     → DC CVAU, DSB, IC IVAU, DSB, ISB      (to PoU)
     → or: __builtin___clear_cache()

Am I powering down a core or cluster?
     → the set/way flush of everything

Am I changing page tables?
     → TLB maintenance (chapter 15), plus cache maintenance
       only if the table walker is not coherent

Anything else?
     → you probably do not need cache maintenance. Check
       whether you actually have an ORDERING problem.
```

How it shows up

Symptom	Cause
Device reads garbage or previous contents	Missing clean before the transfer
Buffer never appears to update after DMA	Missing invalidate after the transfer
DMA result correct only sometimes	Missing invalidate *before* the transfer; speculation pulled in a stale line
Neighbouring data corrupted by an invalidate	Partial cache line — the buffer was not line-aligned
JIT or module code executes garbage	Missing `DC CVAU` / `IC IVAU` / `ISB`
Self-modifying code works on one core, not another	Missing `ISB` on the other core
Maintenance loop misses the last line	Start not rounded down to a line boundary
Hardcoded 64-byte stride fails on some SoC	Line size differs — read `CTR_EL0`
Set/way flush does not fix an SMP issue	Not broadcast — use VA operations
Corruption starting DMA immediately after cleaning	Missing `DSB`; the writeback had not completed
Next boot stage runs stale code	Image not cleaned to PoC before handing over with the MMU off

Check yourself

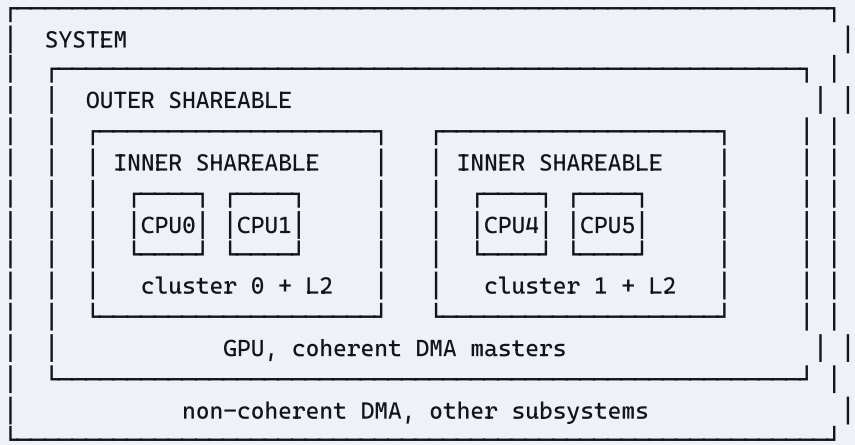
- ✓ Define clean, invalidate and clean-and-invalidate, and say which can lose data.
- ✓ Decode `DC CIVAC` and `IC IVAU` from the mnemonic.
- ✓ Say why VA operations are preferred over set/way on SMP.
- ✓ Write a maintenance loop correctly, including line size and alignment.

- ✓ Give both DMA sequences, and explain why an invalidate is also needed before a device-to-CPU transfer.
- ✓ Give the full six-step sequence for making written instructions executable.
- ✓ Explain why a `DSB` is required after maintenance.
- ✓ Explain what goes wrong when a DMA buffer is not cache-line aligned.

Coherency and shareability domains

Shareability decides which observers hardware keeps coherent, and how far a barrier or a maintenance operation propagates. It is set per page, costs nothing to get right, and produces impossible-looking multi-core bugs when got wrong.

The domains



```
The BOUNDARIES are IMPLEMENTATION DEFINED. On a typical SoC:
   Inner Shareable  = one CPU cluster, kept coherent by the
                      cluster interconnect
   Outer Shareable  = all clusters plus coherent DMA masters,
                      via the system interconnect (CHI/ACE)
   Non-shareable    = this core only; NO coherency maintained

Software cannot query the boundaries directly. It relies on the
SoC's documentation and, in Linux, on the device tree telling it
which masters are coherent.
```

WHAT SHAREABILITY ACTUALLY CONTROLS

Two things, and they are the same mechanism seen from two sides:

1. **Which observers hardware keeps coherent** for this page. Inside the domain, a write by one observer is automatically visible to the others — no cache maintenance needed.
2. **How far a barrier or maintenance operation propagates.** `DMB ISH` orders accesses within the inner domain; `TLBI ...IS` broadcasts to the inner domain. Going wider costs more.

Shareability applies only to **Normal cacheable** memory. It is ignored for Device memory and for Normal Non-cacheable, both of which are coherent by construction because nothing caches them.

Setting it

```
/* In a page table descriptor, SH[9:8] (chapter 14): */
   00   Non-shareable
   10   Outer Shareable
   11   Inner Shareable
   01   reserved

/* Linux: */
#define PTE_SHARED  (_AT(pteval_t, 3) << 8)     /* Inner Shareable */
/* — and PROT_NORMAL always includes it. Every normal Linux
   mapping is Inner Shareable, because SMP requires it.       */

/* In barriers and maintenance, the domain is a suffix: */
        dmb     ish          /* inner shareable  — the usual   */
        dmb     osh          /* outer shareable                */
        dmb     sy           /* full system — widest, slowest  */
        dmb     nsh          /* non-shareable — this core only */

        tlbi    vae1is       /* IS = broadcast to inner domain */
        tlbi    vae1os       /* OS = outer                     */
        tlbi    vae1         /* no suffix = this core only     */
```

The rule that matters

NON-SHAREABLE MEMORY IS NOT KEPT COHERENT — AT ALL

Marking SMP-shared memory Non-shareable takes it *out* of the coherency domain. Hardware then does not snoop it, and two cores can hold different values indefinitely. No barrier fixes this, because it is not an ordering problem: the cores genuinely disagree about the contents of memory.

The symptom is a variable that "does not update" on one core, or a lock that both cores appear to hold. It is easy to misdiagnose as a missing barrier and spend days adding `DMB`s that cannot help.

```
/* WRONG for anything SMP */
pte = pa | PTE_VALID | PTE_AF | PTE_ATTR(NORMAL_WB);   /* SH = 00 */

/* RIGHT */
pte = pa | PTE_VALID | PTE_AF | PTE_ATTR(NORMAL_WB) | PTE_SH_INNER;
```

Mismatched attributes

```
If two observers map the SAME physical memory with DIFFERENT
memory types or shareability, the architecture says the result is
UNPREDICTABLE. Real consequences:

  · one observer's writes may sit in a cache the other does not
    snoop
  · a Non-cacheable read may bypass a cache holding dirty data
  · loss of atomicity — exclusives may not work

COMMON WAYS THIS HAPPENS ACCIDENTALLY:

  1. The kernel's LINEAR MAP covers all of RAM as Normal
     Write-Back Inner-Shareable. If a driver then ioremaps some
     of that same RAM as Device or Non-cacheable, the SAME
     PHYSICAL PAGES now have two conflicting mappings.
     → this is why Linux refuses to ioremap normal RAM, and why
       reserved DMA regions are marked `no-map` in the device
       tree so the linear map excludes them.

  2. A guest and a hypervisor mapping the same page with
     different stage-1 and stage-2 attributes. The combining
     rule (chapter 16) makes the stricter one win, which is
     safe — but a guest expecting cacheable access to something
     the hypervisor forced Non-cacheable will be very slow.

  3. Firmware and OS disagreeing about a shared region across a
     handover — one running with the MMU off (everything is
     Device) and one with it on.

The fix is always the same: exactly ONE mapping per physical
page, or identical attributes on every mapping of it.
```

Coherent and non-coherent masters

```
/* Whether a DMA master participates in coherency is a property of
   how the SoC integrator wired it up:                          */

   ACE / CHI      fully coherent: the master can snoop CPU caches
                  AND be snooped
   ACE-Lite       I/O coherent: the master can snoop CPU caches,
                  but has no cache of its own to be snooped.
                  This is the common case for DMA engines.
   AXI            not coherent at all: software must do cache
                  maintenance

/* Software learns which from the device tree: */
        dma_engine@2c000000 {
                compatible = "vendor,dma";
                reg = <...>;
                dma-coherent;          /* ← this property */
        };

/* And the DMA API acts on it: */
        dev->dma_coherent = of_dma_is_coherent(node);
/* dma_map_single() then emits cache maintenance, or does not.

   The single most important consequence: the SAME driver source
   is correct on both kinds of SoC, PROVIDED it uses the DMA API.
   Hand-rolled cache maintenance is either wasted work or a
   correctness bug, depending on the platform.               */
```

Choosing the barrier domain

Domain	Orders accesses visible to	Use for
`nsh`	This PE only	Local TLB and cache maintenance in boot code
`ish`	The inner shareable domain	**Almost everything in SMP kernel code**
`osh`	The outer shareable domain	Synchronising with a coherent DMA master outside the cluster
`sy`	Everything, including Device memory and non-coherent masters	MMIO ordering, DMA handoff, the conservative choice

```
/* Cost increases with width. `dsb sy` may have to wait for
   transactions to reach the far side of the interconnect, which
   on a large SoC is hundreds of cycles.

   Use the narrowest correct domain. In practice:
     · CPU-to-CPU synchronisation        → ish
     · after TLBI ...IS                  → ish
     · before starting DMA on a
       non-coherent device               → sy
     · MMIO write that must land         → sy
     · single-core boot code             → nsh                */

/* Linux's naming maps directly:
        smp_mb()   → dmb ish
        mb()       → dsb sy         (used for MMIO / DMA)
        dma_wmb()  → dmb oshst
        __iowmb()  → dsb st, before an MMIO write            */
```

Exclusives and the shareability domain

```
/* LDXR/STXR rely on an EXCLUSIVE MONITOR. There are two:

     LOCAL monitor    per-PE, tracks one address
     GLOBAL monitor   in the interconnect, tracks addresses for
                      the coherency domain

   For Non-shareable memory, only the local monitor is used -
   which means exclusives between two cores DO NOT WORK. A
   spinlock in Non-shareable memory will let both cores in.

   For Inner Shareable memory, the global monitor participates
   and exclusives are correct across the domain.

   This is another reason the shareability attribute is not
   optional for shared data - and it is why a lock that
   "sometimes lets two threads in" is often a page-attribute
   bug rather than a logic bug.                              */

/* The reservation granule (CTR_EL0.ERG) is the size the monitor
   tracks - often 64 or 128 bytes. Two locks within one granule
   cause FALSE SHARING of the reservation: each STXR clears the
   other's, producing livelock-like retry storms. Pad locks to
   the granule, exactly as you pad against cache-line false
   sharing (CA chapter 15).                                  */
```

Diagnosing shareability problems

```
# what did the kernel actually map?
cat /sys/kernel/debug/kernel_page_tables | head -40
#   ...  RW NX SHD AF UXN MEM/NORMAL
#              ^^^ SHD = shareable. Its ABSENCE on SMP memory is
#                  the thing to look for.

# ask the hardware for one address (chapter 12)
        at   s1e1r, x0
        mrs  x1, par_el1
        /* PAR_EL1[9:8] = shareability actually applied
           PAR_EL1[63:56] = memory attributes            */

# is this device coherent?
grep -l dma-coherent /proc/device-tree/*/*/
cat /sys/bus/platform/devices/*/of_node/dma-coherent 2>/dev/null

# in the kernel
pr_info("coherent=%d\n", dev_is_dma_coherent(dev));
```

DISTINGUISHING THE THREE FAILURE MODES

When shared data misbehaves on multi-core, decide which of these you have before touching anything:

- **Ordering** — both cores eventually agree, but saw the writes in the wrong sequence. Fix with barriers or acquire/release (chapter 21).
- **Coherency** — the cores durably disagree about a value. Check shareability, and check for mismatched mappings.
- **Atomicity** — an update was lost. Check exclusives, and check that the memory is shareable so the global monitor applies.

Adding barriers to a coherency problem is the most common wasted debugging effort in multi-core work.

How it shows up

Symptom	Cause
A variable never updates on the other core	Memory marked Non-shareable
Adding barriers does not help	It is a coherency problem, not an ordering one
A spinlock lets two cores in	Exclusives on Non-shareable memory — no global monitor
Two locks in one structure cause retry storms	Both inside one exclusives reservation granule
Works single-core, fails on SMP	Shareability, or a genuinely missing barrier
Corruption after `ioremap` of normal RAM	Mismatched attributes with the linear map
Reserved DMA region behaves erratically	Not marked `no-map`; the linear map also covers it
Driver correct on one SoC, corrupts on another	One master is coherent and the other is not
`dsb sy` in a hot path is slow	Widest domain; use `ish` where it suffices

Check yourself

- ✓ Name the shareability domains and say what determines their boundaries.
- ✓ State the two things shareability controls.
- ✓ Explain why shareability is ignored for Device memory.
- ✓ Say what happens to SMP data marked Non-shareable, and why barriers do not fix it.
- ✓ Give two ways mismatched attributes arise accidentally, and the fix.
- ✓ Explain the difference between ACE, ACE-Lite and plain AXI for a DMA master.
- ✓ Choose the right barrier domain for four different situations.
- ✓ Explain why exclusives fail on Non-shareable memory.
- ✓ Distinguish ordering, coherency and atomicity failures by symptom.

The weak memory model

ARM permits your memory accesses to become visible to other cores in almost any order. This is not a bug or an implementation detail — it is the specification, and it is why lock-free code that has worked on x86 for a decade can fail the first time it runs on ARM.

What "weak" means

THE GUARANTEE

ARM guarantees that a single thread observes its own accesses in program order. It guarantees *nothing* about the order in which *other* observers see them, unless you use a barrier or an ordered access.

Accesses to the *same* location are always coherent and ordered — that is a separate guarantee (CA ch. 15). The weakness is entirely about accesses to *different* locations.

Reordering	x86-64 (TSO)	ARM (weak)
Load → Load	Not allowed	**Allowed**
Load → Store	Not allowed	**Allowed**
Store → Store	Not allowed	**Allowed**
Store → Load	**Allowed**	Allowed

```
Why ARM chose this:

  Enforcing order costs hardware. A store buffer that must drain
  in order, load queues that must not reorder, and snoop
  responses that must be sequenced all consume area, power and
  latency. Relaxing them lets the core:

     · retire stores into a buffer and continue
     · issue loads as soon as their address is known
     · let the interconnect route messages by any path
     · merge and reorder writes for bandwidth

  The cost is moved to SOFTWARE, which must ask for ordering
  where it genuinely needs it — which is a small fraction of the
  time. Given that, the trade is clearly correct for a
  power-sensitive architecture.

  x86 made the opposite choice for compatibility reasons, and
  pays for it in hardware complexity.
```

The canonical failure

```
/* Both variables start at 0. */

/* Core 0 — producer */          /* Core 1 — consumer */
data = 42;                       while (flag == 0)
flag = 1;                                ;
                                 use(data);        /* may read 0! */
```

```
Three independent things can produce the failure:

  1. COMPILER reordering — nothing in the source forbids swapping
     the two stores, since they are independent single-threaded.

  2. STORE BUFFER — the store to `data` retires into a buffer and
     has not yet reached the coherency point when `flag`'s store
     does. Other cores see flag=1 first.

  3. LOAD reordering on the consumer — the load of `data` can
     issue BEFORE the load of `flag`, because its address is known
     and there is no dependency between them.

  Point 3 is the one that surprises people most: even if the
  producer's stores are ordered, the CONSUMER can still break it.
  Both sides need ordering.
```

Dependencies that *do* order

```
/* Not everything requires an explicit barrier. Some orderings
   come free from the dependency structure.                    */

/* ADDRESS DEPENDENCY — guaranteed ordered */
        ptr = atomic_load(&head);
        val = ptr->field;          /* the second load CANNOT be
                                      reordered before the first —
                                      its address depends on it   */
/* This is what makes RCU readers free on ARM (OS chapter 09):
   rcu_dereference() relies on exactly this.                   */

/* DATA DEPENDENCY on a STORE — guaranteed ordered */
        x = load(&a);
        store(&b, x);              /* ordered: b's value needs a  */

/* CONTROL DEPENDENCY on a STORE — ordered, but fragile */
        if (load(&a))
                store(&b, 1);      /* the store cannot be
                                      speculated before the load */

/* CONTROL DEPENDENCY on a LOAD — NOT ordered */
        if (load(&a))
                y = load(&b);      /* the second load CAN be
                                      speculated. No ordering.   */
```

> **DO NOT RELY ON CONTROL DEPENDENCIES**
> They order stores but not loads, they are not expressible in the C or C++ memory model, and the compiler is entitled to remove them — by turning a branch into a conditional select (`CSEL`), or by hoisting a store that occurs on both paths. The Linux kernel documents this at length in `Documentation/memory-barriers.txt` and the advice is: use `smp_load_acquire()` or an explicit barrier instead. Address dependencies are safe; control dependencies are a trap.

Fixing it

```
/* Option 1: explicit barriers */
/* Core 0 */                        /* Core 1 */
data = 42;                          while (flag == 0)
DMB ISHST;                                  ;
flag = 1;                           DMB ISHLD;
                                    use(data);

/* Option 2: acquire/release — cheaper, and the modern idiom */
/* Core 0 */                        /* Core 1 */
data = 42;                          while (LDAR(flag) == 0)
STLR(flag, 1);                              ;
                                    use(data);

/*  STLR — store-release:  no EARLIER access may be reordered
                           after it
    LDAR — load-acquire:   no LATER access may be reordered
                           before it

   Together they form a RELEASE-ACQUIRE PAIR: everything core 0
   did before the release is visible to core 1 after the acquire.

   Cheaper than a standalone barrier because the ordering is
   attached to an access the core was performing anyway — the
   core can keep other work in flight.                          */
```

The C and C++ view

```
#include <stdatomic.h>

_Atomic int flag = 0;
int data = 0;                       /* a plain int is fine now */

/* producer */
data = 42;
atomic_store_explicit(&flag, 1, memory_order_release);

/* consumer */
while (atomic_load_explicit(&flag, memory_order_acquire) == 0)
        ;
use(data);                          /* guaranteed to see 42 */
```

`memory_order`	Guarantee	AArch64 instruction
`relaxed`	Atomicity only	Plain `LDR` / `STR`, or a plain atomic
`consume`	Address dependencies (deprecated in practice)	Plain load — ARM gives it for free
`acquire`	Later accesses cannot move before	`LDAR`
`release`	Earlier accesses cannot move after	`STLR`
`acq_rel`	Both, for RMW	`LDAXR` / `STLXR`, or `CASAL`
`seq_cst`	Plus one global total order	`LDAR` / `STLR` (plus `DMB` in some cases)

```
/* Linux kernel spellings of the same concepts: */
smp_store_release(&flag, 1);
val = smp_load_acquire(&flag);
smp_mb();   smp_rmb();   smp_wmb();      /* full / read / write */
READ_ONCE(x);   WRITE_ONCE(x, v);        /* stop the COMPILER only */
rcu_dereference(p);                       /* address dependency     */

/* READ_ONCE/WRITE_ONCE are worth understanding: they prevent the
   COMPILER from tearing, fusing or inventing accesses, but emit
   NO hardware barrier. They are the minimum for any shared
   variable, even one you think is "just a flag".            */
```

Litmus tests

```
The standard vocabulary for reasoning about memory models. Worth
knowing by name, because papers, kernel documentation and tooling
all use them.

MESSAGE PASSING (MP) — the flag/data case above
   P0: x = 1; y = 1        P1: r1 = y; r2 = x
   Can r1 == 1 && r2 == 0?     ARM: YES.  x86: no.

STORE BUFFERING (SB)
   P0: x = 1; r1 = y       P1: y = 1; r2 = x
   Can r1 == 0 && r2 == 0?     ARM: YES.  x86: YES.
   → the one reordering even TSO allows. Requires a full barrier
     on BOTH sides to prevent; acquire/release is not enough.

LOAD BUFFERING (LB)
   P0: r1 = x; y = 1       P1: r2 = y; x = 1
   Can r1 == 1 && r2 == 1?     ARM: YES.  x86: no.

INDEPENDENT READS OF INDEPENDENT WRITES (IRIW)
   P0: x = 1    P1: y = 1
   P2: r1 = x; r2 = y      P3: r3 = y; r4 = x
   Can P2 and P3 disagree about the ORDER of the two writes?
   ARM: NO — ARMv8 is MULTI-COPY ATOMIC. A write becomes visible
   to all observers at the same time. (ARMv7 was not, which made
   reasoning far harder.)

  Multi-copy atomicity is the single most important simplification
  ARMv8 made over ARMv7, and it is why the ARMv8 model is
  formally tractable.
```

```
# tools that check these mechanically — worth knowing they exist
#   herd7 / diy7        the ARM/Inria memory model simulator
#   litmus7             runs litmus tests on real hardware
#   linux/tools/memory-model/   the kernel's formal LKMM, with
#                       its own herd7 model and documentation

# run a litmus test on your own machine and watch it fail:
litmus7 MP.litmus
#   Histogram (4 states)
#   ...
#   1     :>0:X0=1; 0:X1=0;   ← the reordering, observed
```

Device memory is different

```
/* Device memory (chapter 11) has its OWN ordering rules, and they
   are much stronger:

     Device-nGnRnE   no gathering, no reordering, no early ack —
                     accesses arrive in program order
     Device-nGnRE    reordering still forbidden between Device
                     accesses to the same peripheral

   But note what is NOT guaranteed: ordering between a Device
   access and a NORMAL memory access. That combination needs an
   explicit barrier, and it is exactly the DMA handoff case:  */

        /* fill the DMA buffer — Normal memory */
        memcpy(buf, data, len);

        /* the buffer writes must be VISIBLE before the device
           is told to start                                    */
        dsb     sy                    /* or dma_wmb() in Linux */

        /* start the transfer — Device memory */
        writel(START, regs + CTRL);

/* Linux's writel() includes a barrier for exactly this reason;
   writel_relaxed() does not, and is for when you have already
   ordered things yourself or genuinely do not care.        */
```

Porting from x86

THE CODE WAS ALWAYS WRONG; X86 HID IT

x86's TSO forbids three of the four reorderings, which happens to be enough for most naive lock-free code to work by accident. On ARM those reorderings are permitted and do occur.

Worse, the failure is **rare and load-dependent**: it needs the store buffer to be occupied, or two cores to interleave in a particular way. It typically passes every test and appears in production, once, on a customer's machine.

Practical steps when porting:

- Search for every shared variable accessed without a lock. Each one is a candidate.
- Replace hand-rolled flags with `_Atomic` and explicit memory orders — the compiler then emits correct code for both architectures.
- Run under ThreadSanitizer, which models the C++ memory model rather than any one CPU.
- Do not "fix" it by adding `volatile`. It constrains the compiler and does nothing to the hardware (C ch. 10).

Practical rules

Situation	Use
Publishing data then a flag	`store-release` on the flag

Situation	Use
Reading a flag then the data	`load-acquire` on the flag
Following a published pointer	Address dependency — free on ARM; use `rcu_dereference`
A counter nobody synchronises on	`relaxed`
Store-buffering pattern (SB)	A full barrier on *both* sides; acquire/release is insufficient
Any shared variable at all	At minimum `READ_ONCE` / `WRITE_ONCE`
DMA handoff	`dsb sy` / `dma_wmb()` before the doorbell
Unsure	`seq_cst` — correct, and you can relax it later with measurement

How it shows up

Symptom	Cause
Works on x86, fails on ARM	Missing ordering that TSO happened to provide
Consumer sees the flag but stale data	Missing release/acquire pairing
Fails only under load, on many cores	The reordering window widened; the bug was always there
Adding a `printf` makes it disappear	Timing changed; the race remains
`volatile` did not fix it	`volatile` is not a barrier
Works with one compiler, fails with another	Relied on a control dependency the optimiser removed
Both cores see zero in an SB pattern	Store buffering — needs a full barrier both sides
DMA starts before the buffer is visible	Missing barrier between Normal and Device accesses
Lock-free queue corrupts occasionally	Insufficient memory order on the head/tail updates

Check yourself

- ✓ State exactly what ARM guarantees about a single thread and about other observers.
- ✓ Give the four reorderings and which x86 permits.
- ✓ Explain the three separate mechanisms that break the flag/data example.
- ✓ Say which dependencies order accesses for free, and which do not.
- ✓ Explain why control dependencies are unsafe to rely on.
- ✓ Give the release-acquire pairing and what it guarantees.
- ✓ Name three litmus tests and say what each demonstrates.
- ✓ Explain multi-copy atomicity and why it simplified ARMv8.
- ✓ Explain why an SB pattern needs more than acquire/release.

Barriers: DMB, DSB and ISB

Three instructions that constrain what the hardware may reorder. They look interchangeable and are not: each solves a different problem, and choosing the wrong one gives you code that is either incorrect or needlessly slow.

The three barriers

	`DMB`	`DSB`	`ISB`
Full name	Data Memory Barrier	Data Synchronization Barrier	Instruction Synchronization Barrier
Guarantees	Memory accesses before it are *observed* before those after it	All prior memory accesses **and maintenance operations** have *completed*	The pipeline is flushed; later instructions are re-fetched
Blocks execution?	No — non-memory instructions continue	**Yes** — execution stalls until everything completes	Yes
Cost	Low	High	Moderate
Use for	Ordering two data accesses	After `TLBI` / `DC` / `IC`; before DMA; before `WFI`	After a system register write; after modifying code

THE DISTINCTION IN ONE LINE EACH

DMB orders. **DSB** waits. **ISB** re-fetches.

DMB says "these accesses must become visible in this order" but does not stall the pipeline. DSB says "nothing proceeds until all of this has actually finished". ISB says "throw away everything already fetched and start again", which is what makes a configuration change take effect.

Domain and direction

```
   DMB / DSB  <domain><direction>

   DOMAIN — how far the ordering propagates (chapter 19)
      sy    full system — widest, includes Device memory and
            non-coherent masters
      ish   inner shareable — the SMP default
      osh   outer shareable
      nsh   non-shareable — this PE only

   DIRECTION — which accesses are constrained
      (none)  both loads and stores
      ld      loads only — orders prior LOADS against later
              loads and stores
      st      stores only — orders prior STORES against later
              stores

   Combined:
      dmb ishst    prior stores visible before later stores
                   → the PRODUCER side of a message-passing pattern
      dmb ishld    prior loads complete before later accesses
                   → the CONSUMER side
      dmb ish      full ordering within the inner domain
      dsb sy       everything, everywhere, completed
      dsb nshst    local stores completed — boot code

   Narrower is cheaper. `dmb ishst` is materially faster than
   `dmb sy`, and in a hot path the difference is measurable.
```

DMB in practice

```
/* The message-passing pattern (chapter 20), fixed with DMB: */

/* producer */                      /* consumer */
buffer[0] = 42;                     while (flag == 0)
dmb ishst;   /* stores ordered */           ;
flag = 1;                           dmb ishld;   /* loads ordered */
                                    use(buffer[0]);

/* Note both sides need one. Ordering the producer's stores does
   not stop the consumer's loads being reordered.            */

/* What DMB does NOT do:
     · it does not FLUSH anything — it constrains ORDER only
     · it does not wait for completion; a store may still be in
       a buffer, just guaranteed to leave before the next one
     · it does not affect instruction fetch
     · it does nothing for Device-memory-to-DMA handoff, where
       you need completion — use DSB                        */
```

Prefer acquire/release

```
/* Ordering attached to the ACCESS is cheaper than a standalone
   barrier, because the core can keep other work in flight. */

/* with barriers */                 /* with ordered accesses */
str  w1, [x0]                       str  w1, [x0]
dmb  ishst                          stlr w2, [x3]      ← one instruction
str  w2, [x3]

ldr  w1, [x0]                       ldar w1, [x0]      ← one instruction
dmb  ishld
ldr  w2, [x3]                       ldr  w2, [x3]

/* LDAR — load-acquire:  no LATER access may move before it
   STLR — store-release: no EARLIER access may move after it

   These are what C11's memory_order_acquire/release compile to,
   and what Linux's smp_load_acquire/smp_store_release emit.

   Rule of thumb: use acquire/release for synchronisation between
   threads; reserve explicit DMB for cases the ordered accesses
   cannot express, and DSB for completion.                  */
```

DSB: when you need completion, not order

```
/* DSB is required whenever a LATER action depends on a prior
   operation having actually FINISHED — not merely being ordered. */

/* 1. After cache or TLB maintenance (chapters 15, 18) */
        dc      cvac, x0
        dsb     ish             /* the writeback has COMPLETED */
        /* only now is it safe to start the DMA */

        tlbi    vae1is, x0
        dsb     ish             /* the invalidate has completed
                                   on every core */
        isb

/* 2. Before starting DMA */
        /* fill the buffer... */
        dsb     sy              /* the data has reached the point
                                   the device will read from */
        writel(START, regs);

/* 3. Before WFI / WFE */
        dsb     sy              /* outstanding transactions must
                                   complete before we sleep, or
                                   they may never do             */
        wfi

/* 4. Before writing SCTLR to enable the MMU (chapter 12) */
        dsb     ish             /* the page tables must be visible
                                   to the table walker */
        msr     sctlr_el1, x0
        isb

/* 5. Before a reset or power-down */
        dsb     sy
```

DSB IS EXPENSIVE

It stalls the core until every outstanding memory transaction has completed — which on a large SoC means waiting for the far side of the interconnect. Hundreds of cycles is normal. A `dsb sy` in a hot loop is a serious performance bug, and using `dsb` where `dmb` would do is the most common form of that mistake.

ISB: making changes take effect

```
/* ISB flushes the pipeline. Instructions after it are re-fetched
   and re-decoded under the CURRENT context.                  */

/* Required after: */

/* 1. Any system register write affecting fetch, translation or
      permissions (chapter 06) */
        msr     sctlr_el1, x0
        isb

        msr     ttbr0_el1, x0
        isb

        msr     vbar_el1, x0
        isb

/* 2. Modifying instructions (chapter 18) */
        dc      cvau, x0
        dsb     ish
        ic      ivau, x0
        dsb     ish
        isb                       /* THIS core may have prefetched
                                     the old bytes */

/* 3. After changing an exception level's configuration and before
      relying on it */

/* ISB does NOT order memory accesses. It is not a substitute for
   DMB, and DMB is not a substitute for it. They constrain
   different machinery: DMB the memory system, ISB the
   instruction pipeline.                                      */
```

The compiler barrier

```
/* Hardware barriers do nothing about COMPILER reordering. A
   compiler that hoists a load out of a loop has already broken
   your code before any instruction executes.               */

#define barrier()  asm volatile("" ::: "memory")

/* The "memory" clobber tells GCC: this statement may read or
   write any memory, so do not cache values in registers across
   it and do not reorder memory accesses past it. It emits NO
   instruction.                                              */

/* Linux's READ_ONCE and WRITE_ONCE are built on this idea: */
#define READ_ONCE(x)      (*(const volatile __typeof__(x) *)&(x))
#define WRITE_ONCE(x, v)  (*(volatile __typeof__(x) *)&(x) = (v))

/* They prevent the compiler from:
     · tearing a single access into several
     · fusing several accesses into one
     · inventing accesses that were not in the source
     · caching the value in a register across a loop

   They emit NO hardware barrier. Every shared variable needs at
   least this, even one you consider "just a flag".         */

/* Every real barrier macro includes the compiler barrier: */
#define smp_mb()   asm volatile("dmb ish" ::: "memory")
/*                                        ^^^^^^^^ essential */
```

The Linux barrier vocabulary

Macro	arm64 expansion	Use for
`barrier()`	compiler only	Stop reordering by the compiler
`smp_mb()`	`dmb ish`	CPU-to-CPU, both directions
`smp_rmb()`	`dmb ishld`	CPU-to-CPU, loads
`smp_wmb()`	`dmb ishst`	CPU-to-CPU, stores
`mb()`	`dsb sy`	Including MMIO and DMA
`dma_wmb()`	`dmb oshst`	Before a DMA descriptor is published
`dma_rmb()`	`dmb oshld`	After reading a DMA completion flag
`smp_store_release()`	`stlr`	Publish
`smp_load_acquire()`	`ldar`	Consume
`isb()`	`isb`	After a system register change

```
/* On a uniprocessor build the smp_* variants compile to just a
   compiler barrier — which is why you use smp_mb() for CPU-to-CPU
   and mb() for device interaction. Using mb() where smp_mb()
   would do costs a dsb sy on every call.                    */
```

MMIO ordering

```
/* Device memory accesses are ordered relative to EACH OTHER
   (chapter 11), but NOT relative to Normal memory accesses.
   The DMA handoff is exactly that combination:              */

        memcpy(dma_buf, data, len);     /* Normal memory */
        dsb     sy                       /* MUST complete first */
        writel(START, regs + CTRL);      /* Device memory */

/* Linux's accessors handle this for you: */
        writel(v, addr);          /* includes a barrier before the
                                     write so prior Normal writes
                                     are visible                  */
        readl(addr);              /* includes a barrier after      */

        writel_relaxed(v, addr);  /* NO barrier — use when you have
                                     already ordered things, e.g.
                                     several register writes in a
                                     row where only the last needs
                                     ordering                     */

/* The common optimisation: use _relaxed for a burst of register
   writes, then a single full writel() or an explicit barrier at
   the point where ordering actually matters. This can be a
   significant win in a hot driver path.                     */

/* And the POSTED WRITE trap: a write to Device-nGnRE may be
   acknowledged before it reaches the device. To be certain it
   has landed — before releasing a reset, say — you must READ
   BACK from the same peripheral:                            */
        writel(v, regs + CTRL);
        (void)readl(regs + CTRL);        /* forces completion */
```

Cost, and choosing

```
Approximate, and highly implementation dependent — but the
ORDERING is reliable:

   barrier()            0 cycles      (no instruction)
   ldar / stlr          few cycles    (attached to the access)
   dmb ishst/ishld      ~5–20         (one direction, narrow)
   dmb ish              ~10–30
   dmb sy               ~20–50
   dsb ish              ~20–100       (waits for completion)
   dsb sy               ~50–500+      (waits for the whole system)
   isb                  ~10–30        (pipeline flush)

DECISION PROCEDURE:

   Ordering two data accesses between threads?
        → acquire/release, or the narrowest DMB

   Need something to have COMPLETED before proceeding?
        → DSB, narrowest domain that is correct

   Changed a system register or wrote instructions?
        → ISB

   Only worried about the compiler?
        → barrier(), READ_ONCE, WRITE_ONCE

   Handing a buffer to a device?
        → DSB, and use the DMA API which does it for you
```

How it shows up

Symptom	Cause
Consumer sees the flag but stale data	Missing barrier on one or both sides
System register change has no effect	Missing `ISB`
TLB or cache maintenance seems not to happen	Missing `DSB` after it
DMA reads a partially filled buffer	No `DSB` before starting the transfer
Device does not see a register write	Posted write; read back to force completion
Hot loop unexpectedly slow	`dsb sy` where `dmb ishst` would do
Adding `volatile` did not fix a race	`volatile` is not a barrier
Works at `-O0`, fails at `-O2`	Compiler reordering; missing `"memory"` clobber
Core hangs in `WFI`	No `DSB` before it; a transaction never completed
Barrier added, coherency bug persists	It is a shareability problem, not ordering (ch. 19)

Check yourself

- ✓ Give the one-line distinction between DMB, DSB and ISB.
- ✓ Explain the domain and direction suffixes and give three useful combinations.
- ✓ Show a message-passing pattern with barriers, and say why both sides need one.

- ✓ Explain why acquire/release is cheaper than a standalone DMB.
- ✓ Give four situations that specifically require DSB.
- ✓ Give three situations that require ISB.
- ✓ Explain what the `"memory"` clobber does and why every barrier macro includes it.
- ✓ Explain posted writes and how to force a register write to land.

Atomics: exclusives and LSE

Because ARM is load/store, atomicity needs dedicated instructions. Two generations exist — the original retry-loop exclusives and the newer single-instruction atomics — and the difference between them is the difference between a system that scales to 64 cores and one that collapses at eight.

Why dedicated instructions

```
/* From chapter 03: read-modify-write is three instructions. */
        ldr     w1, [x0]
        add     w1, w1, #1
        str     w1, [x0]
/* Any other core can interleave. One increment is lost.      */

/* You cannot fix this with barriers — a barrier orders accesses,
   it does not make a sequence indivisible. You need hardware
   that can detect interference.                              */
```

Load-exclusive / store-exclusive

```
The mechanism: an EXCLUSIVE MONITOR watches an address.

   LDXR  marks the address as exclusively reserved by this PE
   STXR  succeeds ONLY if the reservation is still valid, and
         reports success or failure in a register

   The reservation is CLEARED by:
      · any store to the same reservation granule by any observer
      · a STXR from this PE (success or failure)
      · a CLREX instruction
      · an exception entry or return
      · a context switch
      · sometimes, spuriously — the architecture permits it

So the pattern is always a RETRY LOOP:
```

```
/* atomic increment */
1:      ldaxr   w1, [x0]        /* load-acquire exclusive          */
        add     w1, w1, #1
        stlxr   w2, w1, [x0]    /* store-release exclusive:
                                   w2 = 0 success, 1 failure       */
        cbnz    w2, 1b          /* retry on failure                */

/* compare and swap, built from the same primitive */
1:      ldaxr   w1, [x0]
        cmp     w1, w_expected
        b.ne    2f
        stlxr   w2, w_desired, [x0]
        cbnz    w2, 1b
2:      clrex                   /* release the reservation if we
                                   are abandoning the sequence     */

/* The ordered variants (LDAXR/STLXR) combine exclusivity with
   acquire/release semantics - one instruction instead of an
   exclusive plus a barrier (chapter 21).                    */
```

RULES FOR EXCLUSIVE LOOPS

- **Keep the body tiny.** Only register operations between LDXR and STXR. Any memory access, function call or exception can clear the monitor and cause an infinite retry.
- **Never take an exception inside one.** Exception entry clears the reservation, so a loop that is interrupted every iteration never completes — a livelock that looks like a hang.
- **Always `CLREX` when abandoning** a sequence, or a stale reservation can make an unrelated later STXR succeed when it should not.
- **They do not work on Device memory.** Undefined behaviour — the monitor requires cacheable memory (chapter 11).
- **They need shareable memory** for cross-core correctness — the global monitor only participates for Inner or Outer Shareable pages (chapter 19).

The reservation granule

```
/* The monitor tracks a GRANULE, not a single address. Its size is
   in CTR_EL0.ERG — typically 64 or 128 bytes.               */

static unsigned exclusives_granule(void)
{
        uint64_t ctr;
        asm volatile("mrs %0, ctr_el0" : "=r"(ctr));
        return 4U << ((ctr >> 20) & 0xF);      /* ERG field */
}

/* CONSEQUENCE: two independent locks inside one granule interfere.
   Each STXR clears the other's reservation, so both loops retry
   endlessly under contention — a livelock-like collapse that
   looks like terrible lock performance.                     */

struct bad {
        spinlock_t lock_a;      /* same granule */
        spinlock_t lock_b;      /* → they fight */
};

struct good {
        spinlock_t lock_a __attribute__((aligned(128)));
        spinlock_t lock_b __attribute__((aligned(128)));
};

/* This is the same class of problem as cache-line false sharing
   (CA chapter 15), one level down. Pad to the LARGER of the
   cache line size and the reservation granule.              */
```

Large System Extensions

```
/* ARMv8.1 added single-instruction atomics. No loop, no monitor,
   no retries.                                                */

        ldadd   w1, w2, [x0]     /* atomic add; w2 = OLD value    */
        ldclr   w1, w2, [x0]     /* atomic AND NOT (bit clear)    */
        ldeor   w1, w2, [x0]     /* atomic XOR                    */
        ldset   w1, w2, [x0]     /* atomic OR (bit set)           */
        ldsmax, ldsmin, ldumax, ldumin
        swp     w1, w2, [x0]     /* atomic exchange               */
        cas     w1, w2, [x0]     /* compare and swap              */
        casp    x0, x1, x2, x3, [x4]   /* 128-bit CAS             */

/* Each has ordering variants: */
        ldadda   /* acquire */    ldaddl   /* release */
        ldaddal  /* both    */    ldadd    /* relaxed */
        casal, swpal, ...

/* And a store-only form when the old value is not needed —
   cheaper, because no result must be returned:              */
        stadd   w1, [x0]         /* == ldadd with wzr as dest    */
```

WHY LSE SCALES AND EXCLUSIVES DO NOT

An exclusive loop requires the line to be brought into *this* core's cache in an exclusive state. Under contention, N cores fight over one line: it ping-pongs, most STXRs fail, and throughput *decreases* as cores are added.

An LSE atomic can be executed **near memory** — at the point of coherency, in the interconnect or a system cache. The line never moves. Contention becomes a queue at one place rather than a fight between N caches. Measured difference on a heavily contended counter at 64 cores can be an order of magnitude.

Detecting and using LSE

```
/* Query ID_AA64ISAR0_EL1.Atomic (bits [23:20]) >= 2 */

static bool has_lse(void)
{
        uint64_t isar0;
        asm volatile("mrs %0, id_aa64isar0_el1" : "=r"(isar0));
        return ((isar0 >> 20) & 0xF) >= 2;
}

/* Linux PATCHES ITSELF at boot: the same kernel image contains
   both an exclusive loop and an LSE instruction, and the
   alternatives framework replaces one with the other based on
   what the CPU reports. One binary, optimal everywhere.     */

/* Building for LSE explicitly: */
gcc -march=armv8.1-a           /* or +lse */
gcc -moutline-atomics          /* the DEFAULT since GCC 10:
                                  emits calls to runtime-dispatched
                                  helper functions, so one binary
                                  works on both, with a small
                                  call overhead                  */

# check what your distro built with
readelf -a /lib/aarch64-linux-gnu/libc.so.6 | grep -i lse
grep -o 'atomics' /proc/cpuinfo | head -1     # "atomics" = LSE present
```

From C

```
#include <stdatomic.h>

atomic_int counter = 0;

atomic_fetch_add(&counter, 1);                    /* → ldaddal */
atomic_fetch_add_explicit(&counter, 1,
                          memory_order_relaxed);   /* → ldadd   */

int expected = old;
atomic_compare_exchange_strong(&v, &expected, desired);   /* → casal */

/* _weak may fail spuriously and is cheaper inside a loop —
   it maps directly onto the exclusive retry pattern:      */
do {
        old = atomic_load_explicit(&v, memory_order_relaxed);
        new = f(old);
} while (!atomic_compare_exchange_weak_explicit(
                &v, &old, new,
                memory_order_release, memory_order_relaxed));

/* Choose the WEAKEST correct memory order. seq_cst is the default
   and the most expensive; relaxed is free for a statistics
   counter nobody synchronises on (chapter 20).            */

/* Is it actually lock-free? Check — a large atomic may be
   implemented with a hidden mutex, which is a correctness
   problem in a signal handler or an interrupt context:    */
atomic_is_lock_free(&obj);
ATOMIC_LLONG_LOCK_FREE          /* compile-time: 2 = always */
```

128-bit atomics

```
/* Needed for lock-free structures that must update a pointer and
   a tag together — the standard ABA defence (OS chapter 10).  */

        casp    x0, x1, x2, x3, [x4]      /* LSE, ARMv8.1        */
        ldxp    x0, x1, [x2]              /* exclusive pair       */
        stxp    w3, x4, x5, [x2]

/* In C: */
struct alignas(16) tagged_ptr {
        void    *ptr;
        uint64_t tag;
};
_Atomic struct tagged_ptr head;
/* atomic_compare_exchange on this compiles to CASP if LSE is
   present, LDXP/STXP otherwise. The 16-byte ALIGNMENT is
   mandatory — an unaligned 128-bit atomic is not atomic.   */

/* ARMv8.4 adds LSE2, which guarantees that ordinary aligned
   128-bit loads and stores are atomic — removing the need for
   the pair instructions in some cases.                     */
```

Building a spinlock

```
/* A minimal correct spinlock, showing acquire/release placement */

void spin_lock(uint32_t *lock)
{
        uint32_t tmp;
        asm volatile(
        "       sevl\n"                 /* prime the event register */
        "1:     wfe\n"                  /* sleep until an event     */
        "2:     ldaxr   %w0, [%1]\n"    /* load-ACQUIRE exclusive   */
        "       cbnz    %w0, 1b\n"      /* held? go back to sleep   */
        "       stxr    %w0, %w2, [%1]\n"
        "       cbnz    %w0, 2b\n"      /* lost the race, retry     */
        : "=&r"(tmp)
        : "r"(lock), "r"(1)
        : "memory", "cc");
}

void spin_unlock(uint32_t *lock)
{
        asm volatile("stlr wzr, [%0]"    /* store-RELEASE            */
                     :: "r"(lock) : "memory");
        /* STLR on the exclusive monitor's granule generates an
           EVENT, waking the WFE sleepers. No explicit SEV needed. */
}

/* Note WFE: spinners sleep in a low-power state instead of
   burning cycles. This is why ARM spinlocks are far more power-
   efficient than a naive busy loop (chapter 07).

   Real kernels use a QUEUED spinlock (qspinlock) instead: each
   waiter spins on its OWN cache line, so the coherence traffic
   does not grow with the number of waiters - the same insight
   as MCS locks (OS chapter 10).                              */
```

Measuring atomic performance

```
# uncontended vs contended is the whole story
perf stat -e instructions,cycles ./bench

# on ARM, the relevant PMU events
perf stat -e ldrex_spec,strex_spec,strex_fail_spec ./prog
#   a high strex_FAIL ratio means heavy contention and exclusive
#   retry storms - the signal to switch to LSE, or to reduce
#   sharing entirely

perf stat -e mem_access,bus_access,l2d_cache_wb ./prog
perf c2c record ./prog          # which lines are contended

# a quick empirical check: plot throughput against thread count.
#   flat or rising  -> fine
#   FALLING         -> the line is ping-ponging; look for false
#                      sharing, granule collisions, or exclusives
#                      under contention
```

THE ORDERING OF REMEDIES

When atomic operations are the bottleneck, in order of effectiveness: **(1) stop sharing** — per-CPU or per-thread counters aggregated later; **(2) reduce frequency** — batch updates; **(3) weaken the memory order** — a statistics counter needs only `relaxed`; **(4) use LSE**; **(5) use a better lock** — queued rather than test-and-set. Most real wins come from (1), not from micro-optimising the atomic itself.

How it shows up

Symptom	Cause
Counter loses increments	Plain read-modify-write instead of an atomic
Exclusive loop never completes	An exception or memory access inside the loop clearing the monitor
Two adjacent locks perform terribly together	Same reservation granule — pad them apart
Throughput falls as cores are added	Exclusive contention; try LSE and reduce sharing
Atomics do not work on a shared region	Memory is Device, or Non-shareable
Lock lets two threads in	Non-shareable memory — no global monitor
128-bit atomic is not atomic	Not 16-byte aligned
Same binary slow on a newer CPU	Built without LSE and without `-moutline-atomics`
Lock-free structure corrupts under load	ABA — needs a tagged pointer or safe reclamation
Atomic in a signal handler deadlocks	Not lock-free; check `atomic_is_lock_free`

Check yourself

- ✓ Explain why atomicity needs dedicated instructions on a load/store architecture.
- ✓ Describe the exclusive monitor and list four things that clear a reservation.
- ✓ Give three rules for writing an exclusive retry loop.
- ✓ Explain the reservation granule and the bug two adjacent locks can cause.
- ✓ Explain why LSE scales better than exclusives under contention.
- ✓ Say how Linux ships one binary that uses LSE only where available.
- ✓ Explain `compare_exchange_weak` versus `strong` and which maps to what.
- ✓ Explain the role of `WFE` in a spinlock and why unlock needs no `SEV`.

The GIC: architecture

A separate hardware block that collects interrupt signals from every peripheral, prioritises them, decides which core should handle each, and enforces the secure/non-secure split. Understanding its structure is what makes interrupt routing, affinity and virtualisation comprehensible.

Why a dedicated block

```
A CPU core has ONE interrupt input (two, counting FIQ). A SoC has
hundreds of interrupt sources and several cores. Something must:

   · multiplex hundreds of sources onto a few core inputs
   · PRIORITISE — a timer tick must not delay a critical fault
   · ROUTE — decide which core handles which interrupt
   · MASK selectively, per source and per priority
   · handle EDGE versus LEVEL signalling per source
   · enforce SECURITY — keep secure interrupts away from the
     normal world (security track)
   · support VIRTUALISATION — inject interrupts into a guest
     without a hypervisor trap on every one

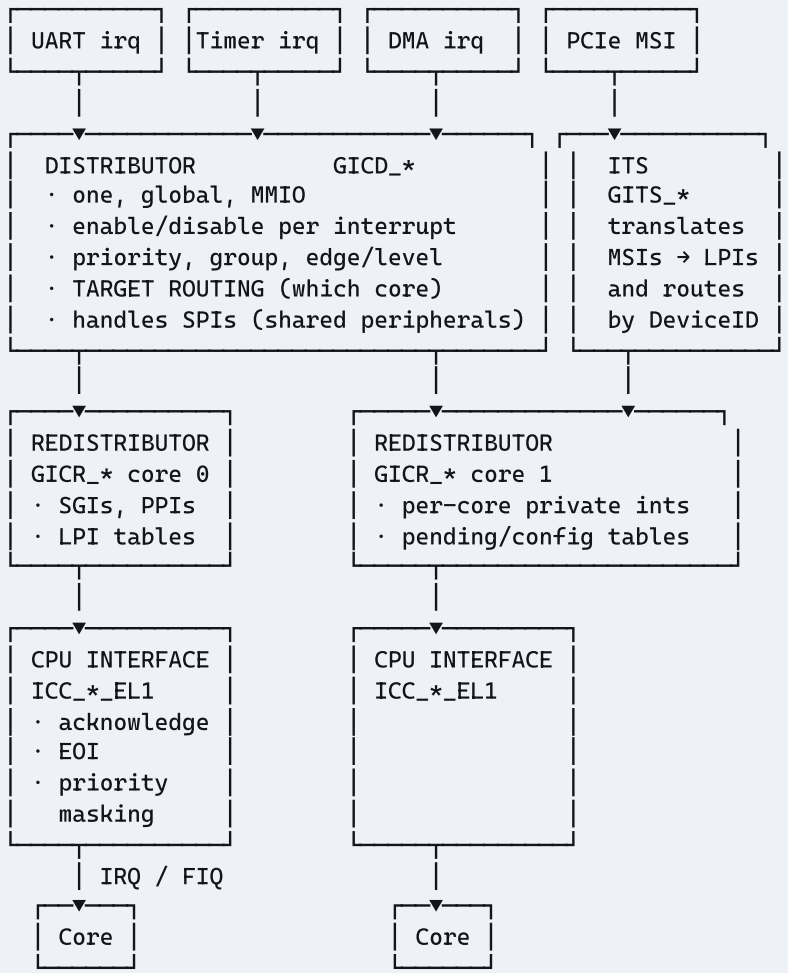
That block is the Generic Interrupt Controller. It is architected
by Arm, so the programming model is the same across every SoC —
which is why one Linux driver serves them all.
```

Versions

Version	Brought	CPU interface
GICv2	Up to 8 cores, basic virtualisation	MMIO (`GICC_*`)
GICv3	Affinity routing, LPIs and the ITS, large core counts, four security groups	**System registers** (`ICC_*_EL1`)
GICv4	Direct injection of virtual LPIs — a guest receives an MSI with no hypervisor exit	System registers

The move from MMIO to system registers in GICv3 matters: acknowledging an interrupt becomes an `MRS` rather than a device read, which is dramatically faster and removes the barriers that MMIO access requires (chapter 11).

The components



Interrupt ID ranges

Range	Type	Scope	Used for
0–15	**SGI** — Software Generated	Per core	Core-to-core IPIs: TLB shootdown, rescheduling, function calls, stop-CPU
16–31	**PPI** — Private Peripheral	Per core	Per-core devices: the generic timer, the PMU, the virtual maintenance interrupt
32–1019	**SPI** — Shared Peripheral	Global	Ordinary devices: UART, DMA, Ethernet
1020–1023	Special	—	1023 = spurious, returned when there is nothing to handle
8192+	**LPI** — Locality-specific Peripheral	Global	Message-signalled interrupts (MSI/MSI-X). Effectively unlimited.

```
# see the mapping on a live system
cat /proc/interrupts
#            CPU0    CPU1    CPU2    CPU3
#   3:      102394   98211  101002   99887   GICv3  30 Level  arch_timer
#                                               ^^ PPI 30 — per core,
#                                                  hence counts on all
#  24:       15221       0       0       0   GICv3  56 Level  uart-pl011
#                                               ^^ SPI — routed to CPU0
#  IPI0:      8842    9021    8877    8990   Rescheduling interrupts
#  IPI1:       221     198     205     211   Function call interrupts
#                                           ^^^^ these are SGIs
```

Affinity routing

```
/* GICv3 identifies cores by their MPIDR affinity hierarchy rather
   than by a bitmask — which is what allows more than 8 cores. */

        mrs     x0, mpidr_el1
/*  MPIDR_EL1:
       Aff0 [7:0]    core within a cluster (or thread)
       Aff1 [15:8]   cluster
       Aff2 [23:16]  group of clusters
       Aff3 [39:32]  higher level still                       */

/* An SPI's target is written to GICD_IROUTER<n>: */
        GICD_IROUTER(intid) = (aff3 << 32) | (aff2 << 16) |
                              (aff1 << 8)  |  aff0;
/* or with bit 31 set (Interrupt_Routing_Mode = 1) it means
   "any participating core" — 1-of-N delivery, which lets the
   GIC pick an idle core.                                     */

/* Sending an SGI is a SYSTEM REGISTER write, not MMIO: */
        msr     ICC_SGI1R_EL1, x0
/*  x0 encodes: the target affinity, a 16-bit target list within
    the cluster, and the SGI number. That is how Linux sends a
    reschedule IPI or a TLB shootdown request.               */
```

```
# control affinity from userspace
cat /proc/irq/24/smp_affinity_list
echo 2 > /proc/irq/24/smp_affinity_list        # pin to CPU2
echo 3 > /proc/irq/24/smp_affinity             # bitmask form

# irqbalance moves them automatically — and is usually wrong for
# latency-sensitive work. Disable and pin by hand:
systemctl stop irqbalance

# keep interrupts entirely off the real-time cores
# kernel cmdline: irqaffinity=0,1 isolcpus=2,3
```

Security groups

```
Every interrupt belongs to a GROUP, and the group determines
which exception level receives it and as which signal:

   Group 0          → FIQ, always taken to EL3
                      Secure firmware's interrupts

   Secure Group 1   → IRQ when in the secure world,
                      FIQ when in the non-secure world
                      Trusted OS interrupts

   Non-secure Group 1 → IRQ
                        Ordinary OS interrupts

  THE CONSEQUENCE that matters: a Non-secure OS clearing PSTATE.I
  cannot mask secure interrupts, because they arrive as FIQ and
  are routed to EL3. The secure world can always preempt the
  normal world — which is what makes a TEE's timing guarantees
  meaningful (security track).

  Configured in GICD_IGROUPR / GICD_IGRPMODR, and only writable
  from the secure world.
```

Priority and preemption

```
/* 8-bit priority values, and LOWER NUMBER = HIGHER PRIORITY.
   (This trips people up constantly.)                          */

        GICD_IPRIORITYR(intid) = 0x80;     /* mid priority */

/* Not all 8 bits are necessarily implemented - write 0xFF and
   read back to discover how many are: */
static unsigned priority_bits(void)
{
        writeb(0xFF, GICD_IPRIORITYR(0));
        return 8 - __builtin_ctz(readb(GICD_IPRIORITYR(0)));
        /* commonly 4 or 5 bits → 16 or 32 usable levels */
}

/* THREE registers control what gets through: */

   ICC_PMR_EL1      Priority Mask: interrupts with priority
                    NUMERICALLY >= this value are blocked.
                    0xFF = allow everything, 0x00 = block all.

   ICC_BPR1_EL1     Binary Point: splits the priority field into
                    a GROUP part and a SUB-priority part. Only the
                    group part participates in PREEMPTION, so this
                    controls how much nesting you allow.

   ICC_RPR_EL1      Running Priority: the priority of the
                    interrupt currently being handled. A new
                    interrupt preempts only if its group priority
                    is higher.

/* Linux uses PMR for "pseudo-NMI": rather than masking with
   PSTATE.I (which blocks everything), it raises PMR so that
   ordinary interrupts are blocked but a high-priority NMI still
   gets through. That is how arm64 gets NMIs without hardware
   NMI support.                                                 */
```

The ITS and MSIs

```
A PCIe device signals an interrupt by WRITING to an address —
there is no wire. The GIC must turn that write into an interrupt
for a specific core.

   device writes (DeviceID, EventID) to GITS_TRANSLATER
        |
   ┌────▼──────────────────────────────────────────┐
   |  ITS — Interrupt Translation Service          |
   |                                               |
   |  Device Table:  DeviceID → an ITT             |
   |  ITT:           EventID  → (LPI ID, Collection) |
   |  Collection Table: Collection → Redistributor|
   └────┬──────────────────────────────────────────┘
        ▼
   the LPI is made pending in the target redistributor's
   PENDING TABLE (in memory), and the core is signalled

  Two levels of indirection, both table-driven, because there can
  be tens of thousands of LPIs and they must be redirected when
  a VM migrates between cores.

  Software configures it with COMMANDS in a queue, exactly like
  the SMMU (security track):
     MAPD    map a DeviceID to an ITT
     MAPTI   map an EventID to an LPI and collection
     MOVI    move an LPI to a different collection (core)
     INV     invalidate cached configuration
     SYNC    wait for completion

  GICv4 adds direct injection: a VM's LPI is delivered to the
  guest WITHOUT a hypervisor exit at all.
```

Virtualisation support

```
/* Without hardware help, every guest interrupt would need a
   hypervisor trap: take the interrupt at EL2, work out that it
   belongs to a guest, and inject it. The GIC provides a LIST
   REGISTER mechanism to avoid that.                          */

   ICH_LR<n>_EL2      List Registers — the hypervisor writes a
                      virtual interrupt here, and the GIC delivers
                      it to the guest DIRECTLY. The guest
                      acknowledges and EOIs it with its own
                      ICC_* registers, with NO exit.

   ICH_HCR_EL2        hypervisor control: enable virtual
                      interfaces, request maintenance interrupts

   ICH_VMCR_EL2       the guest's virtual control state

   ICV_*_EL1          the guest's view — when HCR_EL2.IMO is set,
                      the guest's ICC_* accesses are REDIRECTED
                      to these virtual registers

/* Cost: the hypervisor must still populate the list registers on
   entry and read back state on exit, and there are only a few
   (typically 4–16). A guest with many pending interrupts causes
   MAINTENANCE INTERRUPTS to refill them.

   GICv4's direct injection removes even that for LPIs.      */
```

Initialising the GIC

```
/* Distributor — once, globally */
        GICD_CTLR = 0;                          /* disable while
                                                   configuring */
        for each SPI:
                GICD_ICENABLER = all;           /* disable      */
                GICD_ICPENDR   = all;           /* clear pending */
                GICD_IPRIORITYR = 0xA0;         /* default prio  */
                GICD_ICFGR     = level or edge;
                GICD_IGROUPR   = 1;             /* NS Group 1    */
                GICD_IROUTER   = target affinity;
        GICD_CTLR = ARE_NS | EnableGrp1NS;      /* affinity routing
                                                   + enable       */

/* Redistributor — per core */
        GICR_WAKER &= ~ProcessorSleep;          /* wake it        */
        wait until (GICR_WAKER & ChildrenAsleep) == 0;
        configure SGIs and PPIs in GICR_SGI_base

/* CPU interface — per core, SYSTEM REGISTERS */
        msr     ICC_SRE_EL1, #1        /* enable system register
                                          access — MUST be first  */
        isb
        msr     ICC_PMR_EL1, #0xFF     /* unmask all priorities   */
        msr     ICC_BPR1_EL1, #0
        msr     ICC_IGRPEN1_EL1, #1    /* enable Group 1          */
        isb

/* The GICR_WAKER dance is a common bring-up trap: a
   redistributor comes out of reset ASLEEP and delivers nothing
   until woken, with no error to indicate why.               */
```

Device tree description

```
gic: interrupt-controller@2f000000 {
        compatible = "arm,gic-v3";
        #interrupt-cells = <3>;
        interrupt-controller;
        reg = <0x0 0x2f000000 0x0 0x10000>,     /* GICD  */
              <0x0 0x2f100000 0x0 0x200000>;    /* GICR  */
        interrupts = <GIC_PPI 9 IRQ_TYPE_LEVEL_HIGH>;  /* maintenance */

        its: msi-controller@2f020000 {
                compatible = "arm,gic-v3-its";
                msi-controller;
                reg = <0x0 0x2f020000 0x0 0x20000>;
        };
};

/* And a device referencing it: */
        interrupts = <GIC_SPI 56 IRQ_TYPE_LEVEL_HIGH>;
/*                    ^type    ^number  ^trigger
   Note the SPI number here is RELATIVE to 32: SPI 56 is INTID 88.
   Mixing these up is a very common device tree error, and the
   symptom is an interrupt that never fires.              */
```

How it shows up

Symptom	Cause
Interrupt count stays at zero	Wrong INTID (SPI numbering offset), not enabled, or wrong trigger type
Nothing works on secondary cores	`GICR_WAKER` not cleared for those redistributors
All interrupts land on CPU0	No affinity spreading; `GICD_IROUTER` or `smp_affinity`
Latency spikes on real-time cores	Interrupts not steered away from them
Interrupt fires once then never again	Not EOI'd, or an edge interrupt lost while masked
Spurious INTID 1023 returned	Acknowledged when nothing was pending — a race or a stale read
Secure OS cannot preempt the normal world	Interrupt in the wrong group
MSI never arrives	ITS tables not mapped, or `MAPD` / `MAPTI` not issued
Guest misses interrupts under load	List registers exhausted; maintenance interrupts thrashing
Higher-priority interrupt does not preempt	Binary point grouping them at the same preemption level

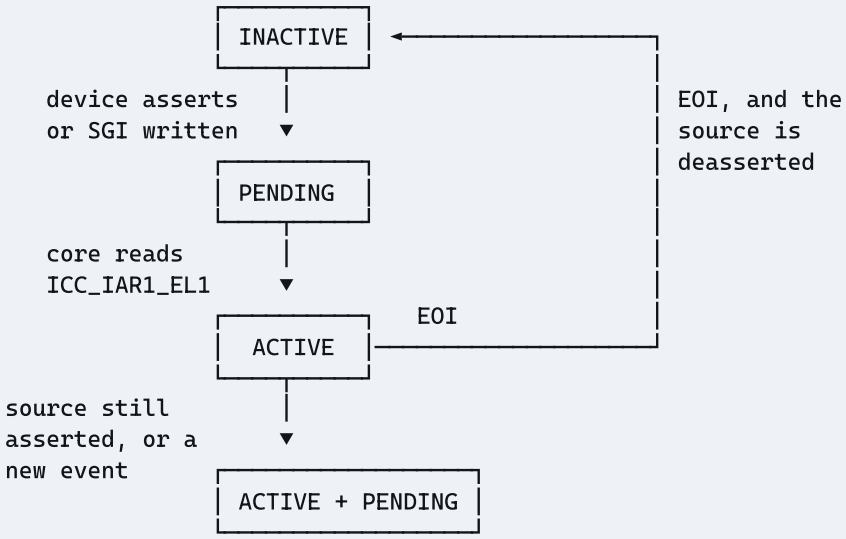
Check yourself

- ✓ Give seven jobs the GIC performs that a bare interrupt line cannot.
- ✓ Name the GIC components and what each is responsible for.
- ✓ Give the interrupt ID ranges and an example of each type.
- ✓ Explain affinity routing and why GICv2's bitmask did not scale.
- ✓ Explain the security groups and why a Non-secure OS cannot mask secure interrupts.
- ✓ State the priority convention and explain what PMR, BPR and RPR each do.
- ✓ Explain how Linux implements pseudo-NMIs using PMR.
- ✓ Describe the ITS's two levels of translation and why both are needed.
- ✓ Explain how list registers let a guest handle an interrupt without a hypervisor exit.

The GIC: interrupt lifecycle

An interrupt moves through a defined state machine from assertion to completion. Every interrupt bug — storms, lost edges, spurious IDs, priority failures — is a specific wrong transition in that machine.

The state machine



ACTIVE means "a core is handling it". While active, the GIC will NOT signal the same interrupt again — which is what prevents an interrupt from re-entering its own handler.

ACTIVE+PENDING is the interesting state: the interrupt fired again while being handled. After EOI it goes straight back to PENDING and fires immediately.

The complete flow

```
/* 1. The device asserts its interrupt line, or writes an MSI
      doorbell. */

/* 2. The distributor (or redistributor, for PPIs/SGIs) marks the
      INTID PENDING, checks it is enabled, and compares its
      priority against what the target core is running. */

/* 3. If it wins, the GIC asserts IRQ or FIQ to that core. */

/* 4. The core takes the exception — if PSTATE.I permits, and if
      the priority passes ICC_PMR_EL1 (chapter 28 for the entry
      sequence). */

/* 5. ACKNOWLEDGE: the handler reads the acknowledge register.
      This returns the INTID and moves it PENDING → ACTIVE. */
        mrs     x0, ICC_IAR1_EL1
        /* x0 = INTID, or 1023 (spurious) if nothing was pending */

/* 6. SERVICE the device — and crucially, CLEAR THE INTERRUPT
      CONDITION AT THE DEVICE, not just at the GIC. */
        writel(status, regs + IRQ_STATUS);      /* W1C at source */

/* 7. END OF INTERRUPT: write the INTID back. This drops the
      running priority, allowing lower-priority interrupts. */
        msr     ICC_EOIR1_EL1, x0

/* 8. ERET back to the interrupted code. */
```

> **STEP 6 BEFORE STEP 7, ALWAYS**
>
> If you EOI without clearing the condition at the device, a level-triggered line is still asserted. The GIC immediately re-signals it, the core re-enters the handler, and nothing else ever runs. The system appears hung with 100% CPU in the interrupt handler.
>
> Linux's spurious-interrupt detector eventually notices and prints `"irq N: nobody cared (try booting with the "irqpoll" option)"`, then disables the line. That message is a diagnosis, not a fix.

EOI modes

```
/* ICC_CTLR_EL1.EOImode selects one of two behaviours: */

/* EOImode = 0 — the simple case, and the default */
        msr     ICC_EOIR1_EL1, x0
/*      does BOTH: drops the running priority AND deactivates
        the interrupt. One write, done.                      */

/* EOImode = 1 — priority drop and deactivation are SEPARATE */
        msr     ICC_EOIR1_EL1, x0     /* priority drop only    */
        ...
        msr     ICC_DIR_EL1, x0       /* deactivate            */

/* Why the split exists: it lets you re-enable higher-priority
   interrupts (by dropping priority) while the current interrupt
   remains ACTIVE, so it cannot re-fire. This is essential for:

     · THREADED interrupt handlers — Linux drops priority when
       the hard handler returns, but does not deactivate until
       the threaded handler completes, preventing a storm from
       a level-triggered device whose condition is cleared late

     · VIRTUALISATION — the hypervisor drops priority, injects
       the interrupt into a guest, and deactivates only when the
       guest EOIs it                                          */

/* Linux uses EOImode=1 when running as a host hypervisor,
   EOImode=0 otherwise. You can see which in dmesg:          */
//   GICv3: Using split EOI/Deactivate mode
```

Edge and level

	Level-triggered	**Edge-triggered**
Pending while	The source is asserted	Latched on the transition
Cleared by	Deasserting at the *device*	Acknowledge, or writing `GICD_ICPENDR`
Sharing	**Possible** — each handler checks and clears its own	Unsafe — two simultaneous edges register as one
Can be missed?	No — the line stays asserted	**Yes**, if masked at the wrong moment
Failure mode	Interrupt storm	Silent hang, waiting for an event that already happened
Configured in	`GICD_ICFGR<n>`, two bits per interrupt	

```
/* The edge-triggered race, and the standard defence: */

static irqreturn_t isr(int irq, void *dev)
{
        u32 status;

        do {
                status = readl(regs + STATUS);
                if (!status)
                        break;
                writel(status, regs + STATUS);   /* clear */
                handle(status);
        } while (readl(regs + STATUS));          /* RE-CHECK */

        return IRQ_HANDLED;
}

/* Without the loop, an event arriving between handle() and the
   return produces no new edge — the device has already raised
   its line and lowered it. The interrupt is lost forever and the
   device waits for a response that never comes.

   The symptom: the device works fine at low rates and hangs
   under load. Extremely common, and easy to misattribute.  */
```

Shared interrupt lines

```
/* Several devices on one level-triggered SPI. Every handler is
   called; each must determine whether it was theirs.       */

static irqreturn_t my_isr(int irq, void *dev_id)
{
        struct my_dev *d = dev_id;
        u32 status = readl(d->regs + STATUS);

        if (!(status & MY_IRQ_PENDING))
                return IRQ_NONE;        /* NOT OURS — essential */

        writel(status, d->regs + STATUS);
        /* ... handle ... */
        return IRQ_HANDLED;
}

/* Returning IRQ_HANDLED when it was not yours breaks the kernel's
   spurious-interrupt detection: it can no longer tell that
   nobody serviced the line, so a genuinely stuck interrupt is
   never caught and the machine simply hangs.

   Registering with IRQF_SHARED requires a valid dev_id, because
   that is how free_irq identifies which handler to remove.  */
        request_irq(irq, my_isr, IRQF_SHARED, name, d);
```

Masking, at four levels

```
There are four independent places an interrupt can be blocked.
Diagnosing "my interrupt never fires" means checking all four,
from the source outward:

  1. AT THE DEVICE       the peripheral's own interrupt enable
                         → readl(regs + IRQ_ENABLE)

  2. AT THE DISTRIBUTOR  GICD_ISENABLER / GICD_ICENABLER
                         → per-INTID enable
                         → Linux: /proc/interrupts shows it only
                           if a handler is registered

  3. AT THE CPU INTERFACE  ICC_PMR_EL1 priority mask, and
                           ICC_IGRPEN1_EL1 group enable

  4. AT THE CORE         PSTATE.I (IRQ) or PSTATE.F (FIQ)
                         → local_irq_disable() in Linux

  A fifth, easily forgotten: the interrupt may be routed to a
  DIFFERENT CORE than the one you are watching. Check
  /proc/interrupts across all CPUs, not just CPU0.
```

Software-generated interrupts

```
/* SGIs are how cores talk to each other. Sending one is a system
   register write.                                              */

        msr     ICC_SGI1R_EL1, x0

/*  x0 encodes:
       [55:48] Aff3      [39:32] Aff2      [23:16] Aff1
       [27:24] SGI ID (0-15)
       [15:0]  TargetList - a bitmask of cores WITHIN that Aff1
                            cluster
       [40]    IRM - 1 means "all cores except self"          */

/* Linux's IPI usage - visible in /proc/interrupts: */
   IPI0  Rescheduling         wake a core to run the scheduler
   IPI1  Function call        run a function on another core
   IPI2  CPU stop             halt for panic or reboot
   IPI3  CPU crash stop
   IPI4  Timer broadcast      wake a core in deep idle for a timer
   IPI5  IRQ work             deferred work from NMI context
   IPI6  CPU wakeup

/* Note what is NOT an IPI on ARM: TLB shootdown. TLBI ...IS
   broadcasts in hardware (chapter 15), so no interrupt is needed
   - a genuine architectural advantage over x86, which must send
   an IPI and wait for acknowledgement.                      */
```

Interrupt latency, decomposed

```
 device asserts
      │  ① propagation to the GIC, arbitration              ~10s ns
      │  ② the core has interrupts DISABLED somewhere    ◄── DOMINANT
      │     (a spinlock, a critical section)                and VARIABLE
      │  ③ exception entry: ELR/SPSR/ESR, vector fetch       ~10s cycles
      │  ④ the handler stub saves 30 registers               ~30 cycles
      │  ⑤ read ICC_IAR1_EL1, dispatch to the handler        ~10s cycles
      ▼
 your ISR's first instruction
      │  ⑥ ISR duration
      ▼
 bottom half / thread wakeup
      │  ⑦ PREEMPTION disabled somewhere                 ◄── the other
      │  ⑧ scheduler decision + context switch               big term
      ▼
 your task runs

② and ⑦ are the terms that ruin guarantees, because they depend
on the LONGEST such region anywhere in the kernel — including
in a driver you did not write.

PREEMPT_RT attacks exactly these: most spinlocks become sleeping
mutexes and handlers become threads, bounding both (OS ch. 19).

MEASURING it:
   cyclictest -t4 -p 90 -i 200 -m -D 3600     ← report the MAX
   ftrace irqsoff tracer → finds the longest disabled region
                           AND its stack trace
```

The Linux view

```
/* Linux abstracts the GIC behind IRQ DOMAINS, which map a
   hardware interrupt number to a Linux virtual IRQ number.  */

        hwirq (GIC INTID 88)  ──irq_domain──►  virq (Linux irq 24)

/* Why: an SoC may have several cascaded controllers (a GPIO
   controller behind an SPI, for instance). Each gets a domain,
   and drivers use virq numbers without caring which controller
   is underneath.                                              */

        irq = platform_get_irq(pdev, 0);      /* resolves the DT
                                                 specifier → virq */
        devm_request_threaded_irq(dev, irq, hard, thread,
                                  IRQF_ONESHOT, name, data);

/* The chip operations the GIC driver implements: */
struct irq_chip {
        void (*irq_mask)(struct irq_data *);
        void (*irq_unmask)(struct irq_data *);
        void (*irq_eoi)(struct irq_data *);
        int  (*irq_set_affinity)(struct irq_data *, const cpumask_t *, bool);
        int  (*irq_set_type)(struct irq_data *, unsigned int flow);
};

/* Return values, and why they matter: */
   IRQ_HANDLED      it was mine and I dealt with it
   IRQ_NONE         NOT mine — required on shared lines
   IRQ_WAKE_THREAD  wake the threaded handler
```

Debugging interrupts

```
# is it firing at all, and on which core?
watch -n1 'cat /proc/interrupts | grep -E "CPU|uart"'

# what does the kernel think the configuration is?
cat /sys/kernel/debug/irq/irqs/24
#   handler:  handle_fasteoi_irq
#   status:   0x00000000
#   istate:   0x00000000
#   ddepth:   0
#   wdepth:   0
#   dstate:   0x02400200
#   node:     0
#   affinity: 0-3
#   effectiv: 0
#   domain:  :interrupt-controller@2f000000
#    hwirq:   0x38            ← the raw GIC INTID
#    chip:    GICv3

cat /sys/kernel/debug/irq/domains/*

# trace them
echo 1 > /sys/kernel/debug/tracing/events/irq/enable
cat /sys/kernel/debug/tracing/trace_pipe

# how long do handlers take?
perf record -e irq:irq_handler_entry -e irq:irq_handler_exit -a
sudo bpftrace -e 'tracepoint:irq:irq_handler_entry {
        @start[cpu] = nsecs; }
    tracepoint:irq:irq_handler_exit /@start[cpu]/ {
        @us = hist((nsecs - @start[cpu]) / 1000); }'

# find long interrupts-disabled regions
echo irqsoff > /sys/kernel/debug/tracing/current_tracer
echo 0 > /sys/kernel/debug/tracing/tracing_max_latency
cat /sys/kernel/debug/tracing/trace
```

THE FIVE-QUESTION CHECKLIST FOR "MY INTERRUPT NEVER FIRES"

1. **Is the device generating it?** Read its status register directly, in a loop.
2. **Is the INTID right?** Device tree SPI numbers are relative to 32.
3. **Is the trigger type right?** An edge configuration on a level source fires once, then never.
4. **Is it enabled at all four levels?** Device, distributor, CPU interface, PSTATE.
5. **Is it routed to the core you are watching?** Check every CPU column.

In practice, the answer is (2) or (3) most of the time, and both are device tree errors rather than driver bugs.

How it shows up

Symptom	Cause
System hangs at 100% CPU in the handler	EOI'd without clearing at the device — a storm
`"irq N: nobody cared"`	A shared handler returned `IRQ_HANDLED` without handling it, or nothing owns the line

Symptom	Cause
Device works at low rate, hangs under load	Lost edge — add the re-check loop
Interrupt fires exactly once	Not EOI'd, or configured edge when it is level
Count stays zero	Wrong INTID, wrong trigger, not enabled, or routed elsewhere
Spurious INTID 1023	Acknowledged with nothing pending — a race, or a stale read
All interrupts on CPU0, poor scaling	No affinity spreading
Latency spikes on isolated cores	Interrupts not steered away
High-priority interrupt does not preempt	Binary point grouping both at one preemption level
Threaded handler storms on a level interrupt	Needs `IRQF_ONESHOT` and split EOI mode

Check yourself

- ✓ Draw the interrupt state machine and explain what ACTIVE prevents.
- ✓ Give the eight steps from device assertion to `ERET`.
- ✓ Explain why clearing at the device must precede EOI.
- ✓ Explain the two EOI modes and give two uses for the split form.
- ✓ Compare edge and level on sharing and on lost interrupts.
- ✓ Write an edge-safe handler and explain the re-check loop.
- ✓ Say why returning `IRQ_HANDLED` incorrectly breaks spurious detection.
- ✓ Name the four masking levels and the fifth thing to check.
- ✓ Explain why ARM needs no IPI for TLB shootdown.

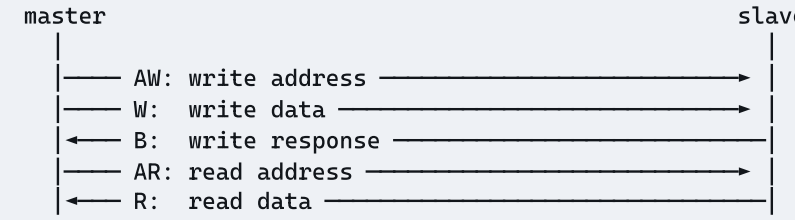
AMBA: APB, AHB, AXI, ACE and CHI

The interconnect is where a load instruction finally becomes electrical activity. Which protocol a block speaks tells you its performance class — and the sideband signals a transaction carries are the foundation of everything in the security track.

The protocol family

Protocol	Year	Character	Typical use
APB	1996	Simple, no bursts, one transfer at a time, two clock cycles minimum	Slow peripheral registers: UART, I2C, GPIO, timers
AHB	1999	Single shared bus, pipelined address/data, bursts	Cortex-M systems, simpler SoCs
AXI	2003	**Five independent channels**, out-of-order via IDs, multiple outstanding transactions	The workhorse: memory controllers, DMA, GPU
ACE	2011	AXI plus coherency: snoop channels	Coherent CPU clusters
ACE-Lite	2011	Can snoop others, has no cache to be snooped	I/O-coherent DMA masters
CHI	2013	Packet-based, credit flow control, scalable mesh	Large multi-core and server SoCs

AXI's five channels



```
Each channel is INDEPENDENT, with its own VALID/READY handshake.
Two consequences that matter enormously:

1. OUTSTANDING TRANSACTIONS. Because address and data are
   separate channels, a master can issue many addresses before
   any data returns. This is how a memory system hides 200-cycle
   DRAM latency — keep dozens of requests in flight rather than
   waiting for each. Little's Law again (CA chapter 18).

2. OUT-OF-ORDER COMPLETION. Each transaction carries an ID
   (AWID/ARID), and responses may return in any order. A slow
   DRAM read does not block a fast SRAM read behind it.

The write response channel (B) is why a write can be ACKNOWLEDGED
before it reaches the endpoint — the "early ack" in
Device-nGnRE (chapter 11), and the reason a posted write needs
a read-back to force completion.
```

What a transaction carries

> **THIS LIST IS THE FOUNDATION OF THE ENTIRE SECURITY TRACK**
> An AXI transaction is far more than an address and some data:

Signal	Carries	Used by
`AxADDR`	The physical address	Everything
`AxID`	Transaction ID — from which the SoC derives a **master ID** or **StreamID**: *who is asking*	SMMU, XPU
`AxPROT[1]`	The **NS bit**: Secure or Non-secure	**TrustZone — this one wire is the entire bus-level enforcement**
`AxPROT[0]`	Privileged or unprivileged	Peripheral protection
`AxPROT[2]`	Instruction or data fetch	Execute-never enforcement
`AxCACHE`	Cacheability and bufferability, derived from the page table's `AttrIndx`	Caches, write buffers
`AxLEN`, `AxSIZE`, `AxBURST`	Burst length, width and type	Memory controller efficiency
`AxLOCK`	Exclusive access	The global exclusive monitor (ch. 22)
`AxUSER`	Implementation-defined sideband	Vendor-specific: often carries a StreamID or QoS tag
`AxQOS`	Quality-of-service priority	Arbitration under contention

> **PAGE TABLE BITS BECOME WIRES**
> The `NS` and `AttrIndx` fields you set in a translation descriptor (chapter 14) are not abstractions. They are converted into `AxPROT[1]` and `AxCACHE` on the bus, and hardware downstream — the SMMU, the TZASC, an XPU — makes allow-or-deny decisions from them.
>
> Setting a bit in a page table entry is *setting a signal on the interconnect*. Once you see that, the whole security track stops being a separate subject.

ACE and coherency

```
ACE adds three SNOOP channels to AXI:

   AC   snoop address    the interconnect asks a master
                         "do you have this line?"
   CR   snoop response   "yes, modified" / "no" / "yes, clean"
   CD   snoop data       the master supplies the line

  This is how MESI is implemented in hardware (CA chapter 15).
  When core 0 wants a line that core 1 holds modified, the
  interconnect snoops core 1, gets the data, and forwards it -
  without going to DRAM at all.

  ACE          full coherency: can snoop AND be snooped.
               For CPU clusters with caches.
  ACE-Lite     can snoop others, but has no cache of its own.
               For DMA masters that need to see CPU-cached data.
               This is what `dma-coherent` in the device tree
               actually means (chapter 19).
  AXI          no coherency at all. Software must do cache
               maintenance (chapter 18).

  The DISTRIBUTED VIRTUAL MEMORY (DVM) messages ride on the same
  channels: TLB invalidations, instruction cache invalidations and
  synchronisation. That is what makes TLBI ...IS broadcast in
  hardware rather than needing an IPI (chapter 15).
```

CHI: scaling past a bus

```
Broadcast snooping does not scale. With 64 cores, every coherent
access would snoop 63 caches.

CHI (Coherent Hub Interface) replaces the bus model entirely:

   · PACKET-BASED, not signal-based. Requests, responses, snoops
     and data are messages on a mesh network.
   · CREDIT-BASED flow control - no combinatorial ready/valid
     paths spanning the chip.
   · A HOME NODE per address range keeps a DIRECTORY of which
     caches hold which lines, so invalidations are sent
     point-to-point rather than broadcast.
   · Scales to hundreds of nodes on a 2-D mesh.

            ┌─────┐ ┌─────┐ ┌─────┐ ┌─────┐
            │ CPU├─┤ CPU├─┤ HN ├─┤ MC │      HN = home node
            └──┬──┘ └──┬──┘ └──┬──┘ └──┬──┘      MC = memory controller
            ┌──┴──┐ ┌──┴──┐ ┌──┴──┐ ┌──┴──┐      SN = slave node
            │ CPU├─┤ CPU├─┤ SN ├─┤ IO │
            └─────┘ └─────┘ └─────┘ └─────┘

  Implementations: Arm CMN-600/650/700, and every Neoverse-based
  server SoC.

  The practical consequence for software: latency now depends on
  DISTANCE across the mesh. Two cores adjacent to each other
  communicate faster than two on opposite corners, and memory
  attached to a near controller is faster than a far one. This is
  NUMA appearing inside a single chip, and it is why scheduler
  and allocator locality matters even on "one socket".
```

APB: still everywhere

```
/* The simplest protocol, and the one most peripheral registers
   actually sit behind.                                        */

   PSEL, PENABLE, PWRITE, PADDR, PWDATA, PRDATA, PREADY, PSLVERR

/* A transfer takes a minimum of TWO cycles (setup then access),
   with no pipelining and no bursts. That is why:

     · a register read behind an APB bridge can cost 20–100 CPU
       cycles even though the peripheral is "on chip"
     · reading a status register in a tight polling loop is
       genuinely expensive
     · the APB clock is often much slower than the CPU clock,
       multiplying the cost further

   Practical consequence: minimise register accesses in hot
   paths. Cache values in software where the hardware permits,
   batch writes, and prefer a single wide read over several
   narrow ones. A driver that reads six status registers per
   interrupt is doing something measurably expensive.       */
```

Interconnect topology

```
   SHARED BUS        one set of wires, arbitration decides who
                     drives. Simple, cheap, does not scale.
                     → AHB, APB

   CROSSBAR          every master to every slave. Full parallelism
                     between disjoint pairs; area grows as N×M.
                     → small AXI interconnects (NIC-400)

   NETWORK ON CHIP   routers and links; packets find their way.
                     Scales to dozens of masters, at the cost of
                     variable latency.
                     → CMN, and most large SoC fabrics

   POINT TO POINT    dedicated links, switched.
                     → PCIe, and CHI links

A typical SoC has SEVERAL of these, layered:

   CPU cluster ──CHI──► coherent mesh ──► memory controllers
                              │
                         ──AXI──► GPU, DMA, video
                              │
                         ──AXI──► APB bridge ──► UART, I2C, GPIO
                                                 SPI, timers

  Reading a UART register therefore crosses a mesh, an AXI
  interconnect and an APB bridge. That is the real reason MMIO
  is slow — not the peripheral, the journey.
```

Quality of service and bandwidth

```
/* AxQOS gives each transaction a 4-bit priority. Interconnect
   arbiters use it to decide who wins under contention.      */

/* Why it matters in real systems: a display controller MUST get
   its data before the scan-out deadline or the screen tears.
   A CPU running a batch job can wait. Without QoS, the CPU's
   bandwidth-hungry memcpy starves the display.

   Typical assignment on a phone SoC:
      display / camera   highest — hard real-time deadlines
      GPU                high
      CPU                medium
      background DMA     low

   Configured in the interconnect's registers, usually by
   firmware, and often exposed to Linux via the interconnect
   framework:                                                */

        &display {
                interconnects = <&mmss_noc MASTER_MDP &mc_virt SLAVE_EBI1>;
                interconnect-names = "mdp0-mem";
        };

/* And in the driver: */
        path = of_icc_get(dev, "mdp0-mem");
        icc_set_bw(path, avg_bw, peak_bw);

/* MPAM (ARMv8.4) extends this to cache and memory bandwidth
   PARTITIONING, which is what mixed-criticality systems need to
   bound interference between a real-time and a best-effort
   guest (OS chapter 19).                                    */
```

Bus errors

```
/* A slave can respond with an error, and the response reaches
   the core as an ABORT.                                      */

   AXI RRESP / BRESP:
      OKAY        normal completion
      EXOKAY      exclusive access succeeded
      SLVERR      the slave signalled an error — unclocked
                  peripheral, illegal register, denied access
      DECERR      no slave at that address — a DECODE error

/* How software sees them:

   SYNCHRONOUS — for a read, or a non-posted write, the core is
   still waiting, so the abort is precise:
      ESR_EL1.EC   = 0x24/0x25 (data abort)
      ESR_EL1.DFSC = 0b010000  (synchronous external abort)
      FAR_EL1      = the address

   ASYNCHRONOUS — for a POSTED write, the core moved on long ago.
   The error arrives as an SError, and the reported PC has
   NOTHING to do with the cause. This is the hardest fault class
   to attribute, and it is exactly what an XPU denial of a posted
   write produces (security track, chapter 20).

   Mitigation: ESB (Error Synchronization Barrier) at known
   points confines an SError to a bounded region of code, making
   attribution possible. The RAS extension adds error records
   describing what failed.                                    */
```

Observing the interconnect

```
# the memory map — what lives where
cat /proc/iomem

# interconnect bandwidth requests (where the framework is used)
cat /sys/kernel/debug/interconnect/interconnect_summary

# PMU events for bus traffic
perf stat -e bus_access,bus_access_rd,bus_access_wr,\
bus_cycles,mem_access ./prog

# many SoCs expose interconnect PMUs — CMN, DSU, memory controller
perf list | grep -iE 'cmn|arm_dsu|imc'
perf stat -e arm_cmn/hnf_cache_miss/ ./prog

# bandwidth saturation is the usual finding: if bus_access is
# high and IPC is low with few cache misses, you are waiting on
# the interconnect, not on DRAM latency.

# in a JTAG debugger, most vendors provide interconnect trace —
# Arm CoreSight can capture bus transactions directly, which is
# the definitive way to see what actually reached a peripheral.
```

How it shows up

Symptom	Cause
Register access is far slower than expected	APB bridge with a slow clock; batch or cache accesses
External abort reading a peripheral	DECERR — nothing at that address; or SLVERR — unclocked
SError with an unrelated PC	A posted write was rejected long after it was issued
Write appears to succeed but has no effect	Posted write; read back to force completion
Display tearing under CPU load	QoS not configured; CPU starving the display of bandwidth
DMA works but is not coherent	Master is on plain AXI, not ACE-Lite
Latency varies with which cores communicate	Mesh distance — NUMA within one chip
Exclusives fail on a shared region	`AxLOCK` not supported by that slave, or Device memory
Access denied with no obvious reason	An interconnect firewall checking master ID and NS bit
Bandwidth-bound despite low miss rates	Interconnect saturation, not DRAM

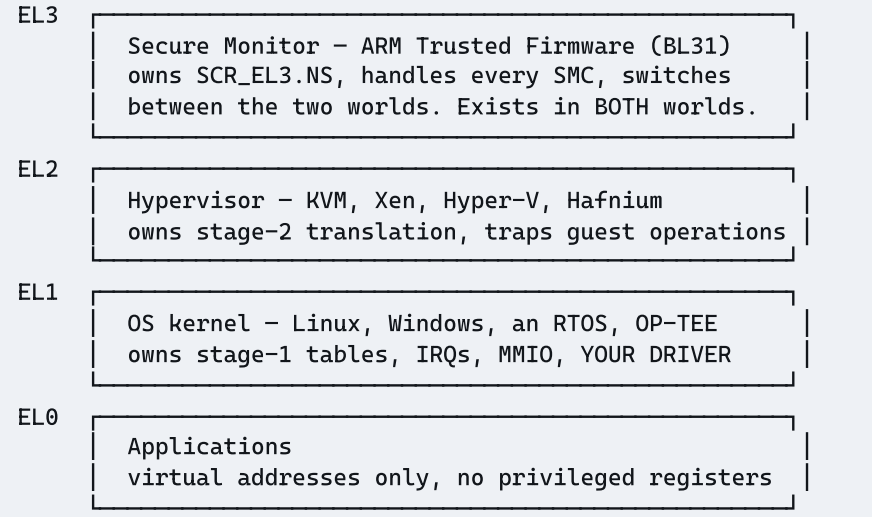
Check yourself

- ✓ Name the AMBA protocols and say what class of block uses each.
- ✓ Explain AXI's five channels and the two properties they enable.
- ✓ List what a transaction carries besides address and data, and why security depends on it.
- ✓ Explain how a page table bit becomes a bus signal.
- ✓ Distinguish ACE, ACE-Lite and plain AXI for a DMA master.
- ✓ Explain why CHI replaced broadcast snooping and what that means for software locality.
- ✓ Say why an APB register read can cost a hundred cycles.
- ✓ Distinguish SLVERR from DECERR, and synchronous from asynchronous aborts.
- ✓ Explain what QoS is for and give an example where its absence is visible.

Exception levels

ARMv8 replaced ARMv7's processor modes with four numbered privilege levels. Every piece of system software on the machine is defined by which one it runs at, and the vocabulary of exception levels is shared by kernels, hypervisors and secure firmware alike.

The four levels



```
Higher number = more privilege, and privilege is strictly
NESTED: EL3 can do everything EL2 can, EL2 everything EL1 can.
There is no "EL0-only" capability — which is why AP bits cannot
express one (chapter 14) and PAN exists instead.

Orthogonal to all of this is the SECURITY STATE (Secure or
Non-secure), giving S-EL0, S-EL1 and S-EL2 as separate
execution contexts with their own register banks.
```

What each level uniquely controls

Level	Owns	Cannot
EL0	Its own general registers, and whatever memory EL1 mapped for it	Access system registers, execute privileged instructions, disable interrupts, touch MMIO
EL1	`TTBR0/1_EL1`, `SCTLR_EL1`, `VBAR_EL1`, interrupt masks, cache and TLB maintenance, device access	See or change stage-2 translation; escape a hypervisor
EL2	`VTTBR_EL2` (stage 2), `HCR_EL2` (traps), virtual interrupts, guest timers	Change the security state
EL3	`SCR_EL3` — the NS bit itself — interrupt routing, SMC handling	—

Which levels exist is a design choice

```
/* EL2 and EL3 are OPTIONAL. Never assume — query. */

        mrs     x0, id_aa64pfr0_el1
/*  ID_AA64PFR0_EL1:
       [3:0]    EL0 support   [7:4]   EL1
       [11:8]   EL2 support   [15:12] EL3
       0 = not implemented, 1 = AArch64 only, 2 = both states  */

static bool has_el2(void)
{
        uint64_t pfr0;
        asm volatile("mrs %0, id_aa64pfr0_el1" : "=r"(pfr0));
        return ((pfr0 >> 8) & 0xF) != 0;
}

/* Typical configurations:
     simple embedded SoC     EL0, EL1 only
     phone / tablet          all four
     server                  all four, plus S-EL2
     Cortex-M                none of this — a different model
                             entirely (chapter 02)             */

/* And note: a level EXISTING is not the same as being USED.
   Linux boots at EL2 on most platforms and immediately drops to
   EL1 unless KVM is enabled. Which level you are at right now:  */
        mrs     x0, CurrentEL        /* bits [3:2] hold the EL */
        lsr     x0, x0, #2
```

Moving between levels

> **UP ONLY BY EXCEPTION, DOWN ONLY BY `ERET`**
>
> You can never simply *jump* to a higher exception level. The only way up is to take an exception — and the entry point is the *higher* level's vector table, at an address *it* chose. That is what makes privilege enforceable: the caller supplies a number, never an address.

Direction	Mechanism
EL0 → EL1	`SVC`, an interrupt, or a fault
EL1 → EL2	`HVC`, a trapped operation, a stage-2 fault, or a routed interrupt
Any → EL3	`SMC`, a Secure interrupt, or an external abort routed to EL3
Downward	`ERET` — target EL from `SPSR_ELx.M`, target PC from `ELR_ELx`
Sideways (world switch)	EL3 changes `SCR_EL3.NS`, then `ERET`s

```
/* Dropping from EL3 to EL1 — what firmware does at the end of
   boot (OS chapter 18):                                      */

        /* configure the world we are about to enter */
        mov     x0, #(1 << 10)          /* RW=1: EL1 below is AArch64 */
        orr     x0, x0, #(1 << 0)       /* NS=1: Non-secure           */
        msr     scr_el3, x0

        /* the PSTATE to install on ERET */
        mov     x0, #0x3C5              /* M=0b0101 (EL1h), DAIF masked */
        msr     spsr_el3, x0

        ldr     x0, =kernel_entry
        msr     elr_el3, x0

        eret                            /* now at EL1, Non-secure */

/* SPSR.M[3:0] encodes the target:
      0b0000 EL0t     0b0100 EL1t     0b1000 EL2t     0b1100 EL3t
                      0b0101 EL1h     0b1001 EL2h     0b1101 EL3h

   The t/h suffix selects SP_EL0 (thread) or SP_ELx (handler)
   as the stack pointer — chapter 04.                         */
```

Where an exception is taken

```
An exception does NOT always go to the next level up. Routing is
configurable, and this is the mechanism virtualisation is built
from.

   SYNCHRONOUS exceptions (faults, SVC)
        → normally the current EL, or EL1 if from EL0
        → HCR_EL2 trap bits can redirect specific ones to EL2
        → HCR_EL2.TGE routes ALL EL0 exceptions to EL2
          (used when the host runs at EL2 with VHE)

   IRQ / FIQ / SError
        → SCR_EL3.{IRQ,FIQ,EA}   route to EL3
        → HCR_EL2.{IMO,FMO,AMO}  route to EL2 instead of EL1

   The typical configuration on a virtualised system:
        IRQ  → EL2   the hypervisor decides which guest gets it,
                     and injects a VIRTUAL interrupt via the GIC
                     list registers (chapter 23)
        FIQ  → EL3   secure interrupts, unmaskable by the guest
        SMC  → EL3   always

   And on a non-virtualised system:
        IRQ  → EL1   straight to the kernel
        FIQ  → EL3   if a secure world exists

  An exception can never be taken to a LOWER level than the one
  that was executing. So EL2 code's faults go to EL2 or EL3,
  never to EL1.
```

Per-level register banks

```
/* Each level has its OWN copy of the exception-handling
   registers. These are genuinely separate registers, not views: */

   ELR_EL1, ELR_EL2, ELR_EL3          return address
   SPSR_EL1, SPSR_EL2, SPSR_EL3       saved PSTATE
   ESR_EL1, ESR_EL2, ESR_EL3          syndrome
   FAR_EL1, FAR_EL2, FAR_EL3          fault address
   VBAR_EL1, VBAR_EL2, VBAR_EL3       vector base
   SP_EL0, SP_EL1, SP_EL2, SP_EL3     stack pointers
   TTBR0_EL1/EL2/EL3, TCR_*, MAIR_*, SCTLR_*

/* Banking these is what allows an exception at EL2 to occur while
   EL1's ELR still holds a pending return — the two do not
   collide.

   But note what is NOT banked: X0–X30. There are no banked
   general-purpose registers in AArch64 (chapter 04), which is
   why every handler must save them in software.            */

/* And Secure/Non-secure banking: the EL1 register set is banked
   AGAIN by security state, so the secure OS and the normal OS
   each have their own SCTLR_EL1, TTBR0_EL1 and so on, selected
   by SCR_EL3.NS. EL3 sees whichever the current state selects,
   which is why the monitor must save and restore them
   explicitly on a world switch.                            */
```

What runs where, in practice

Level	Non-secure	Secure
EL0	Applications, libraries	Trusted applications (keymaster, DRM, biometrics)
EL1	Linux, Windows, an RTOS	Trusted OS: OP-TEE, Trusty, QSEE
EL2	KVM, Xen, Hyper-V, pKVM	Secure partition manager: Hafnium (ARMv8.4+)
EL3	ARM Trusted Firmware — one monitor serving both worlds	

VHE: the host at EL2

```
/* The original design assumed a hypervisor was a small separate
   program at EL2 with the host OS at EL1. That is wrong for KVM,
   where the "hypervisor" IS Linux.                          */

/* Without VHE: Linux runs at EL1 with a small stub at EL2, and
   every VM entry/exit crosses between them — saving and
   restoring the host's EL1 state each time.

   With VHE (HCR_EL2.E2H = 1, ARMv8.1):
     · EL2 gains TTBR1_EL2 and behaves like the EL1&0 regime
     · EL0 can run directly under EL2 (host userspace)
     · accessing the _EL1 register names AT EL2 is REDIRECTED to
       the _EL2 equivalents
     · the _EL12 accessors reach the real guest EL1 state

   Result: an unmodified Linux kernel runs at EL2, host
   userspace at EL0, guests at EL1. The host never leaves EL2,
   so VM exits are far cheaper.                              */

        mrs     x0, id_aa64mmfr1_el1
        ubfx    x0, x0, #8, #4          /* VH field */
        cbz     x0, no_vhe

/* You can see which mode a system is in: */
//   dmesg | grep -i 'hyp mode'
//   kvm [1]: Hyp mode initialized successfully        (no VHE)
//   kvm [1]: VHE mode initialized successfully        (VHE)
```

Determining your level at runtime

```
static inline unsigned current_el(void)
{
        uint64_t el;
        asm volatile("mrs %0, CurrentEL" : "=r"(el));
        return (el >> 2) & 3;
}

/* Boot code commonly branches on this, because firmware may
   hand off at EL2 or EL1 depending on the platform:        */

        mrs     x0, CurrentEL
        cmp     x0, #(2 << 2)
        b.eq    at_el2
        cmp     x0, #(1 << 2)
        b.eq    at_el1
        b       unsupported

at_el2: /* configure EL2, then drop to EL1 - or stay if we are
           going to be a hypervisor */
        bl      init_el2
        b       drop_to_el1

at_el1: /* already where we want to be */
        bl      init_el1

/* Linux's head.S does exactly this, and the "Booted at EL2" /
   "Booted at EL1" distinction determines whether KVM can be
   used at all.                                              */
//   dmesg | grep -i 'CPU: All CPU(s) started at EL'
```

Why EL3 is special

```
EL3 is the only level that exists in BOTH security states
simultaneously. It is not "the most privileged part of the secure
world" - it is the gatekeeper between the worlds.

   Its unique responsibilities:
     · owns SCR_EL3.NS - the bit that selects which world the
       levels below are in
     · saves and restores the ENTIRE state of one world before
       switching to the other, including scrubbing registers so
       nothing leaks
     · dispatches every SMC to the right service (PSCI, a trusted
       OS, a SiP-specific function)
     · routes secure interrupts

   Consequences:
     · EL3 code is the most security-critical on the chip. A bug
       there compromises everything, in both worlds.
     · it should be SMALL. ARM Trusted Firmware's BL31 is tens of
       thousands of lines, deliberately.
     · it stays RESIDENT for the machine's whole life, unlike the
       earlier boot stages.

  The security track covers the world switch, SMC calling
  convention and the TEE stack in detail.
```

How it shows up

Symptom	Cause
KVM will not initialise	Booted at EL1, not EL2 — check firmware and `dmesg`
Undefined instruction on `MRS`	Register requires a higher exception level
`HVC` causes an undefined instruction	EL2 not implemented, or `HCR_EL2.HCD` disables it
`SMC` causes an undefined instruction	EL3 not implemented, or `SCR_EL3.SMD` set
Guest hangs on a system register write	A trap is configured and the hypervisor is not emulating it
Interrupts never reach the kernel	Routed to EL2 or EL3 by `HCR` / `SCR`
Secure interrupt unmaskable by Linux	Delivered as FIQ, routed to EL3 — by design
VM exits unexpectedly expensive	No VHE; host EL1 state saved and restored every exit
Firmware works on one SoC, not another	Assumed EL2 or EL3 exists without querying `ID_AA64PFR0_EL1`

Check yourself

- ✓ Name the four exception levels and what runs at each, in both security states.
- ✓ Explain why privilege being strictly nested means AP bits cannot express "EL0 only".
- ✓ State the rule for moving up and down between levels, and why it makes privilege enforceable.
- ✓ Decode `SPSR.M = 0b0101`.
- ✓ Explain how `HCR_EL2` and `SCR_EL3` change where an interrupt is taken.
- ✓ Say which registers are banked per level and which are not.
- ✓ Explain what VHE changes and why KVM needed it.
- ✓ Explain why EL3 is different in kind from the other levels.

Exception types and the vector table

Sixteen entries of 128 bytes each, indexed by where the exception came from and what kind it was. The layout looks arbitrary until you see what it is optimising for — and then it explains why kernel entry code is structured the way it is.

What counts as an exception

```
ARM uses "exception" as the umbrella term for anything that
diverts execution to a handler. Two families:

  SYNCHRONOUS — caused by the current instruction, reported
                PRECISELY. You know exactly which instruction.

     SVC / HVC / SMC        deliberate calls to EL1 / EL2 / EL3
     Data abort             a load or store failed translation
                            or permission checks
     Instruction abort      the FETCH itself failed
     Undefined instruction  bad encoding, or disabled at this EL
     Alignment fault        unaligned Device access, or SCTLR.A
     Trapped register access a higher EL configured a trap
     PC alignment fault     the PC was not 4-byte aligned
     SP alignment fault     SP was not 16-byte aligned
     Breakpoint / watchpoint / software step

  ASYNCHRONOUS — caused by something outside the instruction
                 stream, taken BETWEEN instructions.

     IRQ      normal interrupt.  Masked by PSTATE.I
     FIQ      fast interrupt.    Masked by PSTATE.F
     SError   System Error — typically an IMPRECISE external
              abort: an ECC failure, or a bus error from a write
              posted long ago. Masked by PSTATE.A.

  SError is the awkward one: the reported PC has NOTHING to do
  with the cause, because the failing transaction retired long
  before the error came back (chapter 25).
```

The vector table

```
VBAR_ELx holds the base address. 16 entries, 128 bytes each,
2 KB total.

VBAR + offset    source of the exception              type

  0x000   Synchronous  ┐
  0x080   IRQ / vIRQ   │  CURRENT EL, using SP_EL0
  0x100   FIQ / vFIQ   │  (SPSel = 0, "EL1t")
  0x180   SError       ┘

  0x200   Synchronous  ┐
  0x280   IRQ / vIRQ   │  CURRENT EL, using SP_ELx
  0x300   FIQ / vFIQ   │  (SPSel = 1, "EL1h")   ← the normal
  0x380   SError       ┘                           kernel case

  0x400   Synchronous  ┐
  0x480   IRQ / vIRQ   │  LOWER EL, AArch64
  0x500   FIQ / vFIQ   │  ← syscalls and user faults land here
  0x580   SError       ┘

  0x600   Synchronous  ┐
  0x680   IRQ / vIRQ   │  LOWER EL, AArch32
  0x700   FIQ / vFIQ   │  (32-bit compatibility)
  0x780   SError       ┘
```

WHY SPLIT BY SOURCE

The handler needs to know immediately whether it must switch stacks and save user state, or whether this is a nested exception already on the kernel stack. Encoding that in the *vector address* means the answer costs zero instructions — no test, no branch, no register read. On a path taken millions of times a second, that matters.

The AArch32 split exists for the same reason: a 32-bit process's register layout differs, so it needs a different save path.

Each entry is code, not an address

```
/* Unlike Cortex-M, where the vector table holds ADDRESSES, on
   A-profile each entry is 128 bytes of actual CODE — 32
   instructions. You either handle it there or branch out.  */

.macro VECTOR_ENTRY label
        .align 7                        /* 128 bytes = 2^7 */
        b       \label
.endm

        .align 11                       /* the table must be 2 KB
                                           aligned */
        .global vector_table
vector_table:
        /* current EL, SP_EL0 — should never happen in a normal
           kernel, so these are error handlers */
        VECTOR_ENTRY  invalid_sync_el1t
        VECTOR_ENTRY  invalid_irq_el1t
        VECTOR_ENTRY  invalid_fiq_el1t
        VECTOR_ENTRY  invalid_err_el1t

        /* current EL, SP_ELx — kernel-mode exceptions */
        VECTOR_ENTRY  el1_sync
        VECTOR_ENTRY  el1_irq
        VECTOR_ENTRY  el1_fiq
        VECTOR_ENTRY  el1_error

        /* lower EL, AArch64 — user-mode exceptions and syscalls */
        VECTOR_ENTRY  el0_sync
        VECTOR_ENTRY  el0_irq
        VECTOR_ENTRY  el0_fiq
        VECTOR_ENTRY  el0_error

        /* lower EL, AArch32 */
        VECTOR_ENTRY  el0_sync_compat
        VECTOR_ENTRY  el0_irq_compat
        VECTOR_ENTRY  el0_fiq_compat
        VECTOR_ENTRY  el0_error_compat

/* Installing it: */
        adr     x0, vector_table
        msr     vbar_el1, x0
        isb                             /* REQUIRED — chapter 06 */
```

ALIGNMENT IS NOT ADVISORY

`VBAR_ELx` requires **2 KB alignment** — the low 11 bits are RES0 and writing a misaligned address silently ignores them. Each entry must be exactly 128 bytes apart. Get either wrong and exceptions dispatch to the wrong handler, or into the middle of an instruction.

The symptom is spectacular and unhelpful: the machine takes an exception and immediately takes another, usually ending in an unrecoverable loop before anything can be printed. Use `.align 11` for the table and `.align 7` per entry, and verify with `readelf -s | grep vector`.

Why 128 bytes matters

```
/* 32 instructions is enough to do real work before branching,
   which several important techniques exploit:               */

/* 1. Linux's KPTI trampoline. When kernel page-table isolation
      is active, the entry code must switch TTBR1 before it can
      touch kernel memory — and that switch has to happen in the
      vector itself, using only registers.                   */

/* 2. Spectre-BHB mitigations. Some cores need a loop of branches
      or a specific instruction sequence at the very start of the
      vector to flush the branch history buffer before any
      speculation on kernel addresses can occur. Linux patches
      the vectors at boot to insert exactly the sequence that
      core requires.                                          */

/* 3. Fast paths. A hypervisor can handle a trivial trap
      entirely within the vector entry and ERET without ever
      building a full context save.                          */

/* Which is why Linux's vectors are generated by a macro with
   several variants, and why `objdump -d` of the vector region
   shows more than a single branch on modern kernels.       */
```

Virtual interrupts

```
/* When HCR_EL2.{IMO,FMO,AMO} are set, physical IRQ/FIQ/SError go
   to EL2, and the entries at EL1 receive VIRTUAL interrupts
   instead — injected by the hypervisor through the GIC list
   registers (chapter 23).                                   */

   HCR_EL2.IMO = 1   physical IRQ    → EL2
                     virtual vIRQ    → EL1
   HCR_EL2.VI  = 1   assert a virtual IRQ to the guest

/* From the guest's point of view nothing is different: it takes
   an exception at VBAR_EL1 + 0x480 exactly as it would on bare
   metal. It cannot tell the interrupt was injected.

   This is what makes guest interrupt handling fast: no
   hypervisor trap is needed for the guest to acknowledge and
   EOI, because the GIC's virtual CPU interface handles it.  */
```

What hardware does on entry

```
Before your first instruction runs, the hardware has ALREADY:

   1. ELR_ELx   ← the address to return to
   2. SPSR_ELx  ← the entire PSTATE at the moment of the exception
   3. ESR_ELx   ← the syndrome: exception class and details
   4. FAR_ELx   ← the faulting address (aborts and watchpoints)
   5. PSTATE    → EL raised, SPSel = 1, and D, A, I, F ALL MASKED
   6. PC        ← VBAR_ELx + the vector offset

  Step 5's masking is not optional and not configurable. The
  reason: ELR_ELx and SPSR_ELx are single registers, not a stack.
  A second exception before your handler saved them would
  overwrite the return address, and you could never get back.

  Your handler saves them to the kernel stack FIRST, and only
  then may unmask to allow nesting. Chapter 28 covers the full
  sequence.

  Note what is NOT saved: X0–X30. Nothing is banked in AArch64
  (chapter 04). Software saves everything.
```

The "impossible" entries

```
/* The four "current EL with SP_EL0" entries should never be taken
   in a correctly configured kernel, which runs with SPSel = 1.
   Reaching one means something is badly wrong — and that is
   exactly why they are worth implementing properly.        */

invalid_sync_el1t:
        /* We cannot trust SP. Switch to a known-good emergency
           stack before doing anything.                       */
        adr_this_cpu x0, emergency_stack, x1
        mov     sp, x0
        bl      panic_bad_mode

/* Common causes of landing here:
     · SPSel accidentally cleared
     · a corrupted SP that faulted during the save sequence
     · a fault in early boot before SP_EL1 was established
     · stack overflow — the guard page faulted, and the fault
       handler could not push a frame

   Linux handles the stack-overflow case specially with an
   OVERFLOW STACK per CPU, so a kernel stack overflow produces a
   readable oops instead of an infinite fault loop. That is worth
   copying in any serious bare-metal system.              */
```

Contrast: Cortex-M

	A-profile	**M-profile**
Table contains	**Code** — 128 bytes per entry	**Addresses** — 4 bytes per entry
Entry 0	A handler	The initial **stack pointer**
Register saving	Entirely software	Hardware stacks R0–R3, R12, LR, PC, xPSR

	A-profile	M-profile
ISR form	Assembly stub, then C	**A plain C function**
Entries	16, by source and type	One per interrupt, hundreds
Base register	`VBAR_ELx`	`VTOR`

The M-profile design costs a fixed ~12 cycles of hardware stacking on every interrupt but removes the software prologue entirely, which is why M-profile interrupt latency is both lower and far more deterministic. A-profile trades that for flexibility and for not paying the cost on exceptions that do not need it.

Inspecting the vectors

```
# where is the table?
sudo cat /proc/kallsyms | grep vectors
#   ffff800008011000 T vectors

# in gdb on a kernel or bare-metal target
p/x $VBAR_EL1
x/16i $VBAR_EL1              # the first entry
x/4i  $VBAR_EL1 + 0x400      # lower EL, synchronous — the syscall path

# check alignment
readelf -s vmlinux | grep -w vectors
#   the address must end in 0x?800 or 0x?000 — 2 KB aligned

# see what Linux patched in
sudo objdump -d --start-address=0x... vmlinux | head -60
#   on a mitigated kernel you will see BHB-flush sequences
#   before the branch
```

> **DEBUGGING A MACHINE THAT RESETS IMMEDIATELY**
> A misaligned or uninstalled vector table produces a system that appears to die instantly with no output. The diagnostic sequence: halt with JTAG at reset, single-step to the point where `VBAR` is written, read it back, and confirm the low 11 bits are zero. Then set a hardware breakpoint on `VBAR + 0x200` and `VBAR + 0x400` — whichever is hit first tells you whether the fault came from kernel or user context, which usually identifies the bug immediately.

How it shows up

Symptom	Cause
Machine resets immediately, no output	Vector table misaligned or `VBAR` never written
Exceptions dispatch to the wrong handler	Entries not exactly 128 bytes apart
Syscalls work but interrupts crash	Only some vector entries implemented
Kernel-mode faults land in the user-mode handler	Confused the 0x200 and 0x400 groups
Landing in an "invalid mode" handler	`SPSel` wrong, or a corrupted SP
Infinite fault loop on stack overflow	No separate overflow stack; the handler cannot push a frame
32-bit process crashes, 64-bit works	AArch32 vector entries not implemented
Guest interrupts never arrive	`HCR_EL2.IMO` set but no virtual interrupt injected

Symptom	Cause
Configuration change has no effect	Missing `ISB` after writing `VBAR`

Check yourself

- ✓ List the synchronous and asynchronous exception types.
- ✓ Explain why SError is harder to attribute than a data abort.
- ✓ Draw the 16-entry table and say what each group of four is for.
- ✓ Explain why the table is split by exception *source*.
- ✓ State the two alignment requirements and the symptom of getting them wrong.
- ✓ Give two things that exploit having 128 bytes per entry.
- ✓ List the six things hardware does before your handler runs.
- ✓ Explain why DAIF is masked on entry and when you may unmask.
- ✓ Give three differences between A-profile and M-profile vectoring.

Taking and returning from an exception

The single most important flow in system software. Six things happen in hardware, atomically, before your first instruction runs — and everything else is software's responsibility. Get this sequence wrong and you corrupt the program you interrupted, in ways that surface far from the cause.

What hardware does

```
  EL0 executing:  svc #0
       │          (or an IRQ arrives, or a load faults)
       ▼
═══════ HARDWARE, ATOMICALLY — nothing you wrote runs here ═══════

  1. ELR_EL1   ← the address to return to
                 · for SVC:      the instruction AFTER the svc
                 · for a fault:  the FAULTING instruction, so it
                                 can be retried after the OS
                                 fixes the mapping
                 · for an IRQ:   the next instruction to execute

  2. SPSR_EL1  ← the entire PSTATE: NZCV, DAIF, the source EL,
                 SPSel, nRW, PAN, and the rest

  3. ESR_EL1   ← the syndrome: exception class + details
                 (chapter 29)

  4. FAR_EL1   ← the faulting virtual address
                 (aborts and watchpoints only; stale otherwise)

  5. PSTATE    → EL = 1
                 SPSel = 1        (switch to SP_EL1)
                 D, A, I, F ALL MASKED
                 PAN set, if SCTLR_EL1.SPAN says so

  6. PC        ← VBAR_EL1 + the vector offset for
                 (source EL, exception type)

═══════════════════════════════════════════════════════════════════
       │
       ▼
  your handler's first instruction
```

NOTICE WHAT IS NOT SAVED

`X0` – `X30` are untouched. AArch64 has **no banked general-purpose registers** (chapter 04). Your handler begins executing with the interrupted code's register values still live, and every one of them must be preserved by software before you can use it.

That saved set is `struct pt_regs` in Linux and the trap frame in Windows, and building it correctly is the entire job of the vector stub.

The entry stub

```
the shape every AArch64 OS has, simplified from Linux's entry.S
```

```
el0_sync:
        /* SP is now SP_EL1 — the kernel stack for this thread.
           The hardware switched it for us because SPSel became 1.
           This is exactly why per-EL stack pointers exist: a
           corrupt user SP cannot take the kernel down.        */

        sub     sp, sp, #S_FRAME_SIZE       /* room for pt_regs   */

        b.eq    el0_ia
        b       el0_inv

el0_svc:
        mov     x0, sp                      /* pass pt_regs to C  */
        bl      do_el0_svc
        b       ret_to_user
```

THE ORDERING RULE

Save `ELR` and `SPSR` before unmasking interrupts. They are single registers, not a stack. A nested exception arriving between entry and the save overwrites the return address, and the interrupted program is unrecoverable.

This is why hardware masks DAIF on entry, and why the mask is cleared only after the save is complete.

The return path

```
ret_to_user:
        /* mask interrupts again — the restore must be atomic with
           respect to a new exception                            */
        msr     daifset, #2

        /* work that must happen before returning to userspace */
        ldr     x1, [tsk, #TSK_TI_FLAGS]
        and     x2, x1, #_TIF_WORK_MASK
        cbnz    x2, work_pending            /* signals? resched?  */

finish_ret_to_user:
        /* restore the exception state */
        ldp     x21, x22, [sp, #16 * 16]
        msr     elr_el1,  x21
        msr     spsr_el1, x22

        ldp     x30, x23, [sp, #16 * 15]
        msr     sp_el0,   x23               /* the user stack     */

        /* restore the general registers */
        ldp     x0,  x1,  [sp, #16 * 0]
        /* ... through x28, x29 ... */

        add     sp, sp, #S_FRAME_SIZE

        eret                                /* back to EL0        */

/* ERET restores PC from ELR_EL1 and PSTATE from SPSR_EL1,
   ATOMICALLY. That atomicity is the point: there is no window in
   which the privilege has changed but the PC has not, or vice
   versa. Any such window would be exploitable.               */
```

The ELR subtlety

Exception	`ELR` points at	Because
`SVC`, `HVC`, `SMC`	The instruction **after**	The call completed; resume past it
Data abort, instruction abort	**The faulting instruction**	The OS fixes the mapping and *retries* it
IRQ, FIQ	The next instruction to execute	Nothing failed; resume normally
Undefined instruction	The undefined instruction	So an emulator can inspect and emulate it
Trapped register access	The trapped instruction	The hypervisor emulates it

```
/* CONSEQUENCE: if you EMULATE an instruction, you must advance
   ELR yourself, or you will re-execute it forever.          */

        mrs     x0, elr_el2
        add     x0, x0, #4              /* A64 is fixed-width */
        msr     elr_el2, x0
        eret

/* This is the single most common hypervisor and emulation bug —
   an infinite loop that looks like a hang, with the guest
   apparently frozen on one instruction. Chapter 31.

   For AArch32 the step is 2 or 4 depending on Thumb, which is
   why compat emulation code reads SPSR to decide.          */
```

Nesting

```
Interrupts CAN nest, once the handler has saved ELR and SPSR:

   EL0 running
        | IRQ (priority 0x80)
        ▼
   el0_irq: save regs, save ELR/SPSR
            msr daifclr, #2          ← now nesting is permitted
            handle interrupt A
        | higher-priority IRQ arrives (priority 0x40)
        ▼
   el1_irq: save regs, save ELR_EL1/SPSR_EL1 to THIS stack frame
            handle interrupt B
            restore, eret
        |
        ▼ back in interrupt A's handler
            finish, restore, eret
        |
        ▼ back to EL0

  Note the second entry used the "current EL, SP_ELx" vector at
  0x280, not the "lower EL" one at 0x480 — which is exactly why
  the table is split by source (chapter 27). The second handler
  does NOT need to switch stacks or save SP_EL0.

  The GIC's priority mechanism decides whether B preempts A
  (chapter 24). Linux by default does NOT nest ordinary
  interrupts — it keeps them masked and relies on short handlers
  plus threaded IRQs instead. Nesting is used for pseudo-NMIs.
```

Dropping to a lower level

```
/* The same ERET mechanism is used to LAUNCH software at a lower
   level — which is how every boot handover works (OS ch. 18). */

/* EL3 firmware handing off to a kernel at EL1: */
        mov     x0, #(1 << 10)          /* SCR.RW = AArch64 below  */
        orr     x0, x0, #(1 << 0)       /* SCR.NS = Non-secure     */
        msr     scr_el3, x0

        mov     x0, #0x3C5              /* SPSR.M = 0b0101 = EL1h  */
                                        /* DAIF all masked         */
        msr     spsr_el3, x0

        ldr     x0, =kernel_entry
        msr     elr_el3, x0

        /* the kernel's boot contract: x0 = DTB, x1-x3 = 0 */
        ldr     x0, =dtb_address
        mov     x1, xzr
        mov     x2, xzr
        mov     x3, xzr

        eret

/* Note there is no "jump to EL1" instruction. ERET is the only
   way down, and it takes its target from SPSR and ELR. Which
   means firmware must construct a plausible "saved state" for a
   context that never actually ran.                          */
```

The cost

```
   hardware entry (steps 1–6)          ~10–20 cycles
   save 31 registers + 3 system regs   ~35 stores, ~20–40 cycles
   dispatch on ESR                     ~5–10 cycles
   ──────────────────────────────────────────────
   entry total                         ~50–100 cycles

   ...handler...

   restore + ERET                      ~50–100 cycles

   Plus the INDIRECT costs, which usually dominate:
     · pipeline flush on entry and on ERET
     · I-cache and branch predictor now hold handler state
     · with KPTI, TWO address-space switches per syscall
     · Spectre-BHB mitigation sequences in the vector

   Which is why a "null" syscall costs 50–500 ns rather than the
   ~30 cycles the register saving suggests, and why io_uring and
   the vDSO exist (OS chapter 03).

  OPTIMISATIONS real kernels use:
     · save only what is needed on the fast path (Linux saves
       everything, for simplicity and for ptrace)
     · a dedicated fast path for SVC that skips fault-handling
       setup
     · the vDSO, removing the exception entirely for
       clock_gettime and similar
```

Stack handling

```
/* Three stack pointers are in play on a user-to-kernel entry:

     SP_EL0   the user stack. Saved into pt_regs, and RESTORED on
              return. The kernel never runs on it.
     SP_EL1   the kernel stack for THIS THREAD. The hardware
              switches to it automatically (SPSel = 1).
     the IRQ stack (Linux)  a separate per-CPU stack that deep
              interrupt handling switches to, so a deeply nested
              interrupt cannot overflow the thread's 16 KB stack.

   And the OVERFLOW stack: Linux reserves a per-CPU stack used
   ONLY when a kernel stack overflow is detected via the guard
   page. Without it, the overflow fault handler would itself fail
   to push a frame, producing an infinite fault loop with no
   diagnostic. With it, you get a readable oops.           */

/* The kernel stack pointer for a thread is established at
   context switch time, from the task structure. `current` is
   read from SP_EL0 while at EL1 — the register is otherwise
   unused there, so Linux repurposes it as a per-CPU pointer to
   the current task (OS chapter 04).                       */
```

Debugging entry and exit

```
# Linux prints the saved state in an oops
dmesg | grep -A25 'Internal error'
#   pc : do_something+0x48/0x120
#   lr : caller+0xb4/0x1f0
#   sp : ffff800009abc000
#   x29: ...  x28: ...  x27: ...
#   Call trace:
#     do_something+0x48/0x120
#     ...
#     el0_svc_common+0x88/0x1a0      ← arrived via a syscall
#   pstate: 60400009 (nZCv daif +PAN -UAO)   ← chapter 05

# in gdb on a kernel target
p/x $ELR_EL1
p/x $SPSR_EL1
p/x $ESR_EL1
p/x $SP_EL0

# breakpoint on the vector itself
b *($VBAR_EL1 + 0x400)      # lower EL, synchronous

# trace syscall entry and exit
echo 1 > /sys/kernel/debug/tracing/events/raw_syscalls/enable
cat /sys/kernel/debug/tracing/trace_pipe

# measure the cost
perf bench syscall basic
perf stat -e raw_syscalls:sys_enter ./prog
```

READING WHICH VECTOR WAS TAKEN

In a crash dump, `SPSR`'s low bits tell you the source context — `0b0000` is EL0t (a user-mode exception, so the 0x400 group), `0b0101` is EL1h (a kernel-mode one, the 0x200 group). Combined with `ESR`'s exception class this pins down exactly which of the sixteen entries ran, which usually identifies the bug immediately.

How it shows up

Symptom	Cause
Interrupted program corrupted after an interrupt	Vector stub failed to save all general registers
Corrupted return address in a nested exception	Unmasked interrupts before saving `ELR` / `SPSR`
Emulated instruction executes forever	`ELR` not advanced past it
Page fault loops on the same address	Correct — until the OS fixes the mapping; if it never does, the OS bug is elsewhere
Returns to the wrong exception level	Wrong `M[3:0]` in `SPSR`
User stack corrupted after a syscall	`SP_EL0` not saved and restored
Infinite fault loop with no output	Stack overflow with no separate overflow stack
Signals never delivered	No work-pending check on the return path
Syscalls unexpectedly slow after a kernel update	KPTI or Spectre mitigations in the entry path
TLS broken after a hand-written context switch	`TPIDR_EL0` not restored

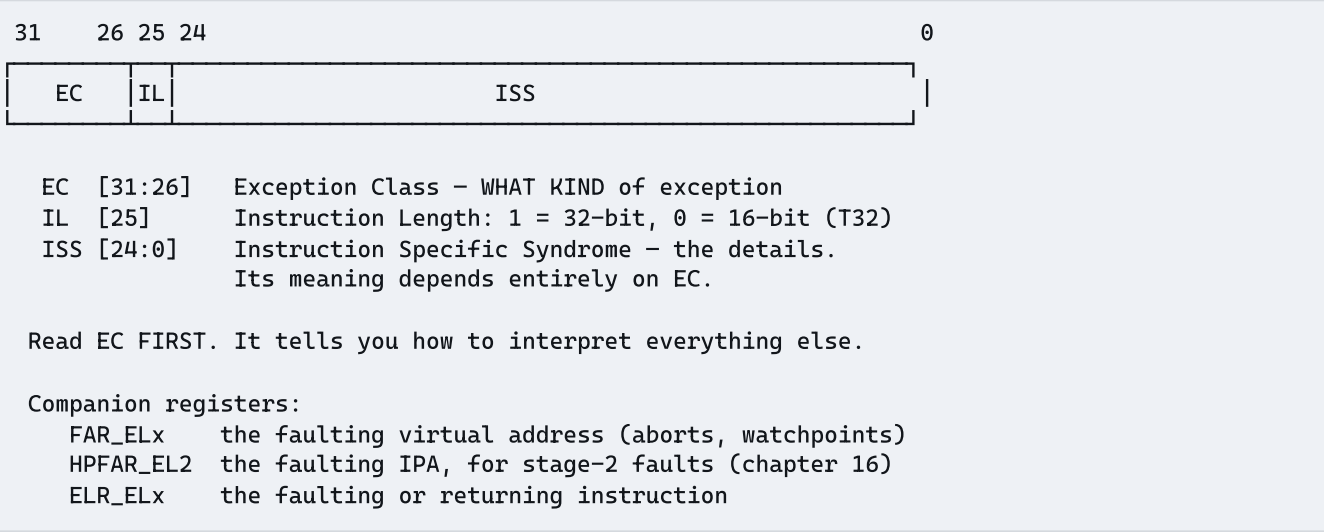
Check yourself

- ✓ List, in order, the six things hardware does on exception entry.
- ✓ Explain why general-purpose registers are not saved and what software must do.
- ✓ State the ordering rule about `ELR` / `SPSR` and unmasking, and why.
- ✓ Say where `ELR` points for an `SVC`, a data abort and an emulated instruction.
- ✓ Explain why `ERET` must be atomic.
- ✓ Explain how nesting works and which vector entry the second exception uses.
- ✓ Show how firmware uses `ERET` to launch a kernel at a lower level.
- ✓ Explain why an overflow stack exists and what happens without one.

ESR: decoding any fault

One register tells you exactly why the last exception happened. Learn its layout and you can read any crash — a kernel oops, a bare-metal hang, a hypervisor trap — and know within seconds what went wrong and where to look next.

The register



Exception classes

EC	Meaning	Usual cause
`0x00`	Unknown reason	A genuinely undefined instruction, or an instruction disabled at this EL
`0x01`	Trapped `WFI` / `WFE`	A hypervisor trapping guest idling
`0x07`	Trapped FP/SIMD access	Lazy FPU switching — `CPACR_EL1.FPEN`
`0x0E`	Illegal execution state	Bad `SPSR` on `ERET`; `PSTATE.IL` set
`0x15`	**`SVC` from AArch64**	**A system call**
`0x16`	`HVC` from AArch64	Hypervisor call
`0x17`	`SMC` from AArch64	Secure monitor call
`0x18`	Trapped `MSR` / `MRS`	A higher EL intercepted a system register access
`0x19`	Trapped SVE access	Lazy SVE state management
`0x20` / `0x21`	Instruction abort, lower / same EL	Fetch failed: unmapped, or execute-never
`0x22`	PC alignment fault	PC not 4-byte aligned — usually a corrupted function pointer
`0x24` / `0x25`	**Data abort, lower / same EL**	**The most common fault**
`0x26`	SP alignment fault	SP not 16-byte aligned (ch. 09)
`0x2C`	Floating-point exception	A trapped FP condition
`0x2F`	SError	Imprecise external abort — see below
`0x30` – `0x35`	Breakpoint, software step, watchpoint	Debug

EC	Meaning	Usual cause
`0x3C`	`BRK` instruction	A software breakpoint — `BUG()` in Linux

> **THE PAIRING RULE**
>
> Notice `0x20` / `0x21` and `0x24` / `0x25`. The lower value means the exception came from a *lower* exception level; the higher means it came from the *same* level. So `EC = 0x24` in a Linux oops means userspace faulted; `0x25` means the kernel did. That single bit tells you immediately whether you are looking at a user bug or a kernel bug.

Data abort ISS

```
EC = 0x24 or 0x25. The ISS layout:

 24 23 22 21 20 19    16 15 14 13 12 11 10  9  8  7  6 5      0
┌──┬──┬──┬──┬──┬────────┬──┬──┬──┬──┬──┬──┬──┬──┬──┬──┬────────┐
│ISV│SAS │SSE│SRT      │SF│AR│VNCR│  │ │EA│CM│S1PTW│WnR│ DFSC │
└──┴──┴──┴──┴──┴────────┴──┴──┴──┴──┴──┴──┴──┴──┴──┴──┴────────┘

   DFSC  [5:0]   Fault Status Code — THE key field
   WnR   [6]     0 = read, 1 = write
   S1PTW [7]     the fault occurred on a stage-1 PAGE TABLE WALK
   CM    [8]     the fault was on a cache maintenance instruction
   EA    [9]     external abort type
   FnV   [10]    FAR is NOT valid
   SET   [12:11] synchronous error type
   AR    [14]    the access was acquire/release
   SF    [15]    64-bit register width
   SRT   [20:16] the destination REGISTER number
   SSE   [21]    sign-extended
   SAS   [23:22] access size: 0=byte 1=half 2=word 3=dword
   ISV   [24]    SAS/SRT/SF/SSE are VALID
```

Fault status codes

DFSC	Meaning	What to check
`0b0000LL`	Address size fault, level LL	Output address exceeds the configured PA size (`TCR.IPS`)
`0b0001LL`	**Translation fault, level LL**	**Not mapped.** Null pointer, missing `ioremap`, or a wrong `TTBR`
`0b0010LL`	Access flag fault, level LL	`AF` clear in the descriptor (ch. 14)
`0b0011LL`	**Permission fault, level LL**	**Mapped, but not for this.** AP bits, XN, or PAN
`0b010000`	Synchronous external abort	**The bus refused it.** Clock, power, or a firewall (ch. 25)
`0b0101LL`	External abort on a table walk	The page table memory itself is unreachable
`0b011000`	Synchronous parity/ECC error	Memory corruption detected by hardware
`0b100001`	Alignment fault	Unaligned Device access, or `SCTLR.A`
`0b110000`	TLB conflict abort	Break-before-make violation (ch. 15)
`0b111101` / `0b111110`	Section/page domain fault	AArch32 only

THE FOUR-WAY TRIAGE

- **Translation fault** — the address is simply not mapped. Null pointer, use-after-free, a missing `ioremap`, or a stale pointer.
- **Permission fault** — it *is* mapped, just not for this operation. Writing to read-only, executing no-execute, EL0 touching an EL1 page, or PAN blocking a kernel access to user memory.
- **Access flag fault** — the `AF` bit was clear. Normal in an OS that uses AF for page aging; a bug in hand-written table code.
- **External abort** — translation *succeeded* and the transaction went out on the bus, and something out there refused it. This is a hardware or platform problem, not a page table one: an unclocked peripheral, a powered-down domain, a wrong address, or an access-control block denying you.

That one distinction — page tables versus the bus — sends you to completely different parts of the system, and it is why reading DFSC first saves hours.

A decoder worth keeping

```
drop this into any bare-metal or kernel fault handler
```

```
static const char *dfsc_name(unsigned dfsc)
{
        switch (dfsc & 0x3C) {
        case 0x00: return "address size fault";
        case 0x04: return "TRANSLATION fault (not mapped)";
        case 0x08: return "access flag fault (AF clear)";
        case 0x0C: return "PERMISSION fault (mapped, wrong perms)";
        }
        switch (dfsc) {
        case 0x10: return "EXTERNAL ABORT (bus refused it)";
        case 0x18: return "parity/ECC error";
        case 0x21: return "ALIGNMENT fault";

        }
}
```

Worked examples

```
/* ESR = 0x96000004, FAR = 0x0000000000000000 */
   EC   = 0x96000004 >> 26 = 0x25   data abort, SAME EL (kernel)
   ISS  = 0x000004
   DFSC = 0x04 = 0b000100          translation fault, level 0
   WnR  = 0                        a READ
   FAR  = 0                        address zero
   → A KERNEL NULL POINTER DEREFERENCE, on a read.
     Level 0 because nothing at all is mapped at address 0.

/* ESR = 0x9200004F, FAR = 0x0000ffff8a3c1000 */
   EC   = 0x24                     data abort, LOWER EL (user)
   DFSC = 0x0F = 0b001111          permission fault, level 3
   WnR  = 1                        a WRITE
   → Userspace wrote to a read-only page. A .rodata write, or a
     copy-on-write page that has not yet been copied (OS ch. 13).

/* ESR = 0x96000010, FAR = 0x0000000040001000 */
   EC   = 0x25                     kernel
   DFSC = 0x10                     EXTERNAL ABORT
   → Translation SUCCEEDED. The bus refused it. Check: is the
     peripheral clocked? Powered? Is an XPU denying access?
     This is NOT a page table problem.

/* ESR = 0x86000007, FAR = 0x0000000000401234 */
   EC   = 0x21                     INSTRUCTION abort, same EL
   DFSC = 0x07 = 0b000111          translation fault, level 3
   → Tried to FETCH from an unmapped page. A corrupted function
     pointer, or a jump into freed memory.

/* ESR = 0x56000000 */
   EC   = 0x15                     SVC from AArch64
   ISS  = 0                        svc #0
   → A normal system call. Not an error at all.
```

SError: the hard one

```
/* EC = 0x2F. The ISS layout is different again: */
   IDS  [24]     IMPLEMENTATION DEFINED syndrome
   AET  [12:10]  Asynchronous Error Type
                   0 = uncontainable
                   1 = unrecoverable
                   2 = restartable
                   3 = recoverable
                   6 = corrected
   EA   [9]      external abort
   DFSC [5:0]    0x00 = uncategorised, 0x11 = asynchronous SError

/* The problem: an SError is reported at an arbitrary later
   instruction. ELR points at whatever was executing when the
   error was finally taken — which has NOTHING to do with the
   transaction that failed.

   Typical causes:
     · a POSTED WRITE rejected by an access-control block long
       after the store retired (chapter 25, security ch. 20)
     · an ECC error discovered on a writeback
     · a device signalling an error asynchronously

   How to narrow it down:
     1. ESB (Error Synchronization Barrier) at known points
        confines an SError to a bounded region, so you can
        bisect where it originates:
              esb
        Place them around suspect code and see which region
        produces it.
     2. The RAS extension adds ERR<n>STATUS records describing
        exactly which node reported the error.
     3. Vendor-specific error registers in the interconnect —
        an XPU usually LATCHES the offending address and master
        ID even when the CPU cannot attribute it.

   Linux prints these when it can:
        dmesg | grep -i 'SError\|RAS\|EDAC'                */
```

Reading a Linux oops

```
Unable to handle kernel NULL pointer dereference at virtual address 0000000000000010

/* Reading it in order:
     EC 0x25   → the KERNEL faulted, not userspace
     FSC 0x06  → translation fault at level 2
     WnR 0     → a READ
     FAR 0x10  → address 16 — a NULL pointer plus a 16-byte
                 field offset. So: a null struct pointer, and
                 the field is at offset 0x10.
     pstate +PAN → PAN was on, so this was NOT an attempt to
                 read user memory
     call trace → arrived via a read() syscall from `cat`

   Conclusion: my_read() dereferenced a null pointer and read the
   member at offset 16. Find it: */

scripts/faddr2line vmlinux my_read+0x48
pahole -C my_device mydriver.ko | grep -A2 'offset:.*16'
```

Stage-2 faults

```
/* Taken to EL2, with ESR_EL2. Two extra things to read: */

   HPFAR_EL2      the faulting IPA:  (HPFAR & ~0xF) << 8
   FAR_EL2        the guest VA, when available
   ESR_EL2.S1PTW  set → the GUEST'S PAGE TABLES are in an
                  unmapped IPA. The guest did nothing wrong; the
                  hypervisor has not mapped the memory holding
                  its tables.

/* And ISV/SAS/SRT are what make MMIO emulation possible without
   decoding the instruction (chapter 16):                    */

        if (esr & ESR_ISV) {
                int size = 1 << ((esr >> 22) & 3);
                int reg  = (esr >> 16) & 0x1F;
                bool wr  = esr & (1 << 6);
                emulate(ipa, reg, size, wr);
        } else {
                decode_instruction_slowly();    /* rare */
        }
```

How it shows up

ESR pattern	Diagnosis
EC 0x25, DFSC 0b0001xx, FAR near 0	Kernel null pointer dereference
EC 0x24, DFSC 0b0001xx	Userspace segfault — normal, handled by the OS
EC 0x25, DFSC 0b0011xx, WnR=1	Kernel wrote to read-only memory
EC 0x25, DFSC 0b0011xx, PAN set	Kernel dereferenced a user pointer directly
DFSC 0b010000	External abort — clock, power, or a bus firewall
S1PTW set	The page tables themselves are unreachable
EC 0x21, DFSC translation	Jumped to unmapped memory — corrupted function pointer
EC 0x26	SP alignment — hand-written assembly, or stack corruption
EC 0x22	PC alignment — a corrupted branch target
DFSC 0b110000	TLB conflict — break-before-make violation
EC 0x2F	SError — the reported PC is meaningless; use ESB to bisect
EC 0x18	A trapped system register — a hypervisor is watching
EC 0x0E	Illegal execution state — usually a bad `SPSR` on `ERET`

Check yourself

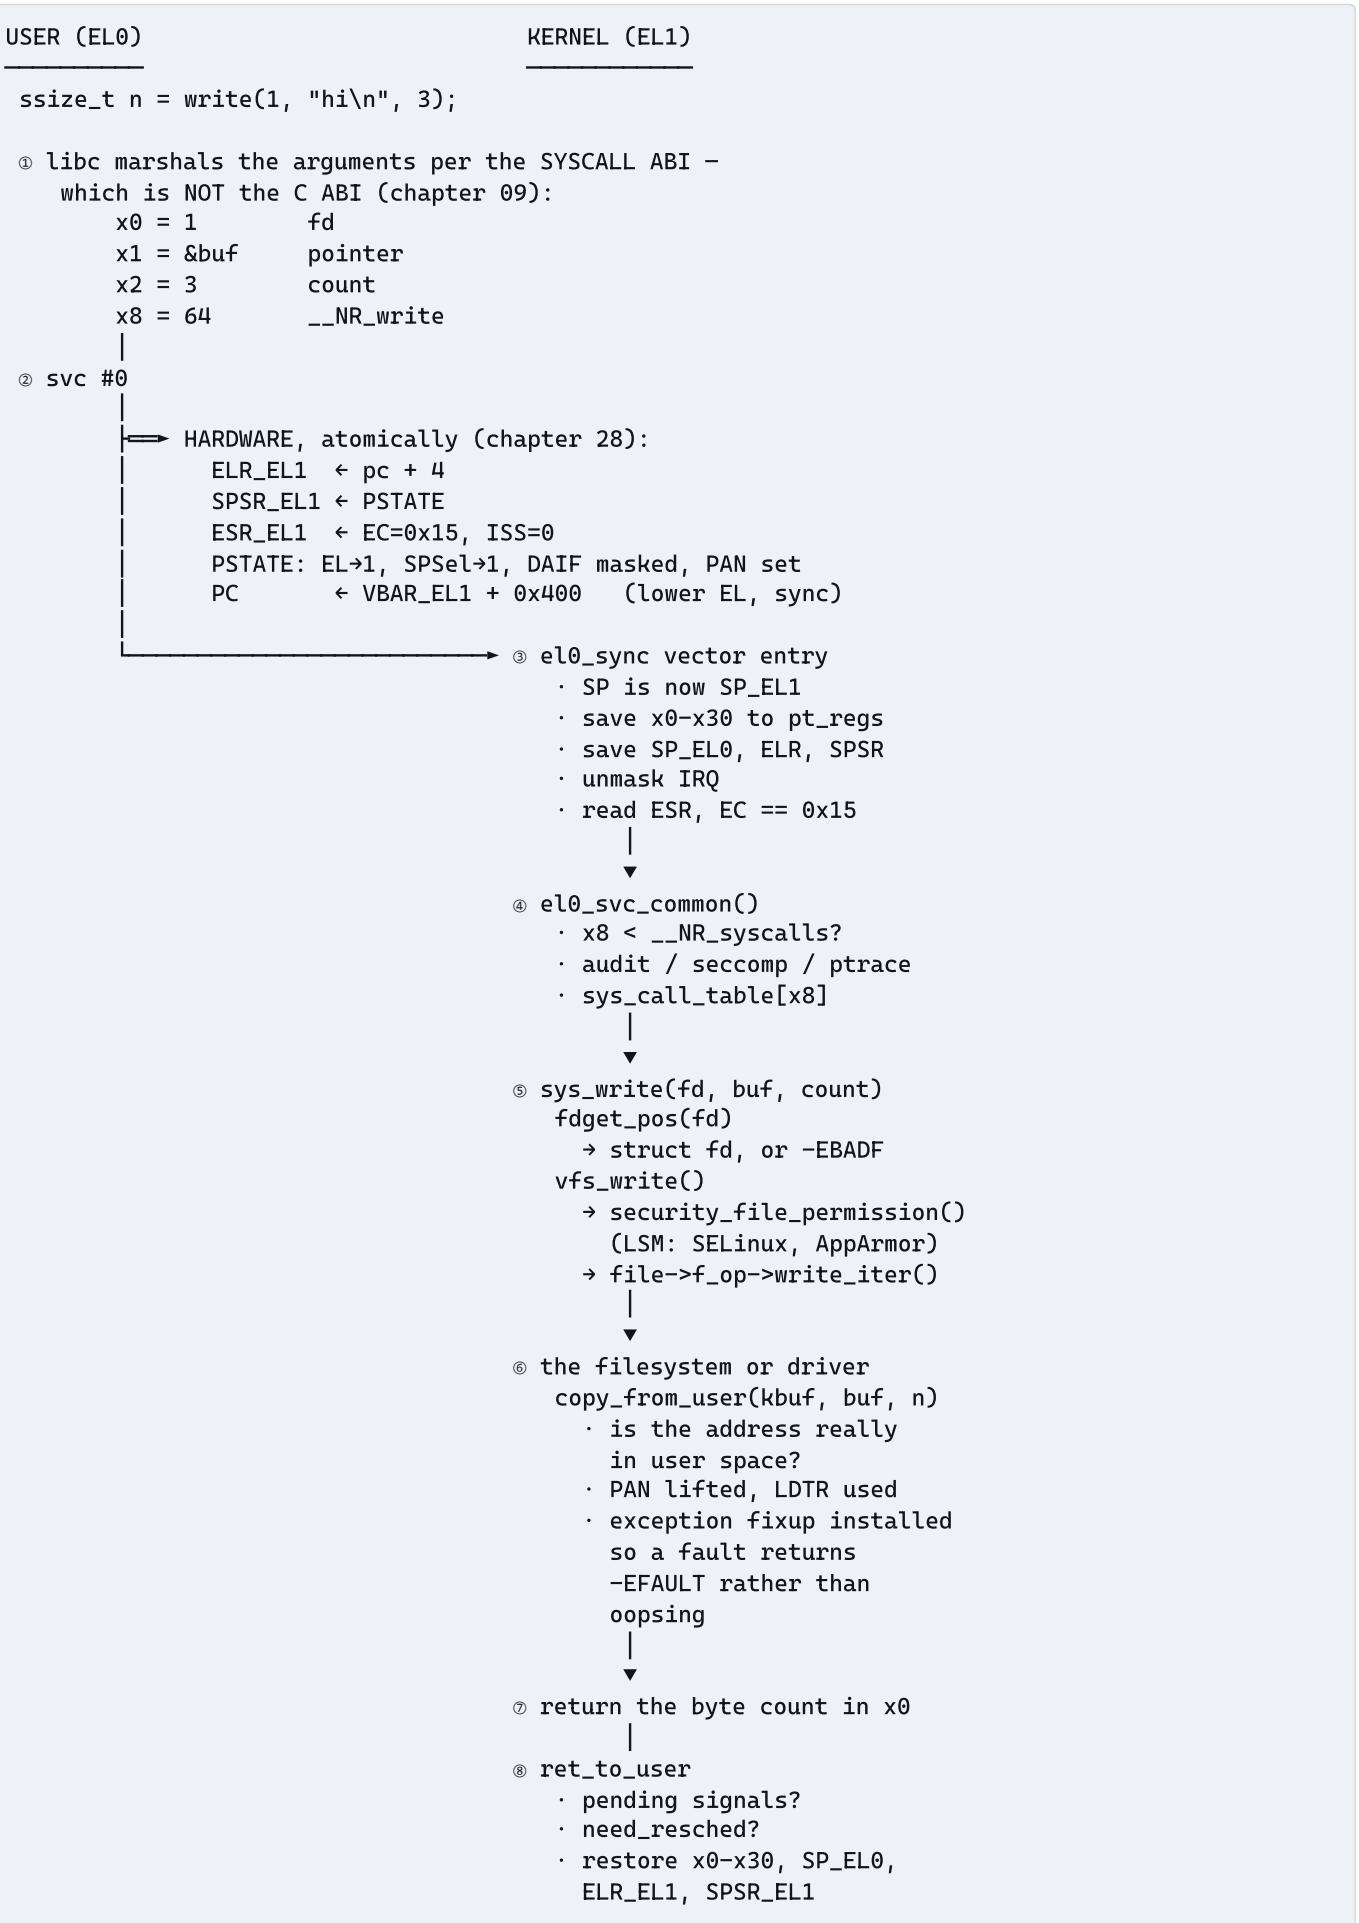
- ✓ Give the three fields of ESR and say which one to read first.
- ✓ Explain the difference between EC 0x24 and 0x25, and why it matters immediately.
- ✓ Give the four main DFSC categories and what each sends you to investigate.
- ✓ Explain why an external abort is not a page table problem.
- ✓ Decode `ESR = 0x96000004, FAR = 0` into plain English.

- ✓ Explain what `S1PTW` means and what it implies about the tables.
- ✓ Explain why SError cannot be attributed from `ELR`, and two ways to narrow it down.
- ✓ Explain how `ISV` / `SAS` / `SRT` enable MMIO emulation.

A system call, end to end

Everything in this track converging on one path. Follow `write(fd, buf, len)` from a C call to the return value, naming every register, every check and every layer — and the whole architecture stops being a collection of separate topics.

The complete path



```
                                          |
        ┌<──────────────────────── ⑨ eret
        |
        ▼
 ⑩ libc: is x0 negative and >= -4095?
        yes → errno = -x0; return -1
        no  → return x0
        |
        ▼
 your code continues
```

Step 1: the syscall ABI

```
/* The syscall ABI differs from the C ABI in two ways that matter: */

   C ABI:       arguments in x0–x7, return in x0
   syscall ABI: arguments in x0–x5 ONLY, syscall number in x8,
                return in x0

/* Why x8 rather than x7? Because it keeps the argument registers
   contiguous and leaves x8 — the indirect result register, which
   a syscall never needs — free for the number.

   Why only six arguments? Because no Linux syscall needs more.
   Those that would (mmap, clone3) pass a POINTER TO A STRUCT
   instead, which is also how they stay extensible (OS ch. 03). */

/* A raw syscall in assembly: */
        mov     x0, #1                  /* fd = stdout */
        adr     x1, msg
        mov     x2, #3
        mov     x8, #64                 /* __NR_write  */
        svc     #0
        /* x0 now holds the result, or a negative errno */

/* From C, without libc: */
static inline long syscall3(long n, long a, long b, long c)
{
        register long x8 asm("x8") = n;
        register long x0 asm("x0") = a;
        register long x1 asm("x1") = b;
        register long x2 asm("x2") = c;
        asm volatile("svc #0"
                     : "+r"(x0)
                     : "r"(x8), "r"(x1), "r"(x2)
                     : "memory", "cc");
        return x0;
}
/* Note "memory": the kernel may modify anything the pointers
   reach, so the compiler must not cache values across it
   (C chapter 18).                                          */
```

Step 4: dispatch

```
/* The syscall table is an array of function pointers — exactly
   the dispatch table pattern from C chapter 12.            */

const syscall_fn_t sys_call_table[__NR_syscalls] = {
        [0 ... __NR_syscalls - 1] = __arm64_sys_ni_syscall,
#include <asm/unistd.h>
};

/* The bounds check is not optional, and on a speculating core it
   must survive speculation (CA chapter 12):                */

        if (scno < __NR_syscalls) {
                scno = array_index_nospec(scno, __NR_syscalls);
                /* → CMP + CSEL + CSDB: a MASK, not a branch, so
                     speculation cannot bypass it            */
                syscall_fn = sys_call_table[scno];
                ret = syscall_fn(regs);
        } else {
                ret = do_ni_syscall(regs, scno);
        }

/* Before dispatch, several hooks may intervene:
     ptrace       a debugger can inspect or change the arguments,
                  or skip the call entirely
     seccomp      a BPF filter can allow, deny, kill or trap
     audit        logging
   Each costs cycles, which is why a heavily-sandboxed process
   has measurably slower syscalls.                          */
```

Step 6: crossing the boundary

> **EVERY BYTE FROM USER SPACE IS HOSTILE**
>
> A system call argument is attacker-controlled input arriving at the highest privilege level. The kernel must assume the caller is malicious, not merely buggy — a local user exploiting a validation gap gets kernel code execution.

```
/* NEVER dereference a __user pointer directly. */

long sys_example(void __user *ubuf, size_t len)
{
        char kbuf[256];

        if (len > sizeof kbuf)
                return -EINVAL;                  /* bound FIRST */
        if (copy_from_user(kbuf, ubuf, len))
                return -EFAULT;                  /* bytes NOT copied */
        ...
}

/* copy_from_user does three things you cannot skip:

   1. RANGE CHECK — is the address really below the user/kernel
      boundary? On arm64 this is a single comparison against
      TASK_SIZE, made speculation-safe.

   2. EXCEPTION FIXUP — an entry in __ex_table maps the faulting
      instruction to a recovery address. If the user page is
      unmapped, the data abort handler finds the fixup and
      returns -EFAULT instead of oopsing. This is what makes
      passing a bad pointer an ERROR rather than a crash.

   3. PAN / LDTR — with PAN enabled (chapter 05), ordinary kernel
      loads from user pages FAULT. The copy routines either lift
      PAN briefly or use the unprivileged LDTR/STTR instructions
      (chapter 08), which behave as EL0 accesses. Either way, a
      pointer aimed at KERNEL memory fails the permission check
      rather than succeeding.                              */

/* The five validation rules (OS chapter 03):
     1. bound every length BEFORE using it
     2. COPY before validating — never validate in place (TOCTOU)
     3. check every index and enum against its range
     4. zero output structures fully — padding leaks stack data
     5. reject unknown flags rather than ignoring them        */
```

Steps 8–10: returning

```
/* ret_to_user is not just a restore. Two things must be checked
   at the boundary, because this is the only safe point to do
   them:                                                        */

   TIF_SIGPENDING     a signal is queued → build a signal frame
                      on the USER stack, and return into the
                      handler instead of the original code
   TIF_NEED_RESCHED   a higher-priority task became runnable →
                      call schedule() before returning

/* This is why signals are delivered "on return to userspace" and
   not at arbitrary points — the kernel needs a known-good state
   to rewrite the return context.                              */

/* The errno convention, at step 10: */
        if ((unsigned long)ret >= (unsigned long)-4095) {
                errno = -ret;
                return -1;
        }
        return ret;

/* The kernel returns a NEGATIVE ERRNO directly (-EINVAL = -22),
   never sets a global. libc translates. This is strictly better
   than errno (C chapter 16): the error travels in the return
   value, so it cannot be clobbered or forgotten.

   The -4095 boundary is why no syscall may return a legitimate
   value in the range -1 to -4095 — mmap returning a high
   address is why it is checked this way rather than just
   testing for negative.                                       */
```

Avoiding the syscall entirely

```
/* Some "syscalls" need no privilege at all. The vDSO is a small
   shared object the kernel maps into every process, containing
   implementations that run in USER MODE.                      */

clock_gettime(CLOCK_MONOTONIC, &ts);
/*  · reads a kernel-maintained page of timekeeping data
    · reads CNTVCT_EL0 — the counter, readable from EL0
      (chapter 32)
    · does the arithmetic
    · returns. NO exception, no privilege change.
    ~25 ns instead of ~300 ns.                                */

cat /proc/self/maps | grep vdso
LD_SHOW_AUXV=1 /bin/true | grep VDSO

/* Also served by the vDSO: gettimeofday, clock_getres, time,
   getcpu, and on some architectures rt_sigreturn.

/* The general principle: the fastest system call is the one you
   do not make. Hence io_uring (shared rings, often zero
   syscalls in steady state), mmap instead of read, and eBPF
   (run the logic kernel-side). OS chapter 03.                */
```

Where the time goes

```
   svc → first kernel instruction        ~15–30 cycles
   save 31 registers + 3 sysregs         ~20–40 cycles
   seccomp / audit / ptrace checks       0 to hundreds
   table lookup + indirect call          ~10 cycles
   ── the actual work ──
   signal / resched checks               ~10 cycles
   restore + eret                        ~30–50 cycles

   Plus, on affected systems:
     KPTI                                two address-space
                                         switches, +100–300 cycles
     Spectre-BHB mitigation              a flush sequence in the
                                         vector, +tens of cycles

   A "null" syscall (getppid) measures roughly:
      no mitigations       ~60–100 ns
      with KPTI + BHB      ~150–400 ns

   Measure your own:
      perf bench syscall basic
      strace -c ./program           ← count them first
```

HVC and SMC follow the same shape

	`SVC`	`HVC`	`SMC`
Target	EL1	EL2	EL3
ESR EC	0x15	0x16	0x17
Vector	`VBAR_EL1` + 0x400	`VBAR_EL2` + 0x400	`VBAR_EL3` + 0x400
Number in	`x8`	The immediate, or `x0`	`x0` (SMCCC)
Used for	System calls	Hypercalls, KVM	PSCI, TEE, SiP services
Disabled by	—	`HCR_EL2.HCD`	`SCR_EL3.SMD`

```
/* The structure is identical: a deliberate synchronous exception
   to a higher level, arguments in registers, a number selecting
   the service, and ERET to return. Once you understand SVC, you
   understand all three.

   The differences are in what the handler does — and for SMC,
   the monitor must also save and restore the ENTIRE state of one
   world before switching (security track).               */

/* A PSCI call, for example — this is how a kernel starts a
   secondary CPU (chapter 33):                             */
        ldr     x0, =0xC4000003         /* PSCI_CPU_ON, SMC64 */
        mov     x1, target_mpidr
        ldr     x2, =secondary_entry
        mov     x3, #0
        smc     #0
        /* x0 = 0 on success, or a negative PSCI error */
```

Watching it happen

```
# count and time every syscall — ALWAYS do this first
strace -c ./program
#   % time     seconds  usecs/call     calls    errors syscall
#   ------ ----------- ----------- --------- --------- --------
#    89.12    0.451203           0   1204811           read
#     → 1.2 MILLION reads. That is the bug, whatever else is true.

strace -f -e trace=openat,read,write ./program
strace -p 1234                  # attach

# lower overhead, system-wide
perf trace ./program
sudo bpftrace -e 'tracepoint:raw_syscalls:sys_enter {
        @[comm, args->id] = count(); }'

# the entry path itself
echo 1 > /sys/kernel/debug/tracing/events/raw_syscalls/enable
cat /sys/kernel/debug/tracing/trace_pipe

# the table
ausyscall --dump | head -20
cat /usr/include/asm-generic/unistd.h | grep __NR_write

# see the vDSO in action — no syscall for clock_gettime
strace -e trace=clock_gettime ./prog     # produces nothing
```

> **`STRACE -C` BEFORE ANYTHING ELSE**
>
> When a program is slow with low CPU usage, this one command usually finds it: a million one-byte reads, thousands of failed `stat()` calls probing for a file, or a `poll()` loop with a zero timeout. All three are extremely common and all three are obvious in the summary. Reach for a profiler only after this comes back clean.

How it shows up

Symptom	Cause
Slow program, low CPU	Syscall-bound — check `strace -c`
Byte-at-a-time I/O 100× slower	One syscall per byte; buffer it
Performance dropped after a kernel update	KPTI or Spectre mitigations on the entry path
Kernel oops on a pointer from userspace	Direct dereference instead of `copy_from_user`
Vulnerability from a caller-supplied length	Length used before being bounded
Exploit changes a value after validation	TOCTOU — validated in place instead of after copying
Kernel stack bytes appear in user output	Struct padding not zeroed
Syscall returns a huge positive number instead of an error	Return value not checked against the -4095 boundary
Sandboxed process is measurably slower	seccomp filter evaluated on every call
`clock_gettime` is suspiciously cheap	Served by the vDSO — no exception at all

Check yourself

- ✓ Give the syscall ABI registers and two ways it differs from the C ABI.
- ✓ List the six things hardware does at `svc #0`.
- ✓ Explain why the syscall number bounds check must be speculation-safe.
- ✓ Give the three things `copy_from_user` does that a `memcpy` does not.
- ✓ Explain how PAN and `LDTR` enforce the boundary in hardware.
- ✓ Say why signals are delivered on return to userspace rather than at arbitrary points.
- ✓ Explain the negative-errno convention and the -4095 boundary.
- ✓ Explain what the vDSO is and why `clock_gettime` needs no exception.
- ✓ Give the three deliberate-exception instructions and what distinguishes them.

Traps and virtualisation

A higher exception level can make specific operations at a lower level raise an exception instead of executing. That single mechanism — configurable trapping — is the whole basis of virtualisation, lazy state management and several security features.

The mechanism

TRAP, EMULATE, RESUME

Set a bit in a control register at EL2 or EL3, and a chosen operation at a lower level stops executing and becomes a synchronous exception instead. The handler reads `ESR` to learn exactly what was attempted, does something equivalent, advances `ELR` past the instruction, and returns. The lower level never knows.

This is how a guest can believe it owns hardware it does not have, and how a kernel can defer expensive state management until it is actually needed.

The trap control registers

Register	Owner	Notable bits
`HCR_EL2`	Hypervisor	`VM` enable stage 2 · `TGE` route all EL0 exceptions to EL2 · `IMO/FMO/AMO` virtualise IRQ/FIQ/SError · `TVM` trap virtual-memory register writes · `TWI/TWE` trap `WFI` / `WFE` · `TID0–3` trap ID register reads · `E2H` VHE
`CPTR_EL2` / `CPACR_EL1`	Hypervisor / kernel	`FPEN`, `ZEN`, `SMEN` — trap FP, SVE and SME access
`MDCR_EL2` / `MDCR_EL3`	Hypervisor / monitor	Trap debug and performance-monitor access
`SCR_EL3`	Secure monitor	`NS` security state · `IRQ/FIQ/EA` routing · `SMD` disable `SMC` · `HCE` enable `HVC`
`HFGRTR_EL2` / `HFGWTR_EL2`	Hypervisor	Fine-grained traps (ARMv8.6): individual registers rather than whole groups

Trapping a system register

```
/* Enable the trap at EL2: */
        mrs     x0, hcr_el2
        orr     x0, x0, #(1 << 26)      /* TVM: trap virtual memory
                                           control register writes */
        msr     hcr_el2, x0
        isb

/* Now a guest at EL1 executing this: */
        msr     ttbr0_el1, x5

/* ...takes a synchronous exception to EL2 with ESR_EL2.EC = 0x18
   (trapped MSR/MRS). The ISS encodes exactly which register and
   which general register were involved:                    */

  ESR_EL2.ISS for EC = 0x18:
     [24:22] Op0      [20:17] Op2      [16:14] Op1
     [13:10] CRn      [9:5]   Rt   <- the general register
     [4:1]   CRm      [0]     Direction: 0 = write (MSR),
                                         1 = read  (MRS)

/* The handler: */
static void handle_sysreg_trap(struct vcpu *v)
{
        u64 esr = read_sysreg(esr_el2);
        u32 iss = esr & 0x1FFFFFF;

        int rt        = (iss >> 5) & 0x1F;
        bool is_read  = iss & 1;
        u32 reg_id    = iss & ~0x3E;    /* the encoding, minus Rt */

        if (is_read)
                v->regs[rt] = emulate_sysreg_read(v, reg_id);
        else
                emulate_sysreg_write(v, reg_id, v->regs[rt]);

        /* ADVANCE past the instruction, or we re-trap forever */
        write_sysreg(read_sysreg(elr_el2) + 4, elr_el2);
}

/* That last step is the single most common bug in this area: the
   guest appears frozen on one instruction, forever. Chapter 28. */
```

Trapping MMIO

```
Device emulation does not use a trap BIT — it uses an absent
stage-2 mapping (chapter 16).

   guest writes to what it believes is a UART register
        |
   ① stage 1 (guest's own tables): VA → IPA. SUCCEEDS.
   ② stage 2 (hypervisor's): that IPA is deliberately UNMAPPED
   ③ stage-2 data abort → EL2
        |
   ④ the hypervisor reads:
        HPFAR_EL2    the faulting IPA → which device register
        ESR_EL2.ISV  are the details valid?
             SAS     access size
             SRT     which guest register
             WnR     read or write
        |
   ⑤ emulate the device, update the model
   ⑥ ELR_EL2 += 4
   ⑦ ERET

  ISV is what makes this fast: without it the hypervisor would
  have to FETCH and DECODE the guest's instruction to work out
  what it was doing. Some access types (load/store pair, some
  SIMD forms) do not set ISV, and those take the slow path.

  COST: a full world switch per register access. A guest driver
  doing ten register writes to send a packet takes ten exits.
  This is exactly why virtio exists (OS chapter 20).
```

Lazy FP and SVE state

```
/* FP/SIMD state is large — 32 x 128-bit V registers, or far more
   with SVE. Saving it on every context switch would dominate the
   cost, and most threads never touch it.                    */

/* The optimisation:
     1. on switch, DISABLE FP access for the incoming thread
     2. if it never uses FP, nothing is saved or restored — free
     3. if it executes an FP instruction, a TRAP fires        */

        mrs     x0, cpacr_el1
        bic     x0, x0, #(3 << 20)      /* FPEN = 0: trap FP     */
        msr     cpacr_el1, x0
        isb

/* The trap handler (ESR.EC = 0x07): */
static void fpsimd_trap(void)
{
        save_fpsimd_state(previous_owner);
        restore_fpsimd_state(current);
        enable_fpsimd();                /* CPACR_EL1.FPEN = 3    */
        /* do NOT advance ELR — we want the instruction RETRIED */
}

/* Note the contrast with the sysreg trap: here we do NOT advance
   ELR, because we want the original instruction to execute now
   that FP is enabled. Whether to advance depends entirely on
   whether you EMULATED the instruction or ENABLED it.      */

/* Which is also why kernel code may not use FP freely: its state
   is not saved on kernel entry. Code that needs it must bracket
   it explicitly (C chapter 16):                             */
        kernel_neon_begin();
        /* SIMD crypto or checksum */
        kernel_neon_end();
```

Trapping WFI and WFE

```
/* A guest executing WFI would halt the PHYSICAL core, which the
   hypervisor cannot allow — it wants to schedule another vCPU.  */

        HCR_EL2.TWI = 1     /* trap WFI → ESR.EC = 0x01 */
        HCR_EL2.TWE = 1     /* trap WFE                 */

/* The handler treats it as "this vCPU is idle": */
static void handle_wfx_trap(struct vcpu *v, bool is_wfe)
{
        if (is_wfe)
                kvm_vcpu_on_spin(v);      /* likely spinning on a
                                             lock — yield         */
        else
                kvm_vcpu_block(v);        /* genuinely idle — block
                                             until an interrupt    */
        advance_elr(v);
}

/* The WFE case is interesting: a guest spinning on a lock held by
   a DESCHEDULED vCPU wastes its entire timeslice. Trapping WFE
   lets the hypervisor detect that and yield to the lock holder —
   the "lock holder preemption" problem, and one of the reasons
   paravirtualised spinlocks exist.                        */
```

Trapping identification

```
/* HCR_EL2.TID0–TID3 trap reads of the ID registers, so the
   hypervisor can present a guest with a DIFFERENT feature set
   than the hardware actually has.                          */

/* Why this matters:
     · LIVE MIGRATION. A VM migrating between hosts must see the
       same features throughout, so the hypervisor advertises the
       intersection of the cluster's capabilities.
     · big.LITTLE. Cores in one system genuinely differ. A guest
       migrating between them would see the feature set change
       under it, which no OS expects. The hypervisor normalises.
     · SECURITY. Hiding a feature with a known erratum.

   The cost: every ID register read becomes an exit. Guests read
   them mostly at boot, so this is acceptable — but a guest that
   polls one in a loop will be very slow.                  */
```

Fine-grained traps

```
/* Original trap bits are coarse: HCR_EL2.TVM traps ALL
   virtual-memory register writes, even ones the hypervisor does
   not care about. Every unnecessary trap is a world switch.

   ARMv8.6 adds FINE-GRAINED TRAPS: individual bits for
   individual registers.                                    */

        HFGRTR_EL2      fine-grained READ traps
        HFGWTR_EL2      fine-grained WRITE traps
        HFGITR_EL2      fine-grained INSTRUCTION traps
        HDFGRTR_EL2 / HDFGWTR_EL2   debug registers

/* So a hypervisor can trap exactly TTBR0_EL1 writes without
   trapping TCR_EL1, VBAR_EL1 and the rest. Measurably fewer
   exits on a memory-management-heavy guest.

   The general principle: every trap is a cost, so the
   architecture keeps adding ways to trap LESS.            */
```

Nested virtualisation

```
Running a hypervisor INSIDE a guest. ARMv8.3 (NV) and 8.4 (NV2)
make it practical.

   L0 hypervisor at EL2 (the real one)
        |
   L1 hypervisor - believes it is at EL2, actually runs at EL1
        |
   L2 guest at EL1

  The problem: L1 executes EL2 instructions and accesses EL2
  registers, but it is at EL1. Without help, EVERY one of those
  traps to L0, which must emulate it - including L1's own stage-2
  table management, which L0 must SHADOW into real stage-2 tables.
  Enormously slow.

  NV (ARMv8.3): HCR_EL2.NV makes EL2 register accesses from EL1
  trap cleanly and defines the semantics, so emulation is
  correct rather than ad hoc.

  NV2 (ARMv8.4): HCR_EL2.NV2 REDIRECTS L1's EL2 register accesses
  to MEMORY - a VNCR page - instead of trapping. L1 writes what
  it thinks is VTTBR_EL2 and it lands in a memory structure L0
  reads later. No exit at all for the common case.

  Used for: nested containers-in-VMs, developing hypervisors
  inside a VM, and confidential computing stacks.
```

TGE and the host

```
/* HCR_EL2.TGE — "Trap General Exceptions" — routes ALL EL0
   exceptions to EL2 instead of EL1.                        */

/* Why: when a HOST kernel runs at EL2 with VHE (chapter 26), its
   userspace runs at EL0 and its exceptions must reach EL2, not
   the (nonexistent) EL1. TGE does that.

   TGE also implicitly:
     · disables stage-2 translation for EL1&0
     · makes EL1 accesses behave as if no guest is present

   So a VHE host runs with TGE=1 normally, and CLEARS it when
   entering a guest. That one bit is the boundary between "host
   context" and "guest context", and toggling it is a large part
   of what a VM entry does.                                 */

/* You can see the transition in KVM's world-switch code:
   __activate_traps / __deactivate_traps in
   arch/arm64/kvm/hyp/                                      */
```

The cost of a trap

```
   guest instruction
        │  exception entry to EL2          ~20–50 cycles
        │  save guest state (registers,
        │    system registers)             ~100–500 cycles
        │  decode ESR, dispatch            ~20 cycles
        │  EMULATE                         varies
        │  restore guest state             ~100–500 cycles
        │  ERET                            ~20 cycles
        ▼
   ~500–2000 cycles per exit, and more without VHE

  Which is why the whole design direction is TRAP LESS:
     stage-2 translation      instead of shadow page tables
     GIC list registers       instead of trapping every EOI
     virtio                   instead of emulating a real NIC
     device passthrough       instead of any emulation at all
     fine-grained traps       instead of coarse ones
     NV2 memory redirection   instead of nested traps

  MEASURING exits is the first step in any VM performance work:
     perf stat -e kvm:kvm_exit -a sleep 10
     perf record -e kvm:kvm_exit -a && perf report
        → group by exit reason. MMIO dominating means you should
          be using virtio or passthrough.
```

Debugging traps

```
# which exits, and how many?
perf stat -e 'kvm:*' -a sleep 10
perf record -e kvm:kvm_exit -a && perf report --sort=dso,symbol

# KVM's own statistics
ls /sys/kernel/debug/kvm/*/
cat /sys/kernel/debug/kvm/*/vcpu0/*
#   mmio_exits, wfi_exits, wfe_exits, hvc_exits, sys64_exits...

# trace them
echo 1 > /sys/kernel/debug/tracing/events/kvm/enable
cat /sys/kernel/debug/tracing/trace_pipe
#   kvm_exit: ESR_EC: 0x24 (DABT_LOW) ... ipa 0x9000000

# from inside a guest, confirm what it thinks it has
cat /proc/cpuinfo | grep Features
#   compare with the host's — differences mean ID traps are
#   normalising the feature set

# in a hypervisor you are writing: log every unhandled EC once
        pr_warn_once("unhandled trap EC=0x%02x ISS=0x%07x\n", ec, iss);
```

THE TWO QUESTIONS FOR ANY TRAP HANDLER

Did I emulate the instruction, or did I enable something so it can run? If you emulated it, advance `ELR`. If you enabled something, do *not* — the instruction must be retried.

Is this trap on a hot path? If a workload takes millions of a particular exit, the answer is architectural: use a mechanism that does not trap at all. Emulating faster is rarely the right fix.

Where this goes next

Traps are the mechanism; a hypervisor is what you build out of them. The virtualisation track picks up here — HCR_EL2 bit by bit, stage-2 translation, the vGIC, virtio and KVM's implementation of all of it, ending with a working hypervisor in two hundred lines.

How it shows up

Symptom	Cause
Guest frozen on one instruction	`ELR` not advanced after emulation
FP instruction faults repeatedly	`ELR` advanced when it should have been retried
Guest I/O extremely slow	MMIO emulation — one exit per register access
Guest hangs on a system register write	Trap configured but not handled
Guest sees different CPU features than the host	ID register traps normalising for migration
Guest spinlocks perform terribly	Lock holder preemption; needs WFE trapping and yield
Nested VM is unusably slow	No NV2 — every L1 EL2 access traps to L0
Kernel oops after using SIMD in a driver	FP state not saved; needs `kernel_neon_begin()`
Undefined instruction on `HVC`	`HCR_EL2.HCD` set, or EL2 not implemented

Symptom	Cause
Exits dominated by one reason	Use a non-trapping mechanism for that operation

Check yourself

- ✓ Explain the trap-emulate-resume cycle and which register configures it.
- ✓ Decode the ISS of a trapped `MSR` and say what a handler does with it.
- ✓ Explain why MMIO emulation uses an unmapped stage-2 page rather than a trap bit.
- ✓ Say what `ISV` saves the hypervisor from doing.
- ✓ Explain lazy FP switching and why its handler does *not* advance `ELR`.
- ✓ Give two reasons a hypervisor traps ID register reads.
- ✓ Explain what fine-grained traps improve.
- ✓ Explain what NV2 changes about nested virtualisation.
- ✓ Explain what `HCR_EL2.TGE` does and when a VHE host sets it.

The generic timer and counters

One architected timer, present on every ARMv8 core, with a counter readable from user space and comparators for each exception level. It is why `clock_gettime` needs no system call, and why timekeeping code is portable across every ARM SoC.

The system counter

ONE COUNTER, SHARED BY EVERYTHING

A single free-running 64-bit counter in an always-on power domain, incrementing at a fixed frequency, distributed to every core. It never stops, never wraps in any practical timeframe, and is identical on every core — which is exactly what a clocksource needs (OS chapter 17).

```
        mrs     x0, cntpct_el0          /* PHYSICAL count  */
        mrs     x0, cntvct_el0          /* VIRTUAL count   */
        mrs     x0, cntfrq_el0          /* frequency in Hz */

/* Readable from EL0 — no system call, no trap. This is the whole
   reason the vDSO can implement clock_gettime in user mode
   (chapter 30).                                            */

/* Frequency is IMPLEMENTATION DEFINED, commonly 1–100 MHz.
   Typical: 24 MHz, 25 MHz, 50 MHz, 19.2 MHz.

   CNTFRQ_EL0 is NOT set by hardware — FIRMWARE must program it
   at boot, on every core. If firmware forgets, software reads
   zero or garbage and all timekeeping is wrong. This is a
   classic bring-up bug, and Linux warns about it:          */
//   arch_timer: WARNING: Invalid trigger for IRQ
//   arch_timer: frequency not available

/* At 24 MHz, a 64-bit counter wraps after ~24,000 years. Treat
   it as never wrapping — but do use time_after()-style signed
   comparison anyway (OS chapter 17).                       */
```

Physical versus virtual counters

```
 CNTPCT_EL0    the raw physical count
 CNTVCT_EL0    the physical count MINUS an offset

      CNTVCT = CNTPCT - CNTVOFF_EL2

CNTVOFF_EL2 is per-VM, written by the hypervisor. Why:

 · a guest suspended for 10 seconds and resumed should not see
   10 seconds of elapsed CPU time it did not get
 · a guest MIGRATED to another host must see a continuous
   timeline, even though the new host's counter differs
 · a guest booted later should still see its own time starting
   near zero

So the hypervisor adjusts CNTVOFF and the guest's view stays
coherent, with no traps and no emulation.

CONSEQUENCE for software:
   · a guest OS uses the VIRTUAL counter and timer
   · a hypervisor, and firmware at EL2/EL3, uses the PHYSICAL one
   · Linux at EL1 uses virtual; Linux at EL2 (VHE) uses physical
   · reading the wrong one inside a VM gives host time, which
     breaks after any suspend or migration
```

The timers

Timer	Registers	Interrupt	Used by
EL1 physical	`CNTP_*_EL0`	PPI 30	A kernel with no hypervisor; firmware
EL1 virtual	`CNTV_*_EL0`	PPI 27	**A guest OS, and Linux at EL1**
EL2 physical	`CNTHP_*_EL2`	PPI 26	The hypervisor
EL2 virtual	`CNTHV_*_EL2`	PPI 28	A VHE host
EL3 physical	`CNTPS_*_EL1`	PPI 29	Secure firmware
Secure EL1	`CNTHPS_*`, `CNTHVS_*`	PPI 20, 19	A trusted OS (ARMv8.4+)

Each level gets its own comparator so they do not have to coordinate — a hypervisor's timer cannot be disturbed by its guest, and secure firmware's cannot be disturbed by the normal world.

Programming a timer

```
/* Each timer has three registers: */

   CNTV_CTL_EL0    [0] ENABLE
                   [1] IMASK — mask the interrupt output
                   [2] ISTATUS — read-only: has it fired?
   CNTV_CVAL_EL0   64-bit ABSOLUTE compare value
   CNTV_TVAL_EL0   32-bit RELATIVE value, a convenience:
                     writing it sets CVAL = CNTVCT + TVAL
                     reading it gives CVAL − CNTVCT (may go
                     negative once expired)

/* The timer fires when CNTVCT >= CVAL. It is a COMPARATOR, not a
   countdown — which is what makes it immune to drift.      */

/* Absolute deadline — the correct way for periodic work: */
static void timer_set_deadline(uint64_t deadline)
{
        asm volatile("msr cntv_cval_el0, %0" :: "r"(deadline));
        asm volatile("msr cntv_ctl_el0, %0" :: "r"(1UL));  /* enable */
        asm volatile("isb");
}

static void timer_periodic(uint64_t period_ticks)
{
        static uint64_t next;
        uint64_t now;
        asm volatile("mrs %0, cntvct_el0" : "=r"(now));

        if (!next) next = now;
        next += period_ticks;              /* ABSOLUTE, so no drift */
        timer_set_deadline(next);
}

/* Contrast with the relative form: */
        asm volatile("msr cntv_tval_el0, %0" :: "r"(period));
/* Each period restarts from NOW, so the handler's own execution
   time accumulates into permanent drift. Over an hour at 1 kHz
   with a 10 µs handler, that is 36 seconds of drift.
   Use CVAL and absolute deadlines. (OS chapter 17.)       */
```

Delays and timeouts

```
/* A portable microsecond delay, with no calibration loop: */

static void udelay(unsigned us)
{
        uint64_t freq, start, ticks;

        asm volatile("mrs %0, cntfrq_el0" : "=r"(freq));
        ticks = (freq * us) / 1000000;

        asm volatile("isb");                       /* order the read */
        asm volatile("mrs %0, cntvct_el0" : "=r"(start));

        for (;;) {
                uint64_t now;
                asm volatile("isb");
                asm volatile("mrs %0, cntvct_el0" : "=r"(now));
                if (now - start >= ticks)
                        break;
        }
}

/* The ISB matters: without it the counter read can be speculated
   or reordered, and a short delay can complete early. Linux's
   arch_counter_get_cntvct() includes it for exactly this
   reason.

   And note the subtraction: `now - start >= ticks` is correct
   across a wrap; `now >= start + ticks` is not.           */

/* A bounded wait — always prefer this to an unbounded loop: */
static bool wait_for_bit(volatile uint32_t *reg, uint32_t mask,
                         unsigned timeout_us)
{
        uint64_t freq, start, limit, now;

        asm volatile("mrs %0, cntfrq_el0" : "=r"(freq));
        asm volatile("mrs %0, cntvct_el0" : "=r"(start));
        limit = (freq * timeout_us) / 1000000;

        do {
                if (*reg & mask)
                        return true;
                asm volatile("mrs %0, cntvct_el0" : "=r"(now));
        } while (now - start < limit);

        return false;                      /* TIMED OUT — say so */
}
```

Why the vDSO works

```
clock_gettime(CLOCK_MONOTONIC, &ts) with no system call:

   1. read a kernel-maintained page mapped read-only into every
      process. It holds:
         · a base time value
         · the counter value at that base
         · a multiplier and shift for the conversion
         · a sequence counter (a seqlock — OS chapter 09)

   2. read CNTVCT_EL0                      ← EL0-readable
   3. delta = cntvct - base_cycles
   4. ns = base_ns + ((delta * mult) >> shift)
   5. re-check the sequence counter; retry if the kernel updated
      the page mid-read

   ~25 ns, entirely in user mode. Versus ~300 ns for a syscall.

  Two architectural properties make this possible:
     · the counter is readable from EL0 (CNTKCTL_EL1 permits it)
     · it is architected, so ONE vDSO implementation works on
       every ARM SoC

  CNTKCTL_EL1.EL0VCTEN gates EL0 access. A kernel could clear it
  to hide timing from userspace — some hardened configurations do,
  as a side-channel mitigation, at the cost of losing the vDSO
  fast path.
```

The event stream

```
/* WFE waits for an event (chapter 22). If the event never comes,
   the core waits forever — which is a problem for a spinlock
   whose holder was descheduled.

   The generic timer can generate a PERIODIC EVENT STREAM as a
   safety net:                                              */

   CNTKCTL_EL1.EVNTEN    enable the event stream
   CNTKCTL_EL1.EVNTI     which counter bit transition triggers it
   CNTKCTL_EL1.EVNTDIR   rising or falling edge

/* Typically configured for a ~100 µs period. A WFE therefore
   never sleeps longer than that, guaranteeing forward progress
   even if a SEV is missed.

   Linux enables it, and you can see the configuration:     */
//   dmesg | grep -i 'arch_timer.*event stream'
//   arch_timer: Architected timer HYP event stream enabled

/* This is also what makes WFE safe to use in a guest: the
   hypervisor may trap WFE (chapter 31), but the event stream
   ensures the guest wakes anyway.                          */
```

Firmware responsibilities

WHAT MUST BE SET UP BEFORE LINUX BOOTS

- `CNTFRQ_EL0` **on every core**, with the actual counter frequency. Hardware does not set it. If firmware forgets, all timekeeping is wrong or the kernel refuses to boot.
- `CNTVOFF_EL2` **= 0** when handing off to a kernel at EL1 with no hypervisor. Firmware sometimes leaves it non-zero, and the guest's virtual time then starts at an arbitrary offset.
- `CNTHCTL_EL2` configured so EL1 may access the physical counter and timer, if that is intended.
- **The counter must be enabled and running** in the always-on domain before any core reads it.

Linux checks and complains about several of these; the messages are worth recognising during bring-up.

```
/* The device tree describes it: */
timer {
        compatible = "arm,armv8-timer";
        interrupts = <GIC_PPI 13 IRQ_TYPE_LEVEL_LOW>,   /* secure   */
                     <GIC_PPI 14 IRQ_TYPE_LEVEL_LOW>,   /* physical */
                     <GIC_PPI 11 IRQ_TYPE_LEVEL_LOW>,   /* virtual  */
                     <GIC_PPI 10 IRQ_TYPE_LEVEL_LOW>;   /* hyp      */
        clock-frequency = <24000000>;   /* ONLY if firmware failed
                                           to set CNTFRQ - a
                                           documented workaround,
                                           not the normal path    */
        always-on;                       /* survives CPU idle      */
};

/* The PPI numbers here are relative to 16, so PPI 13 is INTID 29
   (chapter 23). Getting this wrong is a common device tree error
   and the symptom is a kernel that boots then hangs with no
   timer interrupts.                                            */
```

The memory-mapped timer

```
/* Besides the per-core system-register timers, the architecture
   defines an optional MEMORY-MAPPED timer block (CNTControlBase,
   CNTReadBase, CNTBaseN).                                      */

/* Why it exists: devices other than CPUs may need the counter -
   a DMA engine timestamping packets, a power controller, a
   coprocessor. They cannot execute MRS.

   Software rarely touches it directly. It appears in device
   trees as:                                                    */
        compatible = "arm,armv7-timer-mem";

/* Its one common use in Linux: providing a clocksource on
   systems where the per-core timer stops in deep idle, since
   the memory-mapped block is in the always-on domain.     */
```

The Linux view

```
/* The generic timer is Linux's clocksource AND clockevent
   (OS chapter 17):                                        */

cat /sys/devices/system/clocksource/clocksource0/available_clocksource
#   arch_sys_counter                    ← the generic timer
cat /sys/devices/system/clocksource/clocksource0/current_clocksource

cat /proc/interrupts | grep arch_timer
#    3:  102394  98211  101002  99887  GICv3  27 Level  arch_timer
#                                              ^^ PPI, so counts on
#                                                 every core

/* Kernel APIs built on it: */
ktime_get()                    /* CLOCK_MONOTONIC, ns          */
ktime_get_real()               /* CLOCK_REALTIME               */
ktime_get_boottime()           /* includes suspend             */
get_cycles()                   /* the raw counter              */
arch_timer_read_counter()

udelay(50);                    /* busy-wait, atomic-safe       */
usleep_range(100, 200);        /* sleeps; allows BATCHING      */
hrtimer_start(&t, ms_to_ktime(10), HRTIMER_MODE_REL);

/* And the tickless machinery (OS chapter 17) programs CVAL for
   the next actual deadline rather than a fixed tick, which is
   what lets an idle core sleep for seconds.               */
```

How it shows up

Symptom	Cause
Kernel hangs after "Calibrating delay loop"	`CNTFRQ_EL0` not set by firmware
All delays are wildly wrong	Wrong `CNTFRQ_EL0`, or a `clock-frequency` DT override that disagrees with the hardware
No timer interrupts; system boots then freezes	Wrong PPI number in the device tree
Guest time jumps after migration	Used the physical counter instead of the virtual one
Guest sees host uptime	`CNTVOFF_EL2` not set
Periodic task drifts over hours	Used `TVAL` (relative) instead of `CVAL` (absolute)
Short delays complete early	Missing `ISB` around the counter read
`clock_gettime` unexpectedly slow	vDSO unavailable, or `CNTKCTL.EL0VCTEN` cleared
Core stuck in `WFE`	Event stream not enabled, and the `SEV` was missed
Timer stops during deep idle	Per-core timer not in the always-on domain; needs a broadcast timer

Check yourself

- ✓ Explain what makes the system counter suitable as a clocksource.
- ✓ Say who must set `CNTFRQ_EL0` and what happens if they do not.
- ✓ Explain the difference between the physical and virtual counters and who uses each.

- ✓ Explain why `CNTVOFF_EL2` exists, with two scenarios.
- ✓ Name the timers per exception level and why each has its own.
- ✓ Explain why `CVAL` avoids drift and `TVAL` does not.
- ✓ Explain the two architectural properties that make the vDSO's `clock_gettime` possible.
- ✓ Say what the event stream is for and what problem it prevents.

Power states, WFI/WFE and PSCI

Two instructions to stop a core, and a standard firmware interface to turn one off entirely. Between them they cover the whole range from an idle loop to booting a secondary CPU — and PSCI is why one kernel image works across every ARM SoC.

WFI and WFE

	`WFI`	`WFE`
Waits for	An **interrupt** (or another wake-up event)	An **event**: `SEV`, an exclusive-monitor release, the event stream, or an interrupt
Wakes on a MASKED interrupt?	**Yes** — even with `PSTATE.I` set	Yes
Event register	Not used	Consumes it if already set, and does not sleep
Used for	The idle loop	Spinlocks, polling loops

THE PROPERTY THAT MAKES `WFI` USABLE

It wakes on an interrupt *even if that interrupt is masked*. So the idle loop can mask interrupts, check whether there is work, and `WFI` — without a race where an interrupt arrives between the check and the sleep. Unmask after waking and the interrupt is then taken normally.

Without that property, every idle loop would have a lost-wakeup window.

```
/* The correct idle loop */
static void cpu_idle(void)
{
        for (;;) {
                local_irq_disable();            /* mask */
                if (need_resched()) {
                        local_irq_enable();
                        schedule();
                        continue;
                }
                dsb(sy);                        /* outstanding
                                                   transactions must
                                                   complete first  */
                wfi();                          /* sleep           */
                local_irq_enable();             /* now take it     */
        }
}

/* The DSB matters: a memory transaction still in flight when the
   core enters a low-power state may never complete, hanging the
   interconnect. Chapter 21.                                    */

/* WFE, in a spinlock (chapter 22) */
1:      ldaxr   w1, [x0]
        cbnz    w1, 2f                  /* held? wait              */
        stxr    w2, w3, [x0]
        cbnz    w2, 1b
        b       3f
2:      wfe                             /* sleep in low power      */
        b       1b
3:      /* acquired */

/* The unlock's STLR to the monitored address generates the event
   automatically — no explicit SEV is needed. And the timer's
   EVENT STREAM (chapter 32) guarantees a wake within ~100 µs
   even if the event is missed entirely.                        */
```

Both are hints

> **NEITHER INSTRUCTION GUARANTEES ANYTHING ABOUT POWER**
>
> `WFI` and `WFE` are *architectural hints*. A conforming implementation may treat them as `NOP`. What actually happens — clock gating, retention, or nothing at all — is entirely implementation defined.
>
> What *is* architected is the wake-up condition. So the correctness of your idle loop does not depend on the power behaviour, which is the right split: software expresses intent, hardware decides the mechanism. Deeper states than the core can enter by itself require firmware, which is what PSCI is for.

The state hierarchy

```
   RUNNING
     │
     │ WFI — the core requests a low-power state
     ▼
   STANDBY / retention            wake: ~ns to µs
     · clocks gated, state PRESERVED in registers and caches
     · the core resumes exactly where it stopped
     · entered directly by WFI; no firmware needed
     │
     │ PSCI CPU_SUSPEND with a deeper state ID
     ▼
   POWER DOWN                     wake: ~10s–100s of µs
     · the core's power domain is turned OFF
     · ALL state is lost: registers, caches, MMU config, GIC
       CPU interface
     · software must SAVE everything before, and RESTORE after
     · the core restarts at a firmware entry point and works its
       way back
     │
     │ all cores in a cluster down
     ▼
   CLUSTER POWER DOWN
     · the shared L2 must be cleaned and invalidated first
     · the cluster's GIC redistributor state saved
     │
     ▼
   SYSTEM SUSPEND                 wake: ms
     · everything except an always-on domain
     · DRAM in self-refresh
     · wake sources configured in the always-on power controller

  Each level saves more power and costs more to leave. The
  BREAK-EVEN calculation from CA chapter 20 governs which one an
  OS governor picks.
```

PSCI

> **POWER STATE COORDINATION INTERFACE**
>
> A standard SMC-based API implemented by EL3 firmware. It abstracts every SoC-specific power controller behind one interface, so a single kernel image can boot secondary cores, idle, suspend and reboot on any platform. Before PSCI, every SoC needed its own `smp_ops` in the kernel — which is why old ARM32 Linux had dozens of platform-specific power drivers and ARM64 has none.

Function	ID (SMC64)	Does
`PSCI_VERSION`	`0x84000000`	Returns the implemented version
`CPU_SUSPEND`	`0xC4000001`	Enter a low-power state, with a resume entry point
`CPU_OFF`	`0x84000002`	Power this core down; does not return
`CPU_ON`	`0xC4000003`	**Start another core** at a given address
`AFFINITY_INFO`	`0xC4000004`	Is that core on, off, or transitioning?
`SYSTEM_OFF`	`0x84000008`	Shut down
`SYSTEM_RESET`	`0x84000009`	Reboot

Function	ID (SMC64)	Does
`SYSTEM_SUSPEND`	`0xC400000E`	Suspend to RAM
`FEATURES`	`0x8400000A`	Query support for a function

```
/* Starting a secondary CPU — this is how every ARM64 SMP kernel
   brings up its cores (OS chapter 18):                    */

#include <linux/arm-smccc.h>

static int cpu_on(u64 mpidr, u64 entry_point, u64 context_id)
{
        struct arm_smccc_res res;

        arm_smccc_smc(0xC4000003,       /* PSCI_CPU_ON, SMC64 */
                      mpidr,            /* which core         */
                      entry_point,      /* PHYSICAL address   */
                      context_id,       /* passed back in x0  */
                      0, 0, 0, 0, &res);

        return (int)res.a0;             /* 0 = success        */
}

/* The target core comes out of reset at entry_point with:
     · the MMU OFF
     · caches OFF
     · at the same EL the caller was at
     · x0 = context_id

   In other words, exactly the same contract as the primary CPU's
   boot entry (OS chapter 18) — which is why the secondary path
   in head.S shares most of its code with the primary path. */

/* PSCI error codes worth recognising: */
   0   SUCCESS
  -1   NOT_SUPPORTED
  -2   INVALID_PARAMETERS
  -3   DENIED
  -4   ALREADY_ON          ← a common bring-up result
  -5   ON_PENDING
  -6   INTERNAL_FAILURE
  -7   NOT_PRESENT
  -8   DISABLED
  -9   INVALID_ADDRESS
```

CPU_SUSPEND and the power state ID

```
/* CPU_SUSPEND takes a platform-specific state ID describing HOW
   deep to go, and where to resume.                          */

        arm_smccc_smc(0xC4000001,       /* CPU_SUSPEND        */
                      power_state,      /* the state ID       */
                      resume_entry,     /* physical address   */
                      context_id,
                      0, 0, 0, 0, &res);

/* The power_state encoding (extended format, PSCI 1.0+):
     [3:0]   state ID — platform specific
     [16]    0 = standby (state preserved)
             1 = POWERDOWN (state LOST)
     [25:24] affinity level: 0 = core, 1 = cluster, 2 = system

   The state IDs come from the DEVICE TREE, so the kernel does
   not need platform knowledge:                              */

cpus {
        idle-states {
                entry-method = "psci";

                cpu_sleep_0: cpu-sleep-0 {
                        compatible = "arm,idle-state";
                        arm,psci-suspend-param = <0x0010000>;
                        entry-latency-us = <300>;
                        exit-latency-us = <1200>;
                        min-residency-us = <2000>;
                        local-timer-stop;    /* ← the timer STOPS  */
                };
        };
        cpu@0 {
                cpu-idle-states = <&cpu_sleep_0>;
        };
};

/* The kernel's cpuidle governor uses entry/exit latency and
   min-residency to decide whether the expected idle duration
   justifies this state — the break-even calculation from
   CA chapter 20, driven entirely by device tree data.     */
```

> **`LOCAL-TIMER-STOP` MATTERS**
>
> In deep states the per-core generic timer loses power and stops. If the kernel programmed it to wake the core, that wake-up never happens. The fix is a **broadcast timer** in the always-on domain: the kernel switches to it before entering such a state, and one core stays awake (or the always-on timer fires) to wake the others. Getting this wrong produces a core that goes idle and never returns — a hang that only appears when the system is quiet.

What must be saved before power-down

```
A POWERDOWN state loses everything. The full sequence:

  1. save all system registers that are not restored by firmware:
       SCTLR_EL1, TCR_EL1, TTBR0/1_EL1, MAIR_EL1, VBAR_EL1,
       TPIDR_EL0/EL1, CPACR_EL1, and the debug registers

  2. save the GIC CPU interface and redistributor state
       ICC_PMR_EL1, ICC_CTLR_EL1, ICC_IGRPEN1_EL1,
       pending SGIs, the redistributor's enable and priority
       state (chapter 23)

  3. CLEAN AND INVALIDATE the caches to the Point of Coherency
       · this is the ONE legitimate use of the set/way
         operations (chapter 18)
       · for a cluster power-down, the shared L2 too
       · and it must be the LAST thing, because anything after
         it may dirty a line again

  4. DSB, then issue PSCI CPU_SUSPEND

  On resume, the core enters at resume_entry with the MMU off and
  must rebuild everything: page tables, MMU, caches, GIC, timers,
  then restore the saved state and return into the idle loop as
  though WFI had simply returned.

  Linux does this in cpu_suspend() / cpu_resume(), and the
  saved-register set is arch/arm64/mm/proc.S's cpu_do_suspend.

  A missing register in that list gives a system that resumes and
  then behaves subtly wrongly — the hardest class of power bug.
```

CPU hotplug

```
# Offlining a core uses PSCI CPU_OFF underneath
echo 0 > /sys/devices/system/cpu/cpu3/online
echo 1 > /sys/devices/system/cpu/cpu3/online

cat /sys/devices/system/cpu/online
cat /sys/devices/system/cpu/offline

/* What the kernel does on offline:
     1. migrate all tasks off that core
     2. migrate all interrupts (set_affinity) off it
     3. migrate timers and hrtimers
     4. run CPU_DYING notifiers in every subsystem
     5. call PSCI CPU_OFF — which does not return

   And on online:
     1. PSCI CPU_ON with the secondary entry point
     2. the core runs head.S's secondary path: MMU, caches, GIC
        redistributor, timer
     3. CPU_STARTING notifiers
     4. mark it online; the scheduler starts using it

   Used for: thermal management, power saving, taking a core out
   of service after a fault, and testing SMP code paths.   */
```

The Linux idle path

```
/* cpuidle chooses a state, then PSCI enters it: */

cat /sys/devices/system/cpu/cpu0/cpuidle/state*/name
#   WFI
#   cpu-sleep
#   cluster-sleep

cat /sys/devices/system/cpu/cpu0/cpuidle/state1/{latency,residency,usage,time}
#   latency    exit latency in µs
#   residency  minimum time that justifies entering
#   usage      how many times it was entered
#   time       total µs spent in it

cpupower monitor
cpupower idle-info

/* If a state's `usage` is zero, the governor never considers it
   worthwhile — usually because the workload wakes too often
   (OS chapter 17: count WAKEUPS, not CPU percentage).

   powertop shows what is causing the wakeups.            */
sudo powertop
```

The spin-table alternative

```
/* Before PSCI, and still on some simple platforms, secondaries
   are released with a SPIN TABLE: each parked core polls a
   memory location until the primary writes an address.     */

cpu@1 {
        device_type = "cpu";
        compatible = "arm,cortex-a53";
        reg = <0x1>;
        enable-method = "spin-table";
        cpu-release-addr = <0x0 0x8000fff8>;
};

/* The parked core runs, from firmware:
        1:      ldr     x0, [release_addr]
                cbz     x0, 1b
                wfe                     ← so it does not burn power
                br      x0

   The primary writes the entry point and issues SEV.

   Why PSCI is better:
     · it also handles CPU_OFF, SUSPEND and SYSTEM_RESET, which
       a spin table cannot
     · the parked core consumes power and holds memory
     · the release address must be reserved from the kernel's
       memory map, which is error-prone
     · no way to power the core down at all

   Use PSCI unless the platform genuinely has no EL3 firmware. */
```

How it shows up

Symptom	Cause
Only one CPU comes online	PSCI not working, wrong MPIDR in the device tree, or firmware returning an error
Secondary CPU hangs on start	Entry point not physically addressed, or MMU/cache state assumed
Core goes idle and never wakes	Timer stopped in a deep state with no broadcast timer
System resumes but behaves subtly wrongly	A system register not in the save/restore list
Interrupts lost after resume	GIC redistributor state not restored
Corruption after cluster power-down	L2 not cleaned to PoC before power was removed
Idle states show zero usage	Wakeups too frequent to justify entry — find them with `powertop`
Core hangs entering `WFI`	No `DSB`; an outstanding transaction never completed
Spinlock spins burn power	No `WFE`, or the event stream is disabled
Reboot does not work	`SYSTEM_RESET` unimplemented; falls back to a watchdog

Check yourself

- ✓ Give the difference between `WFI` and `WFE` and what each is used for.
- ✓ Explain why `WFI` wakes on a masked interrupt, and the race that prevents.
- ✓ Explain why both are hints, and what *is* architected about them.
- ✓ Name the power state levels and what is lost at each.
- ✓ Say what PSCI is and why it removed platform code from the kernel.
- ✓ Show how a secondary CPU is started, and state the entry contract.
- ✓ List the three things that must be saved before a power-down state.
- ✓ Explain `local-timer-stop` and the broadcast timer it requires.
- ✓ Give two reasons PSCI is preferable to a spin table.

Performance monitoring and the PMU

Every ARM core contains counters that measure what the microarchitecture is actually doing. This is ground truth rather than inference — and knowing which events to count turns performance work from guessing into measurement.

What the PMU provides

```
  PMCCNTR_EL0        a dedicated 64-bit CYCLE counter
  PMEVCNTR0-30_EL0   general counters, 32-bit (64-bit in
                     ARMv8.5), each programmable to count one
                     event
  PMEVTYPER0-30_EL0  which event each counter counts, plus
                     filters (count at EL0? EL1? EL2? secure?)

  PMCR_EL0           enable, reset, and how many counters exist
  PMCNTENSET_EL0     enable individual counters
  PMOVSSET_EL0       overflow status — the interrupt source
  PMINTENSET_EL1     enable overflow interrupts
  PMUSERENR_EL0      may EL0 access these directly?

The NUMBER of counters is implementation defined — typically
4 to 6 on a small core, 6 to 8 on a large one. Read it:

      mrs     x0, pmcr_el0
      ubfx    x0, x0, #11, #5        /* N field */

This is why perf multiplexes: ask for more events than there
are counters and it time-slices them, scaling the results.
The scaling factor appears in perf's output, and heavily
multiplexed measurements are correspondingly noisy.
```

The architected events

Event	Number	Counts
`CPU_CYCLES`	0x11	Cycles — the denominator for everything
`INST_RETIRED`	0x08	Instructions architecturally executed
`INST_SPEC`	0x1B	Instructions *speculatively* executed
`L1D_CACHE`	0x04	L1 data cache accesses
`L1D_CACHE_REFILL`	0x03	L1 data cache misses
`L1I_CACHE_REFILL`	0x01	L1 instruction cache misses
`L2D_CACHE_REFILL`	0x17	L2 misses
`LL_CACHE_MISS_RD`	0x37	Last-level read misses — i.e. DRAM accesses
`L1D_TLB_REFILL`	0x05	Data TLB misses
`DTLB_WALK`	0x34	Actual page-table walks
`BR_RETIRED`	0x21	Branches executed
`BR_MIS_PRED_RETIRED`	0x22	Branch mispredicts

Event	Number	Counts
`STALL_FRONTEND`	0x23	Cycles with no instruction issued, front end starved
`STALL_BACKEND`	0x24	Cycles with no instruction issued, back end busy
`MEM_ACCESS`	0x13	All memory accesses
`BUS_ACCESS`	0x19	Accesses that reached the interconnect
`EXC_TAKEN`	0x09	Exceptions taken
`LDREX_SPEC` / `STREX_FAIL_SPEC`	0x6C / 0x6E	Exclusive attempts and failures (ch. 22)

Some events are architected (the same everywhere), most are IMPLEMENTATION DEFINED. Always check the core's TRM for the ones that matter — `perf list` shows what the kernel knows about.

Reading the numbers

```
START with IPC. It tells you which world you are in:

   IPC = INST_RETIRED / CPU_CYCLES

     < 0.5   STALLED. Find out on what.
     0.5–1.5 mixed
     > 2.0   compute bound — further gains need a better
             ALGORITHM, not micro-optimisation

THEN split the stalls:

   STALL_FRONTEND high  → INSTRUCTION supply
        · I-cache misses, ITLB misses, branch mispredicts
        · fixes: code layout, PGO, fewer/more predictable
          branches, smaller hot code

   STALL_BACKEND high   → DATA supply or execution
        · D-cache misses, dependency chains, divides
        · fixes: data layout, blocking, more ILP (CA ch. 19)

THEN the specific rates:

   L1D miss rate    = L1D_CACHE_REFILL / L1D_CACHE
   LLC miss rate    = LL_CACHE_MISS_RD / LL_CACHE_RD
   branch miss rate = BR_MIS_PRED_RETIRED / BR_RETIRED
                      > 2% is worth investigating
   TLB walks/insn   = DTLB_WALK / INST_RETIRED
                      high → try huge pages

AND the speculation waste:

   INST_SPEC vs INST_RETIRED
     a large gap means work was executed and thrown away —
     heavy misprediction (CA chapter 12)
```

Using perf

```
# the standard first look
perf stat ./program
#   12,405,281,113  cycles                    #  2.98 GHz
#   18,204,113,782  instructions              #  1.47  insn per cycle
#    3,201,554,231  branches
#       62,119,882  branch-misses             #  1.94% of all branches

# ARM-specific, by architected name
perf stat -e cycles,instructions,\
l1d_cache,l1d_cache_refill,\
l2d_cache_refill,ll_cache_miss_rd,\
dtlb_walk,itlb_walk,\
br_retired,br_mis_pred_retired,\
stall_frontend,stall_backend ./program

# by raw event number, when the kernel does not know the name
perf stat -e r0011,r0008 ./program        # cycles, instructions

# WHICH function, and which instruction?
perf record -g ./program && perf report
perf record -e l1d_cache_refill ./program && perf annotate

# system-wide
perf stat -a sleep 10
perf top

# what does this kernel expose?
perf list | grep -i arm
ls /sys/bus/event_source/devices/
```

Sampling versus counting

```
COUNTING       program a counter, run, read the total.
               Exact. No overhead beyond the counter itself.
               → perf stat

SAMPLING       program the counter to OVERFLOW after N events,
               and take an interrupt. The handler records the PC.
               → perf record

  Sampling gives you attribution — WHICH code caused the misses —
  at the cost of overhead and of SKID: the PC recorded at the
  overflow interrupt is not exactly the instruction that caused
  the event, because the pipeline had moved on.

  Skid is why perf annotate sometimes blames the instruction
  AFTER the real culprit. Two mitigations:

    SPE — Statistical Profiling Extension (ARMv8.2). Hardware
          samples individual OPERATIONS and records the PC, the
          data address, the latency and the source of the data,
          into a memory buffer. No skid, and vastly richer.

          perf record -e arm_spe// -- ./program
          perf report --sort=symbol,srcline

    BRBE — Branch Record Buffer Extension (ARMv9). A hardware
           branch history, giving exact taken/not-taken paths.

  If your core has SPE, use it. It answers "which load missed,
  and where did the data come from" directly, which counting
  never can.
```

Access control

```
/* By default EL0 cannot touch the PMU. PMUSERENR_EL0 gates it: */

   PMUSERENR_EL0[0]  EN     allow EL0 access to all PMU registers
                 [1]  SW     allow EL0 writes to PMSWINC
                 [2]  CR     allow EL0 to read the CYCLE counter
                 [3]  ER     allow EL0 to read event counters

/* Enabling direct EL0 access removes the syscall from the
   measurement path — essential for microbenchmarks: */
        msr     pmuserenr_el0, #0xF

/* Linux exposes this as a sysctl: */
//   /proc/sys/kernel/perf_user_access   (arm64, 5.17+)

/* Why it is off by default: a cycle counter readable from
   userspace is a high-resolution TIMING SIDE CHANNEL, useful for
   cache-timing attacks. The same reasoning applies to
   CNTVCT_EL0, which hardened configurations sometimes also
   disable (chapter 32).                                    */

/* And the general perf gate: */
//   /proc/sys/kernel/perf_event_paranoid
//     -1  everything
//      0  no CPU events for unprivileged users
//      1  no tracepoints            (common default)
//      2  no kernel profiling       (hardened default)
//      3  no perf at all
```

Reading counters directly

```
/* For a tight microbenchmark, the perf syscall overhead can
   exceed what you are measuring. Read the counter yourself: */

static inline uint64_t read_cycles(void)
{
        uint64_t v;
        asm volatile("isb");                    /* order it */
        asm volatile("mrs %0, pmccntr_el0" : "=r"(v));
        return v;
}

/* Setup, from EL1: */
static void pmu_enable(void)
{
        /* enable the PMU and reset the cycle counter */
        write_sysreg(BIT(0) | BIT(2), pmcr_el0);   /* E | C  */
        /* enable the cycle counter */
        write_sysreg(BIT(31), pmcntenset_el0);
        /* do not divide by 64 */
        write_sysreg(read_sysreg(pmcr_el0) & ~BIT(3), pmcr_el0);
        /* allow EL0 access */
        write_sysreg(0xF, pmuserenr_el0);
        isb();
}

/* Programming an event counter: */
static void pmu_count_event(int counter, uint32_t event)
{
        write_sysreg(counter, pmselr_el0);      /* select        */
        isb();
        write_sysreg(event, pmxevtyper_el0);    /* which event   */
        write_sysreg(BIT(counter), pmcntenset_el0);
        isb();
}

/* The ISBs matter: without them the counter read can be
   reordered relative to the code being measured, giving results
   that vary with unrelated changes (chapter 21).          */
```

MICROBENCHMARKING TRAPS

- **Frequency scaling.** Cycles are a stable unit; seconds are not. Either pin the governor (`cpupower frequency-set -g performance`) or measure cycles.
- **Core migration.** On big.LITTLE the same code runs at very different speeds. Pin with `taskset`.
- **The counter is per-core.** If the thread migrates mid-measurement, the delta is meaningless.
- **Cold caches.** The first iteration measures the miss, not the code. Warm up, then measure.
- **Dead code elimination.** If the result is unused the compiler deletes the work (C ch. 01). Consume it.

The PMU under virtualisation

```
/* MDCR_EL2 controls guest PMU access: */
   MDCR_EL2.TPM    trap all PMU register access to EL2
   MDCR_EL2.TPMCR  trap PMCR_EL0 only
   MDCR_EL2.HPMN   how many counters the guest may use — the
                   rest are reserved for the hypervisor

/* So a hypervisor can:
     · give the guest a virtual PMU (KVM emulates it)
     · partition the counters between host and guest
     · deny access entirely, which is common in cloud
       environments because a cycle counter is a side channel

   Which is why `perf` inside a VM often reports nothing, or
   reports host-visible events that do not correspond to the
   guest's own execution. Check:                            */
//   dmesg | grep -i 'kvm.*pmu'
//   perf stat ./prog     → "not supported" means the PMU is
//                            not exposed to this guest
```

Beyond the core

```
/* Many SoCs expose additional PMUs outside the CPU: */

   DSU PMU        the DynamIQ Shared Unit — the cluster's L3
   CMN PMU        the coherent mesh interconnect (chapter 25)
   SMMU PMU       translation and TLB behaviour of DMA masters
   DDR / memory controller PMU
   GPU, NPU, and other accelerator counters

perf list | grep -iE 'arm_dsu|arm_cmn|smmu|ddr'
perf stat -e arm_cmn_0/hnf_cache_miss/ -a sleep 10
perf stat -e arm_dsu_0/bus_access/ ./prog

/* These answer questions the core PMU cannot:
     · is the interconnect saturated, or is DRAM the limit?
     · which agent is consuming memory bandwidth?
     · are SMMU TLB misses hurting a DMA-heavy workload?

   On a system where several masters share bandwidth (OS
   chapter 19), these are the only way to attribute the
   contention.                                              */
```

A workflow

```
1. MEASURE the thing you actually care about, end to end.
   If it is not repeatable, stop and fix that first.

2. perf stat — get IPC.
      low  → continue to 3
      high → the algorithm is the problem; stop measuring
             microarchitecture

3. Split the stalls: frontend or backend?

4. Drill into the specific rate — cache, TLB, branch.

5. perf record on THAT event → which function, which line.

6. Fix the largest contributor, and ONLY that one.

7. Re-measure. Did the predicted gain appear? If not, the
   model was wrong — that is information.

8. Re-profile. The bottleneck has moved.

Never skip step 1, and never optimise anything perf has not
shown you. CA chapter 18 has the arithmetic that makes this
worth doing in this order.
```

How it shows up

Symptom	Cause
`perf stat` reports `<not supported>`	PMU not exposed — a VM, or `perf_event_paranoid`
Counts scale oddly between runs	Event multiplexing — more events requested than counters exist
`perf annotate` blames the wrong instruction	Sampling skid; use SPE if available
Cycle counts vary 3× between runs	Frequency scaling, or migration between big and LITTLE
Direct counter reads give inconsistent results	Missing `ISB`, or the thread migrated
IPC high but the program is slow	Executing too many instructions — an algorithmic problem
IPC very low, few cache misses	Dependency chains, or frontend bound
Large `INST_SPEC` / `INST_RETIRED` gap	Heavy branch misprediction
High `strex_fail_spec`	Exclusive contention — switch to LSE or reduce sharing
Core counters look fine, throughput is poor	Interconnect or memory controller saturation — use the uncore PMUs

Check yourself

- ✓ Say what the PMU provides and why the counter count matters for `perf`.
- ✓ Explain what IPC tells you and what each range implies for your next step.
- ✓ Distinguish `STALL_FRONTEND` from `STALL_BACKEND` and the fixes for each.
- ✓ Explain the difference between counting and sampling, and what skid is.
- ✓ Say what SPE adds over sampling.
- ✓ Explain why EL0 PMU access is disabled by default.

- ✓ List four microbenchmarking traps and how to avoid each.
- ✓ Explain why `perf` often reports nothing inside a VM.
- ✓ Give a case where core counters are insufficient and an uncore PMU is needed.

Putting it together: one load instruction

Everything in this track converging on a single instruction. Follow `ldr x1, [x0]` from fetch to retirement, naming every structure it touches and every way it can fail — and the whole architecture becomes one connected picture.

The complete journey

```
       ldr  x1, [x0]        with x0 = 0xFFFF_0000_C0DE_1234

① FETCH                                              chapters 10, 12
     PC → I-TLB → L1 I-cache → the instruction word
     the branch predictor has already guessed the next PC
     FAILS: instruction abort — unmapped, or execute-never

② DECODE                                            chapters 03, 07
     fixed 32-bit encoding, decoded in parallel with neighbours
     recognised: 64-bit load, base x0, offset 0
     FAILS: undefined instruction, or trapped by a higher EL

③ RENAME / ISSUE                                          chapter 10
     x1 mapped to a fresh physical register
     the instruction waits until x0 is ready

④ ADDRESS GENERATION                                      chapter 08
     effective address = x0 + 0
     FAILS: nothing yet

⑤ ALIGNMENT CHECK                                         chapter 11
     Device memory → ANY unaligned access faults
     Normal memory → allowed unless SCTLR.A
     FAILS: alignment fault, ESR.DFSC = 0b100001

⑥ TRANSLATION                                    chapters 12, 13, 15
     VA[55] == 1 → TTBR1_EL1
     D-TLB lookup, tagged by ASID
       HIT  → PA and attributes in ~1 cycle
       MISS → hardware walks L0 → L1 → L2 → L3
              up to 4 memory accesses, each cacheable
     FAILS: translation fault, DFSC = 0b0001LL
            the LEVEL tells you which table was wrong

⑦ PERMISSION CHECK                                        chapter 14
     AP[2:1] vs the current EL and the access type
     UXN / PXN for instruction fetches
     PAN: may EL1 touch this EL0-accessible page right now?
     FAILS: permission fault, DFSC = 0b0011LL

⑧ STAGE 2                                                 chapter 16
     only if a hypervisor is active
     IPA → PA via VTTBR_EL2, second permission check
     FAILS: exception to EL2, not EL1. HPFAR_EL2 holds the IPA.

⑨ MEMORY TYPE                                             chapter 11
     AttrIndx → MAIR_EL1 slot → Normal-WB / Device-nGnRE / …
     shareability from SH[1:0]
     determines: cacheable? speculatable? reorderable?

⑩ CACHE                                              chapters 17, 19
     L1 D-cache probe (VIPT — indexed with the VA while the TLB
     produced the tag)
       miss → L2 → cluster L3 → system cache
     coherency maintained across the shareability domain

⑪ INTERCONNECT                                            chapter 25
     an AXI/CHI read carrying:
       ADDR = PA
       ID   = the master ID
       PROT[1] = the NS bit          ← TrustZone
```

```
        CACHE   = the attributes
      → an SMMU may translate it (non-CPU masters)
      → an XPU may REFUSE it
      FAILS: external abort, DFSC = 0b010000
             — translation SUCCEEDED; the bus said no

⑫ MEMORY CONTROLLER → DRAM

⑬ RETURN
      a 64-byte line fills L2 and L1
      x1 receives the requested 8 bytes

⑭ RETIRE                                                  chapter 10
      x1 architecturally updated, IN PROGRAM ORDER
      only NOW is the instruction irrevocable
```

Every failure, mapped

Step	Failure	ESR	First thing to check
①	Instruction abort	EC 0x20/0x21	Is the code mapped? Is the page XN?
②	Undefined instruction	EC 0x00	Optional feature without an ID check (ch. 01)
②	Trapped operation	EC 0x18, 0x07	A hypervisor or lazy-FP trap (ch. 31)
⑤	Alignment fault	DFSC 0b100001	Is this region Device memory?
⑥	Translation fault	DFSC 0b0001LL	Null pointer, missing `ioremap`, wrong TTBR
⑥	Access flag fault	DFSC 0b0010LL	`AF` not set in the descriptor
⑦	Permission fault	DFSC 0b0011LL	AP bits, XN, or PAN
⑥/⑦	Stale mapping used	—	Missing `TLBI` (ch. 15)
⑧	Stage-2 fault	EC 0x24 at EL2	`HPFAR_EL2`; is it an emulated device?
⑨	Wrong memory type	No fault	Cached MMIO, or Device DMA buffer (ch. 11)
⑩	Stale data	No fault	Missing cache maintenance (ch. 18)
⑩	Cross-core disagreement	No fault	Non-shareable mapping (ch. 19)
⑪	External abort	DFSC 0b010000	**Clock, power, or an access-control block**
⑪	Posted-write rejection	SError, EC 0x2F	Imprecise — use ESB to bisect
⑭	Wrong order observed	No fault	Missing barrier (ch. 21)

THE DISTINCTION THAT SAVES THE MOST TIME

Translation fault versus **external abort**. A translation fault means the page tables are wrong — a software problem you can fix by reading descriptors. An external abort means translation *succeeded*, a real bus transaction went out, and something out there refused it — a platform problem: an unclocked peripheral, a powered-down domain, or a firewall.

They send you to completely different parts of the system, and one field in ESR tells you which.

What each step costs

```
   TLB hit + L1 hit                     ~4 cycles
   TLB hit + L2 hit                     ~15 cycles
   TLB hit + LLC hit                    ~40 cycles
   TLB hit + DRAM                       ~200 cycles
   TLB MISS + walk cache hit            +10–20 cycles
   TLB MISS + full 4-level walk         +4 memory accesses
   TLB miss + TWO-STAGE walk            up to 24 accesses  (ch. 16)
   plus a page fault to the OS          ~1–5 µs           (minor)
   plus a page fault to DISK            ~100 µs – 10 ms   (major)

  Which is why the whole architecture exists as it does:
     · TLBs, because walks are expensive
     · walk caches, because even a partial walk is expensive
     · huge pages, because TLB reach is the limit
     · the two-register split, because context switches must not
       flush the TLB
     · ASIDs, for the same reason
     · caches at three levels, because DRAM is 50x a register
```

The parallel picture

```
One load, and a second core doing the same thing:

   Core 0                          Core 1
   ldr x1, [x0]                    str x2, [x0]
      │                               │
      │ both translate the same VA    │
      │ (same ASID, or a Global page) │
      ▼                               ▼
   L1 D-cache                      L1 D-cache
      │                               │
      └──────── COHERENCY ────────────┘        chapters 17, 19
                MESI over ACE/CHI
                automatic WITHIN the shareability domain
                     │
                     ▼
              same physical line

  Coherency is free. ORDERING is not:                chapters 20, 21
     · these two accesses to the SAME address are coherent and
       ordered — that is guaranteed
     · accesses to DIFFERENT addresses may be observed in any
       order unless you use a barrier or an ordered access

  And ATOMICITY is a third thing again:                  chapter 22
     · read-modify-write needs exclusives or LSE
     · which need SHAREABLE, cacheable memory to work at all

  Three separate guarantees, three separate mechanisms, three
  distinct failure modes. Diagnose which one you have before
  reaching for a fix.
```

The isolation stack

```
The same load, seen as a security question — "who is allowed to
touch this?"

   ┌──────────────────────────────────────────────────────┐
   │ EL0 application                                      │
   │   constrained by: stage-1 AP bits, UXN               │
   ├──────────────────────────────────────────────────────┤
   │ EL1 kernel                          chapters 14, 26  │
   │   constrained by: PXN, PAN, WXN, and its own tables  │
   ├──────────────────────────────────────────────────────┤
   │ EL2 hypervisor                      chapters 16, 31  │
   │   constrains EL1 via stage 2 and traps               │
   ├──────────────────────────────────────────────────────┤
   │ EL3 secure monitor                                   │
   │   owns SCR_EL3.NS — the security state itself        │
   ├──────────────────────────────────────────────────────┤
   │ MMU / SMMU              translation + permissions    │
   ├──────────────────────────────────────────────────────┤
   │ INTERCONNECT FIREWALL                    chapter 25  │
   │   the last checkpoint: master ID + address + NS bit  │
   ├──────────────────────────────────────────────────────┤
   │ DRAM · peripherals · fuses                           │
   └──────────────────────────────────────────────────────┘

  Every access is checked at least twice: once by the page tables
  (is this VA mapped, and readable?) and once by the interconnect
  (is this MASTER allowed here, in this security state?).

  Fail either and you get a fault — but a DIFFERENT fault, which
  is exactly the distinction above.

  The security track takes this stack apart in detail.
```

The diagnostic procedure

```
Given any memory-related failure on ARM:

  1. READ ESR FIRST.
       EC tells you the kind. DFSC tells you the cause.
       0x24 vs 0x25 tells you user vs kernel.        chapter 29

  2. Was there a FAULT at all?
       yes → continue at 3
       no  → this is a coherency, ordering or atomicity problem.
             Which one?                          chapters 19–22
               cores durably disagree  → shareability
               wrong order observed    → barriers
               update lost             → atomics

  3. TRANSLATION fault?
       → the address is not mapped. Check the page tables,
         and check the TLB was invalidated.       chapters 13, 15
       → use AT + PAR_EL1 to ask the hardware.        chapter 12

  4. PERMISSION fault?
       → it IS mapped. Check AP, XN, and PAN.         chapter 14

  5. EXTERNAL abort?
       → translation succeeded. This is a PLATFORM problem:
           · is the peripheral clocked and powered?
           · is the address right?
           · is a firewall denying this master?
         Check clocks FIRST — it is the most common cause and
         the cheapest to rule out.                    chapter 25

  6. SError?
       → imprecise. ELR is meaningless. Use ESB to bisect, and
         read the interconnect's latched error registers.

  7. No fault, wrong DATA?
       → memory type (cached MMIO?), or cache maintenance
         (DMA?).                                 chapters 11, 18
```

The tools, in one place

```
# ask the hardware to translate an address           chapter 12
        at      s1e1r, x0
        mrs     x1, par_el1
        /* success: PA + attributes.  failure: F=1 + fault code */

# what did the kernel map?
cat /sys/kernel/debug/kernel_page_tables
cat /proc/self/maps
cat /proc/iomem

# decode a fault                                     chapter 29
dmesg | grep -A25 'Internal error'
scripts/faddr2line vmlinux my_func+0x48

# is it firing?                                      chapter 24
cat /proc/interrupts
cat /sys/kernel/debug/irq/irqs/24

# what is the microarchitecture doing?               chapter 34
perf stat -e cycles,instructions,l1d_cache_refill,\
dtlb_walk,br_mis_pred_retired,stall_frontend,stall_backend ./prog

# coherency and sharing
perf c2c record ./prog && perf c2c report

# is this device coherent?                           chapter 19
grep -l dma-coherent /proc/device-tree/*/*/

# what does this CPU actually implement?             chapter 01
cat /proc/cpuinfo
lscpu -C
```

How the chapters connect

If you are debugging…	Read
A crash with an ESR value	29, then 13 or 14
MMIO that behaves strangely	11, 21, 25
DMA corruption	18, 19
A multi-core race	20, 21, 22
An interrupt that never fires, or never stops	24, then 23
A page table change with no effect	15
Slow code	34, 10, CA 18
A guest behaving oddly	16, 31
Boot that dies silently	12, 27, OS 18
A core that will not start or wake	33
Hand-written assembly corrupting things	04, 09

Check yourself

✓ Name the fourteen steps a load passes through, and which chapter covers each.

- ✓ Give the failure mode at every step and the ESR field that identifies it.
- ✓ Explain why translation fault and external abort send you to different subsystems.
- ✓ Give the cost of a TLB hit, a TLB miss, and a two-stage walk.
- ✓ Distinguish coherency, ordering and atomicity by mechanism and by symptom.
- ✓ Draw the isolation stack and say what checks an access twice.
- ✓ Walk the seven-step diagnostic procedure from an unknown failure to a subsystem.

TRACK COMPLETE

That closes the ARM track: the architecture and its licensing model, the register file and instruction set, the procedure call standard, the pipeline, memory types, the MMU and page walk, descriptors, TLBs, two-stage translation, caches and maintenance, shareability, the memory model, barriers, atomics, the GIC, AMBA, exception levels, vectors, entry and return, ESR decoding, the syscall path, traps, timers, power and PSCI, and the PMU.

Next is isolation and platform security — the SMMU, TrustZone and interconnect firewalls — which is built entirely on the mechanisms in this track: the NS bit on the bus, the descriptors' security attributes, stage-2 translation, and the exception model.

TRACK

Isolation & platform security

SMMU, TrustZone and interconnect firewalls — how a SoC keeps one piece of software away from another's memory.

20 chapters

The threat model of a modern SoC

Before any mechanism makes sense you need to know what it defends against. This chapter sets out who the adversaries are, what they can reach, and why a chip needs four independent isolation layers rather than one good one.

What is worth protecting

Asset	Loss means	Typical location
Device identity keys	The device can be cloned; attestation is worthless	Fuses, secure storage
Disk encryption keys	All user data at rest	Derived in the secure world from a hardware key
Firmware key hashes	An attacker can run arbitrary firmware — total compromise	One-time-programmable fuses
Biometric templates	Irreplaceable — a user cannot change their fingerprint	Secure world only
DRM content keys	Commercial loss; loss of certification	Trusted application
Payment credentials	Direct financial loss	Secure element or TEE
Anti-rollback counters	Old, vulnerable firmware can be reinstalled	Fuses
Integrity of running code	Everything else	Everywhere

Who you are defending against

```
Ordered by capability. Each level can do everything below it.

  1. REMOTE ATTACKER
       sends network traffic, malicious files, malformed input
       defeated by: memory safety, input validation, sandboxing

  2. LOCAL UNPRIVILEGED CODE
       an app on the device, or a compromised process
       defeated by: the MMU, process isolation, seccomp, SELinux

  3. LOCAL PRIVILEGED CODE  (root / EL1 compromise)
       full control of the OS kernel
       THIS is where the security track begins. Everything up to
       here is the OS's job; from here on the OS is ASSUMED
       COMPROMISED.
       defeated by: TrustZone, the SMMU, interconnect firewalls

  4. MALICIOUS OR BUGGY PERIPHERAL
       a DMA-capable device programmed to read anywhere
       defeated by: the SMMU / IOMMU

  5. PHYSICAL ATTACKER, non-invasive
       JTAG probe, bus probing, cold-boot RAM extraction,
       glitching the clock or voltage
       defeated by: fused-off debug, memory encryption, glitch
       detectors, redundant checks

  6. PHYSICAL ATTACKER, invasive
       decapping the die, microprobing, focused ion beam
       defeated by: shields, sensors, and ultimately economics.
       You raise the cost; you do not eliminate the threat.

MOST embedded security work targets levels 3 and 4. Those are
where a mechanism can give a hard guarantee.
```

THE ASSUMPTION THAT DEFINES THIS TRACK

Assume the rich OS will be compromised. Linux is tens of millions of lines with a continuous stream of CVEs. Designing as though a kernel compromise is impossible is designing for a world that does not exist.

So the question becomes: *what still holds when EL1 is fully attacker-controlled?* Everything in this track answers that question, and it is why the mechanisms live in *hardware*, below the kernel, rather than in it.

Four independent layers

```
   +-----------------------------------------------------+
   | 1. MMU — per-process isolation                      |
   |    constrains: CPU accesses                         |
   |    configured by: the OS kernel                     |
   |    defeated by: a kernel compromise                 |
   |    see: ARM chapters 12-16                          |
   +-----------------------------------------------------+
   | 2. SMMU / IOMMU — per-device isolation              |
   |    constrains: DMA from peripherals                 |
   |    configured by: the OS, or a hypervisor           |
   |    defeated by: whoever owns the tables             |
   |    see: chapters 02-07                              |
   +-----------------------------------------------------+
   | 3. TrustZone — world isolation                      |
   |    constrains: EVERYTHING, by security state        |
   |    configured by: EL3 firmware, before the OS runs  |
   |    survives: a full kernel compromise               |
   |    see: chapters 08-16                              |
   +-----------------------------------------------------+
   | 4. XPU / interconnect firewall                      |
   |    constrains: every transaction on the bus         |
   |    configured by: firmware, then LOCKED until reset |
   |    survives: even a compromised secure world        |
   |    see: chapters 17-20                              |
   +-----------------------------------------------------+

WHY FOUR? Each has a different failure mode:

   · the MMU is configured by software you may not trust
   · the SMMU only sees transactions that pass through it, and
     some masters have no SMMU at all
   · TrustZone splits into two worlds, but everything inside one
     world is mutually trusting
   · the XPU is the last checkpoint and can be locked, but it is
     coarse-grained

No single layer covers everything. That is not redundancy — it is
coverage of disjoint threats.
```

Enumerate every master

> **THE CPU IS ONE MASTER AMONG MANY**
>
> A modern SoC has a dozen or more agents that issue memory transactions independently. Every one is a potential path to your assets, and the ones people forget are the dangerous ones.

```
  +------+ +------+ +------+ +------+ +------+ +------+
  | CPU  | | GPU  | | DSP  | | NPU  | | DMA  | | USB  |
  +------+ +------+ +------+ +------+ +------+ +------+
  +------+ +------+ +------+ +------+ +------+ +------+
  |Video | |Camera| |Crypto| | PCIe | | WiFi | |Sensor|
  |codec | |  ISP | |engine| |      | |modem | | hub  |
  +------+ +------+ +------+ +------+ +------+ +------+
  +----------------+ +-------------+ +------------------+
  | Power mgmt MCU | | Debug / JTAG| | Test / DFT ports |
  +----------------+ +-------------+ +------------------+
    ^^^ THE ONES PEOPLE FORGET — often with no SMMU in front
        of them, and full access to memory.

For each master, ask three questions:
   1. What can it address?
   2. Who programs it, and from which security state?
   3. Is there an SMMU or firewall between it and memory?

A single "no" to question 3, on a master a compromised kernel
can program, bypasses everything above it.
```

Attack paths worth knowing

Path	How	Defence
DMA attack	Program a device to read or write arbitrary physical memory	SMMU (ch. 02)
Confused deputy	Trick privileged code into using its authority for you — pass it a pointer into memory you cannot reach	Validate every incoming address (ch. 16)
TOCTOU	Change a value between the check and the use	Copy into private memory, *then* validate
Downgrade	Install older, correctly signed but vulnerable firmware	Anti-rollback fuse counters (ch. 14)
Debug port	Attach JTAG on a production device	Fuse-disabled secure debug (ch. 10)
Cold boot	Freeze DRAM, move it, read the keys	Memory encryption, key scrubbing on suspend
Side channel	Infer secrets from cache timing, power draw or EM emissions	Constant-time code (crypto 19)
Speculation	Spectre-class leaks across a privilege boundary	`CSDB`, index masking (CA 12)
Fault injection	Glitch voltage or clock to skip a signature check	Redundant checks, randomised delays, detectors
Supply chain	Compromise the build, the signing key, or a vendor blob	Reproducible builds, HSM-held keys, review

The trusted computing base

> **TCB: EVERYTHING THAT MUST BE CORRECT FOR SECURITY TO HOLD**
>
> If any component has a bug, the guarantee fails. So the discipline is simple to state and hard to follow: **make the TCB as small as possible**, and be honest about what is in it.

```
A typical TCB for "the disk encryption key stays secret":

   boot ROM                   ~10 KB, immutable, unauditable
   BL2 trusted boot firmware  ~100 KB
   BL31 EL3 monitor (TF-A)    ~50 KB, RESIDENT forever
   trusted OS (OP-TEE)        ~300 KB
   the trusted application    ~10 KB
   the hardware               fuses, crypto engine, TZASC,
                              the SMMU, the interconnect
   ------------------------------------------------------
   TOTAL                      ~500 KB of code

  NOT in the TCB: Linux, Android, every app, every driver.
  Tens of millions of lines that can be fully compromised
  without exposing the key.

  That ratio — 500 KB versus 30 M lines — IS the value of
  TrustZone. And it is why the design principle is:

     EVERY BYTE added to the secure world enlarges the attack
     surface of the most privileged code on the chip. A
     vulnerability in a trusted application is WORSE than one in
     the kernel.

  So a TEE should do as little as possible: hold keys, perform
  one operation, return a result. Not parse untrusted formats.
  Not implement a filesystem. Not run a network stack.
```

Design principles that actually help

Principle	In practice
Least privilege	Every master gets the minimum access it needs; every trusted app gets one capability
Fail closed	The default rule denies. Anything you forgot to configure is refused, not permitted.
Complete mediation	Every access checked, every time. No cached "already allowed" decisions.
Defence in depth	The four layers above. Assume any one will be bypassed.
Economy of mechanism	A small TCB you can audit beats a large one you cannot
Open design	Security from the key, not from secrecy of the mechanism
Separation of duties	The code that verifies is not the code that executes
Lock what will not change	Configuration set before the OS starts should be immutable afterwards

Device lifecycle states

```
Silicon moves through fuse-controlled states, each disabling more
capability. This is why "it works on my dev board" is not
evidence that it works on a production part.

   BLANK / VIRGIN
      no keys fused, debug fully open, secure boot OFF
      for silicon bring-up

   DEVELOPMENT
      test keys fused, debug open, secure boot may run with
      development keys

   SECURED / PRODUCTION
      production key hash fused, secure boot ENFORCED,
      SECURE DEBUG DISABLED, test ports closed
      this is what ships

   RMA / RETURN
      a controlled path to re-enable debug for failure analysis,
      usually requiring a SIGNED unlock token and often
      destroying the device keys first

  Transitions are ONE-WAY, enforced by one-time-programmable
  fuses. You cannot go back.

  CONSEQUENCES you will meet:
     · JTAG stops working on production silicon
     · a peripheral readable on the dev board aborts in the field
     · timing changes because a debug path was removed
     · firmware that worked now fails signature checks

  Always test on a part in the FINAL lifecycle state before
  shipping.
```

What these mechanisms do not do

> **BE HONEST ABOUT THE LIMITS**
>
> - **TrustZone does not stop physical attacks.** An attacker with the die and a probe station reads the bus directly.
> - **A TEE is not a secure element.** It shares the CPU, caches and DRAM with the normal world, so it inherits every side channel. A separate secure element with its own die is a stronger — and slower, and more expensive — guarantee.
> - **Secure boot does not protect a running system.** It verifies what loads; it says nothing about what happens afterwards. Runtime attestation is a separate mechanism.
> - **An SMMU does not help if it is not configured.** Devices left in bypass are unprotected, and this is a very common misconfiguration.
> - **None of this fixes bugs.** A buffer overflow in a trusted application is still a buffer overflow — with more privilege.
>
> Stating the limits precisely is not pessimism; it is what lets you pick the right mechanism for the actual threat.

How this track is organised

Chapters	Cover	Defend against
02–07	The SMMU: why DMA breaks isolation, StreamIDs, stream tables, stages, faults, and the DMA API	Adversary 4 — peripherals
08–16	TrustZone: the NS bit, the two worlds, hardware enforcement, SMC, the TEE stack, secure boot, TrustZone-M, attacks	Adversary 3 — a compromised OS
17–20	Interconnect firewalls: concepts, programming, policy design, debugging	Everything, as the last checkpoint

Every mechanism here is built on the ARM track: the NS bit is `AxPROT[1]` on the bus (ARM 25), stage-2 translation is ARM 16, descriptor security attributes are ARM 14, and the world switch uses the exception model of ARM 28. If those are not solid, read them first.

How it shows up

Symptom	Underlying issue
Works on the dev board, fails in the field	Lifecycle state changed; fuses tightened the configuration
JTAG cannot attach to production silicon	Secure debug fused off — by design
A peripheral reads as zeros only on shipping units	A firewall or TZPC assignment the dev board lacked
A device reads memory it should not	No SMMU, or the SMMU left in bypass
A TEE vulnerability gives full device compromise	Too much code in the secure world
Firmware downgrade reinstates a fixed bug	No anti-rollback counter
Keys recovered from a powered-off device	Cold boot; no memory encryption or key scrubbing
Secure boot passes but the system is compromised at runtime	Boot verification is not runtime integrity

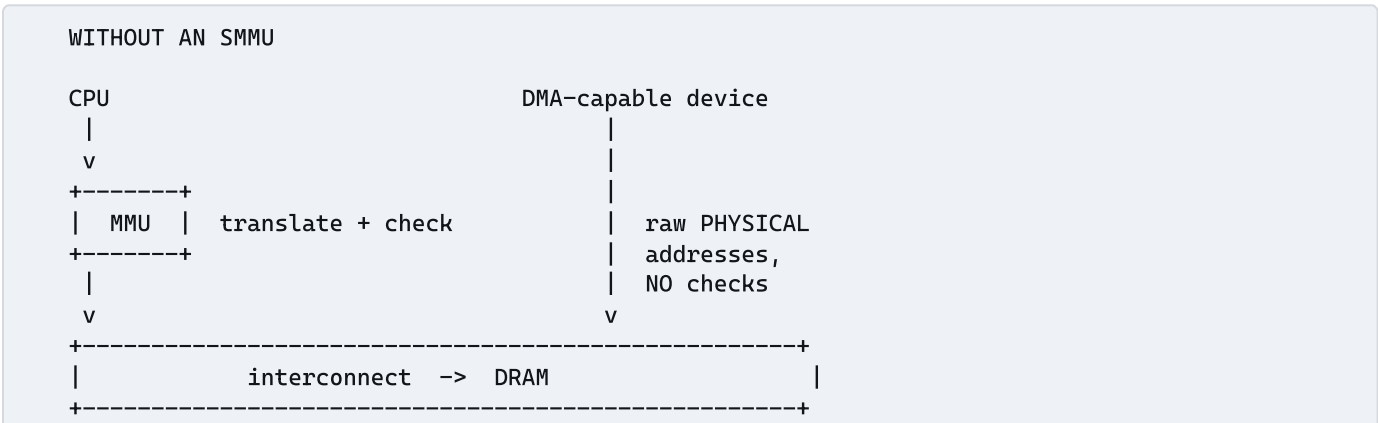
Check yourself

- ✓ Name six adversary classes in order of capability and say where this track begins.
- ✓ State the assumption that motivates hardware-based isolation.
- ✓ Give the four isolation layers, what each constrains, and what defeats each.
- ✓ List five bus masters people forget, and the three questions to ask about each.
- ✓ Define the TCB and explain why its size is the central design concern.
- ✓ Explain the confused deputy and TOCTOU patterns.
- ✓ Name the device lifecycle states and three things that change in the secured state.
- ✓ Give four things these mechanisms explicitly do not protect against.

Why DMA breaks memory protection

The MMU sits between a CPU core and the interconnect. A DMA engine does not go through a CPU core. Every isolation guarantee built out of page tables therefore has a hole in it, and closing that hole is what the SMMU exists to do.

The gap



WHAT THIS MEANS CONCRETELY

An attacker who can program a DMA engine — which on most systems means an attacker who has compromised the kernel, or who can plug in a Thunderbolt device — can:

- Read kernel memory, including disk encryption keys held in RAM.
- Overwrite kernel code or the page tables, escalating from device access to full control.
- Overwrite another VM's memory, escaping the hypervisor.
- Do all of this *with the CPU's MMU perfectly configured*, because the MMU was never involved.

Real attack classes

Attack	Vector	Note
Thunderbolt / PCIe hotplug	Plug a malicious device into a running machine and DMA to arbitrary memory	The "evil maid" attack. Thunderclap (2019) demonstrated it against every major OS.
FireWire	The original — FireWire allowed unmediated DMA by design	Used for years to unlock laptops by patching the password check in RAM
Compromised device firmware	A NIC, GPU or storage controller running attacker code, DMA-ing anywhere	Firmware is rarely audited and often updatable

Attack	Vector	Note
Buggy device	Not malicious — a hardware or firmware bug writing outside its buffer	Far more common than deliberate attacks, and just as destructive
Driver bug	A driver programs a device with an attacker-influenced address	Turns a driver bug into arbitrary physical write
VM escape	A guest with a passed-through device programs it with guest-physical addresses	Without stage-2 IOMMU translation, those are treated as host-physical

Four problems, one solution

```
The SMMU is usually described as a security feature. It solves
FOUR distinct problems, and only one is security:

  1. ISOLATION (security)
       constrain a device to the memory it was given
       -> the whole of this chapter

  2. VIRTUALISATION
       a guest programs a device with GUEST-physical addresses.
       Without translation, the device uses them as HOST-physical
       and scribbles over the host or another guest.
       -> stage 2 makes device passthrough possible at all

  3. SCATTER-GATHER
       a device wanting one large contiguous buffer forces the OS
       to find contiguous PHYSICAL memory, which fragments and
       eventually fails (OS chapter 11).
       -> with translation, physically scattered pages appear
          contiguous to the device

  4. ADDRESS WIDTH
       a legacy 32-bit device cannot reach memory above 4 GB.
       Without translation you need slow BOUNCE BUFFERS: copy the
       data down below 4 GB, DMA, copy back.
       -> with translation, any physical page can be mapped into
          the device's reachable range

  Problems 3 and 4 are why IOMMUs existed long before anyone
  worried about DMA attacks. The security benefit came later,
  and is now the main reason they are mandatory.
```

Putting an MMU in front of the device

```
   WITH AN SMMU

   CPU                              DMA-capable device
    |                                     |
    v                                     v
   +-------+                         +-----------+
   |  MMU  |                         |   SMMU    |
   +-------+                         +-----------+
    |   translate + check              |   translate + check,
    |                                  |   BY STREAMID
    v                                  v
   +-------------------------------------------------+
   |            interconnect  ->  DRAM                |
   +-------------------------------------------------+

  Same idea, same descriptor format, same permission bits. The
  difference is that the SMMU serves MANY devices through one
  block, so it needs the transaction to say WHO is asking.

  That identifier is the STREAMID, and it is the subject of the
  next chapter.

  Terminology: ARM calls it the SMMU (System MMU). The generic
  term is IOMMU. Intel's is VT-d, AMD's is AMD-Vi, and they
  differ in programming model but not in concept.
```

Why the MMU alone is not enough

```
/* A natural question: why not just have the device use virtual
   addresses through the CPU's MMU?

   Three reasons it cannot work:

   1. WHICH page tables? The CPU's MMU uses TTBR0/TTBR1 for the
      CURRENTLY RUNNING process. A device operates asynchronously
      - the process that started the transfer may not be running,
      may have exited, or may be on another core.

   2. The MMU is INSIDE the core. Physically, a device's
      transactions do not pass through it. Routing them there
      would mean routing all DMA through a CPU, which defeats the
      point of DMA entirely.

   3. Devices need their own POLICY. A device should be confined
      to the buffers it was given - not to whatever the process
      that programmed it can see. Those are different sets.

   Hence a separate translation unit, on the device side of the
   interconnect, with its own tables and its own notion of
   identity.                                                  */
```

A second, separate problem

> **ISOLATION AND COHERENCY ARE DIFFERENT ISSUES**
>
> DMA creates two problems and they are often confused:
>
> - **Isolation** — the device can reach memory it should not. Solved by the SMMU.
> - **Coherency** — the device and the CPU disagree about the *contents* of memory it legitimately reached. Solved by cache maintenance or by hardware coherency (ARM 18, ARM 19).
>
> An SMMU does not make DMA coherent, and cache maintenance does not make it isolated. A driver needs to get both right, which is exactly why the DMA API exists to handle them together (chapter 07).

Where the SMMU sits

```
Not every master goes through an SMMU. This is a SoC
INTEGRATION decision, and it is the first thing to establish
about any platform:

   +------+  +------+  +------+  +------+  +------+
   | GPU  |  | NPU  |  | DMA  |  | PCIe |  | PMU  |
   +--+---+  +--+---+  +--+---+  +--+---+  |micro-|
      |         |         |         |      |cntlr |
   +--v---------v---------v---------v--+   +--+---+
   |            SMMU                   |      |
   +-----------------+-----------------+      | NO SMMU
                     |                        | at all
   +-----------------v------------------------v------------+
   |                    interconnect                        |
   +--------------------------------------------------------+

  The power-management microcontroller, a sensor hub, or a
  debug/test port may have direct memory access with nothing in
  front of it. Those masters are outside the SMMU's protection
  entirely, and can only be constrained by an interconnect
  FIREWALL (chapters 17-20).

  So the layered design of chapter 01 is not theoretical: some
  masters are covered by layer 2, some only by layer 4, and you
  must know which is which for your SoC.
```

```
# what does Linux think is behind an IOMMU?
ls /sys/kernel/iommu_groups/
ls -l /sys/kernel/iommu_groups/*/devices/

# is a specific device translated?
ls /sys/bus/pci/devices/0000:01:00.0/iommu_group
ls /sys/bus/platform/devices/*/iommu_group

# a device with NO iommu_group symlink is NOT behind an SMMU
for d in /sys/bus/platform/devices/*; do
  [ -e "$d/iommu_group" ] || echo "no IOMMU: $(basename $d)"
done
```

IOMMU groups

```
The SMMU can only distinguish devices whose transactions carry
DIFFERENT StreamIDs. Sometimes it cannot.

  A PCIe bridge that does not support Access Control Services
  may allow peer-to-peer traffic between devices behind it -
  traffic that never reaches the SMMU at all. Two such devices
  can DMA to each other regardless of what the SMMU says.

  Linux therefore groups devices that CANNOT be isolated from
  each other into one IOMMU GROUP, and treats the group as the
  smallest unit of assignment:

     /sys/kernel/iommu_groups/12/devices/
         0000:01:00.0      <- a GPU
         0000:01:00.1      <- its audio function

  CONSEQUENCE: you cannot pass one device of a group to a VM and
  keep the other on the host. VFIO refuses, because doing so
  would be a false isolation guarantee.

  This is a very common source of "why can't I pass through my
  GPU" - the answer is usually that its group contains something
  else, and the fix is a different slot, ACS support, or (with
  full understanding of the risk) an ACS override.
```

Bypass: the most common misconfiguration

> **AN SMMU THAT IS NOT CONFIGURED PROTECTS NOTHING**
>
> A device whose StreamID has no valid Stream Table Entry can be handled in two ways: **abort** every transaction, or **bypass** translation entirely. Bypass means the device operates exactly as though no SMMU existed.
>
> Bypass is convenient during bring-up and catastrophic in production. Several real systems have shipped with it enabled because a device did not work otherwise and someone turned it on to unblock testing.

```
# Linux kernel command line options that matter here
iommu.passthrough=1              # ALL devices bypass - debug only
arm-smmu-v3.disable_bypass=1     # abort unmatched streams (default
                                 # since 4.20, and the correct setting)
iommu.strict=1                   # invalidate TLBs synchronously on
                                 # unmap. strict=0 is faster and
                                 # leaves a window where a freed page
                                 # is still reachable by the device.

# check what is actually in force
cat /proc/cmdline
dmesg | grep -iE 'smmu|iommu'
#   arm-smmu-v3 2b400000.iommu: ias 48-bit, oas 48-bit (features 0x...)
#   arm-smmu-v3 2b400000.iommu: allocated 65536 entry cmdq
#   iommu: Default domain type: Translated

# "Default domain type: Passthrough" means devices are NOT
# being translated. On a production system that is a finding.
```

What it costs

Cost	Magnitude	Mitigation
Translation latency on a TLB miss	A page-table walk per miss, up to 24 accesses with two stages (ARM 16)	SMMU TLBs, walk caches, huge pages
Map/unmap cost per transfer	Page table edits plus invalidation commands	Persistent mappings, larger buffers, deferred invalidation
Invalidation latency	A command queue round trip plus `CMD_SYNC`	`iommu.strict=0` — faster, and less safe
Memory for tables	Stream tables scale with the StreamID space	Two-level stream tables
Throughput on small transfers	Can be 10–30% on high-rate networking	Larger buffers, or ATS (ch. 05)

These costs are why bypass is tempting and why `iommu.strict=0` exists. Both trade a real security property for measurable performance, and both should be a deliberate, documented decision rather than an accident.

How it shows up

Symptom	Cause
A device writes outside its buffer and corrupts the kernel	No SMMU, or the device is in bypass
Plugging in a Thunderbolt device compromises the machine	Unmediated DMA — the reason IOMMUs became mandatory on laptops
Guest with a passed-through device corrupts the host	No stage-2 IOMMU translation
Large DMA allocation fails on a long-running system	Physical fragmentation; scatter-gather via the SMMU avoids it
32-bit device transfers are slow	Bounce buffers; an SMMU removes the need
Cannot pass a GPU to a VM	Its IOMMU group contains other devices
`Default domain type: Passthrough` in dmesg	Translation disabled — a production finding
Networking throughput drops ~20% after enabling the IOMMU	Map/unmap and invalidation cost on small packets
DMA reads stale data even with the SMMU configured	A coherency problem, not an isolation one

Check yourself

- ✓ Explain in one sentence why the CPU's MMU does not constrain DMA.
- ✓ Give three things an attacker with DMA access can do.
- ✓ Name the four problems an IOMMU solves and say which two predate the security concern.
- ✓ Give three reasons a device cannot simply use the CPU's page tables.
- ✓ Distinguish the isolation problem from the coherency problem, with a symptom of each.
- ✓ Explain why some masters have no SMMU and what constrains them instead.
- ✓ Explain what an IOMMU group is and why VFIO refuses to split one.
- ✓ Say what bypass mode is and why it is a production finding.

SMMU: StreamID and identity

The CPU's MMU serves one core and knows implicitly whose translation to use. The SMMU serves dozens of devices through one block, so every transaction must carry an identifier. Getting that identifier right is the single most common SMMU bring-up problem.

The identity problem

```
  CPU MMU                          SMMU
  -------                          ----
  one core                         MANY devices
  context is IMPLICIT:             context must be EXPLICIT:
    "this core, right now"           "whichever device sent this"
  selected by TTBR0/TTBR1          selected by STREAMID
    plus the ASID                    plus the SubstreamID

So the SMMU's first job on every transaction is:
   look up WHO sent this, and find their translation context.

StreamID is that "who". It arrives as sideband signalling on
the interconnect alongside the address (ARM chapter 25).
```

Where a StreamID comes from

Bus	StreamID derived from	Assigned by
PCIe	The Requester ID: bus:device:function, 16 bits	PCIe enumeration, plus a per-root-complex base offset
On-SoC master	Hard-wired by the SoC integrator, often via `AxUSER` or a dedicated sideband	The chip designer — documented in the TRM
Behind a bridge	The bridge may re-ID transactions, or pass them through	The bridge's configuration
Multi-queue device	Often one StreamID per queue or per virtual function	The device, within a range the SoC allocated

THE NUMBER ONE SMMU BUG

The device tree says StreamID `0x800`; the hardware actually emits `0x801`. The SMMU finds no valid Stream Table Entry, aborts every transaction, and the device does not work.

The fault record tells you the StreamID the SMMU *saw*. Compare that against what you configured — that single comparison resolves most SMMU bring-up problems immediately.

```
arm-smmu-v3 2b400000.iommu: event 0x10 received:
arm-smmu-v3 2b400000.iommu: 0x0000080100000010
                              ^^^^ StreamID 0x801 — but the DT
                                   said 0x800
```

Telling software the StreamID

```
/* Device tree — the embedded case */

smmu: iommu@2b400000 {
        compatible = "arm,smmu-v3";
        reg = <0x0 0x2b400000 0x0 0x100000>;
        interrupts = <GIC_SPI 74 IRQ_TYPE_EDGE_RISING>,   /* eventq   */
                     <GIC_SPI 75 IRQ_TYPE_EDGE_RISING>,   /* gerror   */
                     <GIC_SPI 77 IRQ_TYPE_EDGE_RISING>;   /* cmdq-sync */
        interrupt-names = "eventq", "gerror", "cmdq-sync";
        #iommu-cells = <1>;              /* one cell: the StreamID */
};

/* A device with ONE StreamID: */
dma_engine@2c000000 {
        compatible = "vendor,dma-engine";
        reg = <0x0 0x2c000000 0x0 0x1000>;
        iommus = <&smmu 0x42>;           /* StreamID 0x42 */
        dma-coherent;
};

/* A device with SEVERAL — one per queue, for instance: */
        iommus = <&smmu 0x40>, <&smmu 0x41>,
                 <&smmu 0x42>, <&smmu 0x43>;

/* A whole bus, with a MAPPING rather than a list — used for
   PCIe, where devices appear at enumeration time:          */
pcie@40000000 {
        /* Requester ID -> StreamID:
              <rid-base &smmu stream-base count>              */
        iommu-map = <0x0 &smmu 0x0 0x10000>;
        iommu-map-mask = <0xffff>;
};

/* And a bus whose masters are behind a bridge that re-IDs: */
        iommu-map = <0x100 &smmu 0x800 0x100>;
/*                   ^RID base    ^SID base ^count            */
```

```
/* ACPI — the server and Windows-on-ARM case.

   The IORT (I/O Remapping Table) describes the topology as a
   graph of nodes, each mapping ID ranges to the next node:

      Named component / PCIe root complex
              |  ID mapping: input range -> output base
              v
      SMMUv3 node
              |
              v
      ITS group  (for MSIs — see below)

   Same information, different encoding. Linux parses both and
   presents an identical model to drivers.                   */

# inspect it
sudo cat /sys/firmware/acpi/tables/IORT | xxd | head
sudo iasl -d /sys/firmware/acpi/tables/IORT && less IORT.dsl
```

SubstreamID

```
One device, many contexts.

   StreamID       WHICH DEVICE          "the GPU"
   SubstreamID    WHICH CONTEXT         "process 4271's GPU work"

  Called PASID on PCIe (Process Address Space ID), SubstreamID in
  ARM's terminology. Up to 20 bits.

  WHY it exists: a GPU or accelerator serves many processes at
  once. Without SubstreamIDs, all of them would share one
  translation context, so any process's GPU work could reach any
  other's buffers — no isolation at all between GPU clients.

  With them, each process gets its own Context Descriptor, and
  therefore its own page tables:

     StreamID 0x42 (the GPU)
        +-- SubstreamID 0   -> kernel context
        +-- SubstreamID 1   -> process A's page tables
        +-- SubstreamID 2   -> process B's page tables
        +-- ...

  This is also the mechanism behind SVA — Shared Virtual
  Addressing — where the device's Context Descriptor points at a
  process's OWN page tables, so the device can dereference
  exactly the pointers the application uses, with no mapping
  step at all (chapter 05).
```

How the SMMU uses it

```
 incoming transaction
      StreamID, SubstreamID, address, R/W, NS, privilege
           |
           v
 +--------------------------+
 | STREAM TABLE             |   base = SMMU_STRTAB_BASE
 |   indexed by StreamID    |   entry = STE, 64 bytes
 +--------------------------+
           |
           v
 +--------------------------+

 translation tables - IDENTICAL descriptor format to the CPU's
 (ARM chapter 14)

The next chapter covers these structures in detail. The point
here is the SHAPE: StreamID selects a device, SubstreamID
selects a context within it, and from there everything is the
ordinary ARM translation machinery.
```

StreamID space and table size

```
/* A flat stream table needs 2^StreamIDSize entries of 64 bytes.
   With 16-bit StreamIDs that is 65536 * 64 = 4 MB. With 20-bit
   it is 64 MB. Allocating that when only a dozen devices exist
   is wasteful.                                              */

/* So SMMUv3 supports a TWO-LEVEL stream table: */

   SMMU_STRTAB_BASE_CFG.FMT = 1        /* two-level */

   StreamID[hi] -> L1 descriptor -> a span of L2 entries
   StreamID[lo] -> index within that span

/* Only the spans actually used are allocated. Exactly the same
   sparseness argument as multi-level page tables (ARM ch. 13). */

/* How wide is the StreamID space on this SMMU? */
        SMMU_IDR1.SIDSIZE       /* bits of StreamID supported */
        SMMU_IDR1.SSIDSIZE      /* bits of SubstreamID        */

# Linux reports it at probe:
dmesg | grep smmu
#   arm-smmu-v3 2b400000.iommu: ias 48-bit, oas 48-bit (features 0x00013fbf)
#   arm-smmu-v3 2b400000.iommu: 2-level strtab only covers 0..0xffff
```

MSIs and the StreamID

> **AN MSI IS A MEMORY WRITE, SO IT IS ALSO TRANSLATED**
>
> A device signals an interrupt by writing to an address (ARM 23). That write goes through the SMMU like any other, which means the ITS doorbell address must be *mapped* for that device — otherwise the interrupt silently never arrives, with no fault that obviously points at interrupts.
>
> Linux handles this by reserving an MSI region per device (`iommu_dma_get_resv_regions`) and mapping the ITS translater into every device's address space. When you see a device that transfers data correctly but never raises an interrupt, this is one of the first things to check.
>
> ```
> cat /sys/kernel/iommu_groups/*/reserved_regions
> #   0x0000000008080000 0x000000000808ffff msi
> #                                        ^ the ITS doorbell
> ```

When identity is ambiguous

```
Several situations make StreamIDs less trustworthy than they
look, and each is a real isolation weakness:

  ALIASING — two devices emit the SAME StreamID
       Some SoCs wire several masters to one ID, either by
       oversight or to save sideband wires. The SMMU cannot then
       distinguish them, and they must share one translation
       context. Whatever one can reach, the other can.

  PCIe WITHOUT ACS
       Peer-to-peer traffic between devices under a bridge may
       never reach the SMMU. Linux puts such devices in one
       IOMMU GROUP (chapter 02) and refuses to isolate them
       from each other.

  LEGACY PCI BRIDGES
       Devices behind a PCI-to-PCIe bridge all appear with the
       BRIDGE's Requester ID. Same consequence.

  DMA ALIASES / QUIRKS
       Some devices emit a Requester ID that is not their own —
       a documented hardware bug. Linux keeps a quirk table
       (pci_for_each_dma_alias) mapping the real device to every
       ID it might use.

  In every case the honest response is the same: treat the whole
  ambiguous set as ONE security domain, and do not claim
  isolation you do not have.
```

Verifying the StreamID

```
# 1. what does software think?
cat /proc/device-tree/soc/dma@2c000000/iommus | xxd
#   the second cell is the StreamID

# or from the driver's point of view
ls -l /sys/bus/platform/devices/2c000000.dma/iommu_group
cat /sys/kernel/iommu_groups/*/devices/* 2>/dev/null

# 2. what does the HARDWARE emit? Trigger a transaction and read
#    the fault record — the definitive answer.
dmesg | grep -A4 'event.*received'

# 3. trace map/unmap to confirm the domain is being used at all
echo 1 > /sys/kernel/debug/tracing/events/iommu/enable
cat /sys/kernel/debug/tracing/trace_pipe
#   map: IOVA=0x... paddr=0x... size=...

# 4. SMMU driver internals
ls /sys/kernel/debug/iommu/          # where available
cat /sys/class/iommu/smmu3.0.auto/devices/
```

THE BRING-UP SEQUENCE THAT WORKS

1. Boot with `arm-smmu-v3.disable_bypass=0` temporarily, so unmatched streams bypass rather than abort. If the device now works, the problem is definitely StreamID configuration, not the driver.
2. Re-enable `disable_bypass=1` and read the fault record to learn the StreamID the hardware actually emits.
3. Fix the device tree or IORT to match.
4. Confirm with the `iommu` tracepoints that mappings are being created for the right device.

Never ship with bypass enabled — but it is the fastest way to bisect the problem during bring-up.

How it shows up

Symptom	Cause
`C_BAD_STREAMID` on every transfer	Device tree or IORT StreamID does not match the hardware
Device works with `iommu.passthrough=1` only	Confirms a StreamID or mapping problem
DMA works but interrupts never arrive	The MSI doorbell address is not mapped for that device
Two devices interfere with each other's memory	StreamID aliasing — they share one context
Cannot pass one device of a pair to a VM	They are in the same IOMMU group
Multi-queue device works on queue 0 only	Only one of its StreamIDs is described
Works on one board revision, fails on another	The integrator changed the StreamID assignment
Stream table allocation fails at boot	Flat table for a large StreamID space; needs two-level
GPU clients can see each other's buffers	No SubstreamID support, or not used

Check yourself

- ✓ Explain why the SMMU needs an explicit identifier and the CPU's MMU does not.
- ✓ Say where a StreamID comes from for a PCIe device and for an on-SoC master.
- ✓ Describe the most common SMMU bring-up failure and how the fault record resolves it.
- ✓ Write the device tree for a device with two StreamIDs, and for a PCIe root complex.
- ✓ Explain what a SubstreamID adds and give a concrete case that needs one.
- ✓ Explain why a two-level stream table exists.
- ✓ Explain why an MSI doorbell must be mapped, and the symptom when it is not.
- ✓ Give three situations where StreamID identity is ambiguous, and the correct response.

SMMU: stream tables and context descriptors

SMMUv3 is entirely table-driven: software builds structures in memory and tells the hardware where they are. There is no per-device register bank to program. This chapter walks the lookup chain from a StreamID to a page table.

The lookup chain

The Stream Table Entry

`Config[2:0]`	Behaviour	Use for
`0b000`	**Abort** — every transaction from this stream is terminated	Unconfigured devices. **The correct default.**

`Config[2:0]`	Behaviour	Use for
`0b100`	**Bypass** — no translation, no checks	Debug only (ch. 02)
`0b101`	Stage 1 only	A bare-metal OS isolating its devices
`0b110`	Stage 2 only	Device passthrough to a VM with no guest IOMMU
`0b111`	Both stages	Nested: guest IOMMU plus hypervisor confinement

```
/* Building an STE for stage-1-only translation. Field names
   follow the SMMUv3 spec; the shape is what matters.       */

struct ste {
        uint64_t w[8];          /* 64 bytes */
};

static void ste_make_s1(struct ste *e, uint64_t cd_table_pa,
                        unsigned ssid_bits)
{
        memset(e, 0, sizeof *e);

        /* word 0: valid, config, CD table pointer and format */
        e->w[0] = STE_VALID
                | FIELD_PREP(STE_CONFIG, 0b101)         /* S1 only  */
                | FIELD_PREP(STE_S1FMT, ssid_bits ? 1 : 0)
                | (cd_table_pa & STE_S1CTXPTR_MASK)
                | FIELD_PREP(STE_S1CDMAX, ssid_bits);

        /* word 1: fault behaviour and attribute handling */
        e->w[1] = FIELD_PREP(STE_S1DSS, 0b01)   /* SSID 0 for no-SSID
                                                   transactions      */
                | FIELD_PREP(STE_S1CIR, 0b01)   /* cacheable CD fetch */
                | FIELD_PREP(STE_S1COR, 0b01)
                | FIELD_PREP(STE_S1CSH, 0b11)   /* inner shareable    */
                | FIELD_PREP(STE_STRW, 0b00)    /* EL1&0 regime       */
                | STE_S1STALLD;                  /* terminate rather
                                                    than stall        */

        /* the ZEROED and populated entry must be visible to the
           SMMU before it is marked valid - the SMMU is a separate
           observer reading memory directly (ARM chapter 13)     */
        __asm__ volatile("dsb ishst" ::: "memory");
}

/* And a stage-2 STE, for passthrough to a VM: */
static void ste_make_s2(struct ste *e, uint64_t s2_pgd_pa,
                        unsigned vmid)
{
        memset(e, 0, sizeof *e);
        e->w[0] = STE_VALID | FIELD_PREP(STE_CONFIG, 0b110);
        e->w[2] = FIELD_PREP(STE_S2VMID, vmid)
                | FIELD_PREP(STE_S2T0SZ, 64 - ipa_bits)
                | FIELD_PREP(STE_S2SL0, start_level)
                | FIELD_PREP(STE_S2TG, granule)
                | STE_S2AA64 | STE_S2R;         /* record faults */
        e->w[3] = s2_pgd_pa & STE_S2TTB_MASK;
        __asm__ volatile("dsb ishst" ::: "memory");
}
```

STE AND CD MEMORY HAS ATTRIBUTE REQUIREMENTS

The SMMU fetches these structures itself, as a separate bus master. The memory holding them must be accessible to it and must have *consistent* attributes: if the CPU writes them as cacheable Inner Shareable while the SMMU is configured to fetch them non-cacheable, the SMMU reads stale data. That is a mismatched-attributes bug (ARM 19) with a particularly confusing symptom — a table that looks correct in a memory dump but does not work.

The `S1CIR` / `S1COR` / `S1CSH` fields in the STE, and `SMMU_CR1`'s equivalents for the stream table itself, must match how software writes them.

Two-level stream tables

```
A flat table needs 2^SIDSIZE entries of 64 bytes:

   16-bit StreamID -> 65536 * 64 =  4 MB
   20-bit          -> 1M    * 64 = 64 MB

Wasteful when a dozen devices exist. So:

   SMMU_STRTAB_BASE_CFG.FMT = 1        two-level

   StreamID[hi]  -> L1 descriptor (8 bytes)
                       V, SPAN, L2 table address
   StreamID[lo]  -> index into that L2 table of STEs

   +-------------+
   | L1 desc 0   |--> [ STE ][ STE ][ STE ] ... (SPAN entries)
   | L1 desc 1   |    invalid - no L2 table allocated
   | L1 desc 2   |--> [ STE ][ STE ] ...
   +-------------+

  Only the spans actually used are allocated. Exactly the
  sparseness argument of multi-level page tables (ARM ch. 13).

  SPAN encodes log2(entries + 1), so a span of 0 means the L1
  descriptor is invalid - a common off-by-one when building
  these by hand.
```

The Context Descriptor

```
/* The CD is the SMMU's version of a CPU translation context.
   Compare field by field with ARM chapter 12:              */

   CD field        CPU equivalent
   --------        --------------
   TTB0, TTB1      TTBR0_EL1, TTBR1_EL1
   T0SZ, T1SZ      TCR_EL1.T0SZ / T1SZ
   TG0, TG1        TCR_EL1.TG0 / TG1
   IPS             TCR_EL1.IPS
   IRGN, ORGN, SH  TCR_EL1 walk cacheability and shareability
   EPD0, EPD1      TCR_EL1.EPD0 / EPD1  (disable a TTBR)
   MAIR            MAIR_EL1
   ASID (A)        TTBR0_EL1[63:48]
   AA64            execution state
   nSCFG, ASET     SMMU-specific: NS handling, ASID scope

/* Which is the whole point: the SMMU can be pointed at the
   SAME translation tables a process is using, with the SAME
   ASID, and the device then dereferences exactly the pointers
   the application uses. That is SVA (chapter 05).         */

static void cd_make(struct cd *c, uint64_t ttbr0, unsigned asid)
{
        memset(c, 0, sizeof *c);
        c->w[0] = CD_VALID | CD_AA64
                | FIELD_PREP(CD_T0SZ, 64 - va_bits)
                | FIELD_PREP(CD_TG0, granule_code)
                | FIELD_PREP(CD_IRGN0, 0b01)    /* WB cacheable walks */
                | FIELD_PREP(CD_ORGN0, 0b01)
                | FIELD_PREP(CD_SH0, 0b11)      /* inner shareable    */
                | CD_EPD1                        /* no TTBR1 for a
                                                    device context    */
                | FIELD_PREP(CD_ASID, asid);
        c->w[1] = ttbr0 & CD_TTB0_MASK;
        c->w[3] = mair_value;
        __asm__ volatile("dsb ishst" ::: "memory");
}
```

CD tables

```
Like stream tables, CD tables can be linear or two-level,
depending on how many SubstreamIDs a device uses:

   LINEAR    STE.S1Fmt = 0
             one contiguous array of 2^S1CDMax entries
             fine for a handful of contexts

   TWO-LEVEL STE.S1Fmt = 1 or 2
             for a device with thousands of contexts – a GPU
             serving every process on the system

  And the degenerate case: a device with NO SubstreamIDs uses a
  single CD, with STE.S1CDMax = 0. The CD pointer then points
  directly at one 64-byte descriptor rather than a table.

  STE.S1DSS controls what happens to a transaction that arrives
  WITHOUT a SubstreamID on a device that has them:
       0b00  terminate
       0b01  use SubstreamID 0
       0b10  bypass stage 1

  Getting S1DSS wrong gives a device whose SubstreamID-tagged
  traffic works while its untagged traffic aborts – a confusing
  partial failure.
```

The few registers that exist

Register	Holds
`SMMU_IDR0-5`	Read-only capability: StreamID width, supported granules, stage support, ATS, PRI, coherency of table walks
`SMMU_CR0`	Global enable: `SMMUEN`, `EVENTQEN`, `CMDQEN`, `PRIQEN`
`SMMU_CR1`	Table and queue memory attributes — must match how software writes them
`SMMU_CR2`	Private TLB behaviour, `RECINVSID` (record invalid-StreamID events)
`SMMU_STRTAB_BASE`	Physical address of the stream table
`SMMU_STRTAB_BASE_CFG`	Format (linear or 2-level), `LOG2SIZE`, `SPLIT`
`SMMU_CMDQ_BASE/PROD/CONS`	The command queue
`SMMU_EVENTQ_BASE/PROD/CONS`	The event queue
`SMMU_PRIQ_*`	The page-request queue
`SMMU_GERROR/GERRORN`	Global errors — a malformed command, a queue overflow

That is nearly the whole MMIO interface. Everything else — every device's configuration — lives in memory structures. This is a deliberate contrast with SMMUv2, which had a bank of registers per "context bank" and therefore a hard limit on how many contexts could exist.

Bringing an SMMU up

```
/* The order matters, and several steps are easy to omit. */

/* 1. read capabilities BEFORE assuming anything */
        idr0 = readl(base + SMMU_IDR0);
        idr1 = readl(base + SMMU_IDR1);
        sid_bits   = FIELD_GET(IDR1_SIDSIZE, idr1);
        ssid_bits  = FIELD_GET(IDR1_SSIDSIZE, idr1);
        has_s1     = idr0 & IDR0_S1P;
        has_s2     = idr0 & IDR0_S2P;
        coherent   = idr0 & IDR0_COHACC;    /* are table walks
                                               coherent with the CPU? */

/* 2. DISABLE the SMMU while configuring */
        writel(0, base + SMMU_CR0);
        wait_for_ack(SMMU_CR0ACK, 0);

/* 3. allocate and ZERO the stream table. Every STE must be
      valid-bit-clear or explicitly set to ABORT — never left as
      whatever memory happened to contain.                    */
        strtab = alloc_zeroed(strtab_size);
        for (i = 0; i < nr_entries; i++)
                ste_make_abort(&strtab[i]);

/* 4. allocate the command, event and PRI queues */

/* 5. program the bases and attributes */
        writeq(strtab_pa | fmt, base + SMMU_STRTAB_BASE);
        writel(cfg,               base + SMMU_STRTAB_BASE_CFG);
        writel(queue_attrs,       base + SMMU_CR1);

/* 6. invalidate EVERYTHING cached from a previous boot stage */
        cmdq_issue(CMD_CFGI_ALL);
        cmdq_issue(CMD_TLBI_NSNH_ALL);
        cmdq_issue(CMD_SYNC);

/* 7. enable the queues, THEN the SMMU */
        writel(CR0_CMDQEN | CR0_EVTQEN, base + SMMU_CR0);
        wait_for_ack(...);
        writel(CR0_CMDQEN | CR0_EVTQEN | CR0_SMMUEN, base + SMMU_CR0);
        wait_for_ack(...);

/* Step 3 is the security-critical one: if unconfigured entries
   are left with the valid bit SET from stale memory, unknown
   devices get whatever translation that garbage describes. Zero
   the table, and configure the default as ABORT.          */
```

Secure and non-secure interfaces

```
SMMUv3 has TWO complete programming interfaces, at different
address offsets:

   +0x0000   Non-secure  SMMU_*
   +0x8000   Secure      SMMU_S_*        (present if IDR1.SECURE_IMPL)

  Each has its OWN stream table, command queue, event queue and
  enable bit. They are independent.

  WHY: a device operating in the secure world must be configured
  by secure firmware. If the Non-secure OS could program that
  device's translations, it could redirect a secure DMA engine's
  transfers into normal-world memory - a complete bypass of
  TrustZone.

  And the STE carries security attributes too: STE.NSCFG and
  CD.NSCFG determine whether the resulting transaction is issued
  as Secure or Non-secure, exactly as the descriptor NS bit does
  for the CPU (ARM chapter 14).

  So the SMMU is not merely an isolation device for the normal
  world - it is part of the TrustZone enforcement boundary
  (chapters 08-10).
```

What Linux does

```
/* drivers/iommu/arm/arm-smmu-v3/ - worth reading, and about
   6000 lines. The structures map directly onto the above:  */

struct arm_smmu_device {
        void __iomem            *base;
        struct arm_smmu_strtab_cfg strtab_cfg;   /* stream table   */
        struct arm_smmu_cmdq     cmdq;
        struct arm_smmu_evtq     evtq;
        struct arm_smmu_priq     priq;
        u32                      features;       /* from IDR0-5    */
};

struct arm_smmu_domain {                 /* one per address space  */
        struct arm_smmu_device  *smmu;
        enum arm_smmu_domain_stage stage;         /* S1 or S2      */
        struct io_pgtable_ops   *pgtbl_ops;       /* the page tables */
        struct arm_smmu_ctx_desc cd;              /* the CD         */
};

/* And the generic IOMMU layer above it: */
        iommu_domain_alloc()      create an address space
        iommu_attach_device()     point a StreamID at it
        iommu_map(domain, iova, paddr, size, prot)
        iommu_unmap(domain, iova, size)

/* The io-pgtable library builds the actual tables, and is SHARED
   with the CPU's page table code - because the format is
   identical.                                                  */
```

Inspecting the tables

```
# the SMMU's own view
dmesg | grep -i smmu
#   arm-smmu-v3 2b400000.iommu: ias 48-bit, oas 48-bit (features 0x00013fbf)
#   arm-smmu-v3 2b400000.iommu: allocated 65536 entry cmdq
#   arm-smmu-v3 2b400000.iommu: 2-level strtab only covers 0..0xffff

# domains and groups
ls /sys/kernel/iommu_groups/*/devices/
cat /sys/kernel/iommu_groups/*/type          # DMA, DMA-FQ, identity

# mappings, live
echo 1 > /sys/kernel/debug/tracing/events/iommu/enable
cat /sys/kernel/debug/tracing/trace_pipe
#   map:   IOVA=0x... paddr=0x... size=0x1000
#   unmap: IOVA=0x... size=0x1000

# from a JTAG debugger, walk the tables by hand:
#   1. read SMMU_STRTAB_BASE
#   2. index by StreamID (allowing for the two-level format)
#   3. read the STE's 8 words; check V and Config
#   4. follow S1ContextPtr to the CD
#   5. follow the CD's TTB0 into the page tables, which you can
#      then walk exactly as in ARM chapter 13

# Doing this once by hand makes every later SMMU problem
# tractable.
```

How it shows up

Symptom	Cause
`C_BAD_STE` events	Malformed STE, or the STE memory has attributes the SMMU cannot read coherently
`C_BAD_CD`	Bad TCR-equivalent fields, or a misaligned CD table
Tables look right in a dump but do not work	Mismatched memory attributes between CPU writes and SMMU fetches
Unknown devices get working translations	Stream table not zeroed; stale valid entries
SubstreamID traffic works, untagged traffic aborts	`STE.S1DSS` misconfigured
Stream table allocation fails at boot	Flat format with a large StreamID space; use two-level
Secure device redirected by the normal-world OS	Secure interface not used for secure streams
Changes to an STE have no effect	Missing `CMD_CFGI_STE` and `CMD_SYNC` (ch. 05)
SMMU enable never acknowledges	Queues not enabled first, or a base address the SMMU cannot reach

Check yourself

- ✓ Draw the lookup chain from StreamID to a page table entry.
- ✓ Give the five STE `Config` values and when each is correct.
- ✓ Explain why the default for an unconfigured stream must be abort, not bypass.
- ✓ Map five CD fields onto their CPU system-register equivalents.

- ✓ Explain why the CD's similarity to the CPU's context is the point.
- ✓ Explain when a two-level stream table or CD table is needed.
- ✓ Explain why STE and CD memory attributes must match how software writes them.
- ✓ Say why the SMMU has separate secure and non-secure programming interfaces.

SMMU: stages, queues and invalidation

Two translation stages with two different owners, three queues connecting software to hardware, and an invalidation discipline that mirrors the CPU's exactly. Plus the advanced features — ATS, PRI and SVA — that let a device share a process's address space directly.

Two stages, two owners

	Stage 1	Stage 2
Translates	Device address (IOVA) → IPA	IPA → PA
Owned by	The OS, or a guest OS	**The hypervisor**
Root held in	The Context Descriptor's `TTB0`	The STE's `S2TTB`
Tagged by	ASID	VMID
Purpose	Scatter-gather, per-process isolation, confining a device to its buffers	Confining a whole device to one VM's memory
Guest can change it?	Yes — it is the guest's own	**No** — that is the point

```
  BARE-METAL OS, stage 1 only

    device --> IOVA --[ stage 1, OS tables ]--> PA

  DEVICE PASSED THROUGH TO A VM, stage 2 only

    device --> IPA ---[ stage 2, hypervisor ]--> PA
               ^ the guest programs the device with its own
                 "physical" addresses, and cannot escape

  NESTED — a guest with its own IOMMU driver, both stages

    device --> IOVA --[ stage 1, GUEST ]--> IPA
                      --[ stage 2, HYPERVISOR ]--> PA

Exactly the structure of CPU two-stage translation
(ARM chapter 16), with the same walk-multiplication cost: each
stage-1 table access itself needs a stage-2 translation, so a
full nested walk can be up to 24 memory accesses.

Mitigations are the same too: SMMU TLBs caching the combined
IOVA -> PA translation, walk caches for intermediate
descriptors, and huge pages at stage 2 (a 1 GB block for the
guest's RAM is standard).
```

The three queues

```
Software and the SMMU communicate through circular buffers in
memory, each with producer and consumer indices in registers.

   COMMAND QUEUE          software  ->  SMMU
      CMDQ_BASE, CMDQ_PROD (software writes), CMDQ_CONS (SMMU)
      invalidate a cached STE, CD or TLB entry; synchronise;
      prefetch; respond to a page request

   EVENT QUEUE            SMMU  ->  software
      EVENTQ_BASE, EVENTQ_PROD (SMMU writes), EVENTQ_CONS
      fault records: bad StreamID, translation fault, permission
      fault, external abort. An interrupt signals arrival.

   PRI QUEUE              SMMU  ->  software
      PRIQ_BASE, PRIQ_PROD, PRIQ_CONS
      page requests from a device that supports PRI — "please
      map this address for me". Optional.

  Same design as the GIC's ITS command queue (ARM chapter 23),
  and as virtio and io_uring (OS chapter 08): a shared ring plus
  a doorbell. Recognise the pattern.

  Queue memory attributes must match SMMU_CR1's configuration,
  for the same reason STE memory does (chapter 04).
```

Commands worth knowing

Command	Invalidates	Issue after
`CMD_CFGI_STE`	One cached Stream Table Entry	Modifying an STE
`CMD_CFGI_ALL`	Every cached configuration	Initialisation
`CMD_CFGI_CD`	One cached Context Descriptor	Modifying a CD
`CMD_CFGI_CD_ALL`	All CDs for one StreamID	Tearing down a device's contexts
`CMD_TLBI_NH_VA`	One stage-1 address, by ASID	Unmapping a page
`CMD_TLBI_NH_ASID`	All stage-1 entries for an ASID	Tearing down an address space
`CMD_TLBI_S2_IPA`	One stage-2 IPA	Changing a stage-2 mapping
`CMD_TLBI_S12_VMALL`	Both stages for one VMID	Tearing down a VM
`CMD_TLBI_NSNH_ALL`	Everything non-secure	Initialisation
`CMD_ATC_INV`	A device's own translation cache	**Unmapping, when ATS is in use**
`CMD_PRI_RESP`	—	Answering a page request
`CMD_SYNC`	—	**Wait for everything before it to complete**

> **THE INVALIDATION RULE, EXACTLY AS FOR THE CPU**
>
> Anything you change in memory — an STE, a CD, a page table entry — is invisible to the SMMU until you issue the matching invalidate command *and* a `CMD_SYNC`. This mirrors the CPU's write → DSB → TLBI → DSB → ISB sequence (ARM 15), and omitting it produces exactly the same class of "works sometimes" bug.

```
/* Unmapping a page, correctly: */

        /* 1. clear the descriptor */
        *pte = 0;

        /* 2. make the write visible to the SMMU, which is a
              separate observer reading memory directly       */
        dsb(ishst);

        /* 3. invalidate the SMMU's TLB entry */
        cmdq_issue(CMD_TLBI_NH_VA, asid, iova);

        /* 4. if ATS is in use, invalidate the DEVICE's cache too,
              and WAIT for the device to acknowledge            */
        cmdq_issue(CMD_ATC_INV, sid, ssid, iova, size);

        /* 5. wait for all of it to complete */
        cmdq_issue(CMD_SYNC);
        wait_for_sync_completion();

        /* 6. ONLY NOW is it safe to free or reuse the page */
        free_page(page);

/* Skipping step 5 and freeing immediately leaves a window in
   which the device can still write to a page that now belongs
   to something else. That is a use-after-free with DMA, and it
   is precisely what iommu.strict=0 trades away for speed.  */
```

Strict versus deferred invalidation

```
   iommu.strict=1   (the default)
        every unmap issues an invalidate and waits for CMD_SYNC
        before the IOVA is reused or the page freed.
        SAFE. Costs a command-queue round trip per unmap, which
        on a high-rate NIC is a measurable fraction of the
        packet budget.

   iommu.strict=0   ("lazy" / DMA-FQ)
        unmapped IOVAs go on a flush queue and are invalidated
        in BATCHES, typically every 10 ms or when the queue
        fills. Far fewer syncs.
        UNSAFE WINDOW: between unmap and the batched invalidate,
        the device can still translate and access the page. If
        the page has been freed and reallocated, a malicious or
        buggy device writes to whatever now lives there.

   Which to choose:
      · trusted, on-SoC devices, throughput-critical -> strict=0
        may be a reasonable, documented decision
      · anything hot-pluggable, or any device you do not
        control -> strict=1, always

   cat /sys/kernel/iommu_groups/*/type
   #   DMA      strict
   #   DMA-FQ   deferred (flush queue)
   #   identity bypass
```

ATS: caching translations in the device

```
A PCIe device can ask the SMMU to translate an address in
advance and cache the result in its own ADDRESS TRANSLATION
CACHE (ATC), then issue PRE-TRANSLATED transactions.

   device --> ATS Translation Request --> SMMU
          <-- translated address       <--
   device caches it in the ATC
   device --> transaction marked "already translated" --> memory
                                       (SMMU not consulted)

  BENEFIT: removes the SMMU from the data path entirely. On a
  device doing millions of transfers per second this is a large
  win.

  COST 1 - a new correctness obligation. When software unmaps a
  page it must send CMD_ATC_INV and WAIT for the device's
  response. If the device is slow, buggy, or has been
  hot-unplugged, that wait can stall. Linux has a timeout and
  will report:
       arm-smmu-v3: ATC invalidation timed out

  COST 2 - a TRUST problem. A pre-translated transaction bypasses
  the SMMU's checks entirely. You are trusting the device to
    (a) only use translations it was legitimately given, and
    (b) honour invalidations.
  A malicious device that ignores both has unrestricted access.

  Hence PCIe ACS and the "translation blocking" controls, and
  hence: enable ATS only for devices you trust. Linux will not
  enable it for a device without the appropriate ACS
  capabilities upstream.
```

PRI: page faults for devices

```
/* Normally, a device touching an unmapped address gets an abort.
   With PRI, it can instead REQUEST that the page be mapped:  */

   device --> Page Request (via the PRI queue) --> software
   software pages the memory in, maps it
   software --> CMD_PRI_RESP (success) --> SMMU --> device
   device retries the access

/* This requires STALL mode: STE.S1STALLD = 0, so a faulting
   transaction is HELD rather than terminated. The device's
   pipeline stalls until the response arrives.

   What it enables: DEMAND PAGING for devices. A GPU can be
   given a pointer to memory that is swapped out, and it will
   fault it in exactly as a CPU would.

   What it costs: a stalled transaction occupies device
   resources. A storm of page requests can deadlock a device
   whose queues fill. And it only works if the device supports
   it - most do not.                                        */

/* Check support: */
        SMMU_IDR0.PRI          /* SMMU supports PRI          */
        SMMU_IDR0.STALL_MODEL  /* can it stall, or only
                                  terminate?                 */
```

SVA: sharing a process's address space

> **THE PAYOFF OF THE IDENTICAL DESCRIPTOR FORMAT**
>
> Because the SMMU uses exactly the CPU's translation table format (ARM 14), the OS can point a device's Context Descriptor at a *user process's own page tables*, with the same ASID. The device then dereferences precisely the pointers the application uses — no `dma_map`, no IOVA allocation, no copying.

```
   WITHOUT SVA                       WITH SVA

   app allocates a buffer            app allocates a buffer
   dma_map_single()                  (nothing)
     -> allocate an IOVA
     -> build SMMU page tables
     -> invalidate
   pass the dma_addr_t to the        pass the ORDINARY POINTER
     device                            to the device
   device DMAs                       device DMAs, translating
   dma_unmap_single()                  through the process's own
     -> tear it all down               page tables
                                     (nothing)

  Requirements, all three:
     1. the device supports ATS and PRI, because process memory
        can be swapped out or moved at any time
     2. the SMMU supports SubstreamIDs, so each process gets its
        own CD
     3. the OS wires the process's mm to a CD and keeps the ASID
        in sync, including on TLB invalidation

  Linux API:
        handle = iommu_sva_bind_device(dev, mm);
        pasid  = iommu_sva_get_pasid(handle);
        /* pass pasid to the device; it now sees the process's
           address space */
        iommu_sva_unbind_device(handle);

  Used by: GPU compute, smart NICs, accelerators — anywhere the
  marshalling cost of dma_map dominates the actual work.
```

Performance

Cost	Mitigation
Translation on every transaction	SMMU TLBs; huge pages at both stages
Walk on a TLB miss (up to 24 accesses nested)	Walk caches; cacheable table walks in the CD/STE
Map/unmap page-table edits	Persistent mappings; larger buffers; scatter-gather in one call
Command queue round trip per invalidate	Batching; `iommu.strict=0` (with the trade-off above)
IOVA allocation	Per-CPU IOVA caches (`iova_rcache` in Linux)
SMMU entirely in the data path	ATS — at the cost of trusting the device

```
# is the SMMU the bottleneck?
perf list | grep -i smmu
perf stat -e 'arm_smmu_v3_pmcg_*/cycles/,arm_smmu_v3_pmcg_*/transaction/' \
          -a sleep 10

# many SMMUs have a Performance Monitoring Counter Group (PMCG)
# exposing translation counts, TLB misses and walk counts —
# the same idea as the CPU PMU (ARM chapter 34)

# map/unmap rate
echo 1 > /sys/kernel/debug/tracing/events/iommu/enable
cat /sys/kernel/debug/tracing/trace_pipe | head -100
# a very high map/unmap rate on a networking workload means
# per-packet mapping — consider persistent buffers or SVA
```

The Linux picture

```
/* Almost no driver programs an SMMU directly. The layering: */

   your driver
        |  dma_map_single(dev, buf, size, DMA_TO_DEVICE)
        v
   DMA API   (kernel/dma/mapping.c)
        |  is there an IOMMU for this device?
        +-- no  --> dma_direct: dma_addr == phys (+ offset),
        |           plus cache maintenance if non-coherent
        |
        +-- yes --> dma-iommu layer
                      allocate an IOVA from this device's
                      iova_domain (an allocator, like a small
                      address-space malloc)
                        |
                        v
                    iommu_map(domain, iova, phys, size, prot)
                        |
                        v
                    arm-smmu-v3 driver
                      build page table entries (io-pgtable)
                      queue CMD_TLBI + CMD_SYNC
                        |
                        v
                    returns dma_addr_t = the IOVA
        |
        v
   program the device with that dma_addr_t
   - NEVER a virtual address, NEVER a raw physical address

/* Chapter 07 covers the driver-facing API in full. */
```

How it shows up

Symptom	Cause
STE or page table change has no effect	Missing `CFGI` / `TLBI` and `CMD_SYNC`
Device writes to a freed page	Freed before `CMD_SYNC` completed, or `strict=0`
`ATC invalidation timed out`	Device slow, unplugged, or not honouring invalidations
Device stalls indefinitely	PRI stall mode with no software responding to page requests
Guest translation works, host sees nothing	Stage 1 configured, stage 2 not — or vice versa
Nested guest DMA is very slow	Walk multiplication; use huge pages at stage 2
Networking throughput drops with the IOMMU on	Per-packet map/unmap; batch, or use persistent buffers
Command queue overflows	Software not consuming, or issuing faster than the SMMU drains
SVA bind fails	Device lacks ATS or PRI, or the SMMU lacks SubstreamIDs
Stage-2 change corrupts guest memory	Invalidated stage 1 before stage 2 (ARM 15)

Check yourself

- ✓ Say who owns each translation stage and why the guest cannot change stage 2.
- ✓ Name the three queues and what flows through each.

- ✓ Give the correct unmap sequence, including `CMD_SYNC`, and say what each step prevents.
- ✓ Explain the `iommu.strict=0` trade-off and when it is defensible.
- ✓ Explain what ATS buys and the two costs it introduces.
- ✓ Explain PRI and what stall mode requires of the device.
- ✓ Explain SVA and its three prerequisites.
- ✓ Explain why walk multiplication is worse under nesting and how to mitigate it.

SMMU: faults and debugging

SMMU faults are asynchronous, reported through a queue rather than as an exception, and easy to misread. This chapter is the practical one: decode an event record, work out which of six things went wrong, and fix it.

How a fault is reported

```
Unlike a CPU fault, which is a synchronous exception with ESR
and FAR (ARM chapter 29), an SMMU fault is:

   1. detected while translating a DEVICE transaction
   2. written as a 32-byte EVENT RECORD into the event queue
   3. signalled by an interrupt (or MSI)
   4. read and logged by software, LATER

  So the fault is decoupled from anything the CPU was doing.
  There is no register to read at the moment it happens — the
  event record IS the evidence.

  The transaction itself is either TERMINATED (an abort returned
  to the device) or STALLED, depending on STE.S1STALLD and
  whether the device supports stalling.

  CONSEQUENCE: a device that faults typically reports a bus
  error, a timeout, or simply produces wrong data — and the
  SMMU's event record in dmesg is the only thing that says why.
```

Reading an event record

```
arm-smmu-v3 2b400000.iommu: event 0x10 received:
arm-smmu-v3 2b400000.iommu: 0x0000004200000010
arm-smmu-v3 2b400000.iommu: 0x0000000000000000
arm-smmu-v3 2b400000.iommu: 0x00000000fffff000
arm-smmu-v3 2b400000.iommu: 0x0000000000000000

/* Four 64-bit words. The layout, generally: */

   word 0  [7:0]    event type
           [63:32]  StreamID
   word 1  [31:0]   SubstreamID (if SSV set)
           [32]     SSV - SubstreamID valid
           [33]     PnU - privileged or unprivileged
           [34]     InD - instruction or data
           [35]     RnW - read or write
           [36]     S2  - the fault was at stage 2
           [37]     Class
   word 2  [63:12]  the faulting INPUT ADDRESS (IOVA or IPA)
   word 3           the faulting IPA, for stage-2 faults

/* Decoding the example above:
      type      = 0x10  = C_BAD_STREAMID
      StreamID  = 0x42
      address   = 0xfffff000

   Meaning: a device emitting StreamID 0x42 issued a transaction,
   and there is no valid Stream Table Entry for 0x42.

   The address is almost irrelevant here - the problem is the
   StreamID, not what it tried to touch.                    */
```

The event types

Code	Name	Means	Check
`0x01`	`F_UUT`	Unsupported upstream transaction	The device is issuing something the SMMU cannot handle — an unsupported size or attribute
`0x02`	`C_BAD_STREAMID`	**No valid STE for this StreamID**	**Device tree / IORT StreamID mismatch.** The most common failure.
`0x04`	`F_STE_FETCH`	Could not read the STE	Stream table address wrong, or the memory is unreachable by the SMMU
`0x05`	`C_BAD_STE`	The STE is malformed	Driver bug, reserved bits set, or mismatched memory attributes
`0x06`	`F_BAD_ATS_TREQ`	ATS request from a stream where ATS is not enabled	`STE.EATS`
`0x08`	`F_STREAM_DISABLED`	The stream is configured to abort	Deliberate — an unconfigured device, or `disable_bypass`
`0x0A`	`C_BAD_SUBSTREAMID`	SubstreamID out of range for this STE	`STE.S1CDMax`
`0x0B`	`F_CD_FETCH`	Could not read the CD	`S1ContextPtr`, or CD table memory
`0x0C`	`C_BAD_CD`	The CD is malformed	TCR-equivalent fields, alignment

Code	Name	Means	Check
`0x0D`	`F_WALK_EABT`	External abort during a table walk	The page tables themselves are in unreadable or denied memory
`0x10`	`F_TRANSLATION`	**The address is not mapped**	**Wrong address programmed into the device, or the mapping was torn down early**
`0x11`	`F_ADDR_SIZE`	Address exceeds the configured output size	`dma_set_mask()` versus the SMMU's OAS
`0x12`	`F_ACCESS`	Access flag not set	The `AF` bit in the descriptor
`0x13`	`F_PERMISSION`	**Mapped, but the wrong permission**	**DMA direction mismatch** — mapped `TO_DEVICE` and the device is writing
`0x20`	`F_TLB_CONFLICT`	Overlapping TLB entries	Break-before-make violation
`0x21`	`F_CFG_CONFLICT`	Conflicting cached configuration	An STE or CD changed without invalidation

THE THREE-WAY SPLIT

Group the event types by what they tell you:

- **Configuration faults** (`C_BAD_*`, `F_*_FETCH`) — the SMMU could not find or parse its own tables. A software or integration bug; the device did nothing wrong.
- **Translation faults** (`F_TRANSLATION`, `F_ACCESS`, `F_PERMISSION`) — the tables were fine; the address or the access type was wrong. Almost always a driver bug.
- **Stream faults** (`C_BAD_STREAMID`, `F_STREAM_DISABLED`) — identity. Device tree, IORT, or an unconfigured device.

Triage

```
Device does not work, or corrupts memory
     |
     v
Is a fault reported AT ALL?
   NO  -> the SMMU may be in BYPASS. Check:
            dmesg | grep 'Default domain type'
            cat /proc/cmdline  (iommu.passthrough?)
          A device that "works" with no SMMU configured is a
          SECURITY BUG, not a success.
   YES |
       v
What is the EVENT TYPE?
   |
   +-- C_BAD_STREAMID -----> the StreamID in the record is
   |                         what the HARDWARE emits. Compare
   |                         with the device tree. Fix the DT.
   |
   +-- C_BAD_STE / C_BAD_CD -> driver or integration bug.
   |                         Check memory attributes for the
   |                         table memory (chapter 04).
   |
   +-- F_TRANSLATION ------> the address is not mapped. Look
   |                         at the ADDRESS in word 2:
   |                           looks physical  -> driver passed
   |                                              phys instead of
   |                                              dma_addr_t
   |                           looks like a VA -> driver passed a
   |                                              kernel virtual
   |                                              address
   |                           a valid IOVA    -> unmapped too
   |                                              early, or DMA
   |                                              outlived the
   |                                              mapping
   |
   +-- F_PERMISSION ------> mapped, wrong direction. Check the
   |                        DMA_TO_DEVICE / DMA_FROM_DEVICE
   |                        argument.
   |
   +-- F_ADDR_SIZE -------> dma_set_mask() claims more bits
   |                        than the SMMU's output supports.
   |
   +-- F_WALK_EABT -------> the page tables are in memory the
                            SMMU cannot read. Check the table
                            allocation and any firewall
                            (chapters 17-20).
```

Reading the faulting address

```
/* The address in word 2 is the single most informative field
   after the event type. Learn to recognise the shapes:    */

   0x0000_0000_8xxx_xxxx    looks like a PHYSICAL address on a
                            typical SoC (DRAM at 0x80000000)
                            -> the driver passed phys_to_dma
                               incorrectly, or used virt_to_phys

   0xffff_8xxx_xxxx_xxxx    a KERNEL VIRTUAL address
                            -> the driver passed a kmalloc pointer
                               straight to the device

   0x0000_0000_0000_0000    NULL
                            -> uninitialised descriptor, or a
                               failed allocation not checked

   0x0000_00ff_xxxx_xxxx    a plausible IOVA in the allocated
                            range
                            -> the mapping existed and was torn
                               down. Look for: dma_unmap before
                               the device finished, remove()
                               without quiescing the device, or
                               a driver freeing a buffer early.

   0x0000_0000_08xx_xxxx    the ITS doorbell region
                            -> an MSI write that was not mapped
                               (chapter 03)

/* Cross-check against what was actually mapped: */
echo 1 > /sys/kernel/debug/tracing/events/iommu/enable
cat /sys/kernel/debug/tracing/trace_pipe | grep -i map
#   map: IOVA=0x00000000ff000000 paddr=0x0000000082340000 size=4096
```

The bisection that works

ONE EXPERIMENT HALVES THE SEARCH SPACE

Boot once with `iommu.passthrough=1`.

- **The problem disappears** → it is a mapping or StreamID issue. The device programming is fine; the SMMU configuration is not.
- **The problem persists** → the bug is in how the device is programmed. The SMMU was just the messenger reporting it.

Never ship with passthrough enabled — but during bring-up this single reboot saves hours of speculation.

```
# the sequence that resolves most SMMU bring-up problems

# 1. is the SMMU even active?
dmesg | grep -iE 'smmu|iommu'
#   arm-smmu-v3 ...: ias 48-bit, oas 48-bit (features 0x...)
#   iommu: Default domain type: Translated     <- good
#   iommu: Default domain type: Passthrough    <- NOT translated

# 2. is this device behind it?
ls -l /sys/bus/platform/devices/2c000000.dma/iommu_group
cat /sys/kernel/iommu_groups/*/devices/*

# 3. trigger a transfer and read the fault
dmesg -w & ./trigger_dma

# 4. compare the StreamID in the record with the device tree
hexdump -C /proc/device-tree/soc/dma@2c000000/iommus

# 5. watch the mappings being created
echo 1 > /sys/kernel/debug/tracing/events/iommu/enable
cat /sys/kernel/debug/tracing/trace_pipe

# 6. bisect with passthrough
# add iommu.passthrough=1 to the command line, reboot, retest
```

The driver bugs behind most faults

Bug	Event	Fix
Passed a kernel virtual address to the device	`F_TRANSLATION`, VA-shaped address	Use the `dma_addr_t` from `dma_map_*`
Passed a physical address	`F_TRANSLATION`, PA-shaped address	Same
Unmapped while the transfer was in flight	`F_TRANSLATION`, valid IOVA	Wait for completion before unmapping
Did not quiesce the device in `remove()`	`F_TRANSLATION` after unbind	Stop the hardware *first* (OS 16)
Wrong DMA direction	`F_PERMISSION`	Match `DMA_TO_DEVICE` / `FROM_DEVICE` to reality
DMA to a stack buffer	Varies	Never — the stack is not DMA-able
DMA to `vmalloc` memory	`F_TRANSLATION`	Not physically contiguous; use `kmalloc` or scatter-gather
`dma_set_mask` too optimistic	`F_ADDR_SIZE`	Match the device's real addressing capability
Ignored `dma_mapping_error()`	Varies	Always check
Descriptor ring not `dma_alloc_coherent`	Varies	Rings must be coherent (ch. 07)

Stall mode and hangs

```
/* If STE.S1STALLD = 0 and the device supports stalling, a
   faulting transaction is HELD rather than terminated. The
   device's pipeline stops until software responds.

   Consequences:
     · the device appears HUNG rather than reporting an error
     · a storm of stalled transactions can exhaust the device's
       internal queues and deadlock it
     · software MUST respond with CMD_RESUME, or the device
       never recovers

   Which is why Linux sets S1STALLD = 1 (terminate) unless PRI
   is in use — an unhandled stall is worse than a clean abort. */

/* If a device hangs with no fault reported at all, check: */
        dmesg | grep -i 'stall\|resume'
        cat /sys/kernel/debug/tracing/events/iommu/dev_fault/enable

/* And check the GLOBAL ERROR register — a malformed command or
   a queue overflow is reported there, not in the event queue: */
        SMMU_GERROR vs SMMU_GERRORN
//   arm-smmu-v3: GERROR MSI write aborted
//   arm-smmu-v3: CMD_SYNC timeout at 0x...
//   arm-smmu-v3: unexpected global error reported
```

Faults under virtualisation

```
/* With stage 2 in use, a fault may be at either stage — word 1
   bit 36 (S2) says which, and word 3 holds the IPA.        */

   S2 = 0   a stage-1 fault. The guest's own IOMMU tables are
            wrong, or the guest programmed the device with a bad
            IOVA. The guest's problem.

   S2 = 1   a stage-2 fault. The hypervisor has not mapped that
            IPA for the device. The HOST's problem — usually
            memory the guest owns but the host has not pinned
            and mapped for DMA.

/* A very common case: a guest passed a device a buffer in memory
   the hypervisor had not mapped into the device's stage-2
   tables. VFIO pins and maps all guest memory for exactly this
   reason, which is why passthrough VMs cannot use ballooning
   or overcommit without extra machinery.                   */

# on the host
dmesg | grep -A4 'event.*received'
cat /sys/kernel/debug/tracing/events/iommu/enable
```

The full toolkit

```
# fault records
dmesg -w | grep -i smmu

# mappings, live
echo 1 > /sys/kernel/debug/tracing/events/iommu/enable
cat /sys/kernel/debug/tracing/trace_pipe

# per-event tracepoints
ls /sys/kernel/debug/tracing/events/iommu/
#   add_device_to_group  attach_device_to_domain  map  unmap
#   io_page_fault  dev_fault  dev_page_response

# groups, domains and reserved regions
ls -l /sys/kernel/iommu_groups/*/devices/
cat /sys/kernel/iommu_groups/*/type
cat /sys/kernel/iommu_groups/*/reserved_regions

# SMMU performance counters, where present
perf list | grep -i smmu
perf stat -e arm_smmu_v3_pmcg_*/transaction/ -a sleep 5

# from a JTAG debugger: read SMMU_STRTAB_BASE, index by the
# StreamID from the fault record, and dump the STE. If it is
# zero or invalid, the configuration never reached the hardware.

# bpftrace on the fault path
sudo bpftrace -e 'tracepoint:iommu:io_page_fault {
        printf("%s dev=%s addr=%llx\n", comm, str(args->device),
               args->iova); }'
```

How it shows up

Symptom	Cause
`C_BAD_STREAMID` on every transfer	Device tree or IORT StreamID does not match the hardware
`F_TRANSLATION` with a physical-looking address	Driver passed a physical address instead of `dma_addr_t`
`F_TRANSLATION` with a valid IOVA	Unmapped while DMA was in flight, or on remove without quiescing
`F_PERMISSION`	DMA direction mismatch
`F_ADDR_SIZE`	`dma_set_mask` exceeds the SMMU's output address size
`F_WALK_EABT`	Page tables in memory the SMMU cannot read — check firewalls
Device hangs with no fault logged	Stall mode with no responder; check `GERROR` too
No faults and no isolation	Bypass or passthrough enabled
DMA works, interrupts never arrive	The MSI doorbell is not mapped for that device
Faults only under a hypervisor	Stage-2 mapping missing — check the S2 bit in the record
Faults appear after enabling `strict=0`	Deferred invalidation window; a freed page was still reachable

Check yourself

- ✓ Explain why an SMMU fault is reported differently from a CPU fault.
- ✓ Decode the four words of an event record.

- ✓ Give the three-way grouping of event types and what each group implicates.
- ✓ Given `F_TRANSLATION`, name four address shapes and what each indicates.
- ✓ Describe the passthrough bisection and what each outcome tells you.
- ✓ List five driver bugs that produce SMMU faults, with the event each gives.
- ✓ Explain stall mode and why Linux usually disables it.
- ✓ Say how to tell a stage-1 fault from a stage-2 fault, and whose problem each is.

DMA APIs and coherency in practice

The driver-facing side of everything in the previous five chapters. One API hides whether there is an IOMMU, whether the device is coherent, and whether cache maintenance is needed — which is exactly why hand-rolling any of it is a bug.

What the DMA API hides

```
dma_map_single(dev, buf, size, DMA_TO_DEVICE)
     |
     v
Is there an IOMMU for this device?
   |
   +-- NO  --> dma_direct
   |             dma_addr = phys_addr + a per-device offset
   |             (some SoCs place DRAM at a different address
   |              on the device side of the bus)
   |
   +-- YES --> dma-iommu
                 allocate an IOVA from this device's
                 iova_domain, build SMMU page tables,
                 invalidate, return the IOVA
     |
     v
Is this device COHERENT?
   |
   +-- YES --> nothing more to do
   |
   +-- NO  --> emit cache maintenance:
                 clean before the device reads
                 invalidate before the CPU reads
                 (ARM chapter 18)
     |
     v
returns dma_addr_t — the address the DEVICE must use

FOUR platform differences, one API. This is why the same
driver source is correct on a coherent server with an SMMU and
on a non-coherent MCU with neither.
```

`DMA_ADDR_T` IS NOT A PHYSICAL ADDRESS

It is the address the *device* must be programmed with. With an IOMMU it is an IOVA; without one it is usually the physical address plus a bus offset; on some SoCs it is neither. Treating it as a physical address works on your development board and fails on the next one.

The two kinds of mapping

	Coherent (consistent)	Streaming
Allocate with	`dma_alloc_coherent()`	Any allocator, then `dma_map_*()`
Lifetime	Long-lived — allocated once	One transfer
Cache maintenance	None needed — the API guarantees coherency	Handled by map/unmap/sync

	Coherent (consistent)	Streaming
Cost	May be uncached, so CPU access is slow	Map/unmap cost per transfer
Use for	**Descriptor rings**, doorbell structures, anything both sides poll	**Data buffers**

```
/* COHERENT — for the ring the device and CPU both poll */
struct desc *ring;
dma_addr_t ring_dma;

ring = dma_alloc_coherent(dev, RING_BYTES, &ring_dma, GFP_KERNEL);
if (!ring)
        return -ENOMEM;
/* both sides may access it at any time, with no sync calls.
   On a non-coherent system this memory is UNCACHED, so CPU
   access is slow — keep rings small and do not put bulk data
   here.                                                    */
writel(lower_32_bits(ring_dma), regs + RING_BASE_LO);
writel(upper_32_bits(ring_dma), regs + RING_BASE_HI);
...
dma_free_coherent(dev, RING_BYTES, ring, ring_dma);

/* STREAMING — for the data itself */
dma_addr_t d = dma_map_single(dev, buf, len, DMA_TO_DEVICE);
if (dma_mapping_error(dev, d))          /* ALWAYS check */
        return -ENOMEM;

writel(lower_32_bits(d), regs + DMA_ADDR_LO);
writel(upper_32_bits(d), regs + DMA_ADDR_HI);
writel(len,              regs + DMA_LEN);
writel(DMA_GO,           regs + DMA_CTRL);

/* ... wait for the completion interrupt ... */

dma_unmap_single(dev, d, len, DMA_TO_DEVICE);
/* only NOW may the CPU touch buf again */
```

Buffer ownership

> **BETWEEN MAP AND UNMAP, THE BUFFER BELONGS TO THE DEVICE**
> Touching it from the CPU in that window gives stale or corrupted data on a non-coherent system, and races even on a coherent one. The API models this as an ownership transfer, and the `sync` functions are how you temporarily take it back.

```
/* Peeking mid-transfer, correctly: */
dma_sync_single_for_cpu(dev, d, len, DMA_FROM_DEVICE);
inspect(buf);                                  /* CPU owns it   */
dma_sync_single_for_device(dev, d, len, DMA_FROM_DEVICE);
/* device owns it again                                       */

/* And a partial sync, when only part of a large buffer matters: */
dma_sync_single_range_for_cpu(dev, d, offset, size, DMA_FROM_DEVICE);

/* What the direction argument actually controls: */

   DMA_TO_DEVICE        CPU wrote it, device will read
                        -> map does a CLEAN
                        -> the device must not write it
   DMA_FROM_DEVICE      device will write, CPU will read
                        -> map does an INVALIDATE (and unmap
                           does another)
                        -> the buffer's prior contents are LOST
   DMA_BIDIRECTIONAL    both
                        -> clean and invalidate; more expensive
   DMA_NONE             debugging only

/* The direction is not documentation — it selects the cache
   maintenance and the SMMU permissions. Getting it wrong gives
   either stale data or an F_PERMISSION fault (chapter 06).  */
```

The four rules

Rule	Why	Failure
1. Program the device with `dma_addr_t`	It is neither a virtual nor necessarily a physical address	`F_TRANSLATION`, or DMA to the wrong memory
2. Never DMA to stack memory	Stack buffers are not cache-line aligned, so an invalidate destroys neighbouring stack data	Corruption of unrelated locals; hard to attribute
3. Never DMA to `vmalloc` memory	Virtually contiguous only — the physical pages are scattered	Data lands in the wrong pages
4. Respect ownership	See above	Stale or corrupted data

```
/* Rule 2, made concrete - this is subtler than it looks: */

void bad(struct device *dev)
{
        char buf[64];                   /* on the stack */
        dma_addr_t d = dma_map_single(dev, buf, 64, DMA_FROM_DEVICE);
        /* ... */
}
/* On a NON-COHERENT system, dma_unmap invalidates the cache
   lines covering buf. If buf shares a 64-byte line with other
   locals - a return address, a saved register, a loop counter -
   those are invalidated too, and their dirty values LOST.

   The corruption appears in unrelated variables, after the
   function returns. Almost impossible to trace back.

   CONFIG_DMA_API_DEBUG catches it:
       DMA-API: device driver maps memory from stack           */

/* The fix: heap-allocate, or embed the buffer in a
   cache-line-aligned structure: */
struct my_dev {
        ...
        char buf[64] ____cacheline_aligned;
};
```

Scatter-gather

```
/* For transfers spanning several physically discontiguous pages.
   The SMMU can make them contiguous in the device's view; without
   one, the device must handle a list.                         */

struct scatterlist sgl[N];
sg_init_table(sgl, N);
for (i = 0; i < N; i++)
        sg_set_page(&sgl[i], pages[i], PAGE_SIZE, 0);

int nents = dma_map_sg(dev, sgl, N, DMA_TO_DEVICE);
if (!nents)
        return -ENOMEM;

/* NOTE: nents may be LESS than N. With an IOMMU, adjacent
   physical pages are COALESCED into one device-visible extent.
   Always iterate over the RETURNED count, using the accessors: */
struct scatterlist *sg;
for_each_sg(sgl, sg, nents, i)
        program_descriptor(sg_dma_address(sg), sg_dma_len(sg));
/*                          ^^^^^^^^^^^^^^^^ NOT sg_phys()      */

dma_unmap_sg(dev, sgl, N, DMA_TO_DEVICE);   /* the ORIGINAL N */

/* Using sg->length instead of sg_dma_len(sg), or iterating to N
   instead of nents, is a classic bug that only manifests when
   an IOMMU is present and coalescing occurs.               */
```

Addressing capability

```
/* Tell the core what the device can actually address, BEFORE
   any mapping.                                                */

ret = dma_set_mask_and_coherent(dev, DMA_BIT_MASK(48));
if (ret) {
        /* fall back - do not just fail */
        ret = dma_set_mask_and_coherent(dev, DMA_BIT_MASK(32));
        if (ret)
                return ret;
}

/* What it controls:
     · without an IOMMU: which physical memory may be used.
       A 32-bit device gets memory below 4 GB, or BOUNCE
       BUFFERS (copy down, DMA, copy back) via SWIOTLB.
     · with an IOMMU: which IOVA range is allocated from.

   Claiming more than the device supports gives silent
   corruption (the top bits are dropped) or F_ADDR_SIZE
   (chapter 06). Claiming less costs bounce buffers.

   And note the SEPARATE coherent mask: some devices can DMA
   64-bit for data but need 32-bit for descriptor rings.  */
dma_set_mask(dev, DMA_BIT_MASK(64));
dma_set_coherent_mask(dev, DMA_BIT_MASK(32));
```

Coherent or not

```
/* Whether a device participates in cache coherency is a SoC
   integration property (ARM chapter 19), described in the
   device tree:                                              */

        dma_engine@2c000000 {
                compatible = "vendor,dma";
                reg = <...>;
                dma-coherent;          /* ACE-Lite or CHI      */
                iommus = <&smmu 0x42>;
        };

/* The kernel reads it: */
        dev_is_dma_coherent(dev)

/* And it changes what dma_alloc_coherent returns:
     coherent device     -> ordinary cacheable memory, fast
     non-coherent device -> UNCACHED memory, slow for the CPU

   Which is why a descriptor ring that is fine on one SoC is a
   performance problem on another. If profiling shows a driver
   spending time reading its own ring, check coherency.    */

# is it coherent?
grep -l dma-coherent /proc/device-tree/*/*/ 2>/dev/null
cat /sys/bus/platform/devices/*/of_node/dma-coherent 2>/dev/null

# ACPI equivalent: the _CCA method
```

Reserved and restricted regions

```
/* Some devices must use specific memory: a fixed carveout, a
   region visible to a coprocessor, or contiguous memory for a
   camera or codec.                                          */

/* Reserved memory in the device tree: */
reserved-memory {
        #address-cells = <2>;
        #size-cells = <2>;
        ranges;

        codec_pool: codec@90000000 {
                compatible = "shared-dma-pool";
                reg = <0x0 0x90000000 0x0 0x2000000>;
                no-map;            /* keep it OUT of the linear map,
                                      so attributes cannot conflict
                                      (ARM chapter 19)             */
        };

        cma_pool: linux,cma {
                compatible = "shared-dma-pool";
                reusable;          /* CMA: normally used for movable
                                      pages, reclaimed on demand    */
                size = <0x0 0x8000000>;
                linux,cma-default;
        };
};

video_codec@... {
        memory-region = <&codec_pool>;
};

/* `no-map` versus `reusable` matters:
     no-map    the kernel never maps it at all. Required when
               the region needs different memory ATTRIBUTES than
               the linear map would give it.
     reusable  CMA — the kernel uses it for movable pages and
               reclaims it when a large contiguous allocation is
               needed (OS chapter 11).                       */
```

Debugging DMA

```
# CONFIG_DMA_API_DEBUG — the single most valuable option here.
# It tracks every mapping and catches:
#   · unmapping with the wrong size or direction
#   · CPU access to a device-owned buffer
#   · mapping stack or vmalloc memory
#   · leaked mappings on driver unload
#   · double unmap
CONFIG_DMA_API_DEBUG=y
CONFIG_DMA_API_DEBUG_SG=y

dmesg | grep 'DMA-API'
#   DMA-API: device driver frees DMA memory with different size
#   DMA-API: device driver maps memory from stack
#   DMA-API: cacheline tracking EEXIST, overlapping mappings

echo 1 > /sys/kernel/debug/dma-api/dump      # every live mapping

# SMMU-side view
echo 1 > /sys/kernel/debug/tracing/events/iommu/enable
cat /sys/kernel/debug/tracing/trace_pipe

# and the SWIOTLB, if bounce buffers are in play
dmesg | grep -i swiotlb
cat /sys/kernel/debug/swiotlb/io_tlb_used
```

DIAGNOSING "DMA GIVES WRONG DATA"

Three distinct causes, and the fix for one does nothing for the others:

1. **All zeros, or the previous contents** → the device never wrote there. Check the address you programmed and look for an SMMU fault.
2. **Stale but plausible data** → coherency. Missing `dma_sync`, or the CPU touched the buffer while the device owned it.
3. **Correct data with corruption nearby** → a partial cache line. The buffer is not cache-line aligned — very often it is on the stack.

The Windows equivalent

```
/* Same concepts, different names (Windows track, chapter 18): */

   WDF_DMA_ENABLER_CONFIG_INIT(&cfg, WdfDmaProfileScatterGather64,
                               MAX_LEN);
   WdfDmaEnablerCreate(device, &cfg, ...);

   WdfDmaTransactionCreate(...);
   WdfDmaTransactionInitializeUsingRequest(..., WdfDmaDirectionWriteToDevice);
   WdfDmaTransactionExecute(...);

   /* the callback receives a scatter-gather list */
   for (i = 0; i < SgList->NumberOfElements; i++)
           program(SgList->Elements[i].Address.QuadPart,   /* LOGICAL */
                   SgList->Elements[i].Length);

/* Windows calls dma_addr_t a LOGICAL ADDRESS. Same meaning:
   the address the device must use, which with an IOMMU is an
   IOVA. The three rules above apply identically.          */
```

How it shows up

Symptom	Cause
Device reads garbage or previous contents	Wrong address programmed, or missing clean on a non-coherent system
Buffer never appears to update	Missing invalidate; or the CPU read a cached copy
Unrelated local variables corrupted	DMA to a stack buffer — partial cache line invalidated
Works on one SoC, corrupts on another	One device is coherent, the other is not
Works without an IOMMU, fails with one	Passed a physical address, or ignored scatter-gather coalescing
Only the first scatter-gather entry transfers	Iterated to `N` instead of the returned `nents`
Silent truncation on large addresses	`dma_set_mask` claims more bits than the device has
Transfers unexpectedly slow	SWIOTLB bounce buffers, from a too-small mask
Driver spends time reading its own descriptor ring	Non-coherent device, so the ring is uncached
Large contiguous allocation fails after uptime	Fragmentation; needs CMA or an SMMU with scatter-gather
`DMA-API` warnings in dmesg	Read them — each one names a specific rule violation

Check yourself

- ✓ Name the four platform differences the DMA API hides.
- ✓ Explain what `dma_addr_t` actually is, in the three possible cases.
- ✓ Give the difference between coherent and streaming mappings and what each is for.
- ✓ State the four rules and the failure each prevents.
- ✓ Explain precisely why DMA to a stack buffer corrupts unrelated data.
- ✓ Explain what the direction argument controls, beyond documentation.
- ✓ Say why `dma_map_sg` may return fewer entries than it was given.
- ✓ Explain what `dma_set_mask` controls with and without an IOMMU.
- ✓ Give the three causes of "DMA gives wrong data" and how to tell them apart.

TrustZone: the NS bit

Everything about TrustZone follows from one design decision: add a single extra bit to every bus transaction saying which world it came from, then teach every block in the SoC to respect it. One wire, system-wide.

The whole idea

> **THE RULE**
>
> A **Non-secure master cannot access Secure resources.** A **Secure master can access both.**
>
> This is enforced in hardware — at the memory controller, at each peripheral, at the interrupt controller, at the SMMU and on the interconnect itself. Not by software checks that a compromised kernel could skip.

```
The bit is AxPROT[1] on AXI (ARM chapter 25), universally called
the NS bit:

   NS = 0   this access is SECURE
   NS = 1   this access is NON-SECURE

   CPU core                        peripheral / memory
      |                                    ^
      |  ADDR                              |
      |  DATA                              |
      |  AxPROT[1] = NS  -----------------+  checked HERE
      |  AxID = master id
      |  AxCACHE = attributes

  Where NS comes from, for a CPU access:
     · at EL3, from SCR_EL3.NS
     · at EL0/EL1/EL2, from the current SECURITY STATE, which
       EL3 set via SCR_EL3.NS before dropping down
     · plus the page descriptor's NS bit, for Secure software
       creating a mapping that issues Non-secure accesses
       (ARM chapter 14)

  Where it comes from for a DEVICE access:
     · hard-wired per master, or
     · from the SMMU's STE/CD NSCFG fields (chapter 04), or
     · assigned dynamically by a TZPC (chapter 10)
```

Why this differs from a hypervisor

```
   HYPERVISOR ISOLATION            TRUSTZONE ISOLATION
   --------------------            -------------------
   software isolating software     SILICON isolating silicon
   the hypervisor is code that     the NS bit is a WIRE; the
     can have bugs                   memory controller physically
   a guest escape gives you the      refuses the transaction
     hypervisor's privilege        a compromised EL1 with
   stage-2 tables are configured     arbitrary code execution
     by that software                still cannot read Secure DRAM
                                     - the data never comes back

  Both are useful, and they compose: a system can run a
  hypervisor in the Normal world AND have a Secure world beneath
  both. They defend against different things.

  The practical distinction: a hypervisor protects guests from
  each other, assuming the hypervisor is correct. TrustZone
  protects secrets from the ENTIRE normal-world software stack,
  assuming only that EL3 firmware and the hardware are correct.
```

Security state versus exception level

```
/* These are ORTHOGONAL. A context is identified by BOTH. */

                   Non-secure          Secure
   EL0             applications        trusted applications
   EL1             Linux, Windows      trusted OS (OP-TEE)
   EL2             hypervisor          secure partition mgr (v8.4+)
   EL3             ------- the monitor, in BOTH -------

/* Which security state am I in? There is no register that says
   so directly at EL1 - by design. Secure software knows because
   it was loaded into the secure world; Non-secure software
   cannot tell and should not need to.

   At EL3: */
        mrs     x0, scr_el3
        tst     x0, #1                  /* SCR_EL3.NS */
        /* NS=0: the world below is Secure
           NS=1: the world below is Non-secure */

/* SCR_EL3.NS is the ONE bit that selects which world exists
   below EL3. Changing it and executing ERET is the world
   switch (chapter 11).                                    */
```

Banked state

```
Because the two worlds must not see each other's configuration,
much of the EL1 system register file is BANKED by security
state:

   SCTLR_EL1        one for Secure, one for Non-secure
   TTBR0_EL1        ditto — the two worlds have entirely
   TTBR1_EL1        separate page tables
   TCR_EL1
   MAIR_EL1
   VBAR_EL1         separate vector tables
   ESR_EL1, FAR_EL1, ELR_EL1, SPSR_EL1
   TPIDR_EL0/EL1
   ...

  SCR_EL3.NS selects which bank EL3 sees. So when the monitor
  switches worlds it does NOT have to save and restore these —
  the hardware provides two copies.

  What it DOES have to save and restore: the general-purpose
  registers X0–X30, the FP/SIMD state, and any registers that
  are NOT banked. That is the bulk of the world-switch cost
  (chapter 11).

  NOT banked: the caches and TLBs, which instead TAG their
  entries with the security state so entries from the two
  worlds coexist without leaking (chapter 10).
```

The NS bit in page tables

```
/* Secure software can create a mapping that issues NON-SECURE
   accesses. That is how a trusted OS reads a buffer shared with
   the normal world.                                          */

   descriptor bit 5   NS
        0   accesses through this mapping are SECURE
        1   accesses through this mapping are NON-SECURE

/* Only meaningful in the SECURE translation regime. Non-secure
   software's accesses are always NS=1 regardless of what its
   descriptors say — enforced by hardware, not by the tables. */

/* And in TABLE descriptors there is a separate NSTable bit
   (bit 63): it forces every entry BELOW it to be Non-secure,
   whatever those entries claim. A way to delegate an entire
   subtree safely — useful when secure software builds a
   mapping region for shared buffers.                       */

/* The practical rule for secure software:
     · map your own memory NS=0
     · map shared buffers NS=1
     · NEVER map normal-world memory NS=0, or a normal-world
       pointer becomes a secure access                       */
```

Partitioning memory

```
Physical memory as a TZASC (chapter 10) is typically configured
at boot:

  0x8000_0000  +---------------------------------+
               | Non-secure DRAM                 |  NS=1 permitted
               |   Linux kernel + userspace      |  NS=0 also permitted
               |   ~1.9 GB                       |  (Secure can read it)
  0xFC00_0000  +---------------------------------+
               | SHARED buffer region            |  both worlds
               |   TEE message passing           |
  0xFE00_0000  +---------------------------------+
               | Secure DRAM                     |  NS=1 -> REFUSED
               |   OP-TEE OS + TA heap           |  invisible to Linux
  0xFF00_0000  +---------------------------------+
               | EL3 firmware (BL31)             |  Secure only, and
               |                                 |  often LOCKED so even
  0xFF10_0000  +---------------------------------+  S-EL1 cannot write it

  What "refused" means concretely: the memory controller returns
  an error response, which becomes an external abort at the CPU
  (ARM chapter 29, DFSC 0b010000) — or, on some configurations,
  returns zeros silently. The latter is far harder to debug and
  is why chapter 20 exists.

  Note the LOCKED EL3 region: even the secure world's own OS
  cannot modify the monitor. Privilege inside a world is still
  layered.
```

Everything checks it

Block	Uses the NS bit to
CPU core	Emit it on every fetch and data access, from the current security state
MMU	Separate translation regimes per state; the descriptor `NS` bit
Caches	Tag lines with the security state, so a Non-secure lookup cannot hit a Secure line
TLBs	Same — entries are tagged
TZASC	Per-region DRAM permission by NS state
TZPC	Mark whole peripherals Secure or Non-secure
GIC	Interrupt groups: Group 0 Secure (FIQ), Group 1 per state
SMMU	Separate secure and non-secure programming interfaces and stream tables
eFuses / OTP	Key material readable only by Secure masters
Debug	`SPIDEN` / `SPNIDEN` gate whether JTAG may see the secure world
Interconnect / XPU	Final per-master, per-region check including NS state

> **THE CONSEQUENCE WORTH INTERNALISING**
>
> A single bit is cheap to add to a bus, so it could be added *everywhere*. That is why TrustZone is a system-wide property rather than a CPU feature, and why an SoC that implements it partially — a peripheral that ignores the NS bit, a bus segment that drops it — has a complete bypass. Verifying that every block honours it is a real part of SoC security review.

The symptom this produces

> **"THE PERIPHERAL READS BACK ALL ZEROS"**
>
> If a peripheral is marked Secure in the TZPC, a Linux driver that `ioremap()`s its registers gets an error or zeros — because the access carries NS=1 and the peripheral refuses it. The address is right, the clock is on, the driver is correct, and nothing works.
>
> This is the single most confusing TrustZone symptom for driver authors, because nothing in the normal-world software stack knows the secure world exists. When a peripheral behaves as though it is not there on production hardware but works on a development board, suspect the security configuration before suspecting your driver.

```
/* What you see from Linux: */
        val = readl(base + REG_ID);
        /* val == 0, or 0xFFFFFFFF, or an external abort */

/* dmesg, if it aborts: */
//   Unhandled fault: synchronous external abort (0x96000010)
//                                                    ^^ DFSC
//                                                    external abort

/* How to confirm it is a security issue rather than a clock or
   address problem:
     1. check the clock and power domain first — same symptom
     2. read the SoC TRM for the peripheral's default TZPC
        assignment
     3. if firmware exposes it, query via an SMC
     4. compare against a development board, where the fuses
        and firmware configuration usually differ            */
```

What one bit does not give you

Not protected against	Why	What does help
Physical bus probing	The NS bit is a wire; an attacker with a probe reads the data lines	Memory encryption, on-die placement
Cold-boot DRAM extraction	DRAM contents survive briefly after power loss	Memory encryption, key scrubbing
Side channels	The two worlds share caches, branch predictors and DRAM	Constant-time code, cache partitioning, flushing on switch
Speculation across the boundary	Spectre-class leaks predate the check	`CSDB`, `SB`, index masking
Bugs in secure software	The NS bit does not validate anything	A small, audited TCB (ch. 16)
A block that ignores NS	Enforcement is only as complete as the implementation	SoC security review

Confirming the hardware honours it

```
/* During SoC bring-up or security review, test the NEGATIVE
   cases explicitly. A policy never exercised is a policy you do
   not know works.                                          */

/* From the Normal world, attempt to read Secure DRAM: */
        void __iomem *p = ioremap(SECURE_DRAM_BASE, 4);
        u32 v = readl(p);
        /* EXPECTED: an external abort, or a latched fault in the
           TZASC. If it returns real data, the region is not
           actually protected.                                  */

/* From the Normal world, attempt to program a Secure device: */
        writel(1, secure_dev_base + CTRL);
        /* EXPECTED: refused. Verify by reading back, and by
           checking the peripheral did not act.                 */

/* And from the Secure world, verify you CAN reach both: */
        secure read of Non-secure DRAM   -> should succeed
        secure read of Secure DRAM       -> should succeed

/* Write these as a boot-time self-test on development
   firmware. Chapter 19 covers building the full matrix.  */
```

How it shows up

Symptom	Cause
Peripheral reads all zeros or aborts on production hardware	Assigned to the secure world by the TZPC
External abort with DFSC `0b010000`	The bus refused the access — often a security check
Works on the dev board, fails on shipping units	Different fuse or firmware security configuration
Linux cannot see a memory region present in the TRM	Carved out as Secure DRAM by the TZASC
A secure driver can read normal-world memory	Correct — Secure masters may access both
Normal-world code reads secure memory successfully	**A security bug.** The region is not protected.
Secure interrupt cannot be masked by Linux	Group 0, delivered as FIQ to EL3 — by design
JTAG cannot see secure state	Secure debug fused off
A shared buffer works from Linux, faults from the TEE	Secure mapping created with NS=0 instead of NS=1

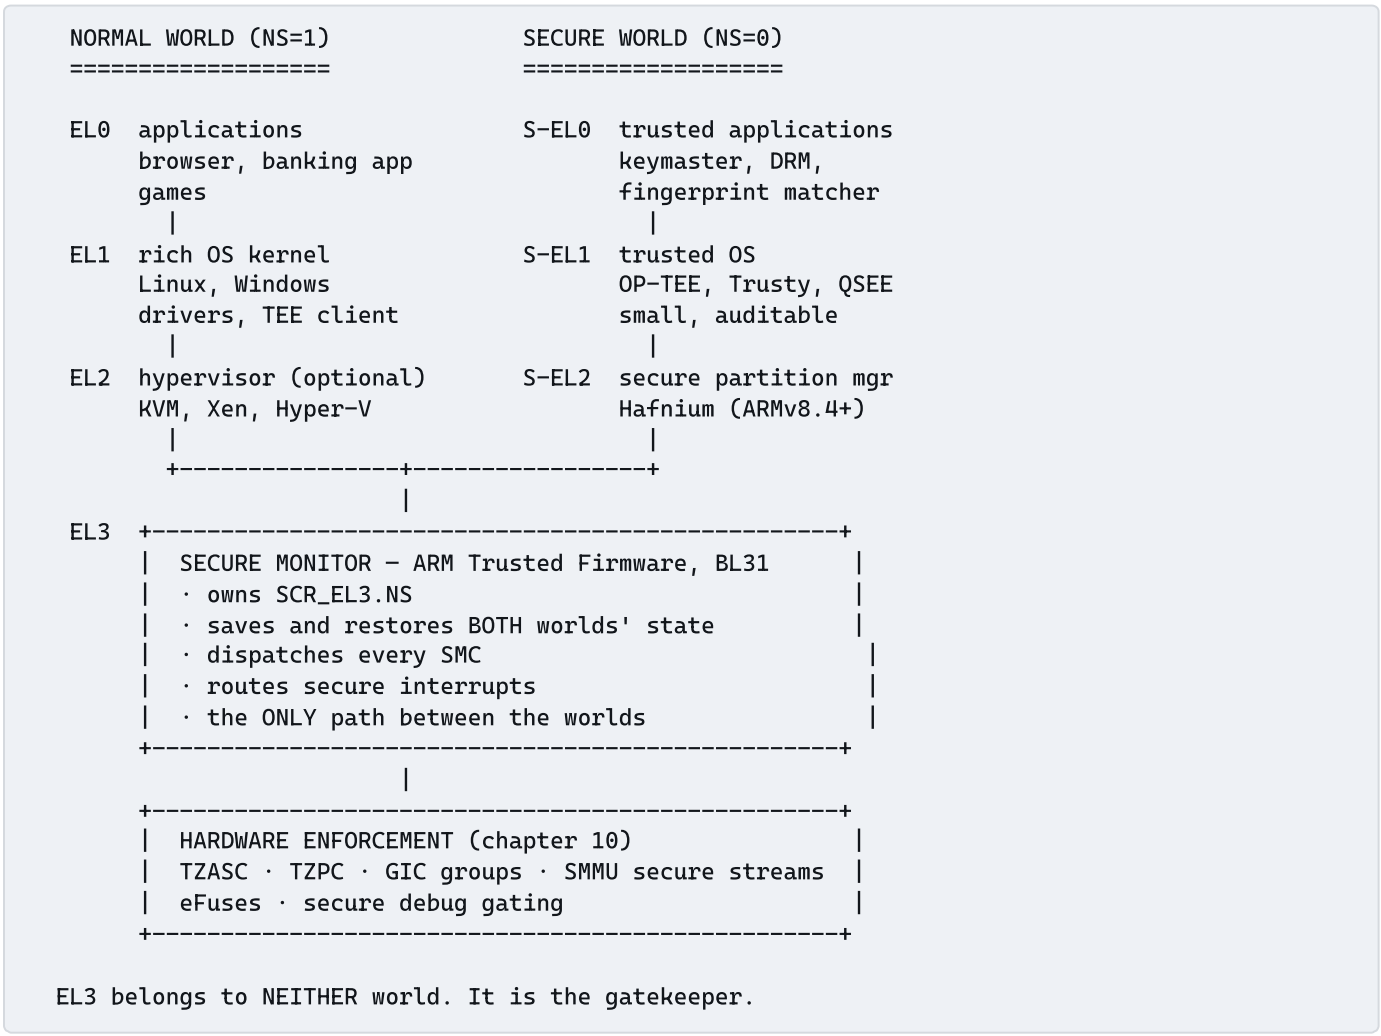
Check yourself

- ✓ State the TrustZone rule in one sentence and name the signal that carries it.
- ✓ Explain why silicon-level isolation differs from hypervisor isolation, and what each assumes.
- ✓ Explain how security state and exception level are orthogonal.
- ✓ Say which EL1 registers are banked by security state and why.
- ✓ Explain the descriptor `NS` bit and the `NSTable` bit.
- ✓ Name six blocks that check the NS bit and what each does with it.
- ✓ Explain the "peripheral reads all zeros" symptom and the order in which to rule out causes.
- ✓ Give four things the NS bit does not protect against.

TrustZone: the two worlds and EL3

One bit splits the machine into two parallel software stacks, each with its own exception levels, page tables and interrupts. Between them sits EL3 — the only code that exists in both, and the most security-critical software on the chip.

The full picture



Why put anything in the secure world

Reason	Concretely
The rich OS is too big to trust	30 M lines with a continuous CVE stream. Assume compromise; keep the secrets elsewhere.
Some secrets must survive kernel compromise	Attestation keys, disk encryption keys, DRM keys, biometric templates, payment credentials
Some operations need a trusted path	"Confirm this payment" must display on a screen the normal world cannot fake and read input it cannot inject
Boot integrity needs an anchor	Secure boot verification runs before the normal world exists at all
Certification requirement	Payment, DRM and eSIM schemes mandate a certified TEE or secure element

What EL3 actually does

```
/* BL31 — the resident EL3 firmware — has four jobs and should
   have no others.                                              */

/* 1. WORLD SWITCHING. Save one world's state, flip SCR_EL3.NS,
      restore the other's, ERET. Chapter 11.                    */

/* 2. SMC DISPATCH. Decode the function ID and route it:
        PSCI            power management (ARM chapter 33)
        SiP             silicon-vendor-specific services
        Trusted OS      forward to S-EL1
        Standard        Arm-defined services (SDEI, RAS, TRNG)  */

/* 3. SECURE INTERRUPT ROUTING. SCR_EL3.{IRQ,FIQ,EA} decide
      which interrupts come to EL3 rather than the current
      world.                                                    */

/* 4. PLATFORM INITIALISATION that must happen once, at the
      highest privilege: TZASC regions, TZPC assignments, SMMU
      secure configuration — then LOCK them.                    */

/* What EL3 must NOT do:
     · parse untrusted input
     · implement a filesystem, a network stack, or crypto
       protocols beyond what boot verification needs
     · grow. TF-A's BL31 is tens of thousands of lines and that
       is a deliberate ceiling.

   Every line at EL3 can compromise BOTH worlds. It is the one
   place where "keep it small" is not a style preference.   */
```

SCR_EL3

Bit	Name	Effect
0	`NS`	**The security state of the world below.** 0 = Secure, 1 = Non-secure.
1	`IRQ`	Route IRQ to EL3
2	`FIQ`	Route FIQ to EL3 — normally set, so secure interrupts reach the monitor
3	`EA`	Route External Aborts and SError to EL3
7	`SMD`	Disable `SMC` entirely — it becomes undefined
8	`HCE`	Enable `HVC`. Cleared means no hypervisor calls.
10	`RW`	Execution state below: 1 = AArch64
11	`ST`	Allow secure EL1 access to the secure timer
12/13	`TWI` / `TWE`	Trap `WFI` / `WFE` to EL3
18	`SIF`	**Secure Instruction Fetch**: forbid the secure world fetching instructions from Non-secure memory
19	`EEL2`	Enable Secure EL2 (ARMv8.4+)

> **`SCR_EL3.SIF` IS A DEFENCE WORTH KNOWING**
> Without it, secure software tricked into branching to a Non-secure address would execute normal-world code *with secure privilege* — total compromise from one corrupted function pointer. Setting `SIF` makes such a fetch fault. It is the secure world's equivalent of `PXN` on user pages (ARM 14), and it should always be set.

The software stack, end to end

Who implements what

Component	Runs at	Notes
TF-A (Trusted Firmware-A)	EL3, BL31	The open-source reference monitor. Also provides PSCI. Almost universal.
OP-TEE	S-EL1	Open source, GlobalPlatform-compliant. **Runs on QEMU** — the best way to learn.
Trusty	S-EL1	Google's, used in Android
QSEE / TEEGRIS / Kinibi	S-EL1	Qualcomm, Samsung, Trustonic. Closed source.
Hafnium	S-EL2	Secure Partition Manager — isolates secure partitions from each other

Component	Runs at	Notes
SPMC / FF-A	S-EL1 or S-EL2	Arm's Firmware Framework: a standard for secure partitions, replacing ad-hoc TEE interfaces

Secure EL2 and partitions

```
The original design had ONE secure OS. That is a problem when
several vendors each want a trusted component:

   a payment applet from a bank
   a DRM component from a content provider
   a biometric matcher from the OEM
   an eSIM applet from a carrier

  With one S-EL1 OS, all four are mutually trusting. A bug in
  any one compromises the others — and the whole secure world.

  ARMv8.4's SECURE EL2 fixes this: a Secure Partition Manager at
  S-EL2 gives each component its own stage-2 translation, so
  they are isolated from each other exactly as VMs are.

   S-EL0   TA          TA          TA
   S-EL1   [partition A] [partition B] [partition C]
   S-EL2   Secure Partition Manager (Hafnium)
                stage-2 isolation between partitions
   EL3     monitor

  FF-A standardises the messaging between partitions and the
  normal world, replacing the vendor-specific SMC interfaces
  that came before.

  Practically: it is how a modern phone runs several vendors'
  trusted code without any of them reading the others' keys.
```

Shared memory: the interesting part

```
/* The two worlds must exchange data. The pattern is always the
   same, and getting it wrong is the classic TEE vulnerability. */

/* 1. The NORMAL world allocates a buffer in NON-SECURE memory */
        shm = tee_shm_alloc(ctx, size, TEE_SHM_MAPPED | TEE_SHM_DMA_BUF);

/* 2. It passes the PHYSICAL ADDRESS in the SMC arguments      */

/* 3. The SECURE world maps it with NS=1 in its own page tables
      (chapter 08) and copies data in and out.                 */
```

SECURE CODE MUST NEVER TRUST A NORMAL-WORLD POINTER

Before dereferencing an address supplied by the normal world, secure software must verify that the *entire* range lies inside non-secure memory. Otherwise the normal world hands the TEE a pointer to *secure* memory and has the TEE read or write it on its behalf.

That is a **confused deputy** attack, and it is behind a substantial number of real TEE CVEs. The check must cover the whole range and must handle integer overflow in `base + length`.

```
static bool ns_range_ok(paddr_t base, size_t len)
{
        paddr_t end;

        if (len == 0)                       return false;
        if (ADD_OVERFLOW(base, len, &end)) return false;  /* wrap! */
        if (!core_pbuf_is(CORE_MEM_NON_SEC, base, len))
                return false;               /* the WHOLE range */
        return true;
}
```

```
/* And the TOCTOU rule: COPY FIRST, then validate the copy.

   WRONG — validating shared memory in place: */
        if (req->len > MAX)  return TEE_ERROR_BAD_PARAMETERS;
        process(req->buf, req->len);
        /* the normal world can change req->len between the two
           reads, because it still has the memory mapped       */

/* RIGHT — one copy into secure memory, then validate: */
        struct req local;
        memcpy(&local, ns_req, sizeof local);   /* from NS memory */
        if (local.len > MAX)  return TEE_ERROR_BAD_PARAMETERS;
        process(local.buf, local.len);          /* the COPY       */
```

What a world switch costs

```
   SMC instruction                        ~20 cycles
   exception entry to EL3                 ~30 cycles
   save the outgoing world's state        ~200-1000 cycles
     X0-X30, FP/SIMD if used, any
     non-banked system registers
   dispatch the function ID               ~50 cycles
   restore the incoming world's state     ~200-1000 cycles
   ERET                                   ~20 cycles
   ------------------------------------------------
   ONE WAY                                ~500-2000 cycles

   A round trip is 1,000-10,000 cycles, and on most designs the
   calling core is unavailable for the whole period.

  CONSEQUENCES for design:
     · never put an SMC in a hot path
     · BATCH work into one call rather than many small ones
     · never call from an interrupt handler or with a spinlock
       held
     · a TEE operation needed at high frequency is probably in
       the wrong place

  Compare: a system call is ~50-500 ns; a VM exit ~500-2000
  cycles. A world switch is the most expensive boundary
  crossing on the chip.
```

Interrupts across the boundary

```
/* The GIC assigns every interrupt to a GROUP (ARM chapter 23),
   and the group plus SCR_EL3 routing decides where it lands.  */

   Group 0            -> FIQ, always to EL3
                         secure firmware's own interrupts
   Secure Group 1     -> IRQ in the secure world,
                         FIQ in the non-secure world
                         the trusted OS's interrupts
   Non-secure Group 1 -> IRQ
                         the normal OS's interrupts

/* THE KEY PROPERTY: a Non-secure OS clearing PSTATE.I cannot
   mask secure interrupts, because they arrive as FIQ and route
   to EL3. The secure world can ALWAYS preempt the normal world.

   That is what makes a TEE's timing guarantees meaningful.  */

/* The reverse case: a normal-world interrupt arriving while the
   SECURE world is running. The monitor must either
     · hold it until the secure operation completes — simple,
       but adds latency to the normal world, or
     · return to the normal world with an "operation preempted,
       call again" status, so long secure operations do not
       block the OS.

   OP-TEE does the latter, via RPC returns. That is why a TEE
   call can return a retry status the client must handle.   */
```

Running the whole stack on QEMU

```
# A complete TrustZone system — TF-A at EL3, OP-TEE at S-EL1,
# Linux at EL1 — on your laptop, no hardware needed. The single
# best way to make this chapter concrete.

mkdir optee && cd optee
repo init -u https://github.com/OP-TEE/manifest.git -m qemu_v8.xml
repo sync -j8
cd build
make toolchains -j4
make run -j$(nproc)

# TWO consoles appear: the normal world (Linux) and the secure
# world (OP-TEE's log). Watch both.

# in the Linux console:
xtest                          # the OP-TEE conformance suite
optee_example_hello_world
optee_example_secure_storage
optee_example_acipher

# Watch the SECURE console while running these: the TA loading,
# the command dispatch, and the return, live.
```

READ `OPTEE_EXAMPLES/HELLO_WORLD/`

About 150 lines split between a normal-world client (TEE Client API) and a Trusted Application (with `TA_InvokeCommandEntryPoint`). Tracing one command through both halves — client, `ioctl`, driver, SMC, monitor, trusted OS, TA, and back — teaches more than any amount of reading.

How it shows up

Symptom	Cause
`SMC` causes an undefined instruction	EL3 not implemented, or `SCR_EL3.SMD` set
TEE calls are very slow	World switch cost — batch the work
System stalls during a TEE operation	No preemption path for normal-world interrupts
One TA can read another's secrets	No S-EL2 partitioning — all TAs are mutually trusting
Normal world crashes the TEE with a bad pointer	Missing non-secure range validation — confused deputy
A validated length changes before use	TOCTOU — validated in shared memory instead of after copying
Secure world executes normal-world code	`SCR_EL3.SIF` not set
Linux cannot mask an interrupt	It is a secure Group 0 or Secure Group 1 interrupt
TEE client receives a retry status	The operation was preempted to service a normal-world interrupt — retry is correct

Check yourself

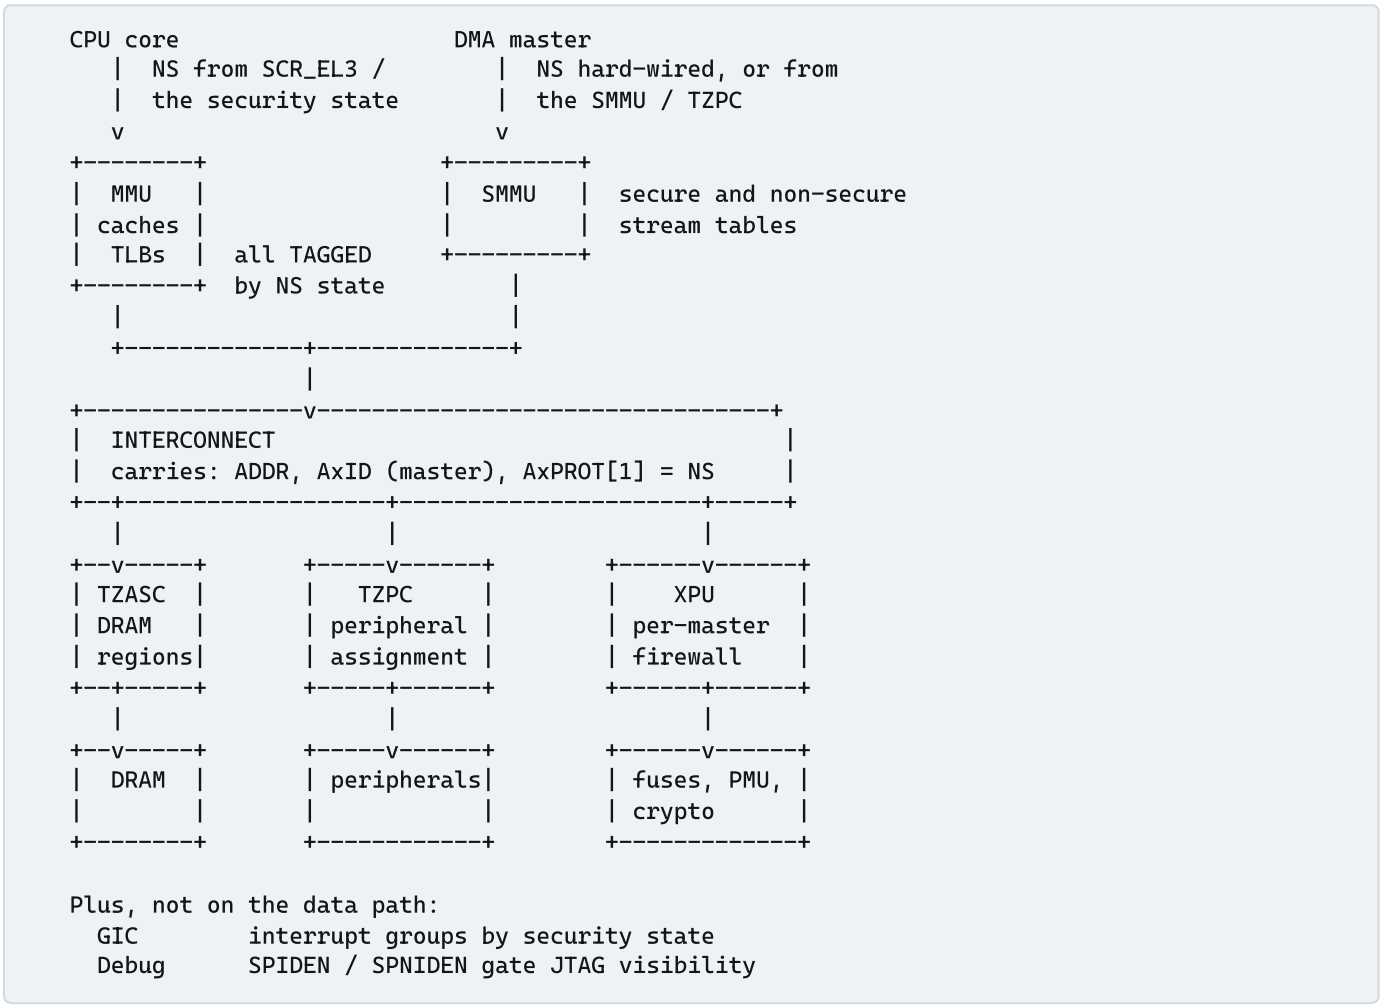
- ✓ Draw the two worlds with their exception levels and say what runs at each.
- ✓ Give EL3's four jobs and three things it must not do.

- ✓ Explain what `SCR_EL3.NS`, `SMD` and `SIF` each control.
- ✓ Explain why `SIF` exists and what it prevents.
- ✓ Trace a TEE call from client application to trusted application and back.
- ✓ Explain what Secure EL2 adds and the problem it solves.
- ✓ Give the confused deputy pattern and write a correct range check, including the overflow case.
- ✓ Explain the TOCTOU rule for shared memory.
- ✓ Say why a secure interrupt cannot be masked by the normal OS.

TrustZone: hardware enforcement blocks

The NS bit is only a promise until something checks it. This chapter covers the blocks that actually do the checking — where they sit, what they can express, and what a partial implementation leaves open.

Where the checks happen



TZASC — memory regions

```
/* The TrustZone Address Space Controller sits in front of the
   memory controller and applies a REGION TABLE.             */

   Per region:
      base address, size (power of two, or a range)
      security setting: Secure only / Non-secure only / both
      per-master read and write permission bitmap
      subregion disable mask (split a region into 8 parts)
      LOCK bit - write-once until reset

   A Non-secure access to a Secure region gets an ERROR
   RESPONSE, which becomes an external abort at the CPU
   (ARM chapter 29, DFSC 0b010000) - or, on some
   configurations, silently returns zeros.

/* Arm's TZC-400 is the common licensed implementation; vendors
   also build their own. Typical: 8 or 9 regions, one of which
   (region 0) is the DEFAULT covering everything not otherwise
   described.                                                */

/* Configuring it - firmware only, and once: */
static void tzc_configure_region(int region, uint64_t base,
                                 uint64_t top, unsigned sec_attr,
                                 unsigned ns_master_bitmap)
{
        tzc_write_region_base(region, base);
        tzc_write_region_top(region, top);
        tzc_write_region_attributes(region,
                (sec_attr << TZC_ATTR_SEC_SHIFT) | TZC_ATTR_REGION_EN);
        tzc_write_region_id_access(region, ns_master_bitmap);
}

/* And the default region must be RESTRICTIVE: */
        tzc_set_action(TZC_ACTION_ERR);          /* fail loudly   */
        tzc_configure_region0(TZC_REGION_S_RDWR, /* secure only   */
                              0);                /* no NS masters */
        /* then open up the specific ranges the normal world needs */

/* Getting region 0 wrong - leaving it permissive - means every
   address you did not explicitly describe is wide open. This is
   the fail-closed principle from chapter 01, applied.      */
```

TZPC — peripheral assignment

```
/* The TrustZone Protection Controller marks whole peripherals
   Secure or Non-secure, often at RUNTIME.                    */

   TZPCDECPROT<n>SET     mark a peripheral NON-SECURE
   TZPCDECPROT<n>CLR     mark it SECURE
   TZPCR0SIZE            how much on-chip SRAM is secure

/* Each bit corresponds to one peripheral, per the SoC's TRM.
   A Non-secure access to a Secure-marked peripheral is refused
   at the peripheral's bus interface.                         */

/* Why RUNTIME assignment is useful:
     · a fingerprint sensor is Secure while enrolling or
       matching, Non-secure the rest of the time
     · a display controller becomes Secure for a trusted-UI
       prompt, then returns
     · a crypto engine is claimed by the TEE for one operation

   The secure world flips the bit, does the work, and flips it
   back. The normal world's driver simply finds the device
   unresponsive in the meantime — which is exactly the
   "reads all zeros" symptom of chapter 08, appearing and
   disappearing.                                              */

/* Which makes for a genuinely confusing bug report: "the sensor
   works, except sometimes". Check whether a TEE operation is
   claiming it.                                               */
```

Caches and TLBs

```
Neither is "banked" — instead every entry is TAGGED with the
security state that created it.

   cache line tag:   address + NS state
   TLB entry tag:    VA + ASID + VMID + NS state + regime

  So a Non-secure lookup cannot HIT a Secure line, even at the
  same address. The two worlds' data coexists in one cache
  without leaking.

  CONSEQUENCES:

  · no cache flush is needed on a world switch for CORRECTNESS,
    which is a large part of why the switch is as fast as it is

  · but a flush may be needed for SECURITY: the two worlds share
    the cache as a RESOURCE, so timing differences leak
    information (chapter 16). Hardened monitors flush or
    partition on switch, at a real performance cost.

  · TLB maintenance from the secure world must specify the right
    regime. TLBI ALLE3 does not invalidate EL1 entries, and
    Secure EL1 entries are distinct from Non-secure EL1 entries
    even at the same VA and ASID.

  · a cache line's NS tag comes from the ACCESS, not the
    address. Secure software creating an NS=1 mapping to shared
    memory (chapter 08) produces Non-secure lines — which is
    correct, and is how sharing works without aliasing.
```

GIC — interrupt groups

Group	Signalled as	Taken to	Used for
Group 0	FIQ	Always EL3	Secure firmware's own interrupts
Secure Group 1	IRQ in the secure world; FIQ in the non-secure world	S-EL1, or EL3	Trusted OS interrupts
Non-secure Group 1	IRQ	EL1 (or EL2)	The normal OS

```
/* Configured in GICD_IGROUPR and GICD_IGRPMODR, writable only
   from the secure world.                                      */

/* The property that matters: a Non-secure OS clearing PSTATE.I
   masks only IRQ. A secure interrupt arrives as FIQ and is
   routed to EL3 by SCR_EL3.FIQ. The normal world CANNOT
   suppress it.

   Without this, a compromised kernel could simply disable
   interrupts and prevent the secure world from ever running —
   a denial of service against the TEE, and a way to defeat any
   secure watchdog.                                            */

/* And the reverse: GICD registers themselves are usually
   Secure-only for the group configuration, so the normal world
   cannot reassign an interrupt to its own group.

   On GICv3 the redistributor and CPU interface state are also
   banked by security state.                                   */
```

SMMU secure interface

```
/* SMMUv3 has TWO complete programming interfaces (chapter 04): */

   +0x0000   Non-secure   SMMU_*
   +0x8000   Secure       SMMU_S_*

/* Each with its own stream table, command queue, event queue and
   enable bit. Independent.

   WHY: a device operating in the secure world must be configured
   by SECURE firmware. If the Non-secure OS could program that
   device's translations, it could point a secure DMA engine at
   normal-world memory — reading secure data out through a
   device the normal world controls. A complete TrustZone
   bypass.

   And the STE and CD carry NSCFG fields determining whether the
   resulting transaction is issued Secure or Non-secure, exactly
   as the page descriptor NS bit does for the CPU.

   So the SMMU is not merely an isolation device for the normal
   world — it is part of the TrustZone boundary itself.     */

/* A common integration gap: an SoC implements the SMMU but not
   its secure interface (SMMU_IDR1.SECURE_IMPL = 0). Secure DMA
   masters are then unprotected, and must be constrained by an
   XPU instead (chapters 17–20).                               */
```

Fuses and one-time-programmable storage

Holds	Read by	Note
Root of Trust public key hash	Boot ROM only, or Secure masters	The anchor for secure boot (ch. 14)
Hardware Unique Key (HUK)	Often only the crypto engine, never software	Per-device; the basis for secure storage
Anti-rollback counters	Secure firmware	Monotonic; prevents downgrade
Lifecycle state	Boot ROM and firmware	Blank / development / secured / RMA

Holds	Read by	Note
Debug enable	The debug authentication logic	Gates `SPIDEN` / `SPNIDEN`
Feature disable	Various	Vendor SKU differentiation

> **THE BEST-DESIGNED HUK IS NEVER VISIBLE TO SOFTWARE**
>
> On a well-built SoC, the hardware unique key is wired directly into the crypto engine's key input. Software asks the engine to "derive a key using the HUK" and receives a *derived* key; it never sees the HUK itself. Even a compromised trusted OS cannot extract it.
>
> A design where software reads the HUK into a register is much weaker — a single memory-disclosure bug in the secure world then reveals the root of all device storage encryption, permanently and unfixably.

Debug authentication

```
Four signals gate what a debugger may see:

   DBGEN     invasive debug (halt, single-step) in the NORMAL world
   NIDEN     non-invasive (trace, PMU) in the normal world
   SPIDEN    invasive debug of the SECURE world
   SPNIDEN   non-invasive of the secure world

  Driven by fuses, by a debug authentication module, or by a
  signed unlock token.

  Typical configurations:
     development part   all four asserted
     production part    DBGEN/NIDEN maybe, SPIDEN/SPNIDEN OFF
     locked-down        all four off

  CONSEQUENCES you will meet:
     · JTAG attaches but cannot see secure state — you can halt
       the core in the normal world and not in the secure one
     · the PMU counts normal-world events only, so a profile
       silently omits secure execution
     · CoreSight trace stops at the world boundary
     · a TEE bug that reproduces only on production silicon is
       very hard to debug — which is why development firmware
       should log aggressively

  RMA UNLOCK: a controlled path back, requiring a token signed
  by the vendor and usually destroying the device keys first so
  that unlocking cannot expose user data.
```

The rest

Block	Enforces
Secure boot ROM	Immutable first stage; verifies everything after it
Crypto engine	Key slots accessible only to Secure masters; some keys never leave the block
True RNG	Entropy source, often Secure-only or with a Secure-only health-test interface
Secure timer / watchdog	A watchdog the normal world cannot disable — so a hung TEE is recoverable
Secure SRAM	On-chip memory, sometimes with no external bus path at all — used for keys in use

Block	Enforces
Memory encryption	Encrypts DRAM contents so bus probing and cold boot recover only ciphertext
Boot-mode straps	Latched at reset; often Secure-readable only, so the normal world cannot learn or change the boot source

Where implementations fall short

ENFORCEMENT IS ONLY AS COMPLETE AS THE SILICON

TrustZone is a system-wide contract, and a partial implementation is a bypass. Real gaps that have shipped:

- **A peripheral that ignores the NS bit.** Its registers are reachable from both worlds regardless of the TZPC.
- **A bus segment that drops or hard-codes NS.** Everything downstream sees a fixed value.
- **A DMA master with no SMMU and no XPU.** Full access to all memory, from whichever world can program it.
- **A TZASC default region left permissive.** Anything not explicitly protected is open.
- **Debug signals not fused off in production.** The most common finding in device security audits.
- **A configuration register left unlocked.** A compromised secure world — or in bad cases the normal world — can widen the policy at runtime.

Verifying each of these is a real part of SoC security review, and it is done by *testing the negative cases*, not by reading the datasheet.

Verifying the configuration

```
/* Write these as a boot-time self-test in development firmware.
   A policy never exercised is a policy you do not know works. */

static void security_selftest(void)
{
        /* 1. Non-secure access to Secure DRAM must FAIL */
        expect_abort(read32_ns(SECURE_DRAM_BASE));

        /* 2. Non-secure access to a Secure peripheral must FAIL */
        expect_abort(read32_ns(SECURE_CRYPTO_BASE));

        /* 3. Secure access to Non-secure DRAM must SUCCEED */
        expect_ok(read32_s(NS_DRAM_BASE));

        /* 4. the TZASC default region must be restrictive */
        assert(tzc_region0_attr() == TZC_REGION_S_RDWR);

        /* 5. every region that should be locked, is */
        for (i = 0; i < nr_regions; i++)
                assert(tzc_region_locked(i) == expected_lock[i]);

        /* 6. debug signals match the lifecycle state */
        if (lifecycle_state() == LC_SECURED)
                assert(!spiden_asserted() && !spniden_asserted());

        /* 7. SCR_EL3 has the expected bits */
        assert(read_scr_el3() & SCR_SIF);
        assert(read_scr_el3() & SCR_FIQ);
        assert(read_scr_el3() & SCR_EA);
}

/* Run it in development builds, on a part in the FINAL
   lifecycle state. Chapter 19 covers building the complete
   access matrix systematically.                          */
```

How it shows up

Symptom	Cause
Peripheral reads zeros or aborts on production units	TZPC marks it Secure
A device works "except sometimes"	Runtime TZPC reassignment during a TEE operation
Linux cannot see a DRAM region in the TRM	Carved out as Secure by the TZASC
External abort, DFSC `0b010000`	TZASC, TZPC or XPU refused the access
Access silently returns zeros instead of aborting	The controller's action is "return zeros" — much harder to debug (ch. 20)
Normal world reads secure memory successfully	**A security bug** — a permissive default region, or a block ignoring NS
JTAG halts in Linux but not in the TEE	`SPIDEN` deasserted — by design
Profile omits secure execution	`SPNIDEN` deasserted
Secure DMA master can be redirected by Linux	SMMU secure interface not implemented or not used
Policy changes at runtime	Configuration registers not locked

Check yourself

- ✓ Name the blocks that check the NS bit and where each sits.
- ✓ Explain what a TZASC region entry contains and why the default must be restrictive.
- ✓ Give a use for runtime TZPC reassignment and the confusing symptom it produces.
- ✓ Explain why caches need no flush on a world switch for correctness, but may for security.
- ✓ Explain why a secure interrupt cannot be masked by the normal OS, and what that prevents.
- ✓ Say why the SMMU needs a separate secure programming interface.
- ✓ Explain why the best HUK designs never expose the key to software.
- ✓ Name the four debug authentication signals and what each gates.
- ✓ List five ways a partial implementation creates a bypass.

The SMC calling convention and the world switch

One instruction crosses the security boundary. This chapter follows it: the register convention, what EL3 does on the way through, how a long secure operation is interrupted, and why the whole design is shaped by the fact that only one world runs at a time.

The instruction

```
        SMC     #imm16          /* Secure Monitor Call */

/* Behaves exactly like SVC and HVC (ARM chapter 30), one level
   up:

     SVC  from EL0  -> EL1     the syscall
     HVC  from EL1  -> EL2     the hypercall
     SMC  from EL1  -> EL3     the secure monitor call

   On execution:
     ELR_EL3   <- address of the instruction AFTER the SMC
     SPSR_EL3  <- PSTATE, including the security state
     ESR_EL3   <- EC 0x17 (AArch64 SMC), ISS = the imm16
     PC        <- VBAR_EL3 + 0x400  (sync, lower EL, AArch64)

   The imm16 is CAPTURED but not used by any real convention -
   everybody passes the function ID in X0 instead, because that
   gives 32 bits instead of 16 and can be computed at runtime. */
```

SMC CAN BE DISABLED, OR STOLEN

`SCR_EL3.SMD = 1` makes `SMC` undefined at EL1 and EL2. And separately, `HCR_EL2.TSC = 1` makes an EL1 `SMC` trap to *EL2* instead of EL3 — which is how a hypervisor filters or virtualises the calls its guests make. A guest that thinks it is talking to firmware may be talking to the hypervisor.

SMCCC — the calling convention

```
Arm's SMC Calling Convention makes the function ID in X0
self-describing:

  bit 31     call type      0 = Yielding, 1 = Fast
  bit 30     calling conv   0 = SMC32,    1 = SMC64
  bits 29:24 owning entity
  bits 23:16 reserved / hint
  bits 15:0  function number

  OWNING ENTITY ranges:
     0x00  Arm architecture calls (SMCCC_VERSION, workarounds)
     0x01  CPU service        (PSCI lives here)
     0x02  SiP service        (vendor firmware)
     0x03  OEM service        (board integrator)
     0x04  Standard Secure    (PSCI, SDEI, FF-A, TRNG)
     0x05  Standard Hypervisor
     0x06  Vendor Hypervisor
     0x30-0x31  Trusted Application calls
     0x32-0x3F  Trusted OS calls

  FAST vs YIELDING:
     Fast     atomic-ish, must not be preempted, returns quickly.
              PSCI, version queries, register reads.
     Yielding may block, may be interrupted by a normal-world
              interrupt, may need to be resumed. TEE requests.

  SMC32 vs SMC64: whether arguments are 32-bit values in W
  registers or 64-bit in X registers. A 32-bit normal world can
  only issue SMC32.
```

```
/* Registers, SMC64: */

   X0        function ID          -> return value / status
   X1..X6    arguments            -> return values X1..X3
   X7        hint / session       (SMCCC 1.2: also an argument)
   X8..X17   volatile             the callee may clobber
   X18       platform register    preserved
   X19..X29  callee-saved         PRESERVED across the SMC
   X30, SP   preserved

/* SMCCC 1.2 extends the argument and result set to X0..X17 for
   SMC64, which is what FF-A uses.

   Standard return codes:
        0   SUCCESS
       -1   NOT_SUPPORTED          (also: unknown function ID)
       -2   INVALID_PARAMETER
       -3   DENIED
   Anything else is service-specific.                          */

/* The unknown-ID rule matters: an SMC with a function ID nobody
   claims must return -1 in X0, not hang and not panic. That is
   how a caller DISCOVERS what firmware supports - it asks, and
   a clean "no" is a valid answer.                             */
```

What EL3 actually does

THE MONITOR IS A CONTEXT SWITCHER, NOT A SERVICE

Almost everything EL3 does is save-and-restore. The interesting work happens in the trusted OS at S-EL1; EL3's job is to make sure that when it starts running, none of the normal world's state is visible to it and vice versa. This is why EL3 code is measured in tens of kilobytes, and why the design goal is to keep it that way (chapter 09).

What the switch costs

Step	Rough cost	Why
SMC exception entry	~30–60 cycles	Pipeline flush, same as any exception
Save NS context	~200–500 cycles	~40 system registers; `MSR` / `MRS` are not cheap and some serialise
Restore secure context	~200–500 cycles	Same again, the other way
`ERET`	~20–40 cycles	Another pipeline flush
FP/SIMD save and restore	+~100 cycles	Skipped if `CPACR` shows it unused; SVE is far worse
Cold caches and TLBs in the other world	Highly variable	The real cost, and the one nobody measures

```
/* Round trip: roughly 1000–4000 cycles for a trivial call, plus
   whatever the trusted OS does, plus the cache effects on both
   sides.

   At 1.5 GHz that is a few microseconds of pure overhead. Fine
   at 100 calls per second. Ruinous at 100,000.

   DESIGN CONSEQUENCE: batch. A TEE interface that asks the
   secure world to encrypt one 16-byte block per SMC will be
   dominated entirely by switching. Pass a buffer of a megabyte
   and the overhead disappears into the noise.

   The same shape of argument as syscall batching (OS chapter 3)
   and as MMIO round trips (ARM chapter 25) — crossing a
   boundary is expensive, so cross it with as much work as you
   can carry.                                                  */
```

Interrupting a long secure call

```
Problem: the trusted OS is halfway through a 50 ms operation and
a normal-world timer interrupt fires. Only one world runs at a
time, so the normal world is FROZEN. Miss enough ticks and Linux
notices - RCU stalls, softlockup warnings, dropped audio.

Solution: the Non-secure interrupt is routed to EL3
(SCR_EL3.IRQ = 1 while in the secure world), which returns to
the normal world with a "please call me back" status.

   Linux                EL3             Trusted OS
   -----                ---             ----------
   SMC(op) ---------->  switch  ------->  starts work
                                             ...
                       <-- NS IRQ arrives, taken to EL3
   <-- X0 = INTERRUPTED, with a resume token
   handles the IRQ
   scheduler runs, other tasks run
   SMC(RESUME, token) ->  switch ----->  continues where it
                                         left off
   <-- X0 = SUCCESS ------------------- done

  In OP-TEE this is OPTEE_SMC_RETURN_RPC_* and RETURN_FROM_RPC.
  In FF-A it is FFA_INTERRUPT and FFA_RUN.

  The secure world must therefore be written so it CAN be
  suspended mid-operation: no unbounded critical sections, and
  state kept in the session rather than on a stack it assumes
  will still be there.

  This is also why YIELDING calls exist as a category. A Fast
  call promises it is short enough that this machinery is
  unnecessary.
```

RPC — the secure world calling back

```
/* The trusted OS has no drivers. It cannot read a file, allocate
   from the kernel, or talk to storage. When it needs any of
   that it returns to the normal world with a REQUEST.       */

   Trusted OS needs to load a TA from disk
        |
        v
   returns X0 = RPC_LOAD_TA, X1 = uuid...
        |
        v
   EL3 switches to the normal world
        |
        v
   tee-supplicant (a userspace daemon) reads the file
        |
        v
   places it in shared memory, SMC(RETURN_FROM_RPC)
        |
        v
   Trusted OS resumes, now with the data

/* Common RPC types: allocate shared memory, free it, load a TA,
   read or write secure storage, get the wall-clock time,
   perform a network request to a provisioning server.       */

/* SECURITY CONSEQUENCE, and it is a big one:

   Everything obtained by RPC comes from an untrusted source.
   The normal world can:
        - return a DIFFERENT TA binary  -> VERIFY THE SIGNATURE
        - return stale secure storage   -> ANTI-ROLLBACK COUNTER
        - lie about the time            -> never trust it for expiry
        - refuse to answer at all       -> handle the failure
        - answer differently each read  -> COPY IN, then validate

   The trusted OS depends on the normal world for AVAILABILITY -
   which is fine, since a normal world that refuses to cooperate
   has only denied itself service. It must never depend on it
   for INTEGRITY.                                            */
```

PSCI: the SMC interface everyone uses

```
/* Most SMCs on a running Linux system never reach a trusted OS at
   all. They are PSCI - Power State Coordination Interface -
   handled entirely inside EL3.                                  */

   PSCI_VERSION            0x84000000
   CPU_SUSPEND             0xC4000001
   CPU_OFF                 0x84000002
   CPU_ON                  0xC4000003
   AFFINITY_INFO           0xC4000004
   SYSTEM_OFF              0x84000008
   SYSTEM_RESET            0x84000009
   PSCI_FEATURES           0x8400000A
   SYSTEM_RESET2           0xC4000012

/* Linux brings up a secondary core: */

static int psci_cpu_on(unsigned long cpuid, unsigned long entry)
{
        return invoke_psci_fn(PSCI_FN_NATIVE(0_2, CPU_ON),
                              cpuid, entry, 0);
}

/* invoke_psci_fn is arm_smccc_smc() or arm_smccc_hvc() depending
   on the CONDUIT, which is read from the device tree:

        psci {
                compatible = "arm,psci-1.0";
                method     = "smc";
        };

   Under a hypervisor the method is "hvc" instead, and the
   hypervisor either handles the call or forwards it. A wrong
   conduit is a classic bring-up failure: SMC from a guest traps
   to EL2 (HCR_EL2.TSC) or is simply undefined, and the
   secondary CPUs never come up.                                 */

/* Which is why "only CPU0 is online" is almost always a PSCI
   problem, not a scheduler problem (ARM chapter 33).        */
```

Issuing an SMC from Linux

```
#include <linux/arm-smccc.h>

static int my_sip_call(u32 arg)
{
        struct arm_smccc_res res;

        arm_smccc_smc(MY_SIP_FUNC_ID,   /* X0 */
                      arg,              /* X1 */
                      0, 0, 0, 0, 0, /* X2..X7 */
                      &res);

        if ((long)res.a0 < 0)
                return -EINVAL;

        return res.a1;                  /* X1 came back here */
}

/* res holds a0..a3 = X0..X3.

   arm_smccc_smc() emits SMC; arm_smccc_hvc() emits HVC. Use
   arm_smccc_1_1_invoke() to pick automatically based on the
   detected conduit - that is what generic code should do.   */

/* CONSTRAINTS on the caller:
     - the call may take a long time; do not hold a spinlock
     - it does not sleep in the Linux sense, but it does BLOCK
       the CPU, so a Yielding call has no place in a truly
       atomic context
     - arguments passed by pointer must be PHYSICAL addresses in
       memory the secure world can reach - a kmalloc'd buffer's
       virtual address is meaningless there
     - that memory must be non-secure and inside the region the
       secure world will accept (chapter 08)
     - and it must be flushed to the point of coherency if the
       two worlds' mappings differ in cacheability           */
```

> **WATCHING SMC TRAFFIC**
> Build TF-A with `DEBUG=1 LOG_LEVEL=40` and it prints every call it handles on the UART. On a QEMU virt machine with OP-TEE this is the fastest way to see the real sequence: PSCI during boot, then the OP-TEE calls once `tee-supplicant` starts, then the RPC round trips inside each one.

FF-A: the newer shape

```
/* The Firmware Framework for Arm A-profile replaces "one trusted
   OS reached by vendor-specific SMCs" with a message-passing
   model between PARTITIONS.                                    */

   FFA_VERSION               negotiate
   FFA_ID_GET                who am I
   FFA_PARTITION_INFO_GET    who else is here
   FFA_MSG_SEND_DIRECT_REQ   send a message, block for the reply
   FFA_MSG_SEND_DIRECT_RESP  the reply
   FFA_MEM_SHARE             share pages with a partition
   FFA_MEM_LEND / DONATE     transfer them
   FFA_MEM_RECLAIM           take them back
   FFA_RUN                   resume a partition
   FFA_INTERRUPT             it was preempted

/* WHY IT MATTERS:
     - several mutually distrusting secure partitions can coexist
       under a Secure EL2 hypervisor (chapter 09), instead of one
       monolithic trusted OS
     - memory sharing is EXPLICIT and revocable, with the manager
       tracking who has what - not an ad hoc agreed region
     - the same interface works for normal-world VMs, so a
       hypervisor can broker access rather than passing SMCs
       through blind

   OP-TEE can run as an FF-A secure partition, and new designs
   generally should. But the older direct-SMC interface is what
   you will meet on most shipping hardware.                     */
```

Designing an SMC interface

RULES THAT KEEP THE BOUNDARY SAFE

- **Validate every argument, every time.** The caller is the attacker. Ranges, sizes, alignment, handles, enum values.
- **Copy shared-memory arguments in before validating.** The other world can rewrite them between your check and your use (chapter 09).
- **Never return a secure pointer.** Return an opaque handle indexed into a table you own.
- **Make calls idempotent or explicitly sequenced.** The normal world can retry, replay, or call from two CPUs at once.
- **Assume concurrency.** Every core can be inside the same call simultaneously; the trusted OS needs real locking.
- **Bound the work.** No operation may run for an unbounded time, because it stalls the normal world.
- **Return `NOT_SUPPORTED` for unknown IDs** — discovery depends on it.
- **Version the interface** from the first release, and negotiate.
- **Keep the surface small.** Every function ID is an entry point into the most privileged code on the SoC.

How it shows up

Symptom	Cause
`SMC` is an undefined instruction	`SCR_EL3.SMD = 1`, or no EL3 implemented
SMC lands in the hypervisor instead of firmware	`HCR_EL2.TSC = 1`
Returns `-1` for a call you implemented	Function ID mismatch, or the SMC32/SMC64 bit is wrong
Only CPU0 comes online	PSCI conduit wrong in DT, or `CPU_ON` failing — check the TF-A log
Secure world reads garbage from your buffer	Virtual address passed instead of physical, or cache not flushed
Works once, fails on retry	Non-idempotent call, or session state not reset
RCU stalls and softlockups during TEE use	A long secure operation that never yields to normal-world interrupts
Random corruption under load	Trusted OS not locking against concurrent calls from multiple cores
Hang inside `arm_smccc_smc`	Firmware never returned — a secure-world crash or deadlock
Callee-saved registers corrupted after the call	Firmware violating the SMCCC — a real firmware bug

Check yourself

- ✓ Place `SMC` alongside `SVC` and `HVC`, and say what each targets.
- ✓ Decode an SMCCC function ID: type, convention, owning entity, number.
- ✓ Explain the difference between a Fast and a Yielding call.
- ✓ List what EL3 saves and restores on a world switch, and estimate the cost.
- ✓ Explain why a TEE interface should batch work.
- ✓ Describe how a long secure operation is interrupted and resumed.
- ✓ Explain what RPC is and why nothing returned by it may be trusted for integrity.
- ✓ Name five PSCI functions and say why a wrong conduit stops secondary CPUs booting.
- ✓ Write a Linux SMC call and state the constraints on any pointer you pass.
- ✓ Give five rules for designing a safe SMC interface.

The TEE software stack and OP-TEE

Six pieces of software cooperate to run one trusted operation. This chapter names every one of them, follows a single request through all six, and gets OP-TEE running on QEMU so you can watch it happen.

The whole stack

```
NORMAL WORLD                          SECURE WORLD
============                          ============

your application                      Trusted Application
     |  libteec                           |  TA framework
     |  (GlobalPlatform Client API)       |  (GP Internal API)
     v                                    ^
+----------------+                  +----+-------------+
| tee-supplicant |                  |   OP-TEE OS      |  S-EL1
| (daemon, EL0)  |                  |   (trusted OS)   |
+--------+-------+                  +----+-------------+
         |  RPC                           ^
         v                                  |
+----------------------+                    |
| optee driver         |  EL1               |
| drivers/tee/optee    |                    |
+----------+-----------+                    |
           |  SMC                           |
           v                                |
+-----------------------------------------+------------+
|  TF-A  BL31 - the secure monitor              EL3     |
+-------------------------------------------------------+

Six pieces, each with one job:

1. your app        wants a secret operation performed
2. libteec         turns API calls into ioctls on /dev/tee0
3. optee driver    turns ioctls into SMCs, manages shared memory
4. TF-A BL31       switches worlds
5. OP-TEE OS       schedules and isolates trusted applications
6. the TA          does the actual work

plus tee-supplicant, off to the side, servicing RPC requests
the secure world cannot perform for itself (chapter 11).
```

The GlobalPlatform APIs

```
/* Two standard APIs, one on each side of the boundary. Learn
   these and your knowledge transfers between OP-TEE, Trusty,
   QSEE and Kinibi.                                          */

/* --- CLIENT API, normal world, libteec ------------------- */

   TEEC_InitializeContext()   connect to the TEE
   TEEC_OpenSession()         start talking to a TA (by UUID)
   TEEC_InvokeCommand()       ask it to do something
   TEEC_CloseSession()
   TEEC_FinalizeContext()
   TEEC_RegisterSharedMemory()  register your own buffer
   TEEC_AllocateSharedMemory()  or let the TEE allocate one

/* --- INTERNAL API, secure world, inside the TA ----------- */

   TA_CreateEntryPoint()          once, when the TA is loaded
   TA_OpenSessionEntryPoint()     per client session
   TA_InvokeCommandEntryPoint()   per command  <- the real work
   TA_CloseSessionEntryPoint()
   TA_DestroyEntryPoint()

   TEE_AllocateOperation()        crypto
   TEE_CipherInit/Update/DoFinal()
   TEE_DigestDoFinal()
   TEE_AsymmetricSignDigest()
   TEE_GenerateRandom()
   TEE_DeriveKey()

   TEE_CreatePersistentObject()   secure storage (chapter 13)
   TEE_OpenPersistentObject()
   TEE_ReadObjectData()

   TEE_Malloc/Free()              heap, inside the TA
   TEE_CheckMemoryAccessRights()  IS this pointer safe to touch?
   TEE_Panic()                    give up loudly
```

The parameter model

```
/* Every invocation carries FOUR parameter slots. Each slot is
   either a VALUE (two 32-bit numbers) or a MEMREF (a shared
   buffer), and each has a direction.                          */

   TEEC_NONE
   TEEC_VALUE_INPUT        a.b: two u32 in
   TEEC_VALUE_OUTPUT       two u32 out
   TEEC_VALUE_INOUT
   TEEC_MEMREF_TEMP_INPUT      a buffer, registered for this call
   TEEC_MEMREF_TEMP_OUTPUT
   TEEC_MEMREF_TEMP_INOUT
   TEEC_MEMREF_WHOLE           a pre-registered shared memory
   TEEC_MEMREF_PARTIAL_INPUT   part of a pre-registered one
   TEEC_MEMREF_PARTIAL_OUTPUT
   TEEC_MEMREF_PARTIAL_INOUT

/* Packed into one word: */
   op.paramTypes = TEEC_PARAM_TYPES(TEEC_VALUE_INPUT,
                                    TEEC_MEMREF_TEMP_OUTPUT,
                                    TEEC_NONE,
                                    TEEC_NONE);

/* And the TA MUST check that it got what it expected: */

TEE_Result TA_InvokeCommandEntryPoint(void *sess, uint32_t cmd,
                                      uint32_t ptypes,
                                      TEE_Param params[4])
{
        uint32_t exp = TEE_PARAM_TYPES(TEE_PARAM_TYPE_VALUE_INPUT,
                                       TEE_PARAM_TYPE_MEMREF_OUTPUT,
                                       TEE_PARAM_TYPE_NONE,
                                       TEE_PARAM_TYPE_NONE);

        if (ptypes != exp)
                return TEE_ERROR_BAD_PARAMETERS;   /* not optional */
        ...
}

/* Skipping that check means the client can pass a VALUE where
   you expect a MEMREF. You then read params[1].memref.buffer -
   which is now an arbitrary 64-bit number the attacker chose,
   dereferenced by the most privileged code in the system.

   This is the single most common OP-TEE TA vulnerability
   class.                                                      */
```

EVERY BUFFER FROM THE CLIENT IS HOSTILE

A MEMREF points into *non-secure shared memory*. The client can change its contents at any moment, including between your bounds check and your read — and on another CPU it does not even need your call to return first.

- Check `params[i].memref.size` before trusting it, and check it against what you will actually write.
- Call `TEE_CheckMemoryAccessRights()` to confirm the buffer is where it claims to be.
- **Copy the input into TA-local memory, then validate the copy, then use only the copy.**
- Write outputs once, at the end. Never use the shared buffer as scratch space.
- Never place a secret in an output buffer before deciding the caller is entitled to it.

One request, end to end

```
app: TEEC_InvokeCommand(&sess, CMD_SIGN, &op, &origin)
  |
  v
libteec: build struct tee_ioctl_invoke_arg, translate the
         parameters, ioctl(fd, TEE_IOC_INVOKE, &arg)
  |
  v
optee driver (optee_invoke_func):
     get a free "call queue" entry
     translate each MEMREF: virtual -> the shared-memory cookie
       and physical address the secure world understands
     fill an optee_msg_arg in the shared memory pool
     arm_smccc_smc(OPTEE_SMC_CALL_WITH_ARG, msg_pa, ...)
  |
  v
TF-A BL31: save NS context, SCR_EL3.NS = 0, restore secure
           context, ERET to S-EL1
  |
  v
OP-TEE OS:
     entry from the monitor, pick the thread for this call
     find the session, find the TA
     is the TA loaded? -> if not, RPC to tee-supplicant to
                          fetch it, VERIFY ITS SIGNATURE, map it
     map the shared buffers into the TA's address space,
       NON-SECURE, non-executable
     drop to S-EL0 and call TA_InvokeCommandEntryPoint
  |
  v
TA: validate ptypes, copy input in, do the crypto with a key
    it derived from the HUK, write the result out, return
  |
  v
OP-TEE OS: unmap the buffers, set the return code, SMC back
  |
  v
TF-A BL31: save secure context, SCR_EL3.NS = 1, restore NS,
           ERET to Linux
  |
  v
optee driver: copy results back into the ioctl arg, return
  |
  v
libteec: fill in op.params, set return origin, return
  |
  v
app: TEEC_SUCCESS

  Two privilege boundaries crossed in each direction
  (S-EL0/S-EL1 and the world switch), plus a possible RPC
  excursion in the middle.
```

Where a TA runs

Type	Runs at	Loaded from	Use for
User-mode TA	S-EL0	Signed `.ta` file, fetched by RPC	Almost everything — isolated, crashable, updatable
Early TA	S-EL0	Linked into the OP-TEE binary	Needed before the filesystem exists

Type	Runs at	Loaded from	Use for
Pseudo TA	S-EL1, inside the kernel	Compiled in	Only when it truly needs kernel privilege
Secure partition	S-EL1 under S-EL2	FF-A manifest	Mutually distrusting secure components

> **A PSEUDO TA HAS NO MEMORY PROTECTION AT ALL**
>
> It runs in the trusted OS's own address space, at S-EL1, with full access to secure memory and every system register. A buffer overflow in a pseudo TA is not a crash — it is total compromise of the secure world. Write a user-mode TA unless you can state exactly which S-EL1-only operation forces your hand.

How OP-TEE isolates TAs

```
/* Each user-mode TA gets:

     its own S-EL0 address space, with its own translation
       tables and its own ASID
     its own heap and stack, sized by its manifest
     no access to another TA's memory
     no access to OP-TEE OS memory
     no MMIO mappings unless explicitly granted
     no way to execute privileged instructions

   So the isolation model inside the secure world mirrors
   user/kernel in Linux (OS chapters 4 and 12) - and for the
   same reason. A trusted application is trusted RELATIVE TO
   THE NORMAL WORLD, not absolutely.                          */

/* A TA declares its needs in a header: */

#define TA_UUID  { 0x8aaaf200, 0x2450, 0x11e4, \
                 { 0xab, 0xe2, 0x00, 0x02, 0xa5, 0xd5, 0xc5, 0x1b } }

#define TA_FLAGS                (TA_FLAG_EXEC_DDR | \
                                 TA_FLAG_SINGLE_INSTANCE | \
                                 TA_FLAG_MULTI_SESSION)
#define TA_STACK_SIZE           (2 * 1024)
#define TA_DATA_SIZE            (32 * 1024)

/* SINGLE_INSTANCE  one copy shared by all clients
   MULTI_SESSION    several concurrent sessions allowed
   INSTANCE_KEEP_ALIVE   stays resident after the last session
   SECURE_DATA_PATH      may touch secure buffers (video, DRM)

   Ask for the SMALLEST stack and heap that work. The secure
   world's memory is a scarce, permanently carved-out resource
   (chapter 10), not Linux's elastic pool.                    */
```

The thread model

```
/* OP-TEE has a FIXED number of threads - CFG_NUM_THREADS,
   typically 2 to 8, often one per CPU.

   Each concurrent secure call occupies one. When they are all
   busy the SMC returns OPTEE_SMC_RETURN_ETHREAD_LIMIT and the
   Linux driver puts the caller to sleep until one frees.

   CONSEQUENCES:
     - the secure world does not scale to hundreds of concurrent
       clients; it is not a server
     - a TA that blocks holds a thread the whole time
     - an RPC excursion also holds its thread - the normal world
       is servicing a request from a thread that is still
       "inside" the secure world
     - deadlock is possible: all threads waiting on an RPC that
       needs a thread to complete. This is why tee-supplicant
       must never itself call into the TEE.                  */

/* Each thread has a fixed stack, typically 8 KB. Deep recursion
   or a large local array in a pseudo TA overflows it, and the
   result is a secure-world crash with a stack dump on the
   console - which on production silicon you cannot see
   (chapter 10).                                             */
```

Hands-on: OP-TEE on QEMU

```
# The complete stack - TF-A, OP-TEE, Linux, buildroot, the test
# suite - built from one manifest. Budget an hour and ~20 GB.

mkdir -p ~/optee && cd ~/optee
repo init -u https://github.com/OP-TEE/manifest.git -m qemu_v8.xml
repo sync -j8
cd build
make toolchains -j4
make run -j$(nproc)

# Three windows open: QEMU's own console, a "Normal World" UART
# and a "Secure World" UART. In the QEMU console:
(qemu) c

# Log in as root in the normal world, then:
xtest                     # the full GlobalPlatform test suite
xtest -l 0                # quick pass
optee_example_hello_world # the smallest complete example

# WATCH THE SECURE CONSOLE while these run. Every TA load,
# every panic and every trace line appears there. That split -
# normal-world output in one window, secure-world in another -
# is exactly the boundary this track is about.
```

> **READ `OPTEE_EXAMPLE_HELLO_WORLD` BEFORE WRITING ANYTHING**
>
> It is about 120 lines across the two sides: `host/main.c` does `InitializeContext / OpenSession / InvokeCommand`, and `ta/hello_world_ta.c` implements the five entry points. Every TA you ever write has that skeleton. Copy the `optee_examples` directory structure rather than inventing a build.

The other implementations

TEE	Where	Notes
OP-TEE	Open source, Linaro	GlobalPlatform-compliant; the one to learn on
Trusty	Android / Google	Own API, not GP; C++ and Rust TAs; used for Keymint and Gatekeeper
QSEE / QTEE	Qualcomm	Proprietary; the biggest deployed base
Kinibi	Trustonic	Proprietary; long history on Samsung Exynos
TEEGRIS	Samsung	Replaced Kinibi on newer Exynos parts
Hafnium	Open source	Not a TEE — an S-EL2 partition manager that hosts them

They differ in API and in TA packaging; the *architecture* — normal-world driver, monitor, trusted OS, isolated TAs, RPC to a supplicant — is the same in every one. Learn it once here.

Where this goes next

This chapter is the map; the OP-TEE track is the territory. It takes each of the six pieces above and gives it a chapter — the boot handover from TF-A, the message protocol carried over SMC, RPC and tee-supplicant, the Linux TEE subsystem, and both GlobalPlatform APIs in depth.

It ends in three projects: a secure key store with its own client, and a firmware TPM built as a trusted application that Linux then drives as `/dev/tpm0`. If you want to actually write a TA rather than read about one, start there.

How it shows up

Symptom	Cause
`/dev/tee0` missing	OP-TEE not running, or the driver did not probe — check `dmesg | grep -i optee`
`TEEC_ERROR_ITEM_NOT_FOUND` on open session	TA not found; `tee-supplicant` not running, or the `.ta` is not in `/lib/optee_armtz`
`TEEC_ERROR_SECURITY` on load	TA signature check failed — signed with the wrong key
`TEEC_ERROR_BAD_PARAMETERS`	`paramTypes` disagree between client and TA
`TEEC_ERROR_OUT_OF_MEMORY`	Secure heap exhausted, or `TA_DATA_SIZE` too small
TA panics with a stack dump on the secure console	Bad pointer, failed assertion, or stack overflow inside the TA
Calls block for a long time under load	All OP-TEE threads busy — `ETHREAD_LIMIT`
Everything hangs after an RPC	Thread-exhaustion deadlock, or `tee-supplicant` died
Works on QEMU, fails on hardware	Secure memory carve-out too small, or the TZASC region does not match
Output buffer contains a partial result on error	The TA wrote into shared memory before it had finished — write once, at the end

Check yourself

- ✓ Name all six pieces of the stack and say what each contributes.
- ✓ Distinguish the GlobalPlatform Client API from the Internal API.
- ✓ List the five TA entry points and when each is called.

- ✓ Explain the parameter model and why checking `paramTypes` is a security control.
- ✓ Give four rules for handling a client-supplied buffer inside a TA.
- ✓ Trace one `TEEC_InvokeCommand` through every layer and back.
- ✓ Explain the difference between a user-mode TA and a pseudo TA, and why you should default to the former.
- ✓ Explain OP-TEE's fixed thread pool and the deadlock it can produce.
- ✓ Get `xtest` passing on QEMU and find the secure-world console.

Trusted applications and secure storage

Now write one. A complete trusted application — client side, TA side, build, sign, install — plus the mechanism that lets it keep a secret across reboots on a device whose filesystem the attacker controls.

What belongs in a TA

```
A good TA is SMALL, does ONE thing, and its interface is narrow.

  Good candidates:
    · key generation, storage and use - the key never leaves
    · device attestation and identity
    · payment authorisation
    · biometric template matching (template never leaves)
    · DRM licence handling and content key management
    · secure firmware update verification
    · a monotonic counter, or a rollback-resistant state blob

  Bad candidates:
    · anything large or complex - it is attack surface at the
      highest privilege in the system
    · anything performance-critical per-operation, because of
      the world-switch cost (chapter 11)
    · anything needing drivers, filesystems or a network stack
    · "make this hard to reverse engineer" - obscurity is not
      what the boundary provides
    · business logic that merely wants to be tamper-resistant

  THE TEST: would you be comfortable if this code were audited
  line by line as security-critical? If not, it does not belong
  in the secure world.
```

Identity: the UUID

```
/* A TA is named by a 128-bit UUID, not a filename. It appears
   in three places and they must agree.                       */

/* 1. include/my_ta.h - shared by both sides */
#define TA_MY_UUID \
        { 0x12345678, 0x5b69, 0x11d4, \
          { 0x9f, 0xee, 0x00, 0xc0, 0x4f, 0x4c, 0x32, 0x01 } }

/* 2. ta/user_ta_header_defines.h */
#define TA_UUID  TA_MY_UUID

/* 3. the installed filename, in canonical text form:
      /lib/optee_armtz/12345678-5b69-11d4-9fee-00c04f4c3201.ta

   tee-supplicant builds that path from the UUID the secure
   world asks for. Get any character wrong and you get
   TEEC_ERROR_ITEM_NOT_FOUND with no further explanation.   */

/* Generate a real one - never copy an example's: */
        uuidgen

/* The UUID is also the TA's IDENTITY for secure storage. Change
   it and the TA loses access to everything it previously
   stored, permanently. Choose it once.                       */
```

The TA

```
/* ta/my_ta.c - a key store: generate a key inside the secure
   world, sign with it, and never let it out.              */

#include <tee_internal_api.h>
#include <tee_internal_api_extensions.h>
#include <string.h>
#include "my_ta.h"

        }
}
```

READ THAT DISPATCH FUNCTION AS AN ATTACKER WOULD

The command number, the parameter types, every buffer size, and the contents of every input buffer are all chosen by an untrusted caller. The `ptypes` check, the exact-size check on the digest, the copy-in, the short-buffer path, and writing the output only on success are each there to close a specific hole. Take any one out and there is a real bug.

The client

```
/* host/main.c */

#include <tee_client_api.h>
#include <stdio.h>
#include <string.h>
#include "my_ta.h"

int main(void)
{
        TEEC_Context ctx;
        TEEC_Session sess;
        TEEC_Operation op;
        TEEC_UUID uuid = TA_MY_UUID;
        uint8_t digest[32] = { 0 };
        uint8_t sig[128];
        uint32_t origin;
        TEEC_Result res;

        res = TEEC_InitializeContext(NULL, &ctx);
        if (res != TEEC_SUCCESS)
                errx(1, "InitializeContext: 0x%x", res);

        res = TEEC_OpenSession(&ctx, &sess, &uuid,
                               TEEC_LOGIN_PUBLIC, NULL, NULL,
                               &origin);
        if (res != TEEC_SUCCESS)
                errx(1, "OpenSession: 0x%x origin 0x%x", res, origin);

        /* one-time provisioning */
        memset(&op, 0, sizeof(op));
        op.paramTypes = TEEC_PARAM_TYPES(TEEC_NONE, TEEC_NONE,
                                         TEEC_NONE, TEEC_NONE);
        res = TEEC_InvokeCommand(&sess, TA_CMD_GENERATE_KEY,
                                 &op, &origin);
        if (res != TEEC_SUCCESS)
                errx(1, "GENERATE_KEY: 0x%x", res);

        /* sign something */
        memset(&op, 0, sizeof(op));
        op.paramTypes = TEEC_PARAM_TYPES(TEEC_MEMREF_TEMP_INPUT,
                                         TEEC_MEMREF_TEMP_OUTPUT,
                                         TEEC_NONE, TEEC_NONE);
        op.params[0].tmpref.buffer = digest;
        op.params[0].tmpref.size   = sizeof(digest);
        op.params[1].tmpref.buffer = sig;
        op.params[1].tmpref.size   = sizeof(sig);

        res = TEEC_InvokeCommand(&sess, TA_CMD_SIGN, &op, &origin);
        if (res != TEEC_SUCCESS)
                errx(1, "SIGN: 0x%x origin 0x%x", res, origin);

        printf("signature: %u bytes\n", op.params[1].tmpref.size);

        TEEC_CloseSession(&sess);
        TEEC_FinalizeContext(&ctx);
        return 0;
}
```

`ORIGIN` TELLS YOU WHO FAILED

`TEEC_ORIGIN_API` (libteec), `_COMMS` (the driver or the transport), `_TEE` (the trusted OS) or `_TRUSTED_APP` (your TA's return value). Print it on every failure — the difference between "the TEE could not load your TA" and "your TA returned an error" saves hours.

Building and signing

```
# Layout, matching optee_examples:

my_ta/
  host/     Makefile   main.c
  ta/       Makefile   my_ta.c   user_ta_header_defines.h
            sub.mk     Android.mk
  include/  my_ta.h

# ta/Makefile is three lines - OP-TEE supplies the rest:
BINARY = 12345678-5b69-11d4-9fee-00c04f4c3201
include $(TA_DEV_KIT_DIR)/mk/ta_dev_kit.mk

# ta/sub.mk:
global-incdirs-y += ../include
srcs-y += my_ta.c

# Build:
make -C ta CROSS_COMPILE=aarch64-linux-gnu- \
        TA_DEV_KIT_DIR=.../export-ta_arm64
make -C host CROSS_COMPILE=aarch64-linux-gnu- \
        TEEC_EXPORT=.../out/export

# The build SIGNS the TA automatically with the key in
#   optee_os/keys/default_ta.pem
# and OP-TEE checks that signature before loading (chapter 11:
# never trust what RPC hands you).

# Install:
scp ta/*.ta   root@target:/lib/optee_armtz/
scp host/my_ta root@target:/usr/bin/
```

THE DEFAULT SIGNING KEY IS PUBLIC

`default_ta.pem` ships in the OP-TEE source tree. A product built with it will load a TA written by anyone. Generate a per-product key, keep the private half in an HSM, and build with `TA_SIGN_KEY=`. Better still, on parts that support it, use OP-TEE's asymmetric-key provisioning so the public half is itself anchored in the fuses (chapter 14).

Secure storage: the problem

```
The TA has no filesystem. The bytes must end up somewhere the
NORMAL world controls - eMMC, UFS, a file in /data. So an
attacker with root can read, modify, delete, or restore an old
copy of them.

  Four properties are needed:

  CONFIDENTIALITY  attacker cannot read the contents
     -> encrypt with a key derived from the HUK

  INTEGRITY        attacker cannot modify them undetected
     -> authenticated encryption (AES-GCM), a MAC over
        everything

  BINDING          the blob cannot be moved to another device
     -> the HUK is per-device, so a blob from device A is
        undecryptable on device B

  FRESHNESS        attacker cannot restore an OLD copy
     -> this is the hard one. Encryption and MACs do not help:
        the old blob is authentic, just stale.
        Needs a MONOTONIC COUNTER in hardware, or RPMB.
```

The two backends

	REE filesystem	**RPMB**
Stored in	`/data/tee/`, via `tee-supplicant`	The eMMC/UFS Replay Protected Memory Block partition
Confidentiality	Yes — AES-GCM, HUK-derived key	Yes
Integrity	Yes — hash tree	Yes — HMAC on every access
Device binding	Yes	Yes
Rollback protection	**No** — the whole tree can be restored	**Yes** — a write counter inside the eMMC, monotonic, unresettable
Deletion resistance	No — root can `rm -rf` it	No — but the counter proves it happened
Size	Large	Small: typically 128 KB to 4 MB
Speed	Faster	Slower — one HMAC round trip per block

```
/* RPMB works because the eMMC itself enforces the rules: */

   Provisioning (ONCE, irreversibly):
        the secure world writes an RPMB AUTHENTICATION KEY
        into the eMMC. It can never be read back and never
        changed.

   Every write:
        host sends  { data, write_counter, nonce, HMAC }
        eMMC checks the HMAC with its stored key
        eMMC checks the write_counter matches its own
        on success it writes AND increments the counter

   Every read:
        eMMC returns { data, nonce, HMAC }
        the secure world checks the HMAC and the nonce

   So a replayed write is rejected because its counter is stale,
   and a forged read is rejected because the HMAC will not
   verify. The trusted OS holds the key; Linux merely carries
   the frames (chapter 11's RPC, again - the normal world is
   the transport, never the authority).                    */

/* Select it per object: */
        TEE_CreatePersistentObject(TEE_STORAGE_PRIVATE_RPMB, ...)

/* Or build OP-TEE with CFG_RPMB_FS=y and make it the default.
   Use RPMB for the SMALL things where freshness matters -
   counters, key versions, lock state - and the REE filesystem
   for bulk.                                               */
```

Key derivation

```
/* Never use the HUK directly. Derive per-purpose keys from it,
   binding in the TA's identity so one TA cannot read another's
   storage.                                                 */

static TEE_Result derive_key(const char *label,
                             uint8_t *out, size_t outlen)
{
        /* extra_data mixes in the caller's identity; OP-TEE adds
           the TA UUID internally for TEE_STORAGE_PRIVATE      */
        return tee_otp_get_hw_unique_key_derived(label,
                                                 strlen(label),
                                                 out, outlen);
}

/* PROPERTIES you want:
     - per-device      from the HUK
     - per-TA          UUID mixed in (OP-TEE does this)
     - per-purpose     a distinct label per use - storage,
                       attestation, transport - so compromise
                       of one does not give the others
     - versioned       so a key can be rotated after a fix

   Cryptography chapters 12 and 13 cover KDFs properly; the
   embedded-specific point is only that the ROOT is a hardware
   secret, not a constant in the binary.                   */
```

TA security checklist

BEFORE YOU SHIP A TA

- `paramTypes` checked in every command handler.
- Every `memref.size` validated before use; overflow considered on every size arithmetic.
- Inputs copied into TA memory before validation and use — never validated in place.
- Outputs written once, on success, never used as scratch.
- Secrets zeroed with `TEE_MemFill` before `TEE_Free`.
- Every handle closed and every operation freed on *every* path, including errors.
- Session state freed in `TA_CloseSessionEntryPoint`.
- Error returns carry no information about secret data — no distinct code for "wrong PIN, byte 3".
- Comparisons on secrets are constant-time.
- No secret-dependent branch or memory-access pattern (chapter 16).
- Anything with a retry limit is counted in RPMB, not in RAM or REE storage.
- Stack usage measured, not guessed.
- Signed with a product key, not the default.

Where this goes next

Chapter 12 of the OP-TEE track covers the Internal Core API in full, chapter 15 covers REE FS and RPMB storage properly, and chapter 20 is the one that matters most: writing a TA that survives a client actively trying to break it. The key-store project applies all three.

How it shows up

Symptom	Cause
`ITEM_NOT_FOUND` on open session	UUID mismatch between header and installed filename
`TEEC_ERROR_SECURITY` at load	Signed with a key OP-TEE does not trust
`ERROR_SHORT_BUFFER`	Expected — call again with the size the TA returned
`ERROR_ITEM_NOT_FOUND` from `TEE_OpenPersistentObject`	Not provisioned, or storage wiped, or the UUID changed
Storage works, then fails after a reflash	REE storage wiped with `/data`; the key survived, the blob did not
Old state reappears after a downgrade attack	REE storage has no rollback protection — use RPMB
`ERROR_OUT_OF_MEMORY` after many sessions	Session context leaked in `TA_CloseSessionEntryPoint`
TA panics on the third concurrent client	Not `MULTI_SESSION`-safe, or shared state without locking
RPMB writes fail with a counter error	Two writers, or the key was never provisioned
Works on the dev board, storage empty on production	Different HUK — blobs are device-bound by design

Check yourself

- ✓ Decide whether a given feature belongs in a TA, and justify it.
- ✓ Explain where a TA's UUID appears and why changing it destroys its storage.
- ✓ Write a command handler with correct `paramTypes`, size and copy-in handling.
- ✓ Explain the `SHORT_BUFFER` convention.
- ✓ Use `origin` to localise a failure.
- ✓ Explain why shipping with the default signing key is a vulnerability.
- ✓ Name the four properties secure storage needs, and which one encryption alone cannot give.
- ✓ Explain how RPMB achieves rollback protection and why Linux cannot forge a write.
- ✓ Explain why keys are derived per-TA and per-purpose rather than used directly.
- ✓ Walk the TA security checklist against your own code.

Secure boot and the chain of trust

Every protection in this track assumes the right software is running. Secure boot is what makes that assumption true — a chain from immutable silicon to the kernel, where each link verifies the next before giving it control.

Why it comes first

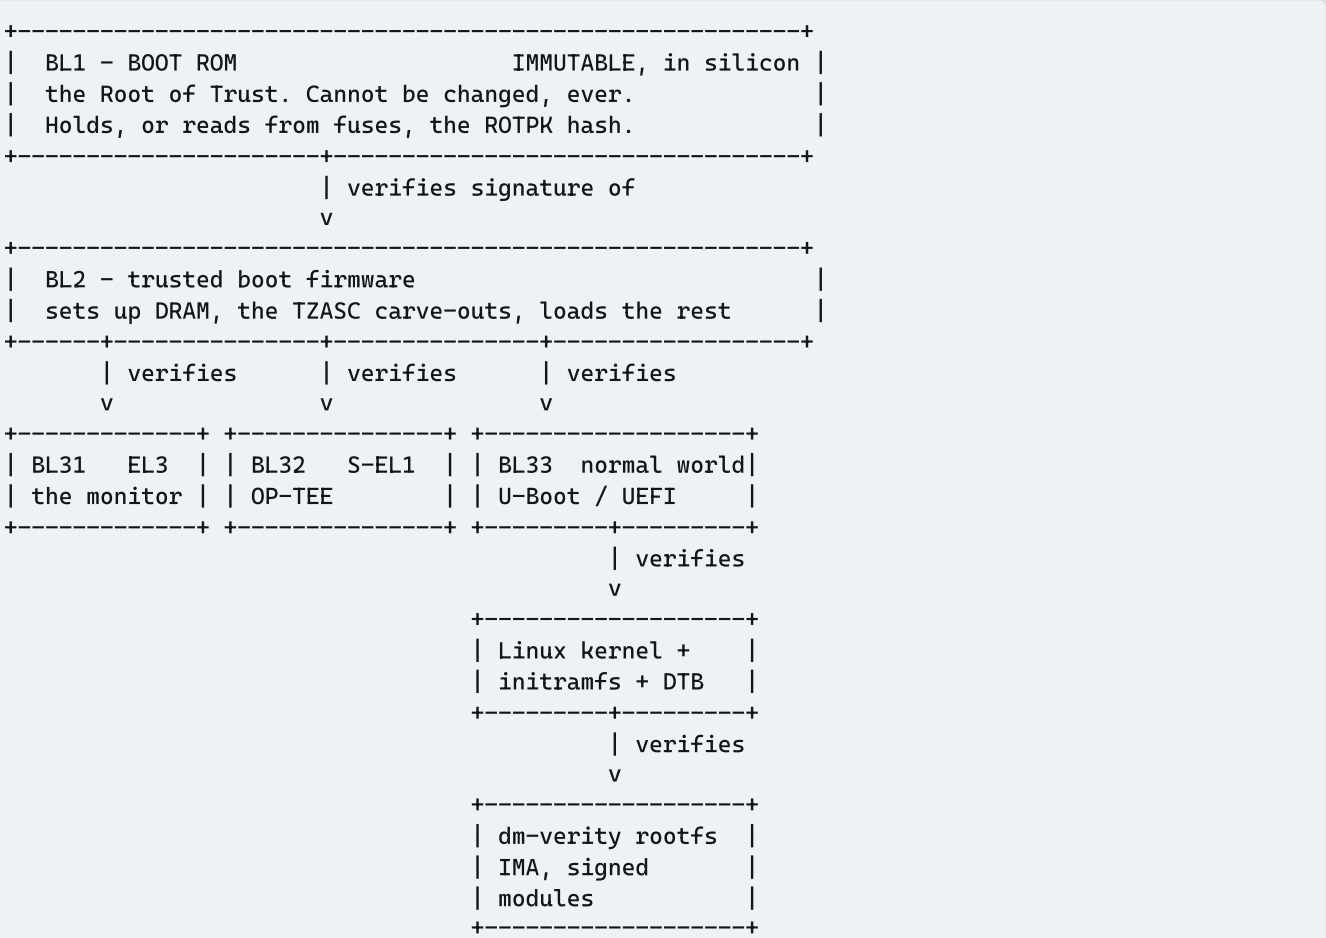
```
TrustZone, the SMMU, the TZASC, the XPU - every one of them is
CONFIGURED BY SOFTWARE at boot.

  So an attacker who controls the first instruction controls
  everything after it. They can:
        set SCR_EL3.NS = 0 and run their own code as "secure"
        leave the TZASC default region wide open
        skip the SMMU setup entirely
        never lock the configuration registers
        assert the debug signals
        load a trusted OS of their own

  and every mechanism in chapters 01-13 evaporates.

  The chain of trust exists to make "the first instruction is
  the one the vendor intended" a property of the SILICON rather
  than a hope.
```

The chain



> **THE CHAIN IS ONLY AS STRONG AS ITS WEAKEST LINK — AND ITS ANCHOR**
>
> A chain that verifies BL2, BL31 and BL32 perfectly but loads BL33 unverified is not a chain of trust; it is a chain of trust that ends early, and everything the normal world does afterwards is unconstrained. The value comes from it being *unbroken*, from an anchor that cannot be replaced.

The root of trust

```
/* Two things must be immutable, or the whole structure is
   circular:

   1. THE FIRST CODE - the boot ROM. Mask ROM, fixed at
      fabrication. It cannot be patched, which means a bug in
      it is unfixable in the field - which is why boot ROMs are
      tiny and are formally reviewed.

   2. THE ROOT KEY - or rather its hash. Full public keys are
      large; fuses are scarce. So the fuses hold

           ROTPK_HASH = SHA-256(root public key)

      typically 256 bits. At boot:
           read the root public key from the image header
           hash it
           compare with the fuses
           if they differ, STOP
           otherwise use it to verify the next stage's signature

      Storing only the hash means the key itself can be large
      (RSA-4096, or an ECDSA P-384 point) while costing 32 bytes
      of OTP.                                                  */

/* WHY FUSES and not flash: fuses are one-time-programmable.
   Blowing them is physical and irreversible. Flash can be
   rewritten by anything that can write flash - which is
   exactly the attacker you are defending against.          */

/* LIFECYCLE: parts ship BLANK (no ROTPK, secure boot off) so
   they can be developed on, and are moved to SECURED during
   manufacturing by blowing the ROTPK and the enable fuse. That
   transition is one-way. Get the key wrong and the part is
   scrap - which is why key provisioning is done by a small
   number of very careful people.                           */
```

What "verify" means

```
/* Signature verification, at each link: */

   1. parse the image header - WITHOUT trusting its contents
   2. extract the certificate / public key
   3. hash that key, compare against the trusted anchor
        (the ROTPK for BL2; a key delegated by it thereafter)
   4. hash the image payload
   5. verify signature(hash, public key)
   6. check the ROLLBACK COUNTER in the header against the
      fused monotonic counter
   7. only now: map it executable and branch to it

/* STEP 1 IS WHERE BUGS LIVE. The header is attacker-controlled
   data being parsed by the most privileged code in the system,
   before any verification has happened. Every field is
   hostile:

        length fields          -> integer overflow, then a
                                  buffer overflow in the ROM
        offsets                -> read or write out of bounds
        counts                 -> unbounded loops
        algorithm identifiers  -> "algorithm: none"
        key sizes              -> a 1-bit RSA key

   Real boot ROM exploits - across several vendors, on hundreds
   of millions of devices - have almost all been header parsing
   bugs, not cryptographic breaks.                          */

/* And the classic logic bug:

        if (verify_signature(img) == 0)      /* WRONG WAY UP  */
                boot(img);                   /* 0 = failure?  */

   or a verify function that returns success on an error path,
   or one whose result is never checked at all. Fail closed
   (chapter 01): the ONLY path to boot() should be through a
   positive confirmation.                                   */
```

Rollback protection

```
Version 1.0 has a remote-code-execution bug. You ship 1.1.
The attacker installs 1.0 again. It is CORRECTLY SIGNED - your
signature check happily accepts it.

  Signatures prove authenticity, never freshness. You need a
  MONOTONIC COUNTER.

     fuses hold:   nv_counter = 3
     image header: nv_version = 3     -> accept
     image header: nv_version = 2     -> REJECT, too old
     image header: nv_version = 4     -> accept, and BURN the
                                         counter to 4

  Counters are usually implemented as a fuse bank blown one bit
  at a time - 32 fuses give 32 increments. They are FINITE, so:

     · do not increment for every release. Increment only when
       a fixed vulnerability makes the old version dangerous.
     · burn the counter only after the new image has proven it
       BOOTS. Burn first and a failed update bricks the device.
     · a device that skipped several versions must still accept
       the newest; compare >= , never == .

  Same problem, same shape as secure storage freshness
  (chapter 13). Cryptography cannot solve it; monotonic
  hardware state can.
```

Trusted Board Boot in TF-A

```
# Arm's reference implementation. Build with verification on:

make PLAT=qemu \
     TRUSTED_BOARD_BOOT=1 \
     GENERATE_COT=1 \
     ARM_ROTPK_LOCATION=devel_rsa \
     ROT_KEY=plat/arm/board/common/rotpk/arm_rotprivk_rsa.pem \
     BL33=u-boot.bin \
     all fip

# TRUSTED_BOARD_BOOT=1   turn on verification
# GENERATE_COT=1         build the certificate chain
# ARM_ROTPK_LOCATION     where the ROTPK hash comes from
# ROT_KEY                the private root key (an HSM in
#                        production - never a file in the tree)

# The output FIP (Firmware Image Package) contains the images
# AND the certificates:

   fiptool info fip.bin

   Trusted Boot Firmware BL2: offset=0x...
   Trusted key certificate: offset=0x...
   SoC Firmware key certificate: offset=0x...
   SoC Firmware BL31: offset=0x...
   Trusted OS key certificate: offset=0x...
   Trusted OS BL32: offset=0x...
   Non-Trusted Firmware key certificate: offset=0x...
   Non-Trusted Firmware BL33: offset=0x...

# The CHAIN OF TRUST is expressed as X.509 certificates: the
# root key signs a "trusted key certificate" containing two
# delegated keys, those sign per-image key certificates, and
# those sign content certificates carrying the image HASHES.

# WHY THE INDIRECTION: the root key can stay in a vault and be
# used once. Day-to-day signing uses the delegated keys, which
# can be rotated without touching fuses.
```

Handing off to Linux

```
# U-Boot verifies the kernel using FIT images and a public key
# compiled into its own device tree - which was itself verified
# by BL2, which was verified by the ROM.

# 1. describe what to sign:
/dts-v1/;
/ {
    images {
        kernel {
            data = /incbin/("Image.gz");
            type = "kernel";  arch = "arm64";  os = "linux";
            compression = "gzip";
            load = <0x40080000>;  entry = <0x40080000>;
            hash { algo = "sha256"; };
        };
        fdt {
            data = /incbin/("board.dtb");
            type = "flat_dt";  arch = "arm64";
            compression = "none";
            hash { algo = "sha256"; };
        };
    };
    configurations {
        default = "conf";
        conf {
            kernel = "kernel";  fdt = "fdt";
            signature {
                algo = "sha256,rsa2048";
                key-name-hint = "prod";
                sign-images = "kernel", "fdt";
            };
        };
    };
};

# 2. sign, embedding the public key into U-Boot's control DTB:
mkimage -f kernel.its -k keys/ -K u-boot.dtb -r kernel.itb

# 3. U-Boot must be built with CONFIG_FIT_SIGNATURE=y and
#    CONFIG_LEGACY_IMAGE_FORMAT=n - otherwise it will happily
#    boot an unsigned legacy image and the chain ends here.

# NOTE sign-images includes the FDT. An attacker who can change
# the device tree can add "init=/bin/sh" via bootargs, remap
# memory, or disable the SMMU node. The DTB is as security
# critical as the kernel.
```

> **THE CHAIN USUALLY BREAKS AT THE LAST LINK**
> Verified firmware, verified U-Boot, verified kernel — and then an unverified root filesystem, an unsigned kernel module, an attacker-editable `bootargs`, or a debug U-Boot console that accepts `tftpboot`. All of the effort upstream buys nothing if the kernel then loads whatever is on `/dev/mmcblk0p5`.

Extending it into Linux

Mechanism	Protects	How
dm-verity	A read-only rootfs	Merkle tree over the block device; the root hash is on the verified kernel command line. Every block is checked *when read*, so tampering is caught even after boot.
fs-verity	Individual files on a writable fs	Per-file Merkle tree; good for APKs and large read-only assets.
IMA / EVM	Arbitrary files	Measures or appraises on open, against signatures in xattrs.
Module signing	Kernel modules	`CONFIG_MODULE_SIG_FORCE=y`; otherwise a module *is* arbitrary kernel code.
Kernel lockdown	The running kernel	Blocks `/dev/mem`, kexec of unsigned images, some BPF, raw MSR/port access.
Encrypted or authenticated `/data`	Mutable state	dm-crypt with a key from the TEE, so it is device-bound (ch. 13).

```
# dm-verity, put together:

veritysetup format rootfs.img hash.img
  # prints: Root hash: a1b2c3...

# the root hash goes on the KERNEL COMMAND LINE, which is
# signed as part of the FIT configuration - so the hash itself
# is anchored to the ROM:

  dm-mod.create="vroot,,,ro,0 <sectors> verity 1 \
        /dev/mmcblk0p3 /dev/mmcblk0p4 4096 4096 \
        <datablocks> 1 sha256 <roothash> <salt>" \
  root=/dev/dm-0 ro

# Now every block read from the rootfs is verified against the
# tree, whose root is verified by the kernel, which was
# verified by U-Boot, which was verified by BL2, which was
# verified by the ROM against a hash in a fuse.

# THE CHAIN IS COMPLETE. Any single byte changed anywhere on
# that path is detected.
```

Measured boot: the other kind

```
VERIFIED boot   refuses to run software that is not signed.
                Enforcement is local and immediate.

MEASURED boot   runs anything, but RECORDS what it ran into a
                tamper-evident log, so a remote party can decide
                whether to trust the result.

  Each stage extends a hash into a PCR before executing:

        PCR[n] = SHA256( PCR[n] || SHA256(next_stage) )

  Extend-only, so the sequence cannot be rewritten - only
  appended to, and any different software produces a different
  final value.

  Then ATTESTATION: a remote server sends a nonce, the device
  returns the PCR values plus the log, signed by a key that
  only genuine hardware holds. The server decides whether that
  configuration may access the service.

  Stored in a TPM (PCRs 0-23) on PC-class hardware, or in the
  TEE on Arm - which is one of the best reasons to have a TEE
  at all (chapter 13's attestation key, used here).

  Most real products want BOTH: verified boot to stop local
  tampering, measured boot so the back end can tell what it is
  talking to.
```

Living with it during development

KEEP A DEVELOPMENT PATH, AND MAKE IT OBVIOUSLY DIFFERENT

- Use **development keys** on dev boards, production keys only in the factory. Never let a production private key exist outside an HSM.
- Support **unlocking** — a signed token, tied to the device ID, that permits unsigned images. Wipe the device keys when it is used, so unlocking cannot expose user data.
- Make the state **visible**: a boot message, a screen, an API. Android's yellow/orange boot warnings exist for this.
- Never ship a build that *skips* verification on a flag — that flag will be found. Ship a build whose verification uses a different key.
- Test the **negative cases** in CI: flip one bit in each image and assert that boot stops at the right stage. An unexercised check is an unknown check.

How it shows up

Symptom	Cause
Device is silent, no UART output at all	ROM rejected BL2 — signature, ROTPK mismatch, or a corrupt header
`Failed to verify` then reset loop	Wrong signing key, or the image changed after signing
Boots after signing but not after a rebuild	Signing not wired into the build — the FIP contains the old certificate

Symptom	Cause
Boots on one board, not another	Different ROTPK fused; boards from different production runs
Older, valid firmware refuses to boot	Rollback counter already burned — working as designed
Update bricks the device	Counter burned before the new image was known to boot
Firmware verified, but any rootfs boots	Chain ends at the kernel — no dm-verity
Verified boot bypassed via the command line	`bootargs` or the DTB not covered by the signature
Attacker loads a module	`MODULE_SIG_FORCE` not set
Signature check passes on a corrupted image	Return value inverted or unchecked — audit that code path by hand
Part accepts unsigned images in the field	Lifecycle state never advanced to SECURED in manufacturing

Check yourself

- ✓ Explain why secure boot is a precondition for every other mechanism in this track.
- ✓ Draw the chain from boot ROM to root filesystem, naming what verifies what.
- ✓ Explain why the fuses hold a hash of the root key rather than the key.
- ✓ List the steps of one verification and say which one attackers target most.
- ✓ Explain why signatures alone cannot stop a downgrade, and how counters fix it.
- ✓ State the two rules for burning a rollback counter safely.
- ✓ Describe TF-A's certificate chain and why the root key is delegated.
- ✓ Explain why the device tree must be covered by the signature.
- ✓ Set up dm-verity and say where its root hash is anchored.
- ✓ Contrast verified boot with measured boot, and say why products want both.

TrustZone-M for microcontrollers

The same idea on a chip with no MMU, no exception levels, and a 20-cycle interrupt latency budget. TrustZone for Armv8-M drops the monitor entirely and puts the boundary in the address map — which changes everything about how you use it.

What is different

	TrustZone-A	TrustZone-M
Security state determined by	`SCR_EL3.NS` — a register	**The address being executed**
Transition	`SMC` into EL3, which switches contexts	Direct call to a valid entry point — *no monitor*
Transition cost	~1000–4000 cycles	**A few cycles**
Exception levels	EL0–EL3	Thread/Handler mode, privileged/unprivileged, in each state
Address translation	MMU, two stages	MPU only — no translation, just permissions
Region control	TZASC, TZPC, SMMU	SAU and IDAU, plus separate secure/non-secure MPUs
Stacks	Per exception level	**Four** — MSP/PSP in each state
Vector table	One `VBAR` per EL	Two — `VTOR_S` and `VTOR_NS`
Typical software	Linux + OP-TEE	Bare metal or an RTOS on each side

THE CORE IDEA: SECURITY IS A PROPERTY OF THE ADDRESS

On Armv8-M there is no bit in a register that says "we are secure now". The processor is in Secure state *because it is executing from a Secure address*. Fetch an instruction from a Non-secure address and the state changes with it. This is why the transition is nearly free — and why the address map *is* the security policy.

The address map

```
Every address is one of three types:

  SECURE (S)
      accessible only from Secure state.
      code and data for the trusted side.

  NON-SECURE (NS)
      accessible from either state.
      the application side.

  NON-SECURE CALLABLE (NSC)
      SECURE memory, but Non-secure code may BRANCH into it -
      and only to an SG instruction. This is the doorway.

  Two units decide which is which:

    IDAU  Implementation Defined Attribution Unit.
          Fixed by the silicon vendor, coarse, cannot be
          changed. Often splits the whole map by an address bit.

    SAU   Security Attribution Unit.
          8 or so programmable regions, configured by SECURE
          software at boot.

  The result is the MORE SECURE of the two:

    IDAU says NS, SAU says S   -> Secure
    IDAU says S,  SAU says NS  -> Secure
    both say NS                -> Non-secure

  So the SAU can never make something less secure than the
  silicon says it is. Fail-closed, in hardware.

  Typical layout on a part with 1 MB flash / 256 KB RAM:

    0x0C00_0000  +-----------------+
                 | Secure flash    |  S    bootloader, secure lib
    0x0C03_0000  +-----------------+
                 | veneers         |  NSC  the SG entry points
    0x0C03_1000  +-----------------+
    0x0803_1000  | NS flash        |  NS   the application
    0x0810_0000  +-----------------+

    0x3000_0000  +-----------------+
                 | Secure RAM      |  S    keys, secure stacks
    0x3000_8000  +-----------------+
    0x2000_8000  | NS RAM          |  NS   application RAM
    0x2004_0000  +-----------------+

  Note the aliasing: 0x0C00_0000 and 0x0800_0000 are the SAME
  physical flash, seen through a Secure and a Non-secure alias.
  Bit 28 is the security alias bit on many parts. That is the
  IDAU doing its coarse split.
```

Crossing the boundary

```
/* NS -> S: the SG instruction */

   Non-secure code does:   BL   secure_function

   The target must be:
      · in an NSC region, and
      · the FIRST instruction there must be SG

   If either fails -> SecureFault. No exceptions, no
   negotiation. This is what stops Non-secure code jumping into
   the MIDDLE of a secure function to skip its checks.

/* S -> NS: the BXNS / BLXNS instructions */

   BXNS  r0       branch, switching to Non-secure
   BLXNS r0       call Non-secure, and come back

   Secure code must use these EXPLICITLY. A plain BX to a
   Non-secure address faults - so you cannot leave the secure
   state by accident.

/* The compiler writes the glue. Two attributes: */

/* An entry point, callable from Non-secure: */
__attribute__((cmse_nonsecure_entry))
int secure_add(int a, int b)
{
        return a + b;
}
/* generates:
        secure_add:
                SG                      ; the required gateway
                B   secure_add_impl     ; jump to the real body
   and on return, clears the caller-saved registers and issues
   BXNS lr.                                                  */

/* A pointer TO Non-secure code, called from Secure: */
typedef void __attribute__((cmse_nonsecure_call)) (*ns_fn)(void);

   ...  ((ns_fn)ns_reset_handler)();   /* compiles to BLXNS */

/* Build with -mcmse. The linker produces an IMPORT LIBRARY: */

   arm-none-eabi-gcc -mcmse ... \
        -Wl,--cmse-implib -Wl,--out-implib=secure_impl.o

/* secure_impl.o contains only the veneer addresses. Link it
   into the NON-SECURE project and its calls resolve to the
   right NSC addresses. Rebuild the secure side and you must
   re-link the non-secure side too - or ship a stable veneer
   table that never moves.                                   */
```

Validating arguments, without an MMU

```
/* Same problem as chapter 12, harder: there is no separate
   address space to copy from. A pointer from Non-secure code
   is just a number, and it might point at SECURE memory. If
   your secure function dereferences it, it reads or writes
   secure memory ON BEHALF OF the attacker - the classic
   confused deputy.                                          */

#include <arm_cmse.h>

__attribute__((cmse_nonsecure_entry))
int secure_hash(const uint8_t *buf, size_t len, uint8_t *out)
{
        const uint8_t *ok_in;
        uint8_t *ok_out;

        /* does the CALLER have read access to this range? */
        ok_in = cmse_check_address_range((void *)buf, len,
                                         CMSE_NONSECURE | CMSE_MPU_READ);
        if (!ok_in)
                return -1;

        ok_out = cmse_check_address_range(out, 32,
                                          CMSE_NONSECURE | CMSE_MPU_READWRITE);
        if (!ok_out)
                return -1;

        /* now safe - but STILL copy in, because Non-secure code
           on an interrupt, or a DMA engine, can change the
           buffer under you (chapter 09's TOCTOU)            */
        sha256(ok_in, len, ok_out);
        return 0;
}

/* cmse_check_address_range() consults the SAU, IDAU and the
   NON-SECURE MPU, and asks: could the caller have done this
   access itself? If not, refuse - do not do it for them.

   Also available:
     cmse_TT(p)             query the attributes of an address
     cmse_TTA(p)            ...using the alternate domain
     cmse_check_pointed_object(p, flags)   for a single object

/* AND the overflow trap: */
        if (len > MAX_LEN || buf + len < buf)
                return -1;
   cmse_check_address_range handles wraparound itself, but any
   arithmetic YOU do on len does not.                        */
```

THREE WAYS SECURE FUNCTIONS LEAK

- **Unchecked pointers.** The caller passes a secure address and your function reads or writes it. Every pointer argument needs `cmse_check_address_range`.
- **Registers left dirty on return.** The compiler clears caller-saved registers for `cmse_nonsecure_entry` functions — but not your own local buffers on the secure stack, and not the FPU registers unless configured.
- **The secure stack.** Values left there are not readable by Non-secure code directly, but they are the raw material for any subsequent bug. Zero secrets before returning.

Interrupts and stacking

```
Interrupts are assigned per-interrupt to a security state, in
NVIC_ITNS (Interrupt Target Non-Secure). Secure by default -
non-secure only if a bit is set, by secure code.

  AIRCR.PRIS      makes all Non-secure priorities the lower half
                  of the range, so a Non-secure interrupt can
                  never preempt a Secure one.
  AIRCR.BFHFNMINS puts HardFault/NMI in the Non-secure state
                  (usually left Secure).

  THE STACKING PROBLEM:

  Secure code is running. A Non-secure interrupt fires. The
  hardware must save the Secure registers - but it cannot push
  them where Non-secure code can read them.

  So the hardware does it FOR you:

     · pushes the secure context onto the SECURE stack
     · ZEROES the registers before entering the NS handler
     · pushes an integrity signature onto the secure stack
     · on return, checks that signature

  This is automatic and free. You do not write it, and you
  cannot get it wrong - which is a large part of why
  TrustZone-M is usable at all in an interrupt-latency budget.

  FOUR STACKS, and each needs its own limit register:
        MSP_S  PSP_S   MSPLIM_S  PSPLIM_S
        MSP_NS PSP_NS  MSPLIM_NS PSPLIM_NS

  SET THE SECURE STACK LIMITS. On Armv8-M a stack overflow with
  a limit register set is a fault; without one it is silent
  corruption of whatever lies below - which on the secure side
  may be your key material.
```

Boot flow

```
/* Reset always enters the SECURE state, at VTOR_S. Secure code
   sets everything up and then hands over - once, and
   irreversibly for that boot.                              */

void secure_main(void)
{
        /* 1. configure the SAU - which regions are NS and NSC */
        SAU->RNR  = 0;
        SAU->RBAR = (NS_FLASH_START & SAU_RBAR_BADDR_Msk);
        SAU->RLAR = (NS_FLASH_END   & SAU_RLAR_LADDR_Msk)
                  | SAU_RLAR_ENABLE_Msk;

        SAU->RNR  = 1;
        SAU->RBAR = (NSC_START & SAU_RBAR_BADDR_Msk);
        SAU->RLAR = (NSC_END   & SAU_RLAR_LADDR_Msk)
                  | SAU_RLAR_NSC_Msk        /* callable */
                  | SAU_RLAR_ENABLE_Msk;

        /* ... regions for NS RAM and NS peripherals ... */
        SAU->CTRL = SAU_CTRL_ENABLE_Msk;

        /* 2. vendor peripheral security - the M-profile
              equivalent of the TZPC (chapter 10)           */
        vendor_set_peripheral_ns(UART0);
        vendor_set_peripheral_ns(TIMER1);
        /* crypto, RNG, flash controller stay SECURE */

        /* 3. interrupt targets */
        NVIC_SetTargetState(UART0_IRQn);      /* -> NS */
        /* everything else stays Secure       */

        /* 4. the secure MPU, for privilege separation INSIDE
              the secure state                              */
        secure_mpu_init();

        /* 5. stack limits - on both sides */
        __set_MSPLIM(SECURE_STACK_BOTTOM);

        /* 6. init the secure services: keys, storage, crypto */
        secure_services_init();

        /* 7. VERIFY the non-secure image before running it
              (chapter 14 - the chain does not stop here)   */
        if (!verify_ns_image())
                fatal();

        /* 8. set up the NS vector table and jump */
        SCB_NS->VTOR = NS_IMAGE_START;

        __TZ_set_MSP_NS(*(uint32_t *)NS_IMAGE_START);
        ns_fn ns_reset = (ns_fn)(*(uint32_t *)(NS_IMAGE_START + 4));

        ns_reset();          /* BLXNS - never returns */
}

/* AFTER THE HANDOVER the SAU should be locked if the part
   supports it, and the secure code that remains is only what
   is reachable through the NSC veneers.                    */
```

TF-M — the reference implementation

```
/* Trusted Firmware-M is to Cortex-M what TF-A is to Cortex-A.
   You almost certainly want to use it rather than build this
   yourself.                                                  */

   BL2                MCUboot - verified boot (chapter 14)
   SPM                Secure Partition Manager - schedules the
                      secure services, isolates them
   Secure partitions  each service in its own MPU region

   Standard services, all with PSA APIs:
     Crypto           psa_import_key, psa_sign_hash, ...
     Internal Trusted Storage    small, on-chip
     Protected Storage           larger, encrypted, off-chip
     Initial Attestation         signed token about the device
     Firmware Update

/* PSA ISOLATION LEVELS:

   Level 1  Secure / Non-secure split only. One secure blob.
   Level 2  ...plus the secure services are isolated from the
            secure "root of trust" using the secure MPU.
   Level 3  ...plus each secure partition is isolated from
            every other one.

   Level 3 costs context switches and RAM; Level 1 means one
   bug in any secure service is total compromise. Most
   certified products target 2 or 3.                       */

/* PSA Certified is the certification scheme built on this. If
   a datasheet says "PSA Certified Level 2", that is what it is
   referring to.                                              */
```

> **WHEN TRUSTZONE-M EARNS ITS KEEP**
>
> On an MCU there is no second processor and no room for a separate secure MCU. TrustZone-M gives you a place to put a device identity key that survives a bug in 200 KB of application firmware — the firmware that parses BLE packets, runs a filesystem, and was written under schedule pressure. That is the realistic use: *a small, auditable secure side holding the keys and the update path*, and everything else outside it.

How it shows up

Symptom	Cause
SecureFault on the first call into secure code	Target not in an NSC region, or no `SG` at the entry — check the linker script
SecureFault immediately after handover	SAU region for NS flash wrong, or `VTOR_NS` set to the wrong address
Non-secure code hangs at reset	`MSP_NS` not initialised from the NS vector table
Undefined instruction on `BXNS`	Built without `-mcmse`
Link error: undefined reference to a secure function	Import library not linked into the non-secure project
Worked, then broke after rebuilding the secure side	Veneer addresses moved — re-link, or fix the NSC region layout
Peripheral unreachable from the application	Still assigned Secure by the vendor's peripheral protection unit
Non-secure interrupt never fires	`NVIC_ITNS` bit not set — interrupts default to Secure

Symptom	Cause
Secure code corrupts itself under load	Secure stack overflow — `MSPLIM_S` not set
Non-secure code reads secure data through a service	Missing `cmse_check_address_range` — a real vulnerability
Return from a secure call faults	Secure stack integrity signature check failed — the secure stack was corrupted

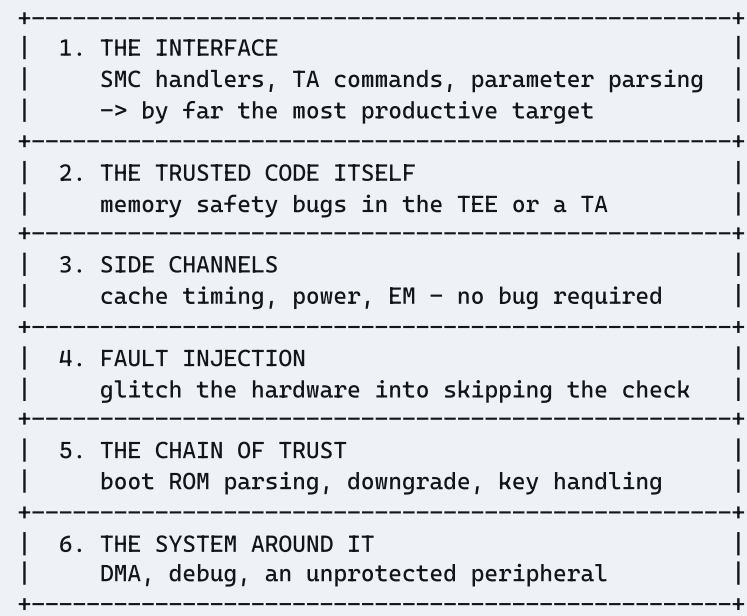
Check yourself

- ✓ State the fundamental difference between TrustZone-A and TrustZone-M.
- ✓ Explain S, NS and NSC memory, and how the SAU and IDAU combine.
- ✓ Explain why `SG` must be the first instruction at an entry point.
- ✓ Write a secure entry point that validates a caller-supplied buffer.
- ✓ Explain why checking the pointer is still not enough on its own.
- ✓ Describe what the hardware does when a Non-secure interrupt preempts secure code.
- ✓ Name the four stacks and say why the secure limit registers matter.
- ✓ Write the boot sequence from reset to the non-secure reset handler.
- ✓ Explain the three PSA isolation levels and their trade-offs.
- ✓ Say what belongs on the secure side of an MCU and what does not.

TEE attacks and mitigations

Every mechanism in this track has been broken on real hardware. Knowing how is not pessimism — it is the only way to build something that holds, and to judge honestly what a TEE is and is not worth.

Where attacks land



Note the ordering. Almost every publicly disclosed TEE compromise has been in layer 1 or 2 - ordinary software bugs in code that happened to be very privileged. The exotic attacks get the conference talks; the boring ones get the CVEs.

1. Interface attacks

```
/* THE CONFUSED DEPUTY - the defining TEE vulnerability. */

/* VULNERABLE: */
static TEE_Result cmd_read_key(uint32_t ptypes, TEE_Param p[4])
{
        /* attacker sets p[0].memref.buffer to a SECURE address */
        memcpy(p[0].memref.buffer, secret_key, 32);
        return TEE_SUCCESS;
}
/* The TA has the privilege to write anywhere. The attacker
   supplies the destination. Result: an arbitrary write
   primitive inside the secure world, driven from userspace. */

/* FIXED: */
        if (!tee_buffer_is_non_secure(p[0].memref.buffer,
                                      p[0].memref.size))
                return TEE_ERROR_ACCESS_DENIED;

/* --- MISSING paramTypes CHECK ------------------------------ */
/* If the TA does not verify ptypes, the client passes a VALUE
   where a MEMREF is expected. params[0].memref.buffer is then
   whatever 64-bit number the attacker put in params[0].value.a.
   Same primitive, reached differently.                       */

/* --- INTEGER OVERFLOW IN A SIZE CHECK ---------------------- */
        if (offset + len > buffer_size)     /* WRAPS */
                return TEE_ERROR_BAD_PARAMETERS;
        memcpy(dst + offset, src, len);
/* offset = 0xFFFFFFF0, len = 0x20 -> sum wraps to 0x10, check
   passes, memcpy writes far out of bounds.                   */
        if (offset > buffer_size || len > buffer_size - offset)
                return TEE_ERROR_BAD_PARAMETERS;   /* no wrap */

/* --- TOCTOU ------------------------------------------------ */
        if (validate(shm->cmd))         /* read 1 */
                execute(shm->cmd);      /* read 2 - DIFFERENT */
/* Another CPU rewrote it in between. Copy in ONCE, then
   validate and use only the copy.                            */

/* --- STATE CONFUSION --------------------------------------- */
/* Call sequence: OPEN, then USE. What if the attacker calls
   USE twice? USE after CLOSE? OPEN twice? Two USEs on two CPUs
   at once? A session state machine that assumes the documented
   order is a use-after-free waiting to happen.               */
```

THE INTERFACE RULES, RESTATED AS ATTACKS

Rule	What it stops
Check `paramTypes`	Type confusion into an arbitrary pointer
Validate every buffer address and size	Confused deputy
Do size arithmetic without wrapping	Overflow into a heap or stack overflow
Copy in before validating	TOCTOU from another CPU or a DMA engine
Write outputs once, on success	Partial-result and error-path leaks
Enforce the session state machine	Use-after-free, double-free, replay
Lock shared state	Races between concurrent calls
Return coarse errors	Oracles that leak secret-dependent detail

2. Memory safety in trusted code

```
/* The secure world is C. It has all of C's problems (see the C
   track, chapter 15) with none of the mitigations you get for
   free in Linux userspace.                                    */

   What is usually MISSING in a TEE:
        ASLR             often none, or very coarse
        stack canaries   sometimes; check your build flags
        NX / W^X         usually yes, but verify
        guard pages      often not - the heap is a fixed array
        a hardened allocator   rarely
        CFI              rarely
        MTE / PAC        only on newer parts, and only if enabled

   And the payoff for a bug is total: S-EL1 code owns the keys,
   the fuses, and the ability to lie to the normal world about
   attestation.

/* MITIGATIONS THAT ARE WORTH THE EFFORT: */

   -fstack-protector-strong    cheap, catches real bugs
   -D_FORTIFY_SOURCE=2
   -Wall -Wextra -Werror       and actually fix the warnings
   -fsanitize=... in a HOST harness, not on target

   CFG_TA_ASLR=y               OP-TEE: randomise TA layout
   CFG_CORE_SANITIZE_KADDRESS  debug builds only
   PAC and BTI on Armv8.3+     enable them

   Fuzz the SMC and TA interfaces on the host, with the same
   code compiled natively. Every TEE interface is a parser, and
   parsers are what fuzzers are good at.

   And: KEEP IT SMALL. A 20,000-line trusted OS can be audited.
   A 500,000-line one cannot, no matter how good the process. */
```

3. Side channels

```
The two worlds SHARE the microarchitecture: caches, branch
predictors, TLBs, the memory controller, the power rail. Sharing
a resource means measuring one another.

  CACHE TIMING (Prime+Probe, Flush+Reload)
     Normal-world code fills a cache set, lets the secure world
     run, then times its own re-access. Slow = the secure world
     evicted it = it touched that set. Repeat, and the pattern
     of accesses reveals the key - because table-driven AES and
     square-and-multiply RSA access memory in key-dependent
     ways.
     -> TruSpy, ARMageddon, and many since.

  BRANCH PREDICTOR
     Same idea, different shared structure. Secret-dependent
     branches leave traces.

  POWER and EM
     Physical access, an oscilloscope and a probe. DPA on a
     naive AES implementation needs a few thousand traces and
     an afternoon.

  MICROARCHITECTURAL SPECULATION
     Spectre-style: train a predictor, make secure code
     speculatively access secret-dependent addresses, read the
     cache. Applies across the world boundary on affected
     cores.

  MITIGATIONS:
     · CONSTANT-TIME code for anything touching a secret:
          no branch on secret data
          no memory INDEX derived from secret data
          no early exit from a comparison
     · bitsliced or table-free crypto, or a hardware engine
     · masking / blinding - randomise the intermediate values
     · flush or partition caches on world switch (costly)
     · disable SMT on the secure side, or do not use SMT
     · use the crypto accelerator: it is not sharing the cache

  ACCEPT THE LIMIT: a TEE does not defend against an attacker
  with physical access, an oscilloscope and time. It defends
  against a compromised NORMAL WORLD. Say so in your threat
  model rather than pretending otherwise.
```

```
/* Constant-time comparison - the smallest example, and the one
   people still get wrong.                                      */

/* LEAKS: returns as soon as it finds a difference, so the time
   reveals how many bytes matched.                              */
int bad_compare(const uint8_t *a, const uint8_t *b, size_t n)
{
        for (size_t i = 0; i < n; i++)
                if (a[i] != b[i])
                        return -1;
        return 0;
}

/* CONSTANT TIME: always touches every byte, no branch on data */
int ct_compare(const uint8_t *a, const uint8_t *b, size_t n)
{
        uint8_t diff = 0;

        for (size_t i = 0; i < n; i++)
                diff |= a[i] ^ b[i];

        return diff;            /* 0 iff equal */
}

/* And the same discipline everywhere: */
        if (secret_flag) x = a; else x = b;     /* leaks       */
        mask = -(uint32_t)!!secret_flag;
        x = (a & mask) | (b & ~mask);           /* does not    */

/* Beware the compiler. It can reintroduce a branch. Check the
   generated assembly for anything genuinely critical, and
   consider a barrier or volatile to pin it down.            */
```

4. Fault injection

```
Do not break the crypto - break the CHECK.

     if (verify_signature(img) != OK)
             fail();            <-- glitch the branch, skip this
     boot(img);

  Techniques, roughly by cost:
     VOLTAGE GLITCH   drop Vcc for nanoseconds. ~$50 of kit.
     CLOCK GLITCH     an extra or shortened clock edge.
     EM PULSE         a coil over the die. No decapsulation.
     LASER            decapsulated die, single-bit precision.
                      Six figures, and a lab.
     ROWHAMMER        software-only DRAM bit flips - a fault
                      attack with no hardware at all.

  Effects: an instruction skipped, a register corrupted, a
  comparison inverted, a loop counter changed.

  SOFTWARE COUNTERMEASURES - none is sufficient alone, but
  together they raise the cost a great deal:

     · DOUBLE-CHECK critical decisions, with different code
     · use non-trivial constants: a "success" value of
       0x5A3C96C3, never 0 or 1, so a cleared register is not
       automatically a pass
     · random delays before sensitive operations
     · redundant loop counters, verified after the loop
     · verify the result of the operation you just did
     · a "flow counter" incremented at each checkpoint and
       validated at the end - so a skipped stage is detectable

  HARDWARE COUNTERMEASURES: voltage and clock glitch detectors,
  light sensors, redundant logic, error-correcting registers.
  If your threat model includes physical attackers, choose
  silicon that has them - you cannot add them later.
```

```
/* Fault-hardened verification, as it is actually written in
   boot ROMs.                                                */

#define FLOW_OK    0x5A3C96C3u
#define FLOW_FAIL  0xA5C36939u

static uint32_t verify_hardened(const image_t *img)
{
        uint32_t r1, r2;
        volatile uint32_t counter = 0;

        r1 = verify_signature(img);
        counter++;

        random_delay();

        r2 = verify_signature(img);     /* again, independently */
        counter++;

        if (r1 != FLOW_OK)  return FLOW_FAIL;
        if (r2 != FLOW_OK)  return FLOW_FAIL;
        if (r1 != r2)       return FLOW_FAIL;
        if (counter != 2)   return FLOW_FAIL;   /* skipped step? */

        return FLOW_OK;
}

        if (verify_hardened(img) == FLOW_OK) {
                if (verify_hardened(img) != FLOW_OK)  /* again */
                        panic();
                boot(img);
        } else {
                panic();
        }

/* Ugly, redundant, and deliberately so. A single glitch must
   not produce a boot. Reviewers should be able to point at
   each redundant check and name the fault it catches.      */
```

Real compromises, and what they teach

Class	What happened	Lesson
TA buffer overflow	Widevine and other TAs on several vendors: a length field from the client overflowed a fixed buffer, giving code execution at S-EL0, then S-EL1 through a second bug	TAs are attack surface; keep them minimal and fuzz them
Confused deputy	Multiple CVEs across vendors where a TA wrote a result to a client-supplied pointer without checking it was non-secure	Validate *every* pointer that crosses the boundary
Downgrade	Old, signed, vulnerable TAs reloaded on patched devices — the signature was still valid	Rollback protection must cover TAs, not just firmware
Boot ROM parsing	Unpatchable ROM bugs on very large device populations, exploited before any signature check ran	Parse nothing you have not verified; keep the ROM tiny
Cache side channel	Academic extraction of AES and RSA keys from a TEE by a normal-world process	Constant-time code, or a hardware engine
Fault injection	Voltage glitching past secure boot on shipped consumer devices with inexpensive equipment	Redundant checks; glitch detectors in silicon

Class	What happened	Lesson
Debug left enabled	Production units with secure debug signals never fused off	Test the production lifecycle state, not the dev board
Unprotected DMA master	A peripheral with neither SMMU nor XPU used to read secure DRAM	Enumerate *every* bus master (ch. 17)

What a TEE is actually worth

> **AN HONEST THREAT MODEL**
>
> **A TEE defends well against:** a compromised normal-world OS, malicious applications, an attacker with root, offline extraction of keys from storage, and cloning a device by copying its filesystem.
>
> **A TEE defends poorly or not at all against:** an attacker with physical access, time and laboratory equipment; side channels, unless the code was written for it; bugs in the trusted code itself; and anything the silicon integration left unprotected.
>
> That is still a great deal of value — it is the difference between "root compromises every device forever" and "root compromises this device's session". Just do not let a datasheet's security bullet points substitute for stating which of the two you are buying.

How it shows up

Symptom	Cause
Secure world crashes on a malformed request	Missing input validation — and a crash means the parser is reachable
A TA works but fails a fuzz run in minutes	Unvalidated length or offset fields
Timing varies with a secret	Non-constant-time comparison or table lookup
Different error codes for different failure reasons	An oracle — collapse them into one
Device boots unsigned images intermittently	Glitch attack, or an unhardened single check
Old firmware still accepted	Rollback counter never burned
Secure memory readable via a peripheral	A bus master outside the SMMU/XPU policy
Attestation passes on a rooted device	Measurement not covering the compromised component
A fix in the TEE does not take effect	The old, signed TA is still loadable

Check yourself

- ✓ Name the six layers where TEE attacks land, and say which produce most real CVEs.
- ✓ Explain the confused deputy and write the check that stops it.
- ✓ Show a size check that overflows, and rewrite it so it cannot.
- ✓ Explain TOCTOU across the world boundary and the copy-in fix.
- ✓ List the exploit mitigations usually missing from a TEE and the build flags that add some back.
- ✓ Explain a cache timing attack and the properties constant-time code must have.
- ✓ Write a constant-time comparison and a branchless select.
- ✓ Explain why fault injection targets the check rather than the crypto, and list four software countermeasures.

- ✓ State plainly what a TEE does and does not defend against.

Access control: XPU concepts

The MMU protects a CPU from itself. The SMMU protects memory from devices that have one. XPUs are the last layer: a firewall in the interconnect that decides, per transaction, whether *this master* may touch *this address* — and it is the one nobody teaches.

The gap XPUs fill

```
Three protection mechanisms, three different questions:

  MMU     "may this VIRTUAL ADDRESS be accessed by the code
           currently running, at its privilege level?"
          Per-CPU. Translates AND checks.

  SMMU    "may this DEVICE's virtual/IO address be translated,
           and to what?"
          Per-StreamID. Translates AND checks.
          Requires the device to be behind an SMMU.

  XPU     "may THIS MASTER touch THIS PHYSICAL ADDRESS, in
           THIS security state, for READ or WRITE?"
          No translation at all. Pure permission check,
          on physical addresses, in the interconnect.

  WHY THE THIRD ONE IS NECESSARY:

  1. Not every master is behind an SMMU. Small DMA engines,
     sensor hubs, audio DSPs, power-management microcontrollers,
     debug blocks, display pipelines - many are wired straight
     to the interconnect.

  2. The SMMU protects DRAM well. It does nothing about
     PERIPHERAL registers. Which master may write the clock
     controller? The fuse controller? Another CPU's mailbox?

  3. TZASC and TZPC (chapter 10) are two-valued: secure or
     non-secure. Real SoCs have more than two principals - a
     modem, an application processor, a video DSP, a sensor
     hub, all mutually distrusting and all NON-SECURE.

  4. Some masters must be constrained BEFORE the SMMU is
     configured - during boot, when a firmware core is running
     and Linux is not.
```

THE NAME

"XPU" is a family, not a standard. Qualcomm calls them XPUs (with variants MPU, PPU, VMIDMT). NXP i.MX has the RDC (Resource Domain Controller), the CSU, and TrustZone-aware AIPSTZ. TI has firewalls. Renesas has the Access Window. Xilinx/AMD has XMPU and XPPU. Arm's own is the TZC family. The *mechanism* is the same everywhere; only the register names and the marketing differ, so learn the model rather than one vendor's manual.

The model

```
 MASTER                            SLAVE
 ------                            -----
 CPU cluster    ---+
 GPU            ---+
 display        ---+          +--> DRAM
 video codec    ---+---> XPU -+--> SRAM
 modem DSP      ---+          +--> peripheral registers
 audio DSP      ---+          +--> fuses, crypto, PMU
 sensor hub     ---+
 DMA engine     ---+

Each transaction on the bus carries:

   ADDRESS        where
   MASTER ID      who   (AxID / AxUSER / a dedicated sideband)
   NS             which world (AxPROT[1])
   PRIVILEGED     AxPROT[0]
   READ / WRITE   direction
   sometimes: a VMID, so one master can be split by which
              virtual machine issued the access

The XPU holds a table of REGIONS:

   +-------------------------------------------------------+
   | region 3                                              |
   |   base   0x8000_0000   size 64 MB                     |
   |   masters allowed: CPU(rw) GPU(r--) DISPLAY(r--)       |
   |   security: non-secure only                           |
   |   locked: yes                                         |
   +-------------------------------------------------------+

Transaction arrives -> find the matching region -> look up
this master's permission -> ALLOW or DENY.

And critically: what happens when NOTHING matches. That is
the DEFAULT, and it should be DENY.
```

Where they sit

Placement	Protects	Trade-off
At the master (a "master-side" or ingress firewall)	Constrains one specific device wherever it goes	One instance per master; a master with several ports needs several
At the slave (memory controller, peripheral bridge)	Everything reaching that slave, from every master	Fewer instances; but the master ID must survive the whole path to get there
In the interconnect fabric	Whole subsystems from one another	Coarse granularity, but catches paths you did not think of
Inside a peripheral (per-register or per-channel)	Fine-grained sharing of one device	Only where the vendor implemented it

> **THE MASTER ID IS ONLY AS TRUSTWORTHY AS THE WIRING**
> An XPU's entire decision rests on the master ID arriving intact and unforgeable. Real integration problems: IDs remapped by a bridge so the XPU sees the bridge's ID and not the originator's; several masters sharing one ID because the sideband was too narrow; an ID that a master can *program*. Any of these collapses the policy to "some device did this", which is not a policy. It is exactly the StreamID integrity question from chapter 03, and it has the same answer: verify it empirically, per SoC.

Granularity and its limits

```
/* Every XPU has hard limits, and they shape your design more
   than any principle does.                                    */

   NUMBER OF REGIONS      typically 8, 16, or 32. Rarely more.
   MINIMUM REGION SIZE    4 KB, 64 KB, or 1 MB depending on
                          the block. Sometimes power-of-two
                          and naturally aligned, sometimes an
                          arbitrary base/limit pair.
   NUMBER OF MASTERS      a bitmap of 8-32 entries, or a list
                          of ID + mask pairs.
   PERMISSION GRANULARITY read/write, sometimes execute,
                          sometimes secure/non-secure
                          independently.

/* CONSEQUENCES you will hit:

   · you cannot give every master a private region - there are
     not enough regions. You will group masters into DOMAINS.

   · buffers must be laid out to MATCH the alignment the XPU
     can express. A 1 MB minimum region means a 4 KB secure
     buffer wastes 1 MB, or worse, cannot be isolated at all
     without moving everything around it.

   · this is a MEMORY MAP DESIGN constraint, decided very early
     in a project. Retrofitting it after the address map is
     frozen is painful and is usually done by giving up on
     some isolation.

   · ID masking lets one entry cover a group:
          match: id & 0xF0 == 0x20
     which is efficient, and also means an accidental grouping
     if the masks are chosen carelessly.                    */
```

What happens on a denial

```
Three possible behaviours, and which one you get changes how
hard debugging is by an order of magnitude:

  1. ERROR RESPONSE
        the bus returns SLVERR or DECERR.
        the master sees an abort. For a CPU that is a
        synchronous or asynchronous external abort
        (ARM ch. 29). For a DMA engine, a channel error.
        BEST: something visibly fails, close to the cause.

  2. RAZ/WI - read as zero, write ignored
        the transaction "succeeds" and does nothing.
        WORST: no error anywhere. A driver reads 0x00000000
        from its ID register and reports "device not present".
        Days are lost to this (chapter 20).

  3. INTERRUPT + LOG, transaction dropped or errored
        the XPU records address, master ID, security state and
        direction in fault registers and raises an interrupt to
        a monitor.
        BEST FOR DEBUGGING, if someone wired the interrupt up
        and someone else wrote the handler.

  ALWAYS configure error responses and the fault interrupt in
  development builds, even if production chooses to be quiet.
  A silent policy is an untestable policy.
```

XPU versus SMMU: choosing

	SMMU	XPU
Translates addresses	Yes — scatter-gather, virtual DMA	No
Per-context (per-process, per-VM)	Yes — thousands of contexts	No — a handful of static regions
Dynamic remapping	Yes, per DMA mapping	Rarely, and expensively
Protects peripheral registers	Not usually	Yes
Works before the OS boots	Needs setup and tables	Yes — a few register writes
Cost in silicon	Large: TLBs, page walkers, queues	Small: comparators
Latency	TLB hit is fast; a walk is not	Fixed, small
Fault reporting	Rich — event queue with full context	Basic — often one fault register

They are complements, not alternatives. A well-built SoC uses the SMMU for masters that need scatter-gather DMA into user or guest memory, and XPUs for the static, coarse questions: which subsystem owns which DRAM carve-out, and who may write the clock and fuse controllers. Where both cover a path, **both** must allow the transaction — and that intersection is itself a defence, since a mistake in one is caught by the other.

Domains: the usable abstraction

```
/* With 16 regions and 20 masters you cannot enumerate pairs.
   So group masters into DOMAINS and write the policy in terms
   of domains.                                                */

   DOMAIN_SECURE     EL3 firmware, the trusted OS, the crypto
                     engine when claimed
   DOMAIN_AP         the application processor and everything
                     Linux drives directly
   DOMAIN_MODEM      the cellular subsystem: its DSP, its own
                     DMA, its dedicated peripherals
   DOMAIN_MEDIA      GPU, display, video codec, camera
   DOMAIN_SENSOR     the always-on sensor hub
   DOMAIN_DEBUG      CoreSight, the debug access port

/* Then the policy is a MATRIX - domains against resources: */

                  secure  AP     modem  media  sensor
   secure DRAM      rw     -      -      -      -
   AP DRAM          rw     rw     -      r      -
   modem DRAM       rw     -      rw     -      -
   shared AP/modem  rw     rw     rw     -      -
   framebuffer      rw     rw     -      rw     -
   fuses            r      -      -      -      -
   clock controller rw     rw     -      -      -
   sensor SRAM      rw     r      -      -      rw

/* This matrix IS the security architecture of the SoC. It
   belongs in a design document, reviewed by people who did not
   write it, and it should be MECHANICALLY DERIVED into the
   register settings rather than hand-written twice
   (chapter 19).

   Note what the matrix makes obvious that prose does not: the
   modem cannot see the framebuffer; the sensor hub cannot see
   AP memory; nothing but secure code reads the fuses. Those
   are decisions. Write them down and they can be argued with. */
```

Why this matters beyond security

> **THE BEST ARGUMENT FOR XPUS IS NOT SECURITY — IT IS DEBUGGING**
>
> A rogue DMA write into another subsystem's memory produces a crash *somewhere else, much later*, in code that is entirely innocent. It is the hardest class of bug on an SoC: no stack trace points at the culprit, and the symptom moves whenever anything is recompiled.
>
> An XPU converts that into an immediate fault at the moment of the bad access, with the offending master's ID in a register. That turns a two-week bug into a two-hour one, and it is why teams that adopt XPU policies for security keep them enabled for reasons that have nothing to do with attackers.

How it shows up

Symptom	Cause
Driver reads all-zero registers, reports "no device"	XPU denying with RAZ/WI

Symptom	Cause
External abort on an MMIO access that used to work	Firmware tightened the policy; this master is no longer allowed
DMA completes but the buffer is unchanged	Writes ignored by the XPU
Works when firmware is old, fails with new firmware	Policy changed — the two must be versioned together
One master works, an identical one does not	Different master IDs; the policy covers only one
Fails only for large transfers	The buffer crosses a region boundary
Fails only sometimes	Buffer address varies; a boundary is crossed only for some allocations
Everything is allowed	Default region permissive, or the XPU never enabled
A subsystem can reach memory it should not	Master ID remapped by a bridge, or shared with another master
Random corruption with no attribution	The exact bug an XPU exists to catch — turn one on

Check yourself

- ✓ State the different question each of the MMU, SMMU and XPU answers.
- ✓ Give four reasons an SoC needs XPUs even though it has an SMMU.
- ✓ List the fields of a bus transaction an XPU decides on.
- ✓ Explain why the master ID's integrity is the foundation of the whole mechanism.
- ✓ Describe how region count and alignment constrain the memory map.
- ✓ Name the three denial behaviours and rank them for debuggability.
- ✓ Say when to use an SMMU, when an XPU, and why overlap is good.
- ✓ Draw a domain-versus-resource matrix for a device you know.
- ✓ Explain the debugging argument for enabling XPUs.

Access control: programming and locking

Now configure one. The register model, the ordering rules that decide whether your policy is ever actually in force, and the locking that stops later code from undoing it.

The register model

```
/* Vendor names differ; the shape does not. A representative
   XPU region block:                                          */

   +0x000  XPU_CTRL          global enable, default action
   +0x004  XPU_STATUS        enabled, locked, error pending
   +0x008  XPU_ERR_STATUS    valid, direction, security, type
   +0x00C  XPU_ERR_ADDR_LO   the address that faulted
   +0x010  XPU_ERR_ADDR_HI
   +0x014  XPU_ERR_MASTER    which master ID
   +0x018  XPU_ERR_CLEAR     write 1 to clear and re-arm
   +0x01C  XPU_IRQ_ENABLE

   /* then N region blocks, 0x20 bytes apart: */
   +0x100  XPU_R0_BASE_LO    region base address
   +0x104  XPU_R0_BASE_HI
   +0x108  XPU_R0_LIMIT_LO   inclusive end, or a size encoding
   +0x10C  XPU_R0_LIMIT_HI
   +0x110  XPU_R0_RD_ALLOW   bitmap: which masters may read
   +0x114  XPU_R0_WR_ALLOW   bitmap: which masters may write
   +0x118  XPU_R0_CONFIG     enable, security, subregion mask
   +0x11C  XPU_R0_LOCK       write 1: frozen until reset

/* THE VARIATIONS you will meet:

   base+limit vs base+size          - and if size, usually a
                                      power of two, naturally
                                      aligned
   master BITMAP vs ID+MASK pairs   - bitmaps are simpler;
                                      ID+mask scales further
   one permission field vs separate secure/non-secure ones
   subregion disable masks          - split a region into 8
   region PRIORITY                  - overlapping regions:
                                      highest index wins, or
                                      lowest, or it is
                                      UNPREDICTABLE. READ THE
                                      TRM. This one bites.  */
```

The ordering that matters

```
Getting the sequence wrong leaves a WINDOW in which the system
is unprotected, or bricks the boot because you locked yourself
out. The safe order:

  1. Program the DEFAULT to DENY, but do NOT enable yet.
  2. Program every specific region: base, limit, permissions.
  3. Verify by reading back every register you wrote.
  4. Add the region containing YOUR OWN code and stack, with
     permission for the master you are running on.
     <-- forget this and step 5 halts the CPU
  5. Enable the XPU.
  6. Test the policy: negative cases, not just positive.
  7. LOCK it.

  AND THE INVERSE ORDER for reconfiguration, which is why you
  should avoid needing it: an XPU cannot usually be "paused",
  so changing a region while masters are active means either
  a brief window of wrong policy, or quiescing everything
  first.

  A DIFFERENT WINDOW to think about: between reset and step 5,
  NOTHING is enforced. Masters that are released from reset
  before the XPU is configured can do anything. So:

     configure the XPU BEFORE releasing other masters from
     reset, or hold them in reset until it is done.

  That single sentence is the most commonly violated rule in
  this whole chapter.
```

Configuring one

```
/* Firmware, running at EL3 during BL2/BL31 (chapter 14).    */

struct xpu_region {
        uint64_t base;
        uint64_t limit;         /* inclusive */
        uint32_t rd_masters;    /* bitmap */
        uint32_t wr_masters;
        uint32_t flags;         /* SECURE_ONLY, NS_ONLY, BOTH */
        bool     lock;
};

static const struct xpu_region policy[] = {
        /* secure firmware DRAM - only the secure domain */
        { .base = 0x0E000000, .limit = 0x0E3FFFFF,
          .rd_masters = M_CPU,
          .wr_masters = M_CPU,
          .flags = XPU_SECURE_ONLY, .lock = true },

        /* the trusted OS carve-out */
        { .base = 0x0E400000, .limit = 0x0EFFFFFF,
          .rd_masters = M_CPU | M_CRYPTO,
          .wr_masters = M_CPU | M_CRYPTO,
          .flags = XPU_SECURE_ONLY, .lock = true },

        /* the normal world's DRAM */
        { .base = 0x80000000, .limit = 0xBFFFFFFF,
          .rd_masters = M_CPU | M_GPU | M_DISPLAY | M_VIDEO | M_DMA,
          .wr_masters = M_CPU | M_GPU | M_VIDEO | M_DMA,
          .flags = XPU_NS_ONLY, .lock = true },
          /* note: DISPLAY reads only. A display controller has
             no business writing DRAM, and a compromised one
             then cannot corrupt the kernel.                 */

        /* modem's private memory - the AP cannot see it */
        { .base = 0xC0000000, .limit = 0xC7FFFFFF,
          .rd_masters = M_MODEM,
          .wr_masters = M_MODEM,
          .flags = XPU_NS_ONLY, .lock = true },

        /* the AP/modem shared buffer - the ONLY overlap */
        { .base = 0xC8000000, .limit = 0xC80FFFFF,
          .rd_masters = M_CPU | M_MODEM,
          .wr_masters = M_CPU | M_MODEM,
          .flags = XPU_NS_ONLY, .lock = true },

        /* fuse controller - secure reads only, no writes at
           runtime by anyone                                  */
        { .base = 0x01790000, .limit = 0x01790FFF,
          .rd_masters = M_CPU,
          .wr_masters = 0,
          .flags = XPU_SECURE_ONLY, .lock = true },
};

int xpu_apply(uintptr_t xpu, const struct xpu_region *r, size_t n)
{
        size_t i;

        if (n > XPU_NR_REGIONS)
                return -EINVAL;          /* fail, do not truncate */
```

```
        /* 1. default DENY, error responses on */
        mmio_write32(xpu + XPU_CTRL,
                     XPU_CTRL_DEFAULT_DENY | XPU_CTRL_ERR_RESP);

        /* 2. program regions */
        for (i = 0; i < n; i++) {
                uintptr_t reg = xpu + XPU_REGION(i);

                mmio_write32(reg + XPU_R_BASE_LO,  (uint32_t)r[i].base);
                mmio_write32(reg + XPU_R_BASE_HI,  r[i].base >> 32);
                mmio_write32(reg + XPU_R_LIMIT_LO, (uint32_t)r[i].limit);
                mmio_write32(reg + XPU_R_LIMIT_HI, r[i].limit >> 32);
                mmio_write32(reg + XPU_R_RD_ALLOW, r[i].rd_masters);
                mmio_write32(reg + XPU_R_WR_ALLOW, r[i].wr_masters);
                mmio_write32(reg + XPU_R_CONFIG,
                             r[i].flags | XPU_R_ENABLE);
        }

        /* disable every region we did NOT program - stale
           entries from a previous boot stage are a real
           hazard                                          */
        for (; i < XPU_NR_REGIONS; i++)
                mmio_write32(xpu + XPU_REGION(i) + XPU_R_CONFIG, 0);

        /* 3. read back and verify (see below) */
        if (xpu_verify(xpu, r, n))
                return -EIO;

        /* 4. enable */
        mmio_write32(xpu + XPU_CTRL,
                     XPU_CTRL_DEFAULT_DENY | XPU_CTRL_ERR_RESP |
                     XPU_CTRL_IRQ_EN | XPU_CTRL_ENABLE);

        dsb(sy);                /* make it visible before we
                                   depend on it (ARM ch. 21) */
        return 0;
}
```

ALWAYS DISABLE THE REGIONS YOU DID NOT PROGRAM

An earlier boot stage — the ROM, or a previous firmware version, or a warm reset path — may have left regions enabled. They persist. A region you never wrote about is not "absent"; it is whatever the last writer left there, and it may be a wide-open range someone added temporarily for bring-up.

Read back, always

```
/* Write-then-verify is not paranoia here. Real reasons a write
   does not take:

     · the region is already LOCKED from an earlier stage
     · the address is not aligned to the granularity, and the
       low bits were silently dropped - so your region is not
       where you think
     · the size is below the minimum and was rounded up
     · you are not allowed to program this XPU from this
       master or this security state
     · the block is not clocked or not out of reset yet
     · a reserved bit rejected the whole write               */

/* And FAIL THE BOOT if verification fails. A system whose
   access-control policy did not apply is not a system that
   should continue booting. "Warn and carry on" here is how
   devices ship unprotected.                                */
```

Locking

```
A policy that can be changed by later code is not a policy - it
is a suggestion. Three mechanisms, usually combined:

  1. PER-REGION LOCK BITS
        write 1 to XPU_Rn_LOCK. Sticky until reset.
        Now that region cannot be moved, resized, or widened.

  2. GLOBAL LOCK
        locks the whole block, including the enable bit and the
        default action. Some blocks also make the lock bit
        itself sticky, so it cannot be cleared.

  3. THE XPU'S OWN REGISTERS PROTECTED BY AN XPU
        the configuration interface is itself a slave. Make it
        reachable only from the secure domain, so even before
        locking, only EL3 firmware could change it.

  ORDER: lock LAST, after verification and after testing. Once
  locked, your only way out is a reset.

  WHAT LOCKING BUYS: an attacker who compromises the normal
  world - or even the trusted OS - cannot widen the policy. The
  configuration window closed in early firmware, in code that
  is much smaller and much more reviewed.

  WHAT TO LEAVE UNLOCKED, deliberately and with a written
  reason: regions that genuinely must change at runtime, such
  as a framebuffer switched to secure for a trusted UI. Those
  become the attack surface, so make the code that changes them
  as small as the SMC handler it lives behind (chapter 11).
```

Dynamic reassignment, when you must

```
/* Use case: a trusted UI. The display buffer must become
   SECURE while a PIN is entered, then return.

   This is a state machine, and every transition is a place to
   get it wrong.                                              */

TEE_Result secure_display_acquire(void)
{
        int ret;

        if (state != DISPLAY_NORMAL)
                return TEE_ERROR_BUSY;      /* no re-entry */

        /* 1. stop the normal world's access FIRST. Order
              matters: if we made it secure while NS DMA was in
              flight, we would get faults, not safety.       */
        ret = display_quiesce_ns();
        if (ret)
                return TEE_ERROR_BUSY;

        /* 2. WIPE the buffer. Whatever the normal world left
              there must not be shown as if it were ours, and
              our content must not leak back later.          */
        memset_secure(fb_va, 0, fb_size);
        cache_clean_range(fb_va, fb_size);

        /* 3. reassign: secure only, CPU and display only */
        ret = xpu_set_region(FB_REGION,
                             M_CPU | M_DISPLAY,   /* read  */
                             M_CPU,               /* write */
                             XPU_SECURE_ONLY);
        if (ret)
                goto out_resume;

        /* 4. verify it took */
        if (xpu_verify_region(FB_REGION, XPU_SECURE_ONLY))
                goto out_resume;

        state = DISPLAY_SECURE;

{
        if (state != DISPLAY_SECURE)
                return TEE_ERROR_BAD_STATE;

        /* WIPE BEFORE HANDING BACK - the PIN pad is still on
           screen. This is the step people forget, and it
           hands the attacker exactly what the trusted UI was
           protecting.                                       */
        memset_secure(fb_va, 0, fb_size);
        cache_clean_range(fb_va, fb_size);

        xpu_set_region(FB_REGION,
                       M_CPU | M_DISPLAY | M_GPU,
```

```
                        M_CPU | M_GPU,
                        XPU_NS_ONLY);

        state = DISPLAY_NORMAL;
        display_resume_ns();
        return TEE_SUCCESS;
}

/* THE RULES for any dynamic reassignment:
     · only secure code may request it
     · quiesce the losing side before the switch
     · WIPE on both transitions
     · verify the change applied
     · make it re-entrant-safe: two CPUs, or a crash mid-way
       does not permanently take the display                */
```

What Linux sees

```
/* Linux is usually a SUBJECT of the policy, not its author -
   the XPU was configured and locked before the kernel started.
   But it must know the shape of it.                          */

/* 1. Memory the kernel must not touch is removed from the
      memory map, in the device tree: */

        reserved-memory {
                #address-cells = <2>;
                #size-cells = <2>;
                ranges;

                optee@e400000 {
                        reg = <0x00 0x0e400000 0x00 0x00c00000>;
                        no-map;          /* do not even MAP it */
                };

                modem_mem: modem@c0000000 {
                        reg = <0x00 0xc0000000 0x00 0x08000000>;
                        no-map;
                };

                shared_mem: shared@c8000000 {
                        reg = <0x00 0xc8000000 0x00 0x00100000>;
                        /* no no-map: the kernel MAY map this,
                           it is the shared window            */
                };
        };

/* "no-map" matters: without it the kernel creates a linear
   mapping, and a speculative access through that mapping can
   fault - producing an SError at a completely unrelated
   moment (ARM chapter 29). With no-map, the memory is never
   mapped and never touched.                                  */

/* 2. A driver claims its share: */

        my_device: dma-thing@1a000000 {
                compatible = "vendor,dma-thing";
                reg = <0x00 0x1a000000 0x00 0x1000>;
                memory-region = <&shared_mem>;
        };

        /* and in probe: */
        ret = of_reserved_mem_device_init(dev);
        /* now dma_alloc_coherent() on this device allocates
           from that region - which is the region the XPU
           policy allows this master to touch. The two
           descriptions must agree, and nothing checks that
           they do except your testing.                       */
```

TWO DESCRIPTIONS OF THE SAME TRUTH

The XPU policy lives in firmware. The reserved-memory nodes live in the device tree. If they disagree, you get either a security hole (the kernel can touch what it should not) or a bug that appears late and far from its cause (the kernel gets memory the hardware will refuse). Generate both from one source, or at minimum test that they agree. Chapter 19 is about making that systematic.

How it shows up

Symptom	Cause
Register writes have no effect	Region already locked, or the block is not clocked/out of reset
Region is not where you programmed it	Base not aligned to the granularity; low bits dropped
System halts the moment you enable the XPU	You did not allow your own code's region
Policy applies but an old, wide region is still active	Unused regions not explicitly disabled
Behaviour differs between cold and warm boot	Warm reset does not clear the block; stale configuration
Overlapping regions behave unpredictably	Priority rules differ per block — check the TRM
A master misbehaves before firmware finishes	Released from reset before the XPU was configured
Trusted UI leaks the previous screen	Buffer not wiped on acquire
PIN pad visible to the normal world afterwards	Buffer not wiped on release
SError at a random later instruction	Kernel speculatively touched a carve-out — add `no-map`
`dma_alloc_coherent` memory rejected by hardware	DT reserved-memory and the XPU policy disagree

Check yourself

- ✓ Sketch an XPU's register map and name what each group does.
- ✓ Give the safe configuration order and say what each step prevents.
- ✓ Explain why other masters must be held in reset until the policy is applied.
- ✓ Write a region table for a device with secure, AP and modem domains.
- ✓ List five reasons a register write silently does not take, and write the read-back check.
- ✓ Explain the three locking mechanisms and when to apply them.
- ✓ Write a safe dynamic reassignment, including both wipes.
- ✓ Explain what `no-map` does and the failure it prevents.
- ✓ Explain why the DT and the firmware policy must be generated from one source.

Access control: designing a policy

Knowing how to program an XPU is the easy half. The hard half is deciding what the policy should *be* — and doing it as engineering rather than as a guess, on a chip with sixty bus masters and a memory map nobody has ever written down in one place.

The method

```
 1. ENUMERATE every bus master. All of them.
 2. ENUMERATE every protected resource.
 3. Build the ACCESS MATRIX: who needs what, and why.
 4. Group masters into DOMAINS to fit the hardware's limits.
 5. Lay out the MEMORY MAP to match the region granularity.
 6. Express the policy as DATA, in one place.
 7. GENERATE the firmware tables and the device tree from it.
 8. TEST the negative cases.
 9. REVIEW, with people who did not write it.

Steps 1 and 2 take a week and feel like clerical work. They
are the whole job. Every failure of a real policy traces back
to a master nobody listed or a resource nobody classified.
```

Step 1: enumerate the masters

```
/* "Every block that can issue a bus transaction." Far more
   than people expect. On a mid-range application SoC:      */

   CPU cluster(s)          often several, with different IDs
                           per core or per cluster
   GPU                     usually several masters: shader,
                           command processor, ...
   display controller      one per pipe
   camera ISP              plus its own DMA
   video encoder/decoder
   audio DSP               and its DMA
   sensor hub / always-on MCU
   modem subsystem         its DSP, its DMA, its own CPU
   Wi-Fi / Bluetooth       often bus masters over PCIe or a
                           dedicated port
   PCIe root complex       and EVERY endpoint behind it
   USB host and device
   SDIO / eMMC / UFS controllers
   Ethernet MAC
   generic DMA engines     several, with many channels
   crypto engine
   power-management controller / SCP
   CoreSight / debug access port     <-- a master, and the
                                         one people forget
   trace funnel writing to memory (ETR)
   a "system cache" or interconnect maintenance block

/* FOR EACH ONE, record:

     what is its master ID, or ID range?
     is the ID fixed, or programmable by that master?
     is it behind an SMMU? which one? which StreamIDs?
     is it behind an XPU? which one?
     what security state does it issue in? fixed or dynamic?
     who controls its firmware, and how is that firmware
       verified?
     when is it released from reset, relative to the XPU
       configuration?

/* SOURCES: the SoC TRM's master ID table, the interconnect
   configuration, the SMMU StreamID mapping, the DT, and -
   this one matters - ASKING THE SoC INTEGRATION TEAM. The
   documentation is routinely incomplete. Blocks get added
   late.

/* AND THEN VERIFY EMPIRICALLY: program a deny-all XPU, run the
   system, and collect the faults. Every master that faults is
   one you now know about. Masters that never appear are either
   idle or not covered - and telling those two apart is the
   point of the exercise.                                   */
```

> **THE MASTER YOU DID NOT LIST IS YOUR VULNERABILITY**
>
> A debug block that can write DRAM. A power-management microcontroller running unsigned vendor firmware with full bus access. A PCIe endpoint that arrives with the user's plug-in card. An audio DSP whose firmware is loaded from the normal-world filesystem. Each of these has been the path around an otherwise sound TrustZone design on shipping hardware. The policy is defined by its *completeness*, not by how carefully you wrote the entries you thought of.

Step 2: enumerate the resources

Class	Examples	Typical rule
Secure code and data	BL31, trusted OS, secure heap, secure stacks	Secure domain only. Locked.
Key material	Fuse controller, key slots, RNG, crypto engine	Secure domain, minimum permissions. Often no write at runtime at all.
Subsystem private memory	Modem heap, DSP firmware and scratch	That subsystem only. Not even the AP.
Shared buffers	AP↔modem IPC, mailboxes, ring buffers	Exactly the two parties. The *only* intended overlaps.
Normal-world DRAM	The kernel and everything it manages	AP domain plus the media masters that need it.
Protected media	DRM decode buffers, framebuffer during trusted UI	Secure or a "protected" domain; write-only for some masters.
System control	Clocks, resets, power, PLLs, thermal	Whoever owns power management. Usually secure or AP, not both.
The access-control blocks themselves	XPU, SMMU secure interface, TZASC config	Secure domain only, then locked.
Debug	CoreSight, ETR buffers, the DAP	Gated by the lifecycle state (ch. 10).

Step 3: the access matrix

```
# One row per resource, one column per domain, and a REASON
# for every non-empty cell. The reason column is what makes
# this a review artifact rather than a table.

resource            secure  ap    modem media sensor debug  reason
------------------------------------------------------------------
bl31_dram            rw      -     -     -     -      -     EL3 only
optee_dram           rw      -     -     -     -      -     TEE only
optee_shm            rw      rw    -     -     -      -     TEE ABI (ch.12)
ns_dram              rw      rw    -     rw    -      -     kernel + media
modem_dram           rw      -     rw    -     -      -     modem private
ap_modem_shm         rw      rw    rw    -     -      -     IPC ring
sensor_sram          rw      r     -     -     rw     -     AP reads results
framebuffer          rw      rw    -     rw    -      -     display path
protected_video      rw      -     -     w     -      -     write-only: the
                                                            codec fills it,
                                                            nothing reads it
                                                            back to the AP
fuse_ctrl            r       -     -     -     -      -     provisioning only
crypto_engine        rw      -     -     -     -      -     secure keys
rng                  rw      rw    -     -     -      -     both need entropy
clock_ctrl           rw      rw    -     -     -      -     Linux CCF drives it
xpu_config           rw      -     -     -     -      -     self-protection
coresight            rw      -     -     -     -      rw    lifecycle gated

# READ THE EMPTY CELLS. They are the security properties:
#   modem cannot see the framebuffer
#   media cannot see modem memory
#   nothing but secure code reads the fuses
#   the AP cannot read protected video back
#
# Each empty cell should survive the question "what breaks if
# we fill this in?" - and if the answer is "nothing", it is a
# property worth keeping.
```

THREE PRINCIPLES, APPLIED CONCRETELY

- **Least privilege.** Start from all-deny and add only what a demonstrated failure requires. Never start from all-allow and subtract.
- **Directionality.** Read and write are separate questions. A display controller reads; it never writes. A video encoder writes a protected buffer; nothing reads it back. Half the value of a good matrix is in the cells that say `r` or `w` rather than `rw`.
- **Justify every allow.** A cell without a reason is a cell nobody can safely remove later, which means it will still be there in five years' worth of derived products.

Step 5: laying out memory to fit

```
The XPU has 16 regions and a 1 MB granule. Your matrix has 24
distinct resource classes. Something has to give - and the
right thing to give is the ADDRESS MAP, decided early.

  BAD LAYOUT - interleaved, needs a region per buffer:

     0x8000_0000  kernel
     0x8010_0000  modem shared
     0x8020_0000  kernel
     0x8030_0000  sensor
     0x8040_0000  kernel
     ...                       -> 20 regions, 4 KB apart,
                                  impossible to express

  GOOD LAYOUT - grouped by DOMAIN, aligned to the granule:

     0x8000_0000  +----------------------+
                  | AP DRAM              |  1 region
                  | 768 MB               |
     0xB000_0000  +----------------------+
                  | AP/modem shared 4 MB |  1 region
     0xB040_0000  +----------------------+
                  | AP/sensor shared 1 MB|  1 region
     0xB050_0000  +----------------------+
                  | (gap - denied)       |
     0xC000_0000  +----------------------+
                  | modem private 128 MB |  1 region
     0xC800_0000  +----------------------+
                  | protected media 64 MB|  1 region
     0xCC00_0000  +----------------------+
                  | secure world 32 MB   |  1 region
     0xCE00_0000  +----------------------+

  Six regions instead of twenty. And note the GAPS: address
  space that matches no region and is therefore denied to
  everyone. Gaps are free - use them as guard bands between
  domains, so an off-by-a-little DMA lands in a fault rather
  than in the neighbour's memory.

  THE RULE: group by WHO MAY TOUCH IT, not by what it is for.
  All AP memory contiguous, all modem memory contiguous, each
  sharing window its own aligned block.

  This decision is made at SoC memory-map definition time,
  which is roughly 18 months before anyone writes the XPU
  driver. Bring the security requirements to that meeting or
  you will spend the project working around its output.
```

Steps 6 and 7: one source of truth

```
# The same policy must appear in at least four places:
#   the firmware's XPU tables
#   the firmware's TZASC/TZC configuration
#   the device tree's reserved-memory nodes
#   the SMMU stream table setup
# and often a fifth: the modem or DSP's own linker script.
#
# Hand-maintaining four copies guarantees they will drift. So
# write the policy ONCE, as data, and generate.

# platform_policy.yaml
domains:
  secure:  { masters: [cpu_s, crypto] }
  ap:      { masters: [cpu_ns, dma0, dma1, usb, ufs] }
  modem:   { masters: [mdsp, mdma] }
  media:   { masters: [gpu, display, venc, vdec] }
  sensor:  { masters: [shub] }

regions:
  - name: ns_dram
    base: 0x80000000
    size: 0x30000000
    access: { ap: rw, media: rw, secure: rw }
    dt_node: false                # the kernel owns it
  - name: ap_modem_shm
    base: 0xB0000000
    size: 0x00400000
    access: { ap: rw, modem: rw, secure: rw }
    dt_node: { name: modem_shm, no_map: false }
  - name: modem_priv
    base: 0xC0000000
    size: 0x08000000
    access: { modem: rw, secure: rw }
    dt_node: { name: modem_mem, no_map: true }
  - name: secure_dram
    base: 0xCE000000
    size: 0x02000000
    access: { secure: rw }
    dt_node: { name: secure_mem, no_map: true }
    lock: true

# Then one generator emits:
#   xpu_policy.c        the firmware table
#   tzc_regions.c       the TZASC configuration
#   reserved-memory.dtsi  the DT nodes
#   policy_test.c       the negative-test list
#   policy.md           a human-readable matrix for review
#
# Now a change is made in ONE place, and the four artifacts
# cannot disagree. This is the single highest-value thing in
# this chapter, and it is a two-hundred-line Python script.
```

Step 8: test the negatives

```
/* Positive tests - "the driver works" - happen anyway. They
   tell you nothing about the policy, because a policy of
   "allow everything" passes all of them.

   NEGATIVE tests are the only ones that measure isolation. */

struct denial_test {
        const char *name;
        uint32_t    master;
        uint64_t    addr;
        bool        write;
};

static const struct denial_test must_fail[] = {
  { "AP reads secure DRAM",        M_CPU_NS, SECURE_DRAM,   false },
  { "AP writes secure DRAM",       M_CPU_NS, SECURE_DRAM,   true  },
  { "AP reads modem private",      M_CPU_NS, MODEM_PRIV,    false },
  { "modem reads AP DRAM",         M_MODEM,  NS_DRAM,       false },
  { "modem reads framebuffer",     M_MODEM,  FRAMEBUFFER,   false },
  { "media writes secure DRAM",    M_GPU,    SECURE_DRAM,   true  },
  { "AP reads protected video",    M_CPU_NS, PROT_VIDEO,    false },
  { "AP writes fuse controller",   M_CPU_NS, FUSE_CTRL,     true  },
  { "AP writes XPU config",        M_CPU_NS, XPU_BASE,      true  },
  { "sensor reads AP DRAM",        M_SHUB,   NS_DRAM,       false },
  { "display writes DRAM",         M_DISPLAY,NS_DRAM,       true  },
  { "unlisted addr, any master",   M_CPU_NS, UNMAPPED_GAP,  false },
};

/* HOW to issue a transaction as a non-CPU master: program that
   master's own DMA to do a small transfer, and check for the
   error. Most subsystems have a test or loopback mode; if not,
   the smallest real operation will do. This is genuine work to
   build, and it is the part that separates a policy you HAVE
   from a policy you KNOW.                                      */

/* RUN THESE:
     · in CI, on real silicon, every night
     · on the FINAL lifecycle state, not a dev part
     · after every firmware change
     · after every DT change
     · and specifically after any "temporary" bring-up widening

   A denial test that starts passing when it should fail is the
   highest-priority bug in the build. Wire it to fail the
   pipeline.                                                  */
```

Step 9: review

> **WHAT A REVIEWER SHOULD BE ABLE TO ASK**
>
> - "Show me the master list, and how you know it is complete."
> - "Which masters are not behind any SMMU or XPU, and why is that acceptable?"
> - "Point at the reason for this `rw`. What breaks if it becomes `r`?"
> - "Which regions are unlocked at runtime, who can change them, and what stops the normal world asking?"
> - "Where is the window between reset and enforcement, and which masters run inside it?"
> - "Show me the negative test for this empty cell, and the CI run where it passed."
> - "Which of these four artifacts is generated, and which is hand-written?"
>
> If any of those questions has no answer, that is the finding — not a comment on the code.

Living with a policy

```
/* Policies rot. Specifically:

   · BRING-UP WIDENING. Someone opens a region to make a new
     block work at 2 a.m., intending to narrow it later.
     -> require every widening to carry an expiry and a ticket;
        fail the build after the date.

   · DERIVED PRODUCTS. A cheaper variant drops the modem, and
     nobody removes its domain - leaving an allow for a master
     that no longer exists, or worse, whose ID has been reused
     by a different block.
     -> regenerate from the policy file per product; never copy
        the generated C.

   · NEW MASTERS mid-project. A block is added; the policy is
     not updated; it works because the default was never
     tightened.
     -> that is why the default is DENY. A new master that
        nobody told you about fails loudly on day one.

   · DEBUG BUILDS diverging. The dev configuration is permissive
     and the production one is not, so the negative tests only
     ever run against the permissive one.
     -> run the denial suite against the PRODUCTION policy on
        production silicon.                                  */
```

How it shows up

Symptom	Cause
A new subsystem faults on everything	Its master ID is not in any region — correct behaviour of a deny-by-default policy
Policy needs more regions than the hardware has	Memory map not grouped by domain; regroup, do not compromise the policy
Buffers fail only at certain sizes or addresses	Crossing a region boundary; alignment does not match the granule
Firmware and DT disagree after a change	Hand-maintained copies — generate them

Symptom	Cause
Isolation works on the dev board, not on production	Different policy build, or lifecycle state differences
An allow nobody can explain	Bring-up widening that was never removed
A master reaches memory the matrix forbids	Master ID shared or remapped — the matrix is describing something the hardware cannot distinguish
Negative tests all pass, but so does everything	The XPU was never enabled — verify `XPU_CTRL`
Corruption during early boot only	A master released from reset before enforcement began

Check yourself

- ✓ List the nine steps and say which two are usually skipped.
- ✓ Enumerate the bus masters of a device you have worked on — all of them.
- ✓ Explain why an unlisted master defeats the policy regardless of its quality.
- ✓ Build an access matrix with a reason in every cell, and read its empty cells aloud as security properties.
- ✓ Explain why read and write must be separate decisions, with an example of each.
- ✓ Redesign an interleaved memory map so it fits sixteen regions.
- ✓ Explain why gaps between domains are worth keeping.
- ✓ Name the four artifacts that must agree, and how to make them agree by construction.
- ✓ Write ten negative tests for a system you know, and say how you would issue each one.
- ✓ List four ways a policy rots and the control that stops each.

Debugging access-control failures

The last chapter of the track, and the one you will actually use. Something is being refused, or worse, silently ignored. Here is how to find out what, who, and why — starting from the two symptoms that look nothing like an access-control problem.

The two faces of a denial

```
LOUD: an abort.

   Linux:  "Synchronous External Abort" / "SError Interrupt"
   TF-A:   an EL3 crash dump
   DMA:    a channel error, a device timeout
   SMMU:   an event in the event queue (chapter 06)

   Annoying, but honest. You get an address and often a
   master.

SILENT: reads return 0, writes vanish.

   "The device isn't present."
   "The ID register reads 0x00000000."
   "DMA completes but the buffer is unchanged."
   "It works on the dev board."

   THIS is the one that costs a week. There is no error
   anywhere in the system, and every layer reports success.
   The driver author reasonably concludes the hardware is
   broken or the address is wrong.

THE TELL for the silent case:

   an MMIO read returning EXACTLY 0x00000000 or 0xFFFFFFFF
   from a register that should have a fixed non-zero value -
   an ID, a version, a revision - is an access problem until
   proven otherwise. Real hardware that is present and
   clocked almost never reads back all-zeros from its ID
   register.

   0x00000000  usually: RAZ/WI denial, or the block is in
               reset, or unclocked
   0xFFFFFFFF  usually: nothing decodes this address at all,
               or the bus returned an error that got
               swallowed
```

Triage: five questions in order

```
/* Work down this list. Each step is cheap and eliminates a
   large class.                                              */

1. IS THE BLOCK POWERED, CLOCKED, AND OUT OF RESET?
      By far the most common cause of all-zero reads, and it is
      not an access-control problem at all.
      -> check the clock and reset drivers, /sys/kernel/debug/clk,
         and the power domain state. Enable the clock by hand
         and read again.

2. IS THE ADDRESS RIGHT?
      Compare the DT reg property against the TRM. Check you
      are reading the right instance - SoCs have four UARTs and
      three of them are wired to nothing.
      -> devmem2 / busybox devmem from userspace, on a
         neighbouring register you know the value of.

3. IS THIS ACCESS DENIED?
      Now the interesting question. Read the XPU fault
      registers, the SMMU event queue, the TZASC fail status.
      -> details below.

4. WHICH MASTER, AND WHICH REGION?
      A fault register usually gives you both. If not,
      bisect - see "when there is no fault register".

5. IS THE POLICY WRONG, OR IS THE CODE WRONG?
      A denial is often CORRECT: the driver really is touching
      something it should not, using the wrong buffer, or
      running on the wrong master. Fix the code before you
      widen the policy. Widening is the last resort, not the
      first.                                                 */
```

> **THE INSTINCT TO RESIST**
>
> When a denial appears, the fastest way to make it go away is to open the region. That is almost always the wrong fix, and it is how policies rot (chapter 19). Ask first: *why is this master touching this address?* Half the time the honest answer reveals a bug — a stale pointer, a buffer allocated from the wrong pool, a DMA descriptor never updated — and the XPU has just done you a large favour.

Decoding a CPU abort

```
Unhandled fault: synchronous external abort (0x96000010)
  at 0xffff800008a01000
[0000000000000000] ESR = 0x96000010

/* ESR_EL1 = 0x96000010, decoded (ARM chapter 29):

     EC   = 0b100101 (0x25)  Data Abort, same EL
     ISV  = 0                no instruction syndrome
     DFSC = 0b010000 (0x10)  SYNCHRONOUS EXTERNAL ABORT,
                             not on a translation table walk

   DFSC 0x10 means: the MMU translated it fine, the transaction
   went out to the bus, AND SOMETHING OUT THERE SAID NO.

   That "something" is an XPU, a TZASC, a peripheral that does
   not decode the address, or a slave in reset. The CPU cannot
   tell you which - it only knows the bus said no.

   FAR_EL1 holds the virtual address. Convert it to physical:
        virt_to_phys(), or read the translation with AT S1E1R
        and TTBR-walk it, or just look at the ioremap that
        produced it.                                          */

/* SYNCHRONOUS vs ASYNCHRONOUS - and this matters a lot:

   Synchronous external abort (DFSC 0x10)
        the faulting instruction is in ELR. Device memory
        (nGnRnE/nGnRE) accesses fault synchronously, so MMIO
        denials point straight at the offending line.

   SError / asynchronous
        a WRITE to Normal memory was posted and completed long
        ago from the CPU's point of view. The abort arrives
        whenever the write finally reached the denier - which
        may be thousands of instructions later, in unrelated
        code, on a different task.
        -> the reported PC IS NOT THE CULPRIT. Do not spend a
           day analysing it.

   TAMING AN SError: insert `dsb sy` after the suspect writes to
   force them to complete, and the abort becomes synchronous
   enough to localise. Or bisect by disabling one master at a
   time.                                                      */
```

Reading XPU fault registers

```
/* Every XPU worth using latches the FIRST fault. Read it. */

void xpu_dump_fault(uintptr_t xpu)
{
        uint32_t st = mmio_read32(xpu + XPU_ERR_STATUS);
        uint64_t addr;

        if (!(st & XPU_ERR_VALID)) {
                INFO("xpu: no fault latched\n");
                return;
        }

        addr  = (uint64_t)mmio_read32(xpu + XPU_ERR_ADDR_HI) << 32;
        addr |= mmio_read32(xpu + XPU_ERR_ADDR_LO);

        ERROR("XPU FAULT\n"
              "  address   : 0x%016llx\n"
              "  master ID : 0x%02x (%s)\n"
              "  direction : %s\n"
              "  security  : %s\n"
              "  privileged: %s\n"
              "  multiple  : %s\n",
              addr,
              mmio_read32(xpu + XPU_ERR_MASTER),
              master_name(mmio_read32(xpu + XPU_ERR_MASTER)),
              (st & XPU_ERR_WRITE)  ? "write" : "read",
              (st & XPU_ERR_NS)     ? "non-secure" : "secure",
              (st & XPU_ERR_PRIV)   ? "privileged" : "unprivileged",
              (st & XPU_ERR_OVF)    ? "yes - more faults occurred"
                                    : "no");

        mmio_write32(xpu + XPU_ERR_CLEAR, 1);   /* re-arm */
}

/* THE OVERFLOW BIT MATTERS. Only the first fault is latched;
   later ones set overflow and are lost. So:

     · clear the fault as soon as you have logged it
     · if overflow is set, you are seeing one of many - fix
       that one, re-run, and look again
     · a repeating fault at 60 Hz is a display or DMA loop;
       one fault at boot is a probe.

/* WIRE THE INTERRUPT UP. An XPU fault interrupt handled in EL3
   that prints this block is worth more than any amount of
   after-the-fact analysis. Do it once, at the start of a
   project, and every subsequent access bug takes minutes.  */
```

The other reporters

Block	Where the evidence is
SMMU	The event queue: StreamID, SubstreamID, IOVA, fault reason. See chapter 06 — richest source on the SoC.
TZC-400	`FAIL_ADDRESS_LOW/HIGH`, `FAIL_CONTROL` (direction, NS, privilege), `FAIL_ID` (master), per filter unit.
Interconnect	Some NoCs have error probes logging the initiator, target, opcode and a timestamp — check whether yours does before building a bisect harness.

Block	Where the evidence is
TF-A	Its exception handlers print an EL3 crash dump with all the ESR/FAR context.
Linux	`dmesg`: external aborts, SErrors, `arm-smmu` fault lines, `rcu` stalls if the secure world hung.
The DMA engine	Per-channel error status, often with the descriptor address that failed — which tells you the buffer, not just the address.

When there is no fault register

```
/* RAZ/WI denials with no logging. You have no evidence, so
   MANUFACTURE some.                                        */

/* TECHNIQUE 1: switch to error responses.
   Most blocks can be told to abort instead of ignoring, even
   if production ships quiet. One build flag turns a
   week-long mystery into a stack trace.                    */
        mmio_write32(xpu + XPU_CTRL, ctrl | XPU_CTRL_ERR_RESP);

/* TECHNIQUE 2: probe from a known-good master.
   Read the same address from EL3 firmware, which is usually
   allowed everything. If EL3 sees the right value and Linux
   sees zeros, it is a policy question, not a hardware one. */

/* TECHNIQUE 3: bisect the policy.
   Open regions one at a time until it works. The one that
   fixes it names the resource; the failing master follows from
   which driver you were exercising. Crude, always works.   */

/* TECHNIQUE 4: bisect the masters.
   Hold subsystems in reset, or disable their DT nodes, one at
   a time. When the corruption stops, the last one you disabled
   is the culprit. This is the standard way to find a rogue
   DMA writer with no XPU at all.                           */

/* TECHNIQUE 5: a canary region.
   Fill a page with a pattern, deny everyone, and scan it
   periodically. If it changes, something is writing where it
   must not - and now you know it exists, which is most of the
   battle.                                                  */

/* TECHNIQUE 6: read a neighbour.
   If register 0x00 reads zero, read 0x04, 0x08, an adjacent
   block's ID register. All zero across a whole peripheral ->
   clock, reset or a whole-block denial. Only one register
   zero -> that register really is zero, and this was never an
   access problem.                                          */
```

A worked example

```
# SYMPTOM
#   New video decoder driver. probe() succeeds, but every
#   decode returns an empty frame. No errors anywhere.

# 1. clocked and out of reset?
   cat /sys/kernel/debug/clk/clk_summary | grep vdec
     vdec_core   1  1  0  300000000        -> yes, enabled

# 2. address right? read the ID register from userspace:
   devmem 0x1c000000
     0x00000000                            -> suspicious.
   devmem 0x1c000004
     0x00000000
   devmem 0x1c000008
     0x00000000                            -> the whole block.
#  TRM says ID should read 0x56444543. So: not present, not
#  clocked (but clk says it is), or DENIED.

# 3. any faults latched? From the TF-A debug console:
   tfa> xpu_dump 0
     XPU FAULT
       address   : 0x000000001c000000
       master ID : 0x04 (CPU_NS)
       direction : read
       security  : non-secure
     -> DENIED. The CPU, non-secure, may not read the decoder's
        registers.

# 4. why? Check the policy:
   grep -A4 vdec platform_policy.yaml
     - name: vdec_regs
       base: 0x1C000000
       access: { secure: rw }
     -> the decoder was classified as a SECURE resource,
        because an earlier product used it for DRM.

# 5. policy wrong, or code wrong?
#  Talk to the team. Conclusion: this product decodes
#  non-protected content on the AP, so the AP legitimately
#  needs the registers - but the PROTECTED OUTPUT BUFFER must
#  still be unreadable by the AP. So the fix is to split the
#  resource, not to open it:

     - name: vdec_regs
       base: 0x1C000000
       access: { ap: rw, secure: rw }       # control plane
     - name: vdec_protected_out
       base: 0xC8000000
       access: { media: w, secure: rw }     # data plane:
                                            # codec writes,
                                            # AP never reads

# 6. regenerate, rebuild firmware, re-run.
#    AND add the negative test:
     { "AP reads protected video output", M_CPU_NS,
       PROT_VIDEO, false },
#    so the day someone widens this by accident, CI says so.
```

> **NOTICE WHAT STEP 5 DID**
> The lazy fix — `access: { ap: rw }` on the whole subsystem — would have worked, shipped, and quietly handed the application processor read access to protected video. Splitting control plane from data plane took ten extra minutes and preserved the property the policy existed for. That distinction, between "make the error go away" and "understand what the error was protecting", is the whole skill.

The toolkit

Tool	Use
`devmem` / `devmem2`	Poke physical addresses from userspace. First thing to reach for.
`dmesg`, `/sys/kernel/debug/clk/clk_summary`	Aborts, SMMU faults, clock and reset state.
TF-A debug console	Read XPU/TZC registers from EL3, where everything is allowed.
JTAG	Halt and inspect — but remember `SPIDEN` gating (ch. 10).
Bus trace / NoC probes	Ground truth on who issued what, if your SoC has them.
A logic analyser on the reset and clock lines	When the software's view of power state is not believable.
The negative test suite	Not a debugging tool — a tool for knowing the bug never comes back.

How it shows up

Symptom	Likely cause	First check
Whole block reads 0x00000000	Unclocked, in reset, or wholly denied	Clock summary, then XPU fault register
Whole block reads 0xFFFFFFFF	Address decodes to nothing	DT `reg` against the TRM
Synchronous external abort, DFSC 0x10	Bus-level denial on MMIO	FAR, then the XPU/TZC fail address
SError at an unrelated instruction	A posted write denied long after issue	`dsb sy` to localise, then bisect masters
DMA "succeeds", buffer unchanged	Writes ignored	Switch the block to error responses
Works from EL3, not from Linux	Policy denies the non-secure master	The access matrix
Works for small buffers only	Larger buffer crosses a region boundary	Region base and limit vs the allocation
Intermittent, allocation-dependent	Same, but only some allocations cross	Print the physical address on failure
Fault overflow bit set	Many faults; you are seeing one	Fix, clear, re-run, look again
Random corruption, no attribution	A master with no XPU coverage at all	Canary region, then master bisection
Fails only on production silicon	Lifecycle state; debug gating; a tighter production policy	Compare the two policy builds directly

Check yourself

- ✓ Name the two faces of a denial and say which costs more time.
- ✓ Explain what an all-zero ID register read tells you, and what it does not.
- ✓ Run the five triage questions in order on a real symptom.
- ✓ Decode `ESR = 0x96000010` and say what it does and does not identify.

- ✓ Explain why an SError's reported PC is not the culprit, and how to localise it.
- ✓ Write a fault-register dump, and explain why the overflow bit matters.
- ✓ Give three techniques for finding a denial with no fault register.
- ✓ Work the video decoder example and explain why splitting the resource beat widening it.
- ✓ Say what you would add to a new project on day one to make all of this take minutes.

END OF THE ISOLATION AND SECURITY TRACK

You have gone from the threat model of an SoC, through the SMMU, TrustZone, the TEE stack, secure boot, real attacks, and access control, to debugging the whole thing. Next comes Linux kernel and drivers, where much of this becomes concrete: DMA APIs against a real SMMU, reserved memory against a real policy, and a driver you write yourself.

TRACK

Virtualisation & hypervisors

EL2, stage-2 translation, the vGIC and virtio — how one machine convincingly pretends to be several, and what that costs.

21 chapters

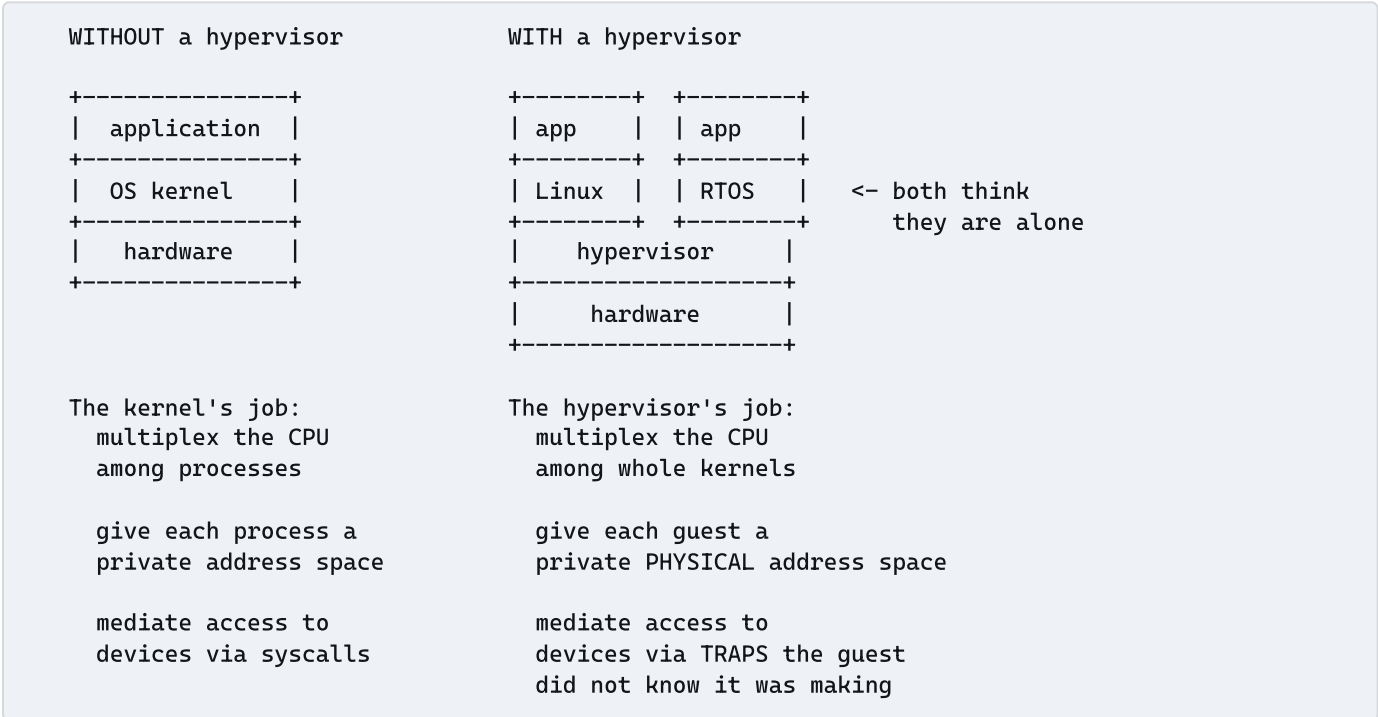
What a hypervisor actually is

A hypervisor is an operating system whose processes are operating systems. Everything else in this track — EL2, stage-2 translation, the vGIC, virtio — is a consequence of that one sentence, because a process that believes it owns the machine needs lying to in ways an ordinary process does not.

The problem it solves

An operating system is written on the assumption that it is alone. It sets up page tables at a physical address it chose. It programs the interrupt controller. It reads a timer and believes the value. It writes to a UART at `0x0900_0000` because the manual says the UART is there.

Now run two of them on one chip. Both want to be alone. Both chose physical addresses. Both programmed the interrupt controller. Neither will tolerate the other, and neither can be modified — that is the whole point, because if you were willing to rewrite the guest you would not need virtualisation, you would need a library.

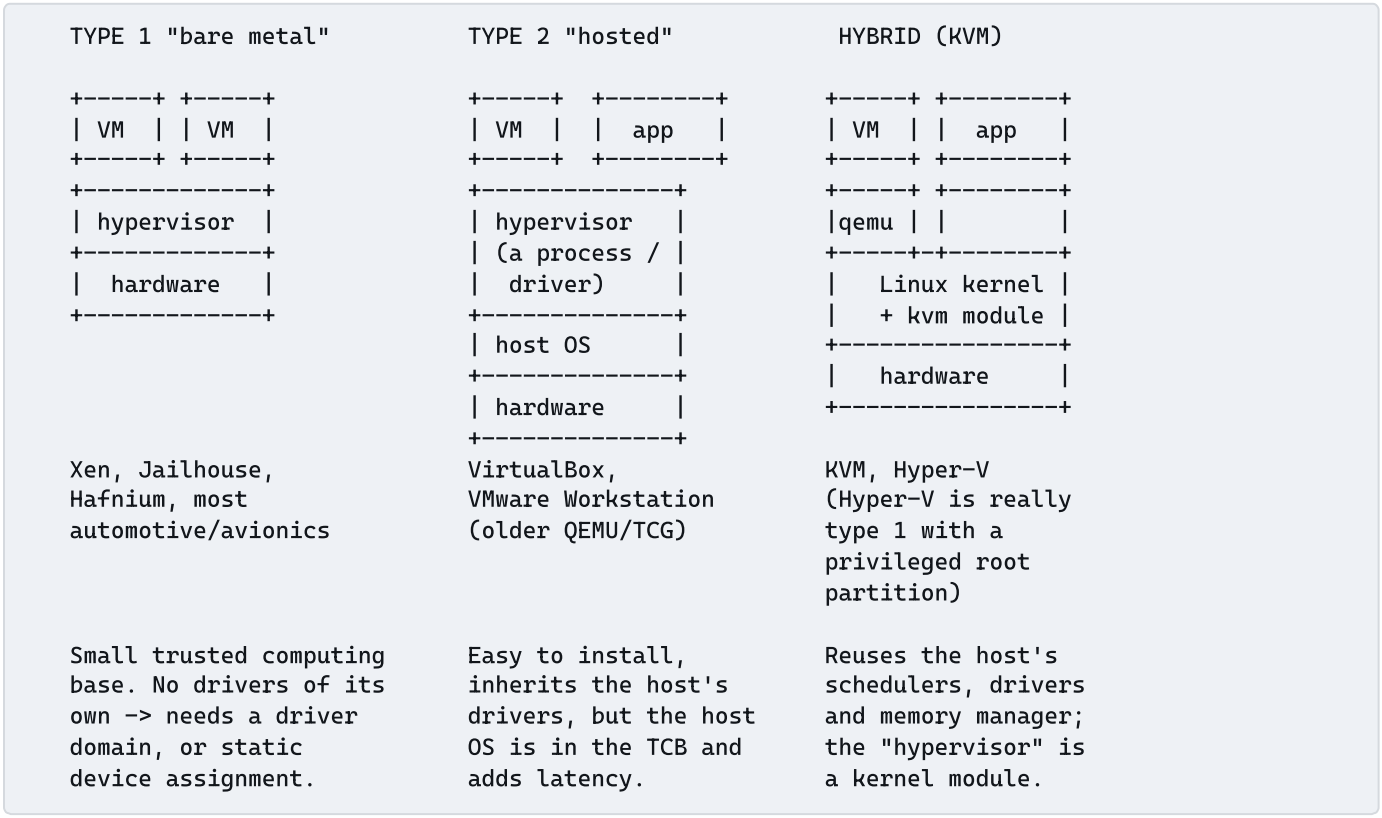


That last row is the interesting one. A process asks for a service by executing `SVC`: it knows it is asking. A guest kernel writes to what it believes is a hardware register: it does not know it is asking. The hypervisor must intercept an operation the guest thought was a plain memory store, work out what the guest meant by it, do something equivalent, and resume the guest as if the store had simply happened.

> **THE DEFINITION WORTH MEMORISING**
>
> A hypervisor gives each guest the *illusion of a whole machine*: its own physical address space, its own CPU, its own interrupt controller, its own timer, and its own devices. Every chapter in this track is one of those illusions, and how the hardware helps you build it.

Type 1 and type 2

The textbook split is between hypervisors that run on bare metal and hypervisors that run inside a host OS. It is a useful first cut and a poor final one, because the interesting systems sit in between.



KVM is the case that breaks the taxonomy, and it is the one you will meet most. The Linux kernel gains the ability to enter EL2 and run a guest; a user-space process (QEMU, crosvm, cloud-hypervisor) supplies the device models and the policy. The scheduler scheduling your vCPU is the ordinary Linux scheduler, and the vCPU is an ordinary thread. That design decision — *a vCPU is a thread* — explains most of KVM's behaviour, good and bad.

Three ways to virtualise

Technique	How	Cost	Where you see it
Trap and emulate	Run the guest directly; privileged operations trap to the hypervisor, which emulates them	One trap per privileged operation — cheap if rare, ruinous if hot	The base mechanism everywhere
Binary translation	Rewrite the guest's instruction stream before running it, replacing awkward instructions	Translation time, cache pressure, enormous complexity	VMware on pre-2006 x86; QEMU's TCG today
Paravirtualisation	Modify the guest to call the hypervisor deliberately	You must be able to change the guest	virtio, Xen PV, PSCI, pvclock, KVM's hypercalls

Real systems use all three at once. An arm64 KVM guest runs natively (trap-and-emulate) for ordinary code, is trapped for GIC and timer access, and deliberately calls the hypervisor for power management via PSCI and for I/O via virtio. Paravirtualisation is not a compromise you make when the hardware is weak — it is the right answer whenever the interface you are emulating is a bad interface. Emulating a 1990s IDE controller register-by-register is possible and pointless; a virtqueue is better in every way.

> **WHY VIRTIO EXISTS AT ALL**
> Emulating a real device means one trap per register access, and real device drivers touch a lot of registers per operation. A virtio device is designed so that the guest can queue many requests into shared memory and then trap *once* to say "there is work". The unit of expensive interaction becomes the batch, not the register. Hold that thought — it recurs in chapter 13.

Why this matters in embedded, not just in the cloud

Server virtualisation is about consolidation and billing. Embedded virtualisation is about *isolation with mixed criticality*, and the shape of the problem is different.

```
A typical automotive or industrial SoC today:

+---------------------+  +---------------+  +--------------+
|  Infotainment       |  |  Instrument   |  | Safety /     |
|  Android or Linux   |  |  cluster      |  | control      |
|  huge, updated often|  |  Linux, must  |  | RTOS, ASIL-B |
|  low trust          |  |  never blank  |  | hard realtime|
+---------------------+  +---------------+  +--------------+
+-------------------------------------------------------------+
|  hypervisor - and its job is NOT consolidation, it is:      |
|    * the RTOS must meet its deadline even when Android melts |
|    * a compromise in Android must not reach the CAN bus      |
|    * the cluster must keep rendering during an infotainment  |
|      restart                                                 |
+-------------------------------------------------------------+

Consequences you will not meet in a cloud hypervisor:
  - static partitioning is often preferred over scheduling
  - device PASSTHROUGH is the norm, not the exception
  - the hypervisor must be small enough to CERTIFY
  - "overcommit" may be forbidden outright
```

This is why the track covers Jailhouse and static partitioning alongside KVM. In a data centre a hypervisor that cannot overcommit memory is useless; in a car a hypervisor that *can* is a hazard.

What virtualisation actually costs

The honest answer is "almost nothing, except at the boundaries, where it is enormous". Guest instructions that do not trap run at native speed — there is no interpreter and no overhead. The cost is concentrated entirely in exits.

```
Rough order-of-magnitude figures on modern arm64 server silicon.
Treat them as ratios, not measurements: measure your own platform
(chapter 21).

  a normal guest instruction ..............  same as native
  a stage-2 TLB hit .......................  same as native
  a stage-2 page-table walk ...............  up to 24 memory accesses
                                             (4 stage-1 levels x
                                              4 stage-2 levels + leaf)
  a trap to EL2 and back (VHE, no work) ....  ~1000-2000 cycles
  an MMIO exit handled inside KVM ..........  ~2-5 us
  an MMIO exit handled by QEMU in user space  ~10-30 us
  a virtio notification + vhost handling ....  ~5-15 us

The lesson: an exit costs roughly a thousand instructions you did
not write. A driver that polls a status register in a tight loop
runs at native speed on hardware and at a few thousand operations
per second in a VM.
```

> **THE CLASSIC EMBEDDED SURPRISE**
>
> Code that "works fine on the board" and is unusably slow in the VM is almost always doing register polling. On hardware each read is ~100 ns; under a hypervisor each read is a trap. The fix is not a faster hypervisor — it is to stop polling, or to pass the device through (chapter 16).

What the rest of this track builds

Illusion	Hardware that provides it	Chapters
A private physical address space	Stage-2 translation	05, 06, 07
A private CPU	EL2, banked registers, the world switch	03, 04, 08, 09
A private interrupt controller	The GIC virtual CPU interface, list registers	10, 11
A private timer	`CNTVOFF_EL2` and the virtual counter	12
Devices	MMIO traps, virtio, the SMMU for passthrough	13, 14, 15, 16
All of it, assembled	KVM, Xen, Jailhouse, Hafnium	17, 18, 19, 20

You need exception levels, translation tables and the GIC before this track will land. If any of those three is shaky, read them first; virtualisation is those three ideas applied a second time, one level up.

How it shows up

Symptom	Cause
Guest boots but is 100x slower than the host	Emulation instead of hardware virtualisation — you are on TCG, not KVM. Check for `-accel kvm` and `/dev/kvm`
A driver that works on hardware crawls in the VM	Register polling; every read is an exit
Guest reports the wrong number of CPUs or wrong memory size	The guest read the real hardware description instead of the one the hypervisor generated — device tree or ACPI table not overridden
Guest hangs immediately after "Starting kernel"	No console: the UART the guest expects is not emulated at the address its device tree claims

Symptom	Cause
Two guests both work alone, neither works together	Overlapping passthrough or a shared device neither expects to share
RTOS misses deadlines only when Linux is busy	The hypervisor is time-slicing where it should be partitioning (chapter 18)
`KVM: entry failed, hardware error`	The CPU refused to enter the guest — usually an invalid stage-2 configuration or an unsupported feature bit

Check yourself

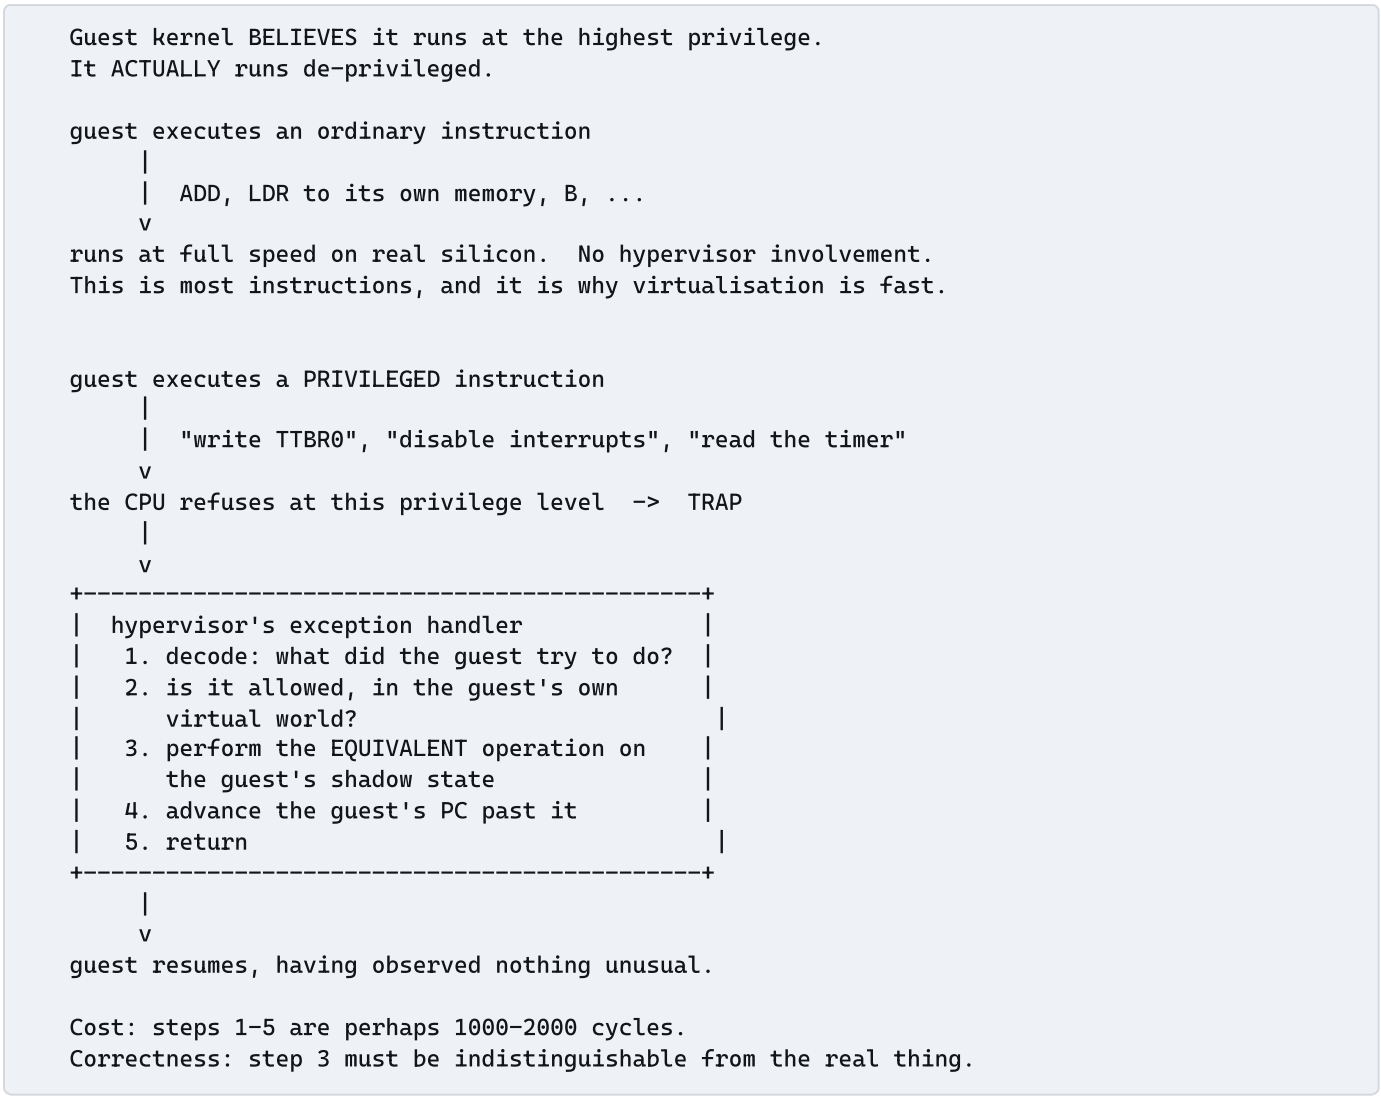
- ✓ Explain in one sentence what a hypervisor provides that an OS kernel does not.
- ✓ Give the difference between a process asking for a service and a guest asking for one.
- ✓ Place KVM, Xen, Jailhouse and VirtualBox on the type-1/type-2 spectrum, and say why KVM is awkward to place.
- ✓ Name the three virtualisation techniques and give a live example of each on an arm64 Linux guest.
- ✓ Explain why paravirtualised I/O is usually better than faithful device emulation, in terms of exits.
- ✓ State two requirements an automotive hypervisor has that a cloud hypervisor does not.
- ✓ Explain why a polling driver is fast on hardware and slow in a VM.
- ✓ List the five illusions a hypervisor must maintain and name the hardware feature behind each.

Trap-and-emulate and the Popek-Goldberg conditions

In 1974 two researchers wrote down the exact property an instruction set must have to be virtualisable. For thirty years most popular architectures failed the test, and the industry built increasingly baroque workarounds. Understanding the test tells you precisely what EL2 was added to fix.

The mechanism, stripped down

Classical virtualisation is one idea: **run the guest at a privilege level lower than it thinks it has, and catch it when it notices.**



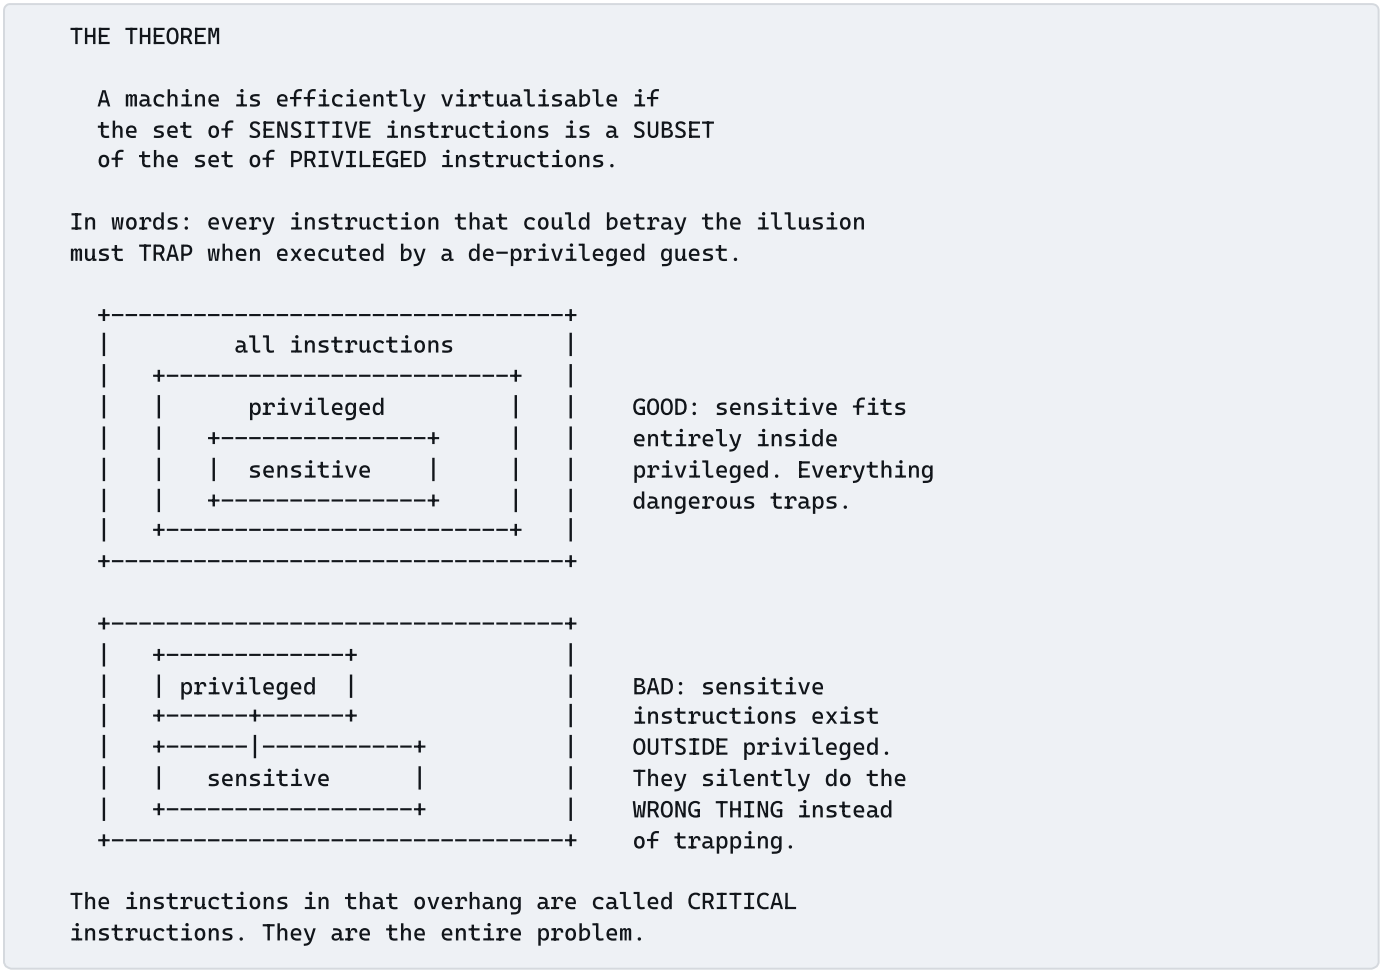
THE INVARIANT

The guest must not be able to tell. Not "must not be able to escape" — *must not be able to tell*. Any observable difference between running natively and running virtualised is a bug, and historically most of them were also security holes.

Popek and Goldberg's instruction classes

The 1974 paper divides every instruction into categories based on two questions: does it touch privileged state, and does its behaviour depend on privileged state?

Class	Definition	AArch64 examples
Privileged	Traps when executed in user mode, works in supervisor mode	`MSR TTBR0_EL1`, `TLBI`, `AT`, `ERET`
Sensitive — control	Changes the configuration of resources: memory mapping, privilege, interrupt state	`MSR SCTLR_EL1`, `MSR DAIFSet`, `MSR VBAR_EL1`
Sensitive — behaviour	Its *result* depends on the privilege level or on real resource configuration	`MRS CurrentEL`, `MRS MIDR_EL1`, reading a physical counter
Innocuous	Everything else	`ADD`, `LDR`, `B`, floating point



Where architectures failed

x86 before VT-x had 17 critical instructions. The canonical one is `POPF`, which pops the flags register. In kernel mode it can change the interrupt-enable flag; in user mode it silently ignores that bit rather than faulting. A de-privileged guest kernel executing `POPF` to disable interrupts would get *no trap and no effect*. The hypervisor never learns the guest wanted interrupts off, and the guest never learns it failed.

Classic ARM (ARMv7-A without the Virtualization Extensions) had its own version of the problem, and it is worth knowing because you meet it on old parts:

```
/* ARMv7-A, no VE. The guest kernel is de-privileged to USR mode. */

    MRS  r0, CPSR        /* reads the mode field. In USR mode the
                            mode bits read back as USR - so a guest
                            that inspects its own mode discovers it
                            is not in SVC. It can TELL. */

    MSR  CPSR_c, #0xD3   /* attempt to switch to SVC and mask IRQs.
                            In USR mode: silently ignored. No trap.
                            The guest believes interrupts are off.
                            They are not. */

    LDM  sp, {r0-r14}^   /* the "^" form accesses USR-mode banked
                            registers - meaningless and unfaulting
                            when you are already in USR mode. */

/* Three sensitive-but-not-privileged instructions, and therefore
   three ways for the illusion to break silently. This is why Xen
   on ARMv7 required PARAVIRTUALISATION: you had to patch the guest
   kernel to replace every critical instruction with a hypercall.  */
```

The three historical workarounds

Approach	How it dodges critical instructions	Price
Binary translation	Scan the guest's instruction stream ahead of execution and rewrite critical instructions into traps or inline emulation	A translator and a translation cache in the trusted computing base; self-modifying guest code is a nightmare
Paravirtualisation	Change the guest source so it never emits a critical instruction — it calls the hypervisor instead	Every guest OS must be ported and maintained; closed guests cannot run at all
Hardware extension	Add a new mode in which the awkward instructions trap	None, once the silicon exists. This is what won

> **WHY "SHADOW PAGE TABLES" WERE THE REAL PAIN**
>
> Even with the instruction problem solved, memory remained hard. The guest builds page tables mapping guest-virtual to *guest-physical* addresses, but the MMU consumes host-physical. Pre-hardware solutions had the hypervisor maintain a hidden *shadow* table composing the two, write-protect the guest's tables to detect edits, and rebuild on every change. It worked, and it cost a fortune on fork-heavy workloads. Stage-2 translation (chapter 5) is the hardware answer, and it is the single biggest reason modern virtualisation is cheap.

How ARMv8-A passes the test

ARM did not try to make EL1 instructions trap by de-privileging the guest into EL0. That was the ARMv7 mistake. Instead it added a *higher* level, EL2, and made trapping **configurable**: the guest genuinely runs at EL1, with real EL1 registers, and the hypervisor selects which EL1 operations should divert to EL2.

```
   ARMv7 approach (broken)        ARMv8 approach (works)

   EL0  app                       EL0  app
        guest kernel  <- squashed
                         in here  EL1  guest kernel, genuinely at EL1
   SVC  hypervisor                     with its own SCTLR_EL1, TTBR0_EL1,
                                       VBAR_EL1 ... all real registers

                                  EL2  hypervisor, and it holds the
                                       CONTROL: HCR_EL2 says which
                                       EL1 operations trap up to here

   Consequence: the guest is NOT de-privileged, so it cannot
   detect de-privileging. Sensitive instructions do not need to
   be privileged - they need to be TRAPPABLE, and HCR_EL2 makes
   almost all of them trappable on demand.

   MRS CurrentEL in a guest reads "EL1" - which is TRUE.
   The lie is not about privilege. The lie is about being alone.
```

This is the key architectural insight of the ARM virtualisation extensions, and it is why HCR_EL2 is the register this whole track revolves around. Popek and Goldberg asked for sensitive ⊆ privileged. ARM instead offered *sensitive ⊆ configurably trappable*, which is strictly more useful: the hypervisor traps what it must emulate and lets the rest run at full speed.

Selective trapping in practice

```
/* Not everything should trap. The art is choosing.        */

  TRAP IT when the guest must not see real hardware state, or
  when you must maintain shadow state:

    guest writes to the GIC distributor      -> trap, emulate
    guest reads the physical counter         -> trap or offset
    guest executes WFI                       -> trap, so you can
                                                schedule another vCPU
    guest reads ID registers (MIDR, ID_AA64*)-> trap, present a
                                                sanitised view
    guest does SMC / HVC                     -> always to EL2/EL3

  DO NOT TRAP when the hardware already isolates it, because a
  trap you did not need is pure cost:

    guest writes TTBR0_EL1, TCR_EL1          -> let it. Stage-2
                                                already constrains
                                                the result.
    guest issues TLBI VAE1                   -> let it. VMID tags
                                                the entries.
    guest takes its own EL0 syscall          -> let it. Never
                                                involves EL2.
    guest sets DAIF                          -> let it, unless you
                                                are virtualising
                                                interrupts strictly.

/* A well-configured arm64 KVM guest running a compile job may
   execute BILLIONS of instructions between exits. A badly
   configured one exits thousands of times a second doing the
   same work.                                                 */
```

How it shows up

Symptom	Cause
Guest works alone, corrupts state when a second guest runs	A sensitive operation is not being trapped — the guest is touching real shared state
Guest detects it is virtualised despite your efforts	An ID register, timer or cache-topology value was not sanitised; the guest read the truth
Guest disables interrupts and still gets interrupted	Interrupt masking is being emulated and the emulation lost a state change — classic critical-instruction bug
Enormous exit rate for an idle guest	`WFI` / `WFE` trapping combined with a guest that spins, or an untrapped-but-should-be timer read
Guest hangs when it re-programs its own page tables	Under shadow paging, a missed write-protect; under stage-2, a stale TLB — see chapter 6
Emulated instruction executes twice	The handler forgot to advance the guest PC past the trapping instruction
Works on one core, breaks on SMP	Shadow state updated without the lock the real hardware provided implicitly

Check yourself

- ✓ State the Popek-Goldberg condition in one sentence, using the words sensitive and privileged.
- ✓ Define a critical instruction and explain why it is worse than an instruction that faults.
- ✓ Give one x86 and one ARMv7 critical instruction and say exactly what goes wrong.
- ✓ Name the three workarounds for a non-virtualisable ISA and one real product that used each.
- ✓ Explain why shadow page tables were expensive and what replaced them.
- ✓ Explain how ARMv8 sidesteps the theorem rather than satisfying it directly.
- ✓ Give two operations a hypervisor should trap and two it should deliberately not, with reasons.
- ✓ List the five steps of a trap-and-emulate handler, and say what breaks if you skip step 4.

EL2 and the ARM virtualisation extensions

EL2 is not simply "one more privilege level". It is a level with its own translation regime, its own vector table, its own timer, its own stack pointer and — crucially — a control register that decides which EL1 operations are allowed to complete without asking permission. This chapter is the anatomy.

Where EL2 sits

```
              NON-SECURE                    SECURE

EL0    application                   trusted application (S-EL0)
         |                                  |
EL1    guest kernel                   trusted OS, e.g. OP-TEE (S-EL1)
         |                                  |
EL2    HYPERVISOR                     S-EL2 partition manager
         |                            (ARMv8.4+, e.g. Hafnium)
         |                                  |
EL3    +-----------------------------------------+
       |  secure monitor - TF-A BL31              |
       |  the only code that switches WORLDS       |
       +-----------------------------------------+
                        |
                    hardware

Two orthogonal axes, and confusing them is the commonest
beginner error on this page:

  EXCEPTION LEVEL  = how much privilege   (EL0 < EL1 < EL2 < EL3)
  SECURITY STATE   = which world          (Non-secure | Secure | Realm)

EL2 is a level. TrustZone is a state. A hypervisor at EL2 and
a trusted OS at S-EL1 are not competing for the same seat;
they are in different worlds, and EL3 arbitrates.
```

> **REALMS, BRIEFLY**
> ARMv9 CCA adds a third security state (Realm) with its own R-EL2 running the Realm Management Monitor. The idea is a guest that even the hypervisor cannot read. It does not change anything in this chapter; it adds a column to the diagram. Chapter 19 covers the secure and realm sides together.

What EL2 actually gives you

Facility	Register(s)	Why it exists
Configurable trapping of EL1/EL0	`HCR_EL2`, `CPTR_EL2`, `HSTR_EL2`, `MDCR_EL2`	Choose what you emulate and what runs natively
A second stage of address translation	`VTTBR_EL2`, `VTCR_EL2`	Give the guest a private "physical" address space
A VM identity for the TLB	`VTTBR_EL2.VMID`	Tag TLB entries so switching guests does not require a full invalidate
Virtual interrupt injection	`HCR_EL2.{VI,VF,VSE}`, GIC list registers	Make an interrupt appear to the guest that no wire produced

Facility	Register(s)	Why it exists
Its own translation regime	`TTBR0_EL2`, `TCR_EL2`, `SCTLR_EL2`	The hypervisor's own mappings, invisible to the guest
Its own exceptions	`VBAR_EL2`, `ELR_EL2`, `SPSR_EL2`, `ESR_EL2`, `FAR_EL2`, `HPFAR_EL2`	Traps land here without disturbing the guest's own EL1 exception state
A timer of its own	`CNTHCTL_EL2`, `CNTHP_*_EL2`, `CNTVOFF_EL2`	Preempt a guest, and shift the guest's view of time
Guest-visible ID control	`VPIDR_EL2`, `VMPIDR_EL2`	Tell the guest a CPU ID and affinity of your choosing
A deliberate call gate	`HVC` instruction	Paravirtualised calls from EL1 into EL2

Register banking: the part that confuses everyone

System registers are *banked* per exception level. `TTBR0_EL1` and `TTBR0_EL2` are two different physical registers. The guest at EL1 writes `TTBR0_EL1` and the hypervisor's own `TTBR0_EL2` is untouched. This is why a guest can run with real EL1 registers without endangering EL2.

```
What is banked (separate copy per level):

  SCTLR_EL1  SCTLR_EL2      system control
  TTBR0_EL1  TTBR0_EL2      translation base
  TCR_EL1    TCR_EL2        translation control
  VBAR_EL1   VBAR_EL2       vector base
  ESR_EL1    ESR_EL2        syndrome
  FAR_EL1    FAR_EL2        fault address
  ELR_EL1    ELR_EL2        return address
  SPSR_EL1   SPSR_EL2       saved state
  SP_EL1     SP_EL2         stack pointer
  MAIR_EL1   MAIR_EL2       memory attributes

What is NOT banked and MUST be saved/restored by hand
on every world switch:

  X0–X30, SP_EL0, PC (via ELR)
  the FP/SIMD register file  (lazily, if you are careful)
  PMU counters, debug/breakpoint registers
  TPIDR_EL0, TPIDRRO_EL0, TPIDR_EL1

THIS asymmetry is exactly why the vCPU context switch
(chapter 8) has the shape it does: the banked half is free,
the unbanked half is a long list of MRS/MSR pairs.
```

> **WHY BANKING IS THE PERFORMANCE STORY**
>
> Because EL1 state is banked away from EL2 state, entering the hypervisor does not destroy the guest's configuration. A trap that the hypervisor can service without touching guest registers — reading `ESR_EL2`, updating a shadow value, returning — costs a few hundred cycles. A full vCPU switch costs thousands, because the unbanked list above must move. Minimising exits matters; minimising *full switches* matters more.

Getting into EL2 in the first place

You do not enter EL2 by asking. On a cold boot the CPU comes up at the highest implemented level (EL3 if TrustZone is implemented), and firmware *drops* into EL2 deliberately. If your bootloader dropped you straight to EL1, no hypervisor can run on that system, and no amount of software will fix it.

```
/* TF-A BL31 preparing to hand off. Simplified. */

    /* Decide the level the next image runs at. */
    scr  = SCR_EL3_RW          /* next level is AArch64      */
         | SCR_EL3_NS          /* next level is Non-secure   */
         | SCR_EL3_HCE;        /* HVC is ENABLED - without
                                  this, HVC is UNDEFINED and
                                  no guest can call EL2      */
    write_scr_el3(scr);

    spsr = SPSR_MODE_EL2h      /* <-- land at EL2, using SP_EL2 */
         | DAIF_ALL_MASKED;
    write_spsr_el3(spsr);
    write_elr_el3(bl33_entry);
    eret;                      /* now executing at EL2         */

/* Linux's own head.S then decides whether to STAY at EL2. */

    mrs     x0, CurrentEL
    cmp     x0, #CurrentEL_EL2
    b.ne    1f                 /* booted at EL1: no KVM, ever  */

    /* We are at EL2. Two choices:
         - stay here  -> VHE, host kernel runs AT EL2 (ch. 9)
         - drop to EL1-> nVHE, only a small stub stays at EL2 */
1:
```

```
# On a running Linux system, ask what happened:

$ dmesg | grep -iE 'kvm|hyp|EL2'
[    0.000000] CPU: All CPU(s) started at EL2
[    0.512430] kvm [1]: Hyp mode initialized successfully
[    0.512461] kvm [1]: VHE mode initialized successfully

# The bad version, and the commonest reason KVM "does not work":
[    0.000000] CPU: All CPU(s) started at EL1
[    0.498112] kvm [1]: HYP mode not available

# EL1 means the firmware or bootloader consumed EL2 and dropped
# you. On many boards this is a U-Boot or vendor-firmware setting;
# on some it is fused. No workaround exists in the kernel.

$ ls -l /dev/kvm            # exists only if EL2 was available
$ grep -c . /sys/module/kvm/parameters/* 2>/dev/null
```

> **THE SINGLE MOST COMMON BRING-UP FAILURE**
>
> `All CPU(s) started at EL1`. Every secondary core must also arrive at EL2, not just the boot core — a firmware that starts CPU0 at EL2 and the rest at EL1 produces a kernel that initialises KVM and then fails on the first vCPU pinned elsewhere. Check `CurrentEL` on every core, not one.

Discovering what the silicon supports

```
/* ID_AA64PFR0_EL1 - the feature register that matters here. */

  bits [11:8]  EL2 support
                 0b0000  EL2 not implemented -> no virtualisation
                 0b0001  EL2 implemented, AArch64 only
                 0b0010  EL2 implemented, AArch64 + AArch32

  bits [15:12] EL3 support (same encoding)

/* ID_AA64MMFR1_EL1 */

  bits [3:0]   VHE          0b0001 = ARMv8.1 VHE present (ch. 9)
  bits [7:4]   VMIDBits     0b0010 = 16-bit VMIDs, else 8-bit
  bits [15:12] HPDS, [19:16] HAFDBS ...

/* ID_AA64MMFR2_EL1 */
  bits [3:0]   CnP, [15:12] IESB, [55:52] E0PD ...

/* From Linux user space, no assembly needed: */
```

```
$ cat /proc/cpuinfo | grep -m1 Features
Features : fp asimd evtstrm aes pmull sha1 sha2 crc32 atomics
           fphp asimdhp cpuid asimdrdm lrcpc dcpop asimddp

$ ls /sys/devices/system/cpu/cpu0/regs/identification/
midr_el1  revidr_el1

# The VMID width decides how many VMs can be resident without
# TLB flushing. 8 bits = 255 usable; 16 bits = 65535.
# On a phone this never matters. On a 128-core server running
# hundreds of containers-in-VMs it very much does.
```

HVC: the deliberate call

`SVC` goes EL0→EL1. `HVC` goes EL1→EL2. `SMC` goes to EL3. They are three doors at three levels, and the calling conventions rhyme.

```
/* A guest asking its hypervisor for something. This is how PSCI,
   KVM's PV features and Xen's hypercalls all work.            */

    mov     x0, #0x84000001        /* PSCI CPU_ON, SMC32 range   */
    mov     x1, target_cpu_mpidr
    mov     x2, entry_point
    mov     x3, context_id
    hvc     #0                     /* trap to EL2                */
    /* x0 now holds the return value, per SMCCC                  */

/* Which door a PSCI call goes through depends on the guest:
     bare-metal Linux at EL1, TF-A at EL3   -> SMC
     Linux guest under KVM                  -> HVC, and KVM
                                               either handles it
                                               or forwards to EL3

   KVM tells the guest which to use through the device tree:

     psci {
         compatible = "arm,psci-1.0";
         method = "hvc";        <-- or "smc" on bare metal
     };

   Getting this wrong gives you a guest that hangs on secondary
   CPU bring-up: it calls SMC, the call sails past EL2 to EL3,
   and firmware tries to power on a PHYSICAL core for a VIRTUAL
   request.                                                    */
```

How it shows up

Symptom	Cause
`kvm: HYP mode not available`	Booted at EL1 — firmware consumed EL2. Not fixable from the kernel
KVM initialises, then fails on some vCPUs	Secondary cores were started at EL1 while the boot core reached EL2
`HVC` takes an undefined-instruction exception	`SCR_EL3.HCE` is clear — EL3 firmware never enabled the door
Guest hangs bringing up secondary CPUs	PSCI conduit mismatch: guest device tree says `smc` where it should say `hvc`
Random guest corruption after a vCPU migrates cores	An unbanked register (FP state, TPIDR, PMU) not saved or restored in the switch
Only a handful of VMs before performance collapses	8-bit VMIDs and rollover forcing global TLB invalidation
Hypervisor faults with `ESR_EL2` pointing at its own code	EL2's own translation regime (`TTBR0_EL2`) is misconfigured — not a guest bug at all
Guest reads the host's real MIDR and mis-detects the CPU	`VPIDR_EL2` / `VMPIDR_EL2` not programmed for the vCPU

Check yourself

- ✓ Draw the four exception levels against the security states, and place a hypervisor and a trusted OS correctly.
- ✓ Name six facilities EL2 provides that EL1 cannot.
- ✓ Explain register banking and list four registers that are banked and four that are not.
- ✓ Explain why banking makes a lightweight trap much cheaper than a full vCPU switch.
- ✓ Describe how a CPU comes to be executing at EL2, and what `SCR_EL3.HCE` controls.

- ✓ Given `All CPU(s) started at EL1`, say what is wrong and where the fix must go.
- ✓ Read `ID_AA64PFR0_EL1` and determine whether EL2 is implemented.
- ✓ Explain what VMID width affects in practice.
- ✓ Compare `SVC`, `HVC` and `SMC`, and explain the PSCI conduit property.

HCR_EL2: choosing what traps

One 64-bit register decides, bit by bit, which operations a guest may perform for itself and which must be brought to the hypervisor for adjudication. Every design decision about isolation, fidelity and performance in an ARM hypervisor is ultimately expressed here.

The idea

```
guest at EL1 executes:  MSR SCTLR_EL1, x0

     HCR_EL2.TVM == 0                HCR_EL2.TVM == 1
     ----------------                ----------------
     the write happens.              EXCEPTION to EL2.
     No exception. Full speed.       ESR_EL2.EC = 0x18
                                     (trapped MSR/MRS)
                                     ISS encodes the register,
                                     the direction and Rt.

                                     hypervisor decides what
                                     "writing SCTLR_EL1" should
                                     mean for THIS guest, then
                                     ERETs.

That is the entire mechanism. HCR_EL2 has about forty such
bits; each one moves a class of operation from "free" to
"mediated". Your hypervisor's personality is the bit pattern
you choose.
```

The bits that matter

Bit	Name	Set it to…
VM	Virtualisation enable	Turn on stage-2 translation. Without this, guest "physical" addresses are real physical addresses. The master switch
RW	Register width	1 = EL1 is AArch64, 0 = AArch32 guest
IMO / FMO / AMO	IRQ / FIQ / SError mask override	Route physical IRQ/FIQ/SError to EL2 instead of EL1, and enable the corresponding virtual interrupt
VI / VF / VSE	Virtual IRQ / FIQ / SError pending	Assert a virtual interrupt into the guest. Software writes the bit; the guest sees an interrupt
TWI / TWE	Trap WFI / WFE	Catch an idling guest so you can schedule someone else
TSC	Trap SMC	Intercept the guest's secure-monitor calls so EL2 can filter or forward them
TVM / TRVM	Trap virtual-memory register writes / reads	Catch `SCTLR_EL1`, `TTBR*_EL1`, `TCR_EL1`, `MAIR_EL1`… Needed for shadowing tricks; expensive, usually off
TTLB	Trap TLB maintenance	Catch guest `TLBI`. Usually off: VMID tagging makes guest TLBIs safe
TID0-TID3	Trap ID register groups	Present a synthetic CPU. TID3 is the one that hides features you have not implemented
TGE	Trap general exceptions	With VHE: EL0 belongs to the host, not a guest. Routes EL0 exceptions to EL2

Bit	Name	Set it to...
E2H	EL2 host	The VHE switch — remaps `*_EL1` accesses at EL2 onto EL2 registers. See chapter 9
PTW	Protected table walk	A stage-1 walk that hits device memory at stage 2 becomes a fault rather than undefined behaviour
FB	Force broadcast	Guest TLBI/cache ops become inner-shareable broadcasts, so the guest need not know it is on SMP
DC	Default cacheable	Force stage-1 to look cacheable while the guest's MMU is off — used during guest boot
TACR / TIDCP / TSW / TPC / TPU	Trap aux control, implementation-defined, cache ops	Cache maintenance and vendor registers; TSW in particular matters for set/way ops

What a real hypervisor sets

```
/* Close to what KVM/arm64 programs for a normal 64-bit guest.
   Compare arch/arm64/include/asm/kvm_arm.h.                  */

  HCR_GUEST_FLAGS =
        HCR_TSC          /* trap SMC: EL2 sees and filters them   */
      | HCR_TSW          /* trap set/way cache ops - a guest doing
                            "clean by set/way" would operate on
                            the WHOLE cache, including other VMs  */
      | HCR_TWE          /* trap WFE  -> yield the pCPU           */
      | HCR_TWI          /* trap WFI  -> block the vCPU thread    */
      | HCR_VM           /* stage-2 ON                            */
      | HCR_PTW          /* protected table walk                  */
      | HCR_TID3         /* trap ID regs: show a sanitised CPU    */
      | HCR_FMO | HCR_IMO /* physical FIQ/IRQ come to EL2, and
                             virtual FIQ/IRQ become available     */
      | HCR_AMO          /* same for SError                       */
      | HCR_RW           /* AArch64 guest                         */
      | HCR_FB           /* broadcast the guest's TLBI/cache ops  */
      | HCR_BSU_IS       /* barriers upgrade to inner-shareable   */
      | HCR_TACR         /* trap ACTLR_EL1                        */
      | HCR_TIDCP;       /* trap impl-defined registers           */

/* Notice what is DELIBERATELY ABSENT:

     no TVM   - the guest may write TTBR0_EL1/SCTLR_EL1 freely.
                Stage-2 makes that safe, and trapping every page
                table change would destroy performance.

     no TTLB  - the guest may invalidate its own TLB entries.
                VMID tagging means it can only hit its own.

     no TRVM  - reads of VM registers are harmless.

   Each absent bit is a decision that the HARDWARE already
   provides the isolation, so software should stay out of the
   way. That is the whole art.                                */
```

> **THE RULE OF THUMB**
>
> Trap when you must maintain state the guest cannot be allowed to own, or when the guest would otherwise observe the truth. Do not trap when stage-2 or VMID tagging already contains the damage. Every unnecessary trap bit is a permanent tax on every guest, for ever.

A worked example: why TSW exists

```
/* AArch64 cache maintenance comes in two flavours:      */

    DC CIVAC, x0     /* clean+invalidate by VIRTUAL ADDRESS.
                        Goes through stage 1 and stage 2, so it
                        can only ever touch memory this guest
                        actually owns.  SAFE - do not trap.   */

    DC CISW,  x0     /* clean+invalidate by SET AND WAY.
                        Addresses a physical cache location by
                        geometry. There is no address, so there
                        is nothing for stage 2 to constrain.

                        A guest looping over every set and way -
                        which is exactly what Linux does when it
                        turns its MMU off during boot or kexec -
                        would clean and invalidate lines
                        belonging to OTHER VMs and to the
                        hypervisor.                           */

/* Hence HCR_EL2.TSW. The guest traps, and the hypervisor does
   something equivalent-but-safe. KVM's historical answer was to
   flush the guest's own stage-2 mappings instead; modern KVM
   mostly just makes the operation a no-op after ensuring the
   guest's memory is coherent, because a guest with stage-2
   enabled has no legitimate need for set/way operations.

   This is the general shape of every trap handler you will
   write: the guest asked for something that means one thing on
   bare metal and something dangerous under virtualisation, and
   you must supply the SPIRIT of the request, not the letter. */
```

Decoding a trap when it arrives

```
/* Every trap to EL2 leaves the reason in ESR_EL2. */

    ESR_EL2[31:26]  EC   exception class
    ESR_EL2[25]     IL   instruction length (1 = 32-bit)
    ESR_EL2[24:0]   ISS  class-specific syndrome

  EC values you will meet constantly:

    0x01  trapped WFI/WFE                (HCR.TWI/TWE)
    0x03  trapped MCR/MRC cp15           (AArch32 guest)
    0x07  trapped SVE/FP/SIMD            (CPTR_EL2)
    0x16  HVC from AArch64               (deliberate hypercall)
    0x17  SMC from AArch64               (HCR.TSC)
    0x18  trapped MSR/MRS/system insn    (HCR.TVM, TID*, TACR...)
    0x20  instruction abort, lower EL    (stage-2 fetch fault)
    0x24  data abort, lower EL           (stage-2 data fault)

/* For EC=0x18 the ISS names the register precisely: */

    ISS[21:20] Op0   ISS[19:17] Op2   ISS[16:14] Op1
    ISS[13:10] CRn   ISS[9:5]   Rt    ISS[4:1]   CRm
    ISS[0]     Direction: 0 = write (MSR), 1 = read (MRS)

/* So a handler looks like: */

static int handle_sysreg_trap(struct vcpu *v)
{
        u64 esr  = read_sysreg(esr_el2);
        u32 iss  = esr & 0x1ffffff;
        int rt   = (iss >> 5) & 0x1f;
        bool is_read = iss & 1;

        const struct sysreg_desc *d = find_desc(iss);
        if (!d)
                return inject_undefined(v);   /* guest gets UNDEF */

        if (is_read)
                vcpu_set_reg(v, rt, d->get(v));
        else
                d->set(v, vcpu_get_reg(v, rt));

        /* ALWAYS advance past the trapping instruction, or you
           will execute it again, for ever.                    */
        vcpu_skip_instr(v);
        return 1;
}
```

> **FORGETTING `VCPU_SKIP_INSTR`**
> The guest re-executes the same instruction, traps again, and the VM appears to hang while burning 100% of a physical CPU. It is the single most common bug when hand-writing a trap handler, and it looks like a livelock rather than a crash. If a guest is stuck, check the exit counter — a constant, enormous exit rate with no progress is this bug.

The other trap registers

Register	Controls	Typical use
`CPTR_EL2`	FP/SIMD, SVE, SME, trace	Trap the first FP use so you can save/restore the register file lazily — a large win, since many guests never touch SVE
`MDCR_EL2`	Debug, PMU, trace buffers	Hide or partition the PMU; stop a guest from single-stepping the host
`HSTR_EL2`	AArch32 CP15 access by CRn	Only for 32-bit guests; a bitmask of coprocessor register groups
`HFGRTR_EL2` / `HFGWTR_EL2` etc.	Fine-grained traps (ARMv8.6)	Trap one individual register rather than a whole group — much cheaper than TVM when you need exactly one
`HCRX_EL2`	Extended HCR bits (ARMv8.7)	Ran out of bits in `HCR_EL2`; newer controls live here

Watching traps on a live system

```
# Every exit KVM takes is counted and typed.

$ sudo perf stat -e 'kvm:*' -a sleep 5
        12,043  kvm:kvm_entry
        12,043  kvm:kvm_exit
         8,911  kvm:kvm_mmio
           520  kvm:kvm_wfx_arm64
            17  kvm:kvm_hvc_arm64

$ sudo perf record -e kvm:kvm_exit -a -- sleep 5
$ sudo perf script | head
# the ESR_EL2 value is in the event, so you can bucket exits by EC

# Or read the per-VM counters directly:
$ sudo cat /sys/kernel/debug/kvm/*/vcpu0/*exits* 2>/dev/null

# A healthy compile-in-a-VM: a few thousand exits per second,
# nearly all MMIO to virtio queues.
# A sick one: hundreds of thousands, dominated by kvm_wfx or by
# MMIO to an emulated legacy device.
```

How it shows up

Symptom	Cause
Guest hangs, one pCPU pinned at 100%, huge exit count	Trap handler not advancing the guest PC — the same instruction traps for ever
Guest takes an unexpected undefined-instruction exception	A trapped system register with no handler; the hypervisor injected UNDEF
Guest detects features the host cannot provide, then crashes	`TID3` not set, or ID registers not sanitised — the guest read the real feature bits
Host memory corruption when a guest boots or kexecs	`TSW` clear: guest set/way cache maintenance reached lines outside the VM
Idle guest still consumes a full pCPU	`TWI` clear, so `WFI` parks the physical core instead of yielding the vCPU thread

Symptom	Cause
Guest's secure-monitor calls reach EL3 unfiltered	`TSC` clear — SMCs pass straight through EL2
Terrible performance on fork-heavy workloads	`TVM` set unnecessarily: every page table register write is an exit
Guest FP state corrupted across a vCPU switch	`CPTR_EL2` lazy-FP logic wrong — trap taken but state not saved before reuse
Guest PMU counts host activity	`MDCR_EL2` not partitioning the PMU

Check yourself

- ✓ Explain what `HCR_EL2.VM` turns on and what happens without it.
- ✓ Explain the IMO/FMO pair: what they route, and what they simultaneously enable.
- ✓ Give three bits KVM sets and three it deliberately leaves clear, with the reasoning for each.
- ✓ Explain why `DC CIVAC` is safe to leave untrapped but `DC CISW` is not.
- ✓ Decode an `ESR_EL2` with `EC=0x18` down to the specific register and direction.
- ✓ Say what happens if a trap handler returns without advancing the guest PC, and how it presents.
- ✓ Name the register that controls FP/SVE trapping and explain lazy FP save.
- ✓ Explain what fine-grained traps buy you over `TVM`.
- ✓ Measure the exit rate of a running guest and classify the exits by cause.

Stage-2 translation

The guest builds page tables and believes their output is a physical address. It is not — it is an *intermediate* physical address, and a second, entirely separate MMU translation that the guest cannot see or configure turns it into the real thing. This is the mechanism that makes modern virtualisation cheap.

Three address spaces, not two

```
BARE METAL                      UNDER A HYPERVISOR

VA  virtual address             VA   virtual address
 |   stage 1                     |    stage 1  - the GUEST'S tables,
 |   TTBR0/1_EL1                 |    TTBR0/1_EL1, guest-controlled
 v                               v
PA  physical address            IPA  INTERMEDIATE physical address
 |                               |      "what the guest calls physical"
 v                               |    stage 2 - the HYPERVISOR'S tables,
memory                           |    VTTBR_EL2, guest cannot see them
                                 v
                                PA   real physical address
                                 |
                                 v
                                memory

The guest's entire world model - "RAM starts at 0x4000_0000,
the UART is at 0x0900_0000" - is a statement about IPAs.
It can be completely false about PAs and the guest will never
know.

Crucially: the guest configures stage 1 FREELY. It writes
TTBR0_EL1 and TCR_EL1 without trapping (HCR_EL2.TVM is clear).
Whatever it produces is confined by stage 2 regardless.
```

WHY THIS REPLACED SHADOW PAGE TABLES

Under shadow paging the hypervisor had to intercept every guest page-table edit and rebuild a composed table. Under stage 2 the hardware composes on the fly. The guest edits its own tables at full speed; the hypervisor only touches stage 2 when the *memory map* changes, which is rare. Fork-heavy workloads went from crippling to free.

The registers

```
/* VTTBR_EL2 - Virtualisation Translation Table Base Register */

   bits [47:1]   BADDR   physical base of the stage-2 table
   bits [63:48]  VMID    the VM identity (or [63:56] if 8-bit)
   bit  [0]      CnP     common-not-private

/* One register carries BOTH the table pointer and the VM tag.
   Switching VMs is therefore literally one MSR. That is not an
   accident - it is what makes a vCPU switch affordable.       */

/* VTCR_EL2 - Virtualisation Translation Control Register     */

   T0SZ   [5:0]    input size: IPA space is (64 - T0SZ) bits
   SL0    [7:6]    STARTING LEVEL of the stage-2 walk
   IRGN0  [9:8]    inner cacheability of table walks
   ORGN0  [11:10]  outer cacheability
   SH0    [13:12]  shareability of table walks
   TG0    [15:14]  granule: 00=4K, 01=64K, 10=16K
   PS     [18:16]  physical address size
   VS     [19]     VMID size: 0 = 8-bit, 1 = 16-bit
   HA/HD  [21:22]  hardware access flag / dirty bit management
   NSW/NSA         secure-world controls

/* Example: 40-bit IPA space, 4K granule, 16-bit VMIDs */

   T0SZ = 64 - 40 = 24
   TG0  = 0b00
   VS   = 1
```

SL0: the part people get wrong

Stage 1 always starts its walk at a level implied by `TCR_EL1.T0SZ`. Stage 2 makes the starting level *explicit*, because the IPA space is usually smaller than a full 48-bit space and starting at level 0 would waste an entire table on one used entry. Getting `SL0` inconsistent with `T0SZ` is the classic silent stage-2 misconfiguration.

```
4K granule. Each level consumes 9 bits, leaf offset is 12.

IPA bits   levels needed         SL0 encoding   concat?
--------   --------------------  ------------   -------
<= 30      2:  L2 -> L3          0b00 (start 2)  no
31..39     3:  L1 -> L2 -> L3     0b01 (start 1)  maybe
40..48     4:  L0 -> L1 ->L2 ->L3 0b10 (start 0)  maybe

The 40-bit case, worked:

  IPA[39:30] -> level 1 index   (10 bits, not 9!)
  IPA[29:21] -> level 2 index   (9 bits)
  IPA[20:12] -> level 3 index   (9 bits)
  IPA[11:0]  -> page offset

Ten bits at the top means 1024 entries, but a 4K table holds
only 512. Stage 2 solves this with CONCATENATED TABLES: you
allocate 2 contiguous 4K tables (8K, 8K-aligned) and the
hardware treats them as one 1024-entry table.

Stage 1 has no such feature. It is unique to stage 2, it
exists purely to avoid a wasteful extra level, and up to 16
tables may be concatenated.
```

THE CONCATENATION TRAP

If your IPA size requires concatenation and you allocate one table instead of two — or allocate two that are not *contiguous and aligned to the total size* — the walk reads garbage for the upper half of the address space. Low addresses work, so the guest boots; the failure appears only when it touches memory above the halfway mark. Diagnose it by checking that `VTTBR_EL2.BADDR` is aligned to `table_size * count`, not merely to 4K.

Stage-2 descriptors differ from stage-1

```
Stage-2 block/page descriptor, lower attributes:

 63    55 54 53 52  51        12 11 10 9  8  7 6 5 4    2 1 0
+--------+--+--+--+-------------+--+--+---+--+---+------+-+-+
| ignored|XN|  |CT| output addr |nG|AF| SH |S2AP| MemAttr |1|V|
+--------+--+--+--+-------------+--+--+---+--+---+------+-+-+

The important differences from stage 1:

S2AP [7:6]   access permissions - and they are ABSOLUTE, not
             relative to a privilege level:
               00  no access
               01  read only
               10  write only   (yes, really)
               11  read/write
             There is no "EL0 vs EL1" split here. Stage 2 does
             not care which privilege level the guest was in;
             that is stage 1's business.

MemAttr[5:2] memory attributes ENCODED DIRECTLY - there is no
             MAIR indirection at stage 2:
               0b0000  Device-nGnRnE
               0b0001  Device-nGnRE
               0b0010  Device-nGRE
               0b0011  Device-GRE
               0b1111  Normal, inner+outer write-back cacheable
               0b0101  Normal, outer WT, inner non-cacheable
               ...

XN [54]      execute never. On ARMv8.2 this widens to XN[54:53]
             so you can forbid execution at EL1 but allow it
             at EL0, or vice versa.

AF [10]      access flag - set by hardware if VTCR_EL2.HA, else
             a fault the hypervisor must service.
```

How the two stages combine

```
/* PERMISSIONS: the strictest of the two wins. Always. */

   stage 1 says RW, stage 2 says RO   -> read only
   stage 1 says RO, stage 2 says RW   -> read only
   stage 1 says X,  stage 2 says XN   -> no execute

/* There is no way for a guest to widen a permission stage 2
   denied. That is the isolation guarantee, in one line.     */

/* MEMORY TYPE: the more restrictive/stronger type wins.      */

   stage 1 Normal WB  + stage 2 Normal WB     -> Normal WB
   stage 1 Normal WB  + stage 2 Device        -> DEVICE
   stage 1 Device     + stage 2 Normal        -> Device
   stage 1 Normal NC  + stage 2 Normal WB     -> Normal NC

/* "Device beats Normal, non-cacheable beats cacheable."

   This has a consequence people trip over constantly: if the
   hypervisor maps guest RAM as Device at stage 2 (perhaps by
   accident, perhaps because it came from a PCI BAR), then the
   guest's careful Normal-cacheable mapping is DOWNGRADED. The
   guest's unaligned accesses now fault, its exclusives may
   fail, and its memcpy throughput collapses. The guest is
   blameless and its page tables look perfect.               */

/* HCR_EL2.DC and HCR_EL2.FWB modify this:

   DC  = 1 : while the guest's stage-1 MMU is OFF, treat its
             accesses as Normal cacheable rather than Device.
             Used during guest boot so early code is coherent.

   FWB = 1 : (ARMv8.4) "forced write-back" - stage 2 OVERRIDES
             stage 1 rather than combining with it. Simplifies
             the hypervisor enormously: you stop caring what the
             guest chose. Modern KVM uses it where available.  */
```

The full walk, counted

```
A single guest load, worst case, 4K granule, 48-bit VA,
40-bit IPA, cold TLB:

stage 1 walk needs 4 table reads (L0,L1,L2,L3).
BUT each of those reads produces an IPA, which must itself
be translated by stage 2 - and stage 2 is a 3-level walk.

  s1 L0 descriptor address (an IPA) -> 3 stage-2 reads
  s1 L1 descriptor address (an IPA) -> 3 stage-2 reads
  s1 L2 descriptor address (an IPA) -> 3 stage-2 reads
  s1 L3 descriptor address (an IPA) -> 3 stage-2 reads
  final IPA from stage 1            -> 3 stage-2 reads
  ------------------------------------------------------
                                      15 stage-2 reads
                                    +  4 stage-1 reads
                                    = 19 memory accesses
                                      for ONE load.

With a 4-level stage 2 it reaches 24. This is why:

  * TLBs matter more under virtualisation, not less
  * huge pages / blocks at stage 2 are a big win (they cut
    stage-2 levels AND increase reach)
  * the walk cache (intermediate descriptors) is critical
  * VMID tagging is essential - flushing on every VM switch
    would mean paying this cost constantly
```

Building a stage-2 table

```
/* Minimal, illustrative. 4K granule, 40-bit IPA, so a 3-level
   walk starting at level 1 with 2 concatenated L1 tables.    */

#define S2_VALID      (1UL << 0)
#define S2_TABLE      (3UL << 0)   /* valid + table            */
#define S2_BLOCK      (1UL << 0)   /* valid + block            */
#define S2_PAGE       (3UL << 0)   /* valid + page (level 3)   */
#define S2_AF         (1UL << 10)
#define S2_SH_IS      (3UL << 8)
#define S2_AP_RW      (3UL << 6)
#define S2_AP_RO      (1UL << 6)
#define S2_MEM_NORMAL (0xfUL << 2)
#define S2_MEM_DEVICE (0x1UL << 2)  /* Device-nGnRE            */
#define S2_XN         (1UL << 54)

static u64 *l1;    /* 2 contiguous 4K pages, 8K-aligned        */

void s2_map_block_2m(u64 ipa, u64 pa, bool device, bool exec)
{
        u64 *l2 = get_or_alloc_l2(l1, ipa);
        u64  attr = S2_BLOCK | S2_AF | S2_SH_IS | S2_AP_RW
                  | (device ? S2_MEM_DEVICE : S2_MEM_NORMAL)
                  | (exec ? 0 : S2_XN);

        l2[(ipa >> 21) & 0x1ff] = (pa & ~0x1fffffUL) | attr;

        /* Publish before any walker can see it. */
        dsb(ishst);
}

void s2_enable(u64 vttbr_base, u16 vmid)
{
        u64 vtcr = (24UL << 0)       /* T0SZ: 40-bit IPA        */
                 | (1UL  << 6)       /* SL0 = 1: start level 1  */
                 | (3UL  << 8)       /* IRGN0 = WBWA            */
                 | (3UL  << 10)      /* ORGN0 = WBWA            */
                 | (3UL  << 12)      /* SH0 = inner shareable   */
                 | (0UL  << 14)      /* TG0 = 4K                */
                 | (2UL  << 16)      /* PS = 40-bit PA          */
                 | (1UL  << 19);     /* VS = 16-bit VMID        */

        write_sysreg(vtcr, vtcr_el2);
        write_sysreg(((u64)vmid << 48) | vttbr_base, vttbr_el2);
        isb();

        /* Only now turn stage 2 on. */
        write_sysreg(read_sysreg(hcr_el2) | HCR_VM, hcr_el2);
        isb();
}
```

Invalidating stage-2 entries

```
/* Stage-2 has its own TLBI instructions, and they take IPAs. */

    TLBI IPAS2E1IS,  x0    /* by IPA, current VMID, inner-shareable
                              x0 = IPA >> 12                    */
    TLBI IPAS2LE1IS, x0    /* ...last level only                */
    TLBI VMALLS12E1IS      /* all stage-1 AND stage-2 entries for
                              the current VMID                   */
    TLBI ALLE1IS           /* all EL1 entries, all VMIDs         */
    TLBI VMALLE1IS         /* stage-1 only, current VMID         */

/* The sequence that actually works when you unmap a page: */

    write the descriptor to 0
    dsb(ishst);                 /* descriptor is visible         */
    tlbi ipas2e1is, ipa >> 12;
    dsb(ish);                   /* invalidation has completed    */
    tlbi vmalle1is;             /* stage-1 entries CACHED THE
                                   COMBINED translation - they
                                   must go too!                  */
    dsb(ish);
    isb();

/* That second TLBI surprises people. A stage-1 TLB entry holds
   a VA -> PA mapping that already folded stage 2 in. Changing
   stage 2 therefore invalidates stage-1 entries, even though
   the guest's stage-1 tables did not change.                  */
```

How it shows up

Symptom	Cause
Guest boots, then dies once it touches high memory	Concatenated tables not allocated contiguously or not aligned to the combined size
Stage-2 walk reads nonsense immediately	`SL0` inconsistent with `T0SZ` — the walk starts at the wrong level
Guest memcpy is 10x slow; unaligned accesses fault	Guest RAM mapped as Device at stage 2; the combine rule downgraded the guest's Normal mapping
Guest exclusives (`LDXR` / `STXR`) never succeed	Same cause — exclusives require Normal memory
Guest sees stale data after the hypervisor remaps memory	Missing `TLBI VMALLE1IS` after the stage-2 invalidate
Second VM sees the first VM's translations	VMID not changed, or VMID rollover without a global invalidate
Guest cannot execute from a page it can read	Stage-2 `XN` set — common when memory was mapped through a device path
Performance collapses under memory pressure	Stage 2 built entirely from 4K pages; no blocks, so every walk is maximal
Works with the guest MMU off, breaks when it turns it on	`HCR_EL2.DC` was papering over a stage-2 attribute mistake that becomes visible once stage 1 is live

Check yourself

- ✓ Define VA, IPA and PA and say which software owns the translation between each pair.
- ✓ Explain why stage 2 replaced shadow page tables and what it bought.
- ✓ Explain what `VTTBR_EL2` holds besides a table address, and why that matters for switch cost.

- ✓ Given a 40-bit IPA and a 4K granule, work out `T0SZ`, `SL0` and whether concatenation is needed.
- ✓ Name three ways a stage-2 descriptor differs from a stage-1 one.
- ✓ State the permission-combining rule and the memory-type-combining rule.
- ✓ Explain how mapping guest RAM as Device at stage 2 breaks a guest that looks correct.
- ✓ Count the memory accesses in a worst-case two-stage walk and say what reduces it.
- ✓ Write the correct invalidation sequence for unmapping a stage-2 page, and justify the second TLBI.

Stage-2 faults and how to decode them

A stage-2 fault is not an error. It is the hypervisor's primary input channel: it is how demand paging, MMIO emulation, dirty tracking, ballooning and copy-on-write all get their work. Learning to read one exactly is the difference between guessing and knowing.

A fault is a request

```
The guest does something perfectly ordinary:

    LDR x0, [x1]        where x1 -> 0x0900_0000 (its UART)
                      or x1 -> 0x4100_0000 (its RAM)

Stage 1 translates: VA -> IPA. Fine, the guest's own tables.
Stage 2 translates: IPA -> PA. And here it may say NO.

    +-------------------------------------------------+
    |  stage-2 descriptor invalid, or permission      |
    |  insufficient  ->  DATA ABORT to EL2            |
    +-------------------------------------------------+
                      |
                      v
    hypervisor asks: WHY did I leave that unmapped?

      "because there is no RAM there, but there IS a
       device model"        -> emulate the access (ch. 13)

      "because I have not allocated backing memory yet"
                           -> allocate, map, retry

      "because I am tracking which pages the guest writes"
                           -> record it, make writable, retry

      "because I swapped it out"
                           -> page it back in, map, retry

      "because the guest is genuinely misbehaving"
                           -> inject an abort into the guest

FIVE different meanings, one hardware event. Everything
depends on decoding it correctly.
```

The three registers that describe a fault

Register	Holds	Caveat
`ESR_EL2`	Exception class and syndrome: what kind of access, what size, which register, why it faulted	The syndrome is only *partly* valid — check `ISV`
`FAR_EL2`	The faulting **virtual** address	Meaningless to the hypervisor on its own — it is a guest VA, in the guest's address space
`HPFAR_EL2`	The faulting **IPA**, bits [47:12], shifted right by 8	This is the one you actually want. It exists *because* `FAR_EL2` is useless

```
/* Reconstructing the faulting IPA */

    u64 hpfar = read_sysreg(hpfar_el2);
    u64 far   = read_sysreg(far_el2);

    u64 ipa = (hpfar & GENMASK(47, 4)) << 8;   /* page-aligned  */
    ipa |= far & 0xfff;                        /* offset in page */

/* HPFAR gives you the PAGE. The low 12 bits of the byte offset
   come from FAR - and that is legitimate, because stage 1 does
   not change the low 12 bits of an address.                   */
```

Decoding ESR_EL2

```
   EC = 0x24  Data Abort from a lower EL   (stage-2 data fault)
   EC = 0x20  Instruction Abort, lower EL   (stage-2 fetch fault)

   ISS layout for a data abort:

    24  23 22 21 20 19  16 15 14 13 12 11 10  9  8  7 6 5     0
   +---+---+---+--+---+-----+--+--+--+--+---+--+--+--+---------+
   |ISV| SAS |SSE| SRT  |SF|AR| VNCR|SET|FnV|EA|CM|S1PTW|WnR|DFSC|
   +---+---+---+--+---+-----+--+--+--+--+---+--+--+--+---------+

   ISV   [24]     Instruction Syndrome Valid. If 0, the fields
                  below are NOT populated and you must decode the
                  guest instruction yourself.
   SAS   [23:22]  access size: 00=byte 01=half 10=word 11=double
   SSE   [21]     sign extend
   SRT   [20:16]  the guest register number involved
   SF    [15]     64-bit register
   AR    [14]     acquire/release semantics
   S1PTW [7]      the fault happened while walking a STAGE-1
                  table - i.e. the guest's own page table lives
                  in a page you have not mapped
   WnR   [6]      1 = write, 0 = read
   DFSC  [5:0]    the actual fault status code
```

DFSC	Meaning	What the hypervisor usually does
`0b000100` – `0b000111`	Translation fault, level 0–3	Nothing was mapped. Allocate and map, or route to a device model
`0b001000` – `0b001011`	Access flag fault, level 0–3	Set AF; used to build a page-age estimate for reclaim
`0b001100` – `0b001111`	Permission fault, level 0–3	Mapped but not with these rights. Dirty tracking, CoW, or a real guest violation
`0b010000`	External abort, not on a table walk	The bus said no. Real hardware error — usually fatal
`0b010100` – `0b010111`	External abort on a table walk	Your stage-2 tables are in unbacked or faulty memory
`0b100001`	Alignment fault	Guest did an unaligned access to Device memory — see the attribute-downgrade trap in chapter 5
`0b110000`	TLB conflict abort	Overlapping TLB entries. Invalidate everything and retry

The ISV=0 problem

When `ISV` is 1 the hardware hands you the access size, direction and register number, and MMIO emulation is trivial. When it is 0 you get none of that, and you must fetch and decode the guest's instruction yourself — from guest memory, at a guest VA, which may itself be unmapped.

```
/* ISV is 0 for, among others:

     - any instruction abort (there is no data operand)
     - load/store multiple  (LDP/STP is fine; LDM on AArch32 is not)
     - loads/stores with writeback in some cases
     - DC ZVA and other cache operations
     - accesses to a page where S1PTW is set
     - anything the implementation simply chose not to report

   Consequence: a hypervisor CANNOT rely on ISV. KVM's answer is
   blunt and correct: if ISV is 0 on an MMIO access, refuse.   */

  if (!(esr & ESR_ELx_ISV)) {
          kvm_pr_unimpl("Data abort outside memslots with no valid syndrome\n");
          return -ENOSYS;      /* the VM dies                   */
  }

/* Which is why a guest driver that does this:

       ldp x0, x1, [x2]        // load pair from an MMIO region

   can kill the VM outright while the equivalent

       ldr x0, [x2]
       ldr x1, [x2, #8]

   works perfectly. It is not a bug in your driver on hardware.
   It is a rule you only discover under virtualisation:

     NEVER use load/store-multiple, DC ZVA, or unaligned access
     on memory-mapped device registers.

   Linux enforces this by making you go through readl/writel,
   which compile to single loads and stores for exactly this
   reason.                                                    */
```

> **THE `MEMCPY`-TO-MMIO BUG**
>
> `memcpy()` into a device region compiles to `LDP` / `STP` and possibly `DC ZVA`. On hardware it usually works. Under a hypervisor it produces `ISV=0` and the VM is killed with "no valid syndrome". Use `memcpy_toio()` / `__iowrite32_copy()`, or explicit `writel()` loops.

S1PTW: the nested fault

```
The guest's stage-1 page table is itself in guest memory.
That memory has an IPA. That IPA needs stage-2 translation.

  guest executes    LDR x0, [x1]
     |
     v
  stage-1 walk needs to read the L2 descriptor
     |  descriptor lives at guest-physical 0x4020_3000
     v
  stage 2 asked to translate IPA 0x4020_3000
     |
     v
  NOT MAPPED  ->  data abort to EL2, with S1PTW = 1

Meaning: "I faulted while fetching the guest's own page
table, not while performing the guest's actual access."

Why you must care:
  * WnR is meaningless-ish: the walk may be a READ even
    though the guest's access was a WRITE. Do not use WnR to
    decide writability here. (With hardware dirty-bit
    management the walk may genuinely write, which is why
    modern code checks both.)
  * ISV is 0.
  * You must map the page and RETRY. Do not try to emulate.
  * If the IPA has no memory behind it at all, the guest has
    put its page tables in a device region or in a hole. That
    is a guest bug and deserves an injected abort.
```

A fault handler, end to end

```
int handle_stage2_abort(struct vcpu *v)
{
        u64  esr   = read_sysreg(esr_el2);
        u32  dfsc  = esr & 0x3f;
        bool write = esr & ESR_ELx_WNR;
        bool s1ptw = esr & ESR_ELx_S1PTW;
        u64  ipa   = (read_sysreg(hpfar_el2) & GENMASK(47,4)) << 8;

        ipa |= read_sysreg(far_el2) & 0xfff;

        /* 1. Is this address backed by guest RAM at all? */
        struct memslot *slot = find_memslot(v->vm, ipa);

        if (!slot) {
                /* No RAM. Either a device we model, or nowhere. */
                if (s1ptw)
                        return inject_abort(v);   /* page tables
                                                     in a hole  */
                if (!(esr & ESR_ELx_ISV))
                        return -ENOSYS;           /* cannot emulate */
                return emulate_mmio(v, ipa, esr); /* chapter 13  */
        }

        /* 2. Backed by RAM. Why did it fault? */
        switch (dfsc & ~3) {                /* mask off the level */
        case FSC_TRANSLATION:               /* nothing mapped     */
                return map_page(v, ipa, slot, write);

        case FSC_ACCESS_FLAG:               /* aging              */
                return set_access_flag(v, ipa);

        case FSC_PERMISSION:
                if (write && dirty_logging_enabled(v->vm)) {
                        mark_page_dirty(v->vm, ipa);
                        return make_writable(v, ipa);
                }
                if (write && is_cow(slot, ipa))
                        return do_copy_on_write(v, ipa);
                return inject_abort(v);     /* genuine violation  */

        case FSC_EXTERNAL:
                return inject_serror(v);    /* the bus said no    */

        default:
                return inject_abort(v);
        }
        /* NOTE: no vcpu_skip_instr anywhere. After mapping a page
           we RETRY the guest instruction; it must run again. This
           is the opposite of a system-register trap.           */
}
```

> **RETRY VERSUS SKIP**
>
> A system-register trap is *emulated*, so you advance the guest PC past it. A stage-2 translation fault is *fixed*, so you leave the PC alone and let the instruction re-execute. Skipping after a translation fault silently drops the guest's load or store; retrying after an emulated MMIO write performs it twice. Both are ugly, intermittent bugs.

Dirty tracking, which is just permission faults on purpose

```
/* Live migration needs to know which guest pages changed while
   it was copying. There is no hardware "dirty log" for stage 2
   on most parts, so KVM builds one out of faults:            */

  1. write-protect every stage-2 mapping        (S2AP = read only)
  2. copy all guest memory to the destination
  3. guest writes a page -> PERMISSION FAULT at stage 2
     handler: record the page number in a bitmap,
              set S2AP = RW, TLBI, retry
  4. re-copy the pages in the bitmap
  5. repeat 3-4 until the dirty set is small
  6. pause the guest, copy the remainder, switch over

/* Cost: one exit per page, per round. A guest writing memory
   faster than you can copy it never converges - that is the
   classic "migration never completes" failure, and the fix is
   either to throttle the guest or to give up and pause it.

   ARMv8.1 hardware dirty-bit management (VTCR_EL2.HD) lets the
   PTW set the dirty bit itself, removing the exit. Where it
   exists, KVM uses it and migration gets dramatically cheaper. */
```

Seeing faults on a live system

```
$ sudo perf stat -e 'kvm:kvm_*' -a sleep 5
       142,551  kvm:kvm_exit
        98,204  kvm:kvm_mmio                # device emulation
        31,880  kvm:kvm_guest_fault         # stage-2 faults
           440  kvm:kvm_set_spte_hva

# Per-fault detail, including the IPA and the ESR:
$ sudo perf record -e kvm:kvm_guest_fault -a -- sleep 2
$ sudo perf script | head -3
 CPU 2 ... kvm_guest_fault: ipa 0x40a13000 hsr 0x93000047 hxfar 0xffff800010a13000

#   hsr  = ESR_EL2  -> 0x93000047
#     EC   = 0x24  data abort, lower EL
#     ISV  = 1
#     WnR  = 1     it was a write
#     DFSC = 0x07  translation fault, level 3
#   So: guest wrote to an unmapped page; KVM will allocate one.

# Inside a guest, the other side of the same story:
$ sudo dmesg | grep -i 'unhandled fault\|synchronous external abort'
```

How it shows up

Symptom	Cause
`Data abort outside memslots with no valid syndrome`, VM killed	`ISV=0` on an MMIO access — the guest used `LDP` / `STP`, `memcpy` or `DC ZVA` on a device region
Guest load returns a stale or wrong value once in a while	Handler advanced the PC after fixing a translation fault, dropping the access
Emulated device sees each write twice	Handler retried instead of skipping after emulating an MMIO access

Symptom	Cause
Infinite fault loop on one address	Descriptor written but no `DSB` / `TLBI`, so the walker keeps seeing the old entry
Guest dies during early boot with an abort on its own page tables	`S1PTW` fault the handler treated as MMIO
Live migration never converges	Guest dirties pages faster than they can be copied; no hardware dirty-bit support and no throttling
Alignment faults inside a guest that works on hardware	Stage-2 attributes downgraded the region to Device
Fault reported at a guest VA that makes no sense	Reading `FAR_EL2` instead of `HPFAR_EL2`
Guest sees SError shortly after an abort	External abort turned into an SError injection — usually genuinely broken hardware or a bad DMA target

Check yourself

- ✓ List five different reasons a hypervisor might deliberately leave a stage-2 mapping absent.
- ✓ Explain why `FAR_EL2` is insufficient and what `HPFAR_EL2` provides.
- ✓ Reconstruct a full faulting IPA from `HPFAR_EL2` and `FAR_EL2`.
- ✓ Decode `ESR_EL2 = 0x93000047` completely.
- ✓ Explain `ISV`, name three cases where it is 0, and say what a hypervisor does then.
- ✓ Explain why `memcpy()` to MMIO can kill a VM but works on bare metal.
- ✓ Define `S1PTW` and explain why `WnR` is unreliable when it is set.
- ✓ State the rule for when to retry the guest instruction and when to skip it.
- ✓ Describe how dirty-page tracking is built from permission faults, and what `VTCR_EL2.HD` changes.

Memory attributes and cacheability under virtualisation

Two independent pieces of software now describe the same byte of memory, and the hardware combines their opinions with a rule neither of them chose. Most "impossible" virtualisation bugs — a guest that boots but corrupts data, a device that reads zeroes, an exclusive that never succeeds — live here.

The combining rule

```
For every access, the CPU has TWO opinions about the memory:

  stage 1 attribute   (guest's MAIR_EL1 + descriptor AttrIndx)
  stage 2 attribute   (hypervisor's descriptor MemAttr[3:0])

and it must produce ONE. The rule is "most restrictive wins":

  TYPE           Device beats Normal
  CACHEABILITY   Non-cacheable beats Write-Through
                 Write-Through   beats Write-Back
  SHAREABILITY   Outer beats Inner beats Non-shareable
  DEVICE STRENGTH nGnRnE beats nGnRE beats nGRE beats GRE

Worked cases:

  s1 Normal WB, s2 Normal WB      -> Normal WB       (good)
  s1 Normal WB, s2 Normal NC      -> Normal NC       (slow)
  s1 Normal WB, s2 Device-nGnRE   -> Device-nGnRE    (broken)
  s1 Device,    s2 Normal WB      -> Device          (fine)
  s1 Normal WB, s2 Device-nGnRnE  -> Device-nGnRnE   (very broken)

The GUEST cannot escape upward. It can only make things
stricter than the hypervisor allowed - never looser.

Which means: if the hypervisor gets stage 2 wrong, the guest
has NO WAY to compensate, and its own page tables will look
completely correct while it misbehaves.
```

THE ASYMMETRY THAT MATTERS

Isolation only requires stage 2 to restrict *permissions*. Restricting *memory type* is a side effect of the same mechanism, and it is almost never what you want for ordinary RAM. Map guest RAM as Normal, Inner-Shareable, Write-Back at stage 2 and let the guest decide. Anything else is a bug waiting for a workload.

What Device memory actually costs a guest

Property	Normal memory	Device memory
Unaligned access	Allowed	**Alignment fault**
`LDXR` / `STXR` exclusives	Work	**Constrained unpredictable** — in practice, never succeed
Speculative reads	Allowed	Forbidden
Access merging / reordering	Allowed	Restricted per nGnRE flavour
Caching	Yes	Never
Throughput for a bulk copy	GB/s	Tens of MB/s

Property	Normal memory	Device memory
`DC ZVA`	Works	Faults

An arm64 Linux guest whose RAM is Device at stage 2 will typically boot — early boot code is careful and aligned — and then die the moment the C library uses an optimised `memcpy`, or the moment `futex` takes an exclusive. The symptom looks like memory corruption or a scheduler hang, and nothing in the guest points at the real cause.

FWB: making the guest's opinion irrelevant

ARMv8.4-S2FWB ("stage-2 force write-back") changes the rule from *combine* to *override*. It exists because the combining rule made a whole class of hypervisor bugs unavoidable.

```
/* Without FWB, the hypervisor has a problem it cannot solve:

   The guest boots with its MMU OFF. All its accesses are
   therefore Device-nGnRnE (that is the architectural default
   when stage 1 is disabled). The hypervisor, meanwhile, has
   the page mapped Normal cacheable and has written the kernel
   image into it THROUGH THE CACHE.

   Guest reads with MMU off  -> Device -> bypasses the cache
                             -> reads STALE DRAM
                             -> reads garbage instead of the
                                kernel it was given.

   Historic fixes, both unpleasant:
     a) HCR_EL2.DC = 1: force the guest's stage-1-disabled
        accesses to be treated as Normal cacheable. Works, but
        it lies to a guest that genuinely wanted Device access
        to a real device before enabling its MMU.
     b) The hypervisor cleans the entire guest image to the
        point of coherency before every VM entry where the
        guest MMU is off. Correct and very slow.              */

/* With HCR_EL2.FWB = 1:

     stage 2 MemAttr is no longer combined - it WINS.

     s2 MemAttr = 0b0110  ->  Normal, Write-Back, whatever
                              stage 1 says. Including when
                              stage 1 is disabled.
     s2 MemAttr = 0b0101  ->  Normal, Non-Cacheable, forced
     s2 MemAttr = 0b0001  ->  Device-nGnRE, forced

   The hypervisor now states the truth once, in one place, and
   the guest's stage-1 attributes only affect ordering and
   sharing - not cacheability. KVM enables FWB whenever the
   silicon has it, and a large amount of cache-maintenance code
   becomes dead.                                              */
```

Who cleans the cache, and when

```
Three participants, three different views of memory:

  the GUEST      writes through its cache
  the HYPERVISOR writes through its cache (a different
                 virtual mapping of the same physical page!)
  a DEVICE doing DMA  may or may not be coherent

ALIASING: the hypervisor maps guest RAM into its own address
space to load a kernel image, to emulate a device, or to
migrate the VM. That is a SECOND virtual mapping of the same
physical memory, potentially with different attributes. On
ARM, mismatched attributes for the same physical address are
architecturally UNPREDICTABLE - not merely slow.

The rules that keep you safe:

1. Hypervisor and guest should both use Normal WB Inner-
   Shareable for RAM. Then the coherent interconnect handles
   it and NO maintenance is needed.

2. If the hypervisor writes guest memory while the guest's
   MMU is off (loading a kernel), it must either
     - clean to the Point of Coherency afterwards, or
     - rely on HCR_EL2.DC / FWB.

3. If a NON-COHERENT device will read that memory, someone
   must clean it. Under passthrough this is the GUEST'S
   driver, and it works - the guest's DC CVAC operates on
   the right physical lines because stage 2 translated the
   address.

4. Never map the same page as Device in one place and Normal
   in another. This is the mismatched-attribute rule, and
   the failure is silent and rare enough to reach
   production.
```

> **THE MISMATCHED-ALIAS BUG**
>
> A hypervisor maps a guest's framebuffer as Device (because it came from a PCI BAR) while the guest maps it Normal Non-Cacheable (because that is what framebuffers want). Both mappings are "reasonable"; together they are architecturally unpredictable. Symptoms: tearing, occasional wrong pixels, and behaviour that changes with CPU model. Fix the hypervisor mapping, not the guest.

HCR_EL2.DC and the boot window

```
/* The window: from "hypervisor ERETs into the guest" to
   "guest sets SCTLR_EL1.M = 1". Perhaps a few thousand
   instructions, and every one of them is dangerous.        */

  HCR_EL2.DC = 1   effect while the guest's stage-1 MMU is OFF:

     the guest's accesses are treated as
         Normal, Inner-Shareable, Write-Back Read/Write-Allocate
     instead of
         Device-nGnRnE

     and stage 1 is forced to behave as if disabled anyway.

  WHY YOU WANT IT:
     the hypervisor wrote the kernel image through its cache;
     the guest can now read it coherently without anyone
     performing cache maintenance.

  WHY IT IS NOT FREE:
     a guest that legitimately wants to touch a real device
     before enabling its MMU now does so through the cache.
     For most guests this never happens. For a bare-metal
     payload that pokes a UART before MMU setup, it does -
     and the character never appears.

  KVM's actual policy (simplified):
     if FWB is available          -> use FWB, leave DC clear
     else if guest MMU is off     -> set DC
     else                         -> clear DC
   and it re-evaluates on every trap that could have changed
   SCTLR_EL1.M. That is one reason KVM traps SCTLR_EL1 writes
   on hardware without FWB, and does not on hardware with it. */
```

Checking what a guest really got

```
# From the HOST, dump KVM's stage-2 view. (Requires
# CONFIG_PTDUMP_DEBUGFS and a debug kernel; not all builds.)
$ sudo ls /sys/kernel/debug/kvm/
  1234-5/    # one directory per VM

# From the GUEST, look at what stage 1 asked for:
$ sudo cat /sys/kernel/debug/kernel_page_tables | head -20

# The practical test, from inside the guest - does it BEHAVE
# like Normal memory?

$ cat > attrtest.c <<'EOF'
#include <stdio.h>
#include <stdint.h>
int main(void) {
        static _Alignas(64) uint8_t buf[128];
        /* 1. unaligned access - faults on Device memory */
        volatile uint32_t *p = (uint32_t *)(buf + 1);
        *p = 0xdeadbeef;
        printf("unaligned ok: %08x\n", *p);

        /* 2. exclusives - never succeed on Device memory */
        uint32_t v = 0;
        int ok = __atomic_compare_exchange_n(&v, &(uint32_t){0}, 1,
                        0, __ATOMIC_SEQ_CST, __ATOMIC_SEQ_CST);
        printf("cas ok: %d\n", ok);
        return 0;
}
EOF
$ gcc attrtest.c -o attrtest && ./attrtest
unaligned ok: deadbeef
cas ok: 1

# A SIGBUS on test 1, or cas ok: 0 forever, means your RAM is
# not Normal memory. That is a stage-2 problem, in the host.

# Throughput is the blunt instrument that finds it fastest:
$ dd if=/dev/zero of=/dev/null bs=1M count=2000
# GB/s = Normal.  Tens of MB/s = Device. There is no middle.
```

Attributes for passed-through devices

```
/* When you assign a real device to a guest (chapter 16), its
   MMIO region must be Device at BOTH stages.               */

   stage 2: MemAttr = 0b0001  Device-nGnRE
            S2AP    = 0b11    read/write
            XN      = 1       never execute a device register

/* Getting this wrong in the permissive direction is the
   dangerous one: mapping a device region as Normal cacheable
   at stage 2 means

     - writes sit in the cache and reach the device late,
       out of order, or merged
     - the CPU may SPECULATIVELY READ device registers, which
       for many devices has side effects (clear-on-read status,
       FIFO pop). A speculative read can dequeue data nobody
       asked for.

   That last one is not theoretical. Speculatively reading a
   UART's RX FIFO loses characters that were never delivered to
   anyone. Always XN and always Device for MMIO.             */

/* And the reverse for the DMA buffers that device will use:
   they are ordinary RAM and must be Normal. A common bring-up
   mistake is to map an entire "device" range - registers AND
   the shared descriptor ring - as Device, then wonder why
   throughput is dreadful.                                   */
```

How it shows up

Symptom	Cause
Guest boots, then SIGBUS on unaligned access in libc	Guest RAM is Device at stage 2
Guest hangs in `futex` or spinlocks; exclusives never succeed	Same — exclusives require Normal memory
Guest memory bandwidth is 10–50x below the host's	Stage 2 forced Non-Cacheable or Device
Guest reads garbage instead of its own kernel image at boot	Hypervisor wrote through the cache; guest read with MMU off as Device. Needs `DC` or FWB or a clean
Bare-metal guest's early UART output is missing	`HCR_EL2.DC` set, so the pre-MMU device write went into the cache
Framebuffer tears or shows stale pixels	Mismatched aliases: Device in one mapping, Normal in another
Passed-through UART loses received characters	MMIO mapped Normal at stage 2; speculative reads popped the FIFO
Passed-through device DMA reads stale data	Descriptor ring mapped Device, or non-coherent device with no cache maintenance
Behaviour differs between two CPU models on the same code	Mismatched-attribute aliasing — architecturally unpredictable, so implementations differ
Everything above disappears on a newer SoC	That SoC has S2FWB and KVM stopped combining

Check yourself

- ✓ State the combining rule for type, cacheability and shareability, and apply it to four stage-1/stage-2 pairs.
- ✓ Explain why a guest cannot compensate for a stage-2 attribute mistake.
- ✓ List five things that break when RAM is Device instead of Normal.
- ✓ Explain the boot-window problem and the two historic fixes for it.
- ✓ Say what `HCR_EL2.DC` does, and give a case where setting it is wrong.
- ✓ Explain what S2FWB changes and why it deletes hypervisor code.
- ✓ Define the mismatched-alias rule and give a realistic example.
- ✓ Give the correct stage-2 attributes for a passed-through device's registers and for its DMA buffers.
- ✓ Describe two tests you can run inside a guest to prove its RAM is Normal memory.

The vCPU and the world switch

A vCPU is a data structure plus a promise: that whenever it runs, the physical CPU looks exactly the way that vCPU last left it. Keeping that promise is the world switch, and its length in instructions is the tax every guest pays on every exit.

What a vCPU is

```
struct vcpu – conceptually, three groups of state:

+-----------------------------------------------------------+
|  GUEST CPU STATE – must be identical on resume            |
|    x0–x30, SP_EL0, SP_EL1, PC (in ELR_EL2), PSTATE        |
|    FP/SIMD/SVE register file                              |
|    SCTLR_EL1 TTBR0_EL1 TTBR1_EL1 TCR_EL1 MAIR_EL1         |
|    VBAR_EL1 ESR_EL1 FAR_EL1 ELR_EL1 SPSR_EL1 AMAIR_EL1    |
|    CONTEXTIDR_EL1 TPIDR_EL0 TPIDRRO_EL0 TPIDR_EL1         |
|    CPACR_EL1 PAR_EL1 CSSELR_EL1 ...                       |
+-----------------------------------------------------------+
|  VIRTUAL HARDWARE – state of the devices this vCPU owns   |
|    vGIC CPU interface + list registers  (chapter 10)      |
|    virtual timer: CNTV_CTL, CNTV_CVAL, CNTVOFF (chapter 12)|
|    virtual PMU counters                                   |
|    MPIDR / MIDR the guest should see (VMPIDR/VPIDR_EL2)   |
+-----------------------------------------------------------+
|  HYPERVISOR BOOKKEEPING – never seen by the guest         |
|    pointer to the owning VM (and thus to VTTBR/VMID)      |
|    exit reason, exit counters                             |
|    pending interrupt injections                           |
|    the host thread this vCPU is running on                |
|    run state: runnable / halted (WFI) / stopped           |
+-----------------------------------------------------------+

In KVM this structure lives in the host kernel and is
reachable from user space through a per-vCPU file
descriptor and a shared page (kvm_run).
```

A VCPU IS A THREAD

In KVM, one vCPU is one host thread that spends its life in a loop: `ioctl(vcpu_fd, KVM_RUN)` enters the guest, returns when something needs handling, user space or the kernel handles it, repeat. Every consequence of that follows: vCPUs are scheduled by the ordinary Linux scheduler, they can be pinned with `taskset`, they show up in `top`, and a vCPU blocked in `WFI` is a thread blocked on a wait queue.

The run loop

```
/* User space (QEMU, crosvm, cloud-hypervisor): one thread per vCPU */

void *vcpu_thread(void *arg)
{
        struct vcpu *v = arg;

        for (;;) {
                ioctl(v->fd, KVM_RUN, 0);     /* blocks in the guest */

                switch (v->kvm_run->exit_reason) {

                case KVM_EXIT_MMIO:
                        /* the guest touched an address we model  */
                        mmio_dispatch(v->kvm_run->mmio.phys_addr,
                                      v->kvm_run->mmio.data,
                                      v->kvm_run->mmio.len,
                                      v->kvm_run->mmio.is_write);
                        break;

                case KVM_EXIT_HYPERCALL:
                        handle_hypercall(v);
                        break;

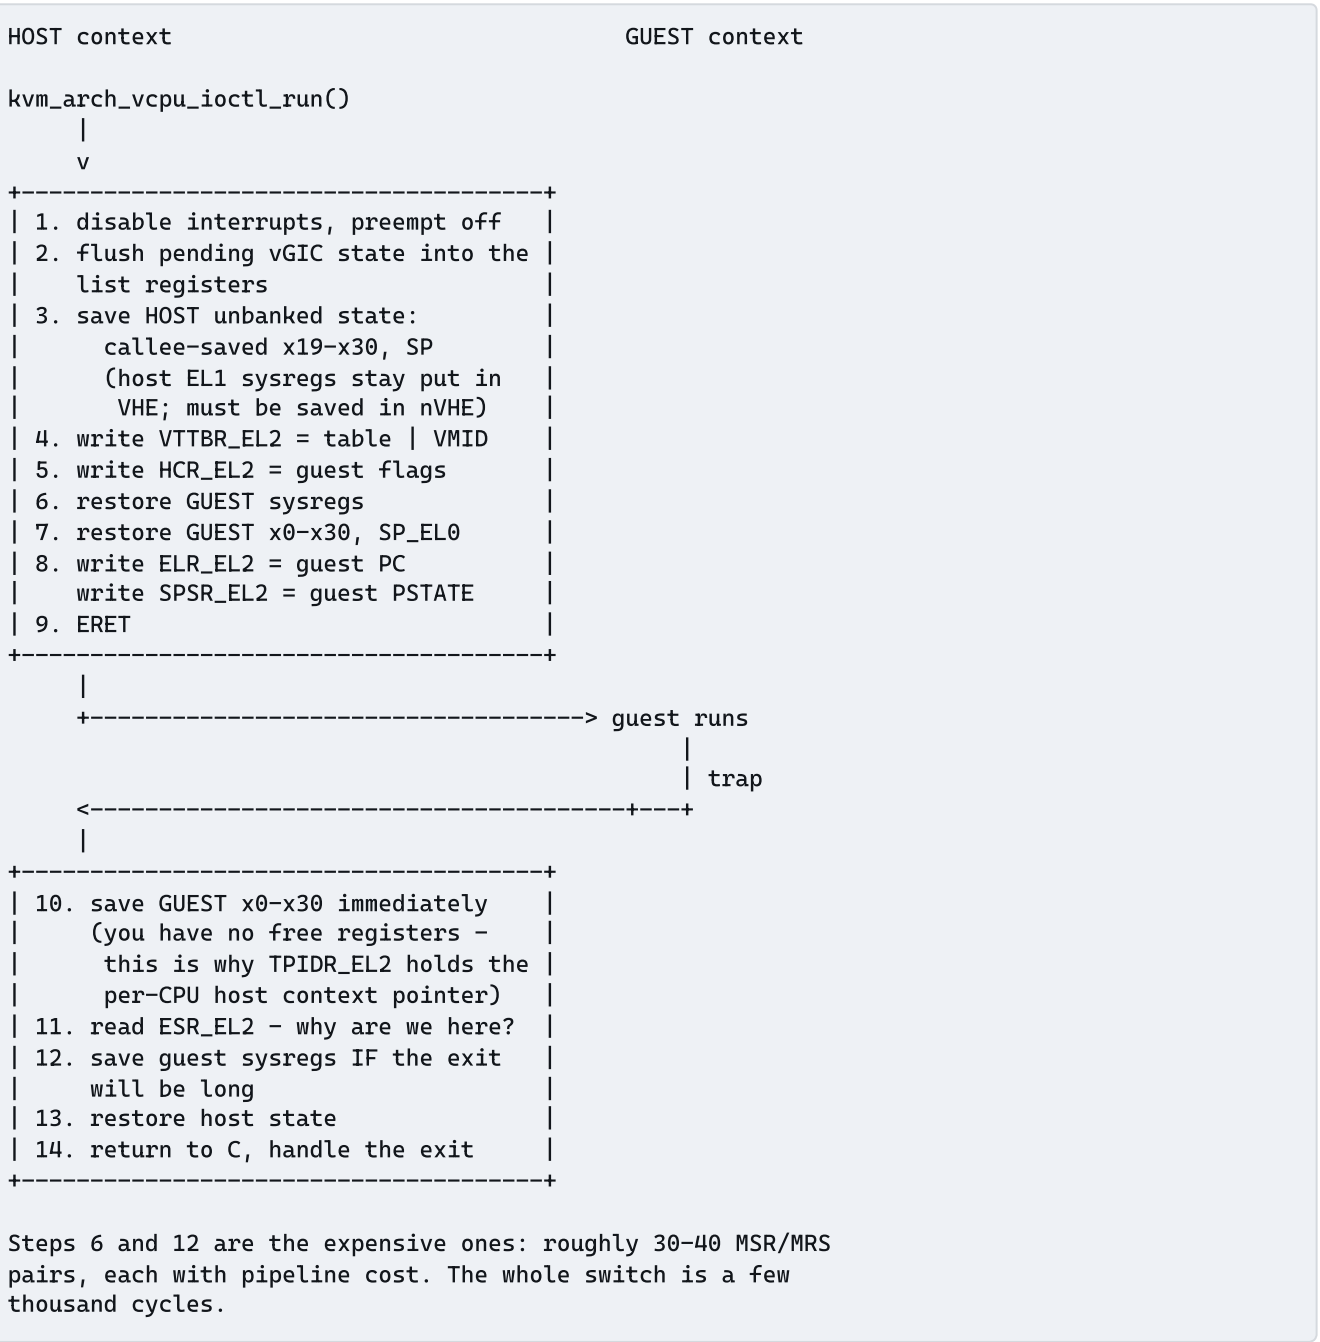
                case KVM_EXIT_SYSTEM_EVENT:   /* PSCI shutdown/reset */
                        return handle_system_event(v);

                case KVM_EXIT_INTR:           /* a host signal       */
                        break;                /* just re-enter       */

                case KVM_EXIT_FAIL_ENTRY:
                        die("entry failed, hw error 0x%llx",
                            v->kvm_run->fail_entry.hardware_entry_failure_reason);
                }
        }
}

/* Note what is ABSENT from that list: stage-2 translation
   faults, timer interrupts, GIC accesses, WFI. Those never
   reach user space - the kernel handles them and re-enters the
   guest without ever returning from the ioctl. That is the
   difference between a "light exit" and a "heavy exit", and it
   is roughly a factor of ten.                                  */
```

The world switch itself



Every optimisation is a form of laziness

Technique	Idea	Saves
Lazy FP/SIMD	Set `CPTR_EL2` to trap the first FP instruction. Only save and restore the register file if the guest actually used it	~1000 cycles per switch for guests that never touch FP; much more with SVE, where the file can be kilobytes
Light exits	Handle the exit in EL2 without restoring host EL1 state at all	Most of steps 12–13. A trapped timer read need not touch guest sysregs
VHE	Host runs at EL2 so its EL1-style registers are already the ones in use	The entire host sysreg save/restore. See chapter 9
VMID tagging	TLB entries carry the VM identity	A full TLB flush per switch — this is enormous
Deferred vGIC sync	Only read back the list registers if the guest could have changed them	Several register reads per exit

Technique	Idea	Saves
Pinned vCPUs	Stop the host scheduler moving a vCPU between physical cores	Cache and TLB warmth, and cross-core IPIs

> **WHY `TPIDR_EL2` MATTERS**
>
> On entry from the guest, every general-purpose register belongs to the guest and must not be clobbered before it is saved. The handler therefore needs one register's worth of scratch and a way to find its own per-CPU data. `TPIDR_EL2` is that anchor: it holds the address of this physical CPU's host context. Read it, stash a register, save the rest. Corrupt it and the hypervisor cannot find itself.

WFI, WFE and the idle guest

```
/* A guest with nothing to do executes WFI. On bare metal that
   parks the core until an interrupt arrives. Under a
   hypervisor that would waste a physical CPU, so HCR_EL2.TWI
   traps it.                                                  */

  guest: WFI
     -> trap to EL2, ESR_EL2.EC = 0x01
     -> KVM: kvm_vcpu_halt()
          the vCPU THREAD blocks on a wait queue.
          the physical CPU runs something else - another vCPU,
          a host process, or genuinely idles.

  later: a virtual interrupt becomes pending for this vCPU
     -> wake the thread
     -> re-enter the guest
     -> the guest's WFI "completes" and it takes the interrupt

/* WFE is different and subtler. A guest spinlock does:

       1: LDAXR w1, [x0]
          CBNZ  w1, 2f
          STXR  w2, w3, [x0]
          CBNZ  w2, 1b
          ... critical section ...
       2: WFE                 // sleep until someone SEVs
          B     1b

   If two vCPUs of the same guest are time-sharing ONE physical
   CPU, and the lock holder is descheduled, the waiter spins
   for its entire time slice waiting for a vCPU that cannot
   run. This is LOCK-HOLDER PREEMPTION, and it is the single
   worst pathology in overcommitted virtualisation.

   Trapping WFE turns the spin into a yield: KVM marks the vCPU
   as yielding and tries to schedule a sibling vCPU of the same
   VM - preferably the one holding the lock. That is
   kvm_vcpu_on_spin(), and it is why HCR_EL2.TWE is set.

   The real fix is not to overcommit vCPUs on a latency-
   sensitive workload. Paravirtualised queued spinlocks help
   on x86; on arm64 the WFE trap plus pinning is the practical
   answer.                                                    */
```

Bringing up a multi-vCPU guest

```
/* The guest cannot power on a CPU - there is no CPU to power
   on. It asks, via PSCI, and the hypervisor creates the
   illusion.                                                  */

  guest CPU0:  HVC  x0=PSCI_CPU_ON, x1=target MPIDR,
                    x2=entry point,  x3=context id
        |
        v
  EL2: find the vCPU whose VMPIDR_EL2 matches x1
       if it is already on          -> return ALREADY_ON
       set its PC = x2, x0 = x3
       set its state = runnable
       wake its host thread
       return SUCCESS
        |
        v
  guest CPU1 begins executing at x2, with x0 = context id,
  MMU off, at EL1.

/* Two details that bite:

   1. VMPIDR_EL2 is what the guest reads as MPIDR_EL1. YOU
      choose the affinity topology. If you hand out MPIDRs that
      imply 4 clusters of 1 CPU, the guest's scheduler builds
      its domains accordingly and may perform badly. Model a
      topology that matches reality, or a flat one.

   2. The PSCI conduit must match. The guest's device tree says
      method = "hvc" (under KVM) or "smc" (bare metal). A
      mismatch means CPU_ON sails past EL2 to EL3, where TF-A
      tries to power on a real core for a virtual request.
      Symptom: guest hangs with "CPU1: failed to boot: -110".  */
```

Measuring the switch

```
# How many exits, and how expensive?

$ sudo perf kvm --host stat live
# live per-exit-reason breakdown, updated continuously

$ sudo perf stat -e kvm:kvm_entry,kvm:kvm_exit -a sleep 10

# Time in the guest vs time in the host, per vCPU thread:
$ ps -T -p $(pgrep -f 'qemu.*mymachine') -o comm,pid,tid,pcpu
COMMAND          PID    TID %CPU
qemu-system-aar 4211   4211  3.1     # main/IO thread
CPU 0/KVM       4211   4219 74.2     # vCPU 0
CPU 1/KVM       4211   4220 71.8     # vCPU 1

# Pin them and watch the exit rate change:
$ taskset -cp 2 4219
$ taskset -cp 3 4220

# The microbenchmark that isolates switch cost: a guest loop
# that does nothing but trap.
#   guest:  1: hvc #0 ; b 1b
# Time N iterations, divide. On modern arm64 with VHE expect
# roughly 1-2 us per round trip if the hypercall is handled in
# the kernel, 10x that if it reaches user space.
```

How it shows up

Symptom	Cause
Guest FP results are wrong, but only sometimes	Lazy FP save/restore lost the register file — the trap fired but the state was not saved before reuse
Guest thread-local storage corrupts across a migration	`TPIDR_EL0` / `TPIDRRO_EL0` not in the save list
Hypervisor crashes with a wild pointer on guest exit	`TPIDR_EL2` clobbered — EL2 lost its per-CPU anchor
Guest is slow only when the host is busy	Lock-holder preemption; vCPUs oversubscribed on physical cores
Idle guest consumes a full physical core	`HCR_EL2.TWI` not set, so guest `WFI` parks real hardware
Guest hangs bringing up CPU1, `failed to boot: -110`	PSCI conduit mismatch or the target MPIDR does not match any vCPU's `VMPIDR_EL2`
Guest scheduler behaves oddly with many vCPUs	Fabricated MPIDR topology implies a cluster layout that does not exist
`KVM_EXIT_FAIL_ENTRY`	The CPU refused `ERET` into the guest — usually an illegal `SPSR_EL2`, or stage-2 not configured
Enormous exit count with a tiny amount of work done	A heavy exit path being taken for something that should be handled in EL2 — check `perf kvm stat`

Check yourself

- ✓ List the three categories of state a vCPU holds and give three examples of each.
- ✓ Explain the statement "a vCPU is a thread" and name three consequences.
- ✓ Walk through the world switch in order and identify the two most expensive steps.

- ✓ Explain why the guest's general-purpose registers must be saved before anything else on exit, and what `TPIDR_EL2` has to do with it.
- ✓ Describe lazy FP save/restore and the register that enables it.
- ✓ Distinguish a light exit from a heavy exit and give an example of each.
- ✓ Explain what trapping `WFI` achieves, and separately what trapping `WFE` achieves.
- ✓ Define lock-holder preemption and give two mitigations.
- ✓ Describe how a guest brings up its secondary CPUs and name two ways it goes wrong.
- ✓ Measure the exit rate of a running VM and identify the dominant exit reason.

VHE: running the host at EL2

The original EL2 design assumed a hypervisor written from scratch. Linux is not that, and KVM paid for the mismatch on every single exit. ARMv8.1's Virtualization Host Extensions fix it by making EL2 look like EL1 to software that runs there — an unusually elegant piece of architecture, and the reason modern arm64 virtualisation is fast.

The problem VHE solves

```
nVHE - the original design

EL0   host processes            guest userspace
EL1   HOST KERNEL  <---------+   guest kernel
                             |
EL2   a small stub of KVM    |
      "the hyp stub"         |
                             |
The host kernel runs at EL1. So does the guest kernel.
They both want SCTLR_EL1, TTBR0_EL1, VBAR_EL1, TPIDR_EL1...
and there is only ONE set of those registers.

Therefore EVERY entry to the guest must:
    save the host's ~25 EL1 system registers
    restore the guest's ~25 EL1 system registers
and every exit must do the reverse.

Worse: KVM's own logic lives at EL1, but only EL2 can do the
switch. So the code is SPLIT - a "hyp" half compiled
separately, with its own tiny address space, that cannot call
ordinary kernel functions, cannot take a lock, cannot print.
Two worlds inside one kernel source tree.
```

```
VHE - ARMv8.1

EL0   host processes            guest userspace
EL1                             guest kernel
EL2   HOST KERNEL + KVM

The host kernel runs AT EL2. The guest kernel keeps EL1 to
itself. Nothing is shared, so nothing must be swapped.

Entering the guest becomes:
    restore the guest's EL1 registers     (they were not in
                                           use by anyone)
    write VTTBR_EL2, HCR_EL2
    ERET

No host save. No host restore. And KVM is ordinary kernel
code running at the level that can do the switch, so the
split disappears.
```

The trick: register redirection

A kernel written for EL1 is full of `msr sctlr_el1, x0` and `mrs x0, ttbr1_el1`. You cannot rewrite all of it, and you should not have to. VHE's insight is to make those instructions *mean something different* when executed at EL2 with `HCR_EL2.E2H` set.

```
With HCR_EL2.E2H = 1, executing AT EL2:

  the instruction        actually accesses
  ----------------       -----------------
  MSR SCTLR_EL1, x0  ->  SCTLR_EL2
  MRS x0, TTBR0_EL1  ->  TTBR0_EL2
  MSR TTBR1_EL1, x0  ->  TTBR1_EL2   (new in VHE - EL2 gained
                                      a second TTBR precisely
                                      so a host kernel with a
                                      high half can live here)
  MSR VBAR_EL1, x0   ->  VBAR_EL2
  MSR TCR_EL1, x0    ->  TCR_EL2     (whose format changed to
                                      match TCR_EL1's)
  MRS x0, CNTV_CTL_EL0 -> CNTHV_CTL_EL2

And when EL2 genuinely needs the real EL1 register - which
KVM does, to load guest state - there is a new suffix:

  MSR SCTLR_EL12, x0 ->  the REAL SCTLR_EL1  (the guest's)
  MSR TTBR0_EL12, x0 ->  the REAL TTBR0_EL1
  MSR VBAR_EL12, x0  ->  the REAL VBAR_EL1

So: an unmodified EL1 kernel runs unmodified at EL2, and the
hypervisor uses the _EL12 forms to touch guest state
explicitly. Two hundred lines of KVM change; the other
twenty million lines of Linux do not.
```

> **WHY `TTBR1_EL2` HAD TO BE INVENTED**
>
> Original EL2 had only `TTBR0_EL2` — one translation base, because a purpose-built hypervisor uses a single flat address space. Linux splits its address space in half: user mappings via `TTBR0`, kernel mappings via `TTBR1`. Without a second base register, Linux simply could not run at EL2. VHE adds it, and reformats `TCR_EL2` to match `TCR_EL1` so the existing kernel code that programs it still works.

TGE: whose EL0 is it?

With the host at EL2, a question appears that did not exist before: when an application traps, does it belong to the host or to a guest? `HCR_EL2.TGE` — Trap General Exceptions — is the answer, and it is flipped on every guest entry and exit.

```
TGE = 1   "EL0 is the HOST's"
          - EL0 exceptions route to EL2
          - EL0 uses the EL2 translation regime
            (TTBR0_EL2, via the E2H remap)
          - stage 2 is effectively disabled for EL0/EL1
          - the virtual timer is not offset

          This is the state while the host is running its
          own processes. An ordinary syscall from an ordinary
          host process arrives at EL2, where the host kernel
          lives, and everything is normal.

TGE = 0   "EL0/EL1 belong to a GUEST"
          - EL0 and EL1 exceptions route to EL1 (the guest
            kernel handles its own syscalls - no exit!)
          - stage 2 applies
          - CNTVOFF_EL2 applies

The sequence around KVM_RUN:

  ... host running, E2H=1, TGE=1 ...
  restore guest EL1 state via _EL12 registers
  HCR_EL2: TGE=0, VM=1, IMO/FMO/AMO=1, ...
  write VTTBR_EL2
  ERET  -> guest at EL1
  ... guest runs; its own syscalls never leave EL1 ...
  trap -> EL2
  HCR_EL2: TGE=1, VM=0
  ... host running again ...

That single bit is the whole context switch, conceptually.
Everything else is bookkeeping.
```

What it is worth

Operation	nVHE	VHE	Why
Save/restore host EL1 sysregs per exit	~25 registers each way	**zero**	Host uses EL2 registers; nothing collides
Trap handled entirely in EL2	Must bounce to EL1 for anything non-trivial	Handled in place	KVM's real code is already at EL2
Round-trip cost (relative)	1.0	~0.4–0.6	Roughly halved on most implementations
KVM code structure	Split into hyp and kernel halves	Ordinary kernel code	No separate address space, no `__hyp_text` restrictions
Debuggability of the hypervisor	Very poor — no printk in hyp	Normal	It is just the kernel

Finding out which mode you are in

```
$ dmesg | grep -i kvm
[    0.512430] kvm [1]: Hyp mode initialized successfully
[    0.512461] kvm [1]: VHE mode initialized successfully      <-- VHE
[    0.512480] kvm [1]: vgic interrupt IRQ9
[    0.512501] kvm [1]: Timer IRQ4

# The other possibilities:
#   "Hyp mode initialized successfully"  alone          -> nVHE
#   "Protected nVHE mode initialized successfully"      -> pKVM
#   "HYP mode not available"                            -> booted at EL1

# Is the hardware capable at all?  ID_AA64MMFR1_EL1.VH != 0
$ sudo dd if=/dev/mem 2>/dev/null   # no - use the kernel's view:
$ dmesg | grep -i 'CPU features'

# Force nVHE on a VHE-capable machine, for comparison:
$ sudo grubby --update-kernel=ALL --args="kvm-arm.mode=nvhe"
# or on the command line:   kvm-arm.mode=nvhe
# Valid values: none, nvhe, protected, nested

# Then measure the same workload both ways. The difference is
# almost entirely in exit-heavy workloads - I/O and interrupts -
# and nearly invisible in a CPU-bound guest.
```

Protected KVM, which needs nVHE

```
   pKVM inverts the trust relationship:

     normal KVM   the host kernel can read all guest memory.
                  It must - it emulates devices, migrates VMs,
                  and swaps guest pages.

     pKVM         a small, auditable hypervisor at EL2 owns
                  stage 2. The HOST is itself constrained:
                  guest memory is unmapped from the host unless
                  the guest explicitly shares it.

   Threat model: protect a guest from a compromised host kernel.
   Used on Android for the Android Virtualization Framework.

   And it deliberately uses the nVHE split, because that split
   is exactly what you want when the EL2 component must be
   small enough to audit:

     EL2   pKVM hypervisor    ~10k lines, no dynamic memory,
                              its own page tables, owns stage 2
     EL1   host Linux         large, untrusted, asks EL2 for
                              permission to do things
     EL1   guest Linux        protected from the host

   So VHE is not universally "better". It is better for the
   common case of a trusted host. When the host is part of the
   threat model, the separation nVHE forces is the point.
```

> **NESTED VIRTUALISATION NEEDS BOTH**
> Running a hypervisor *inside* a guest means emulating EL2 for that guest — including its `E2H` and `TGE` bits, and the register redirection they imply. Chapter 20 covers it; the short version is that VHE makes nested virtualisation harder to implement and much faster when it works.

Writing code that runs at either level

```
/* Linux has to cope with running at EL1 or EL2 from the same
   binary. It does this with alternatives patched at boot.   */

/* arch/arm64/include/asm/kvm_hyp.h, simplified: */

#define read_sysreg_el1(r)   read_sysreg_elx(r, _EL1, _EL12)
#define write_sysreg_el1(v,r) write_sysreg_elx(v, r, _EL1, _EL12)

/* which expands, via an ALTERNATIVE, to either

     mrs x0, sctlr_el1     when running nVHE  (we are at EL2,
                                               EL1 regs are real)
   or
     mrs x0, sctlr_el12    when running VHE   (we are at EL2 with
                                               E2H=1, so _EL1
                                               would hit EL2)

   patched once at boot by the alternatives framework based on
   ARM64_HAS_VIRT_HOST_EXTN.                                    */

/* The lesson for your own EL2 code: NEVER write a bare
   `msr sctlr_el1, x0` in code that might run under VHE. It
   will silently configure the hypervisor instead of the guest,
   and the failure looks like the guest ignoring your writes. */
```

How it shows up

Symptom	Cause
Guest ignores system-register state you set	Wrote `*_EL1` from EL2 under VHE — it went to the EL2 register instead of the guest's
Host kernel corrupts itself when a VM starts	Same bug in reverse: wrote `*_EL12` believing it targeted EL2, or clobbered `TTBR1_EL2`
Host processes stop working while a VM runs	`TGE` not restored to 1 on exit — host EL0 exceptions are routing to the guest's EL1
Exit costs double on new hardware after a kernel change	Fell back to nVHE — check for `kvm-arm.mode=nvhe` on the command line
`VHE mode initialized` absent on capable silicon	Booted at EL1, or firmware left `HCR_EL2.E2H` in a state the kernel rejected
Guest timer runs at the host's rate	`CNTVOFF_EL2` only applies with `TGE=0`; the bit was left set
pKVM refuses to initialise	pKVM requires the nVHE code path plus firmware support; it is not available in every configuration
Hypervisor code faults only under VHE	An `__hyp_text` assumption about a separate EL2 address space that no longer holds

Check yourself

- ✓ Explain the register collision that makes nVHE expensive, and count the registers involved.
- ✓ Explain what `HCR_EL2.E2H` does to an `MSR SCTLR_EL1` executed at EL2.
- ✓ Say why `TTBR1_EL2` had to be added to the architecture.
- ✓ Explain the `_EL12` register suffix and when a hypervisor uses it.
- ✓ Describe what `TGE` selects and where in the run loop it is toggled.
- ✓ Give three things VHE improves besides raw speed.
- ✓ Determine from a running system whether it is in VHE, nVHE or pKVM mode.
- ✓ Explain why pKVM deliberately uses nVHE, and what threat that addresses.
- ✓ Describe the failure mode of writing a bare `msr sctlr_el1` in EL2 code under VHE.

Interrupt virtualisation and the vGIC

A guest must be able to receive an interrupt, acknowledge it, and signal end-of-interrupt — all without trapping, because interrupts are frequent and traps are expensive. The GIC provides a second, virtual CPU interface for exactly this, and a set of list registers through which the hypervisor stages the interrupts it wants the guest to believe in.

The problem

```
An interrupt arrives from real hardware.

1. It must go to the HYPERVISOR first - the guest is not
   allowed to see a wire it does not own, and the interrupt
   may belong to the host, or to a different guest, or to a
   vCPU that is not currently running.

   HCR_EL2.IMO = 1 routes physical IRQ to EL2.

2. The hypervisor decides it belongs to guest G, vCPU 3.

3. If vCPU 3 is running right now: inject it and resume.
   If not: mark it pending; inject when that vCPU next runs.
   (And if the vCPU is halted in WFI: wake its thread.)

4. The guest then does the NORMAL interrupt dance:
     read IAR      to acknowledge and learn the INTID
     run its handler
     write EOIR    to signal completion
     maybe write DIR to deactivate

   Each of those is a register access. If each one trapped,
   a busy guest would exit thousands of times a second just
   to service its own interrupts.

The GIC's answer: give the guest its own CPU interface
registers, which are REAL hardware, and let it drive them
without trapping at all.
```

THE DIVISION OF LABOUR

The *distributor* and *redistributor* (routing, priorities, enables) are emulated in software, because a guest reprogramming them is rare. The *CPU interface* (acknowledge, EOI, priority mask) is virtualised in hardware, because a guest touches it on every single interrupt. Emulate the cold path; virtualise the hot path.

The hardware pieces

Piece	GICv2 name	GICv3 name	Who drives it
Physical CPU interface	`GICC_*`	`ICC_*_EL1`	The hypervisor (and the host)
Virtual CPU interface	`GICV_*`	`ICV_*_EL1`	**The guest**, directly, with no trap
Virtualisation control	`GICH_*`	`ICH_*_EL2`	The hypervisor
List registers	`GICH_LR<n>`	`ICH_LR<n>_EL2`	The hypervisor writes; hardware and guest update

Piece	GICv2 name	GICv3 name	Who drives it
Distributor	`GICD_*`	`GICD_*` + redistributors	Emulated in software

```
GICv3, the essential trick:

The guest executes   MRS x0, ICC_IAR1_EL1
...but HCR_EL2.IMO = 1, so at EL1 that instruction is
REDIRECTED by hardware to ICV_IAR1_EL1 - the VIRTUAL
interface. No trap. The guest reads a virtual INTID out of
real silicon.

Same for ICC_EOIR1_EL1 -> ICV_EOIR1_EL1
         ICC_PMR_EL1   -> ICV_PMR_EL1
         ICC_HPPIR1_EL1-> ICV_HPPIR1_EL1

It is the same redirection idea as VHE's E2H, applied to the
interrupt controller. The guest's driver is unmodified; the
registers it touches are simply different ones.

Meanwhile the hypervisor, at EL2, uses ICH_* to decide what
the virtual interface will report.
```

List registers: the interface between the two

```
ICH_LR<n>_EL2 - typically 4 to 16 of them per CPU.
Each one describes ONE interrupt the guest should see.

 63 62 61 60 59 58 56 55       48 47      32 31          0
+--+--+--+--+-----+-----+---------+---------+------------+
|State|HW|Grp| Pri |     | pINTID            | vINTID     |
+--+--+--+--+-----+-----+---------+---------+------------+

State [63:62]   00 invalid    01 pending
                10 active     11 pending+active
HW    [61]      0 = purely virtual (software generated)
                1 = HARDWARE-BACKED: this virtual interrupt
                    corresponds to physical interrupt pINTID
Group [60]      Group 0 (FIQ) or Group 1 (IRQ)
Priority[55:48]
pINTID[41:32]   the PHYSICAL interrupt this maps to
vINTID[31:0]    what the guest will read from ICV_IAR1_EL1

THE HW BIT IS THE CLEVER PART.

With HW=1, when the guest writes ICV_EOIR1_EL1 with vINTID,
the hardware ALSO deactivates physical interrupt pINTID.
The guest's EOI directly deactivates the real device's
interrupt line - with no trap, no exit, no hypervisor
involvement whatsoever.

That is what makes device PASSTHROUGH performant. Without
it, every EOI would be an exit, and a 100k-interrupts-per-
second NIC would be unusable.
```

One interrupt, end to end

```
/* Case A: an EMULATED device (virtio) wants to interrupt vCPU 2 */

  1. QEMU/vhost decides the virtqueue has data.
  2. It asks KVM to raise virtual INTID 32 on vCPU 2:
        ioctl(vmfd, KVM_IRQ_LINE, {irq: 32, level: 1})
     or, faster, it kicks an irqfd that KVM has pre-bound.
  3. KVM marks INTID 32 pending in its software vGIC model.
  4. If vCPU 2 is running on another physical CPU, KVM sends an
     IPI to force it to exit so the LR can be written.
     If it is halted in WFI, KVM wakes the thread.
  5. On the next guest entry, KVM writes:
        ICH_LR0_EL2 = pending | Group1 | prio | vINTID=32
        HW = 0        (there is no physical interrupt behind it)
  6. ERET. The virtual CPU interface now signals IRQ to EL1.
  7. Guest reads ICV_IAR1_EL1 -> 32.  NO TRAP.
     Guest handles it.
     Guest writes ICV_EOIR1_EL1 = 32. NO TRAP. The LR state
     goes to invalid.
  8. On the next exit, KVM reads back the LRs to learn the
     interrupt completed.

  Exits used: one to inject (maybe zero if the vCPU was already
  going to exit). Zero for the guest's own handling.

/* Case B: a PASSED-THROUGH device (chapter 16)              */

  1. Real device raises physical INTID 137.
  2. HCR_EL2.IMO routes it to EL2. The host's handler runs -
     it does NOT know how to service the device, and must not.
  3. KVM looks up the mapping: physical 137 -> vCPU 2, virtual 137.
  4. It writes:
        ICH_LR0_EL2 = pending | HW=1 | pINTID=137 | vINTID=137
     and does NOT deactivate the physical interrupt.
  5. Guest reads ICV_IAR1_EL1 -> 137, services the real device
     through its passed-through MMIO, writes ICV_EOIR1_EL1.
  6. Because HW=1, the hardware deactivates physical 137 too.

  Exits used: one, for the physical interrupt itself. The
  entire guest-side handling is trap-free.

/* The remaining exit in case B is what GICv4 direct injection
   removes - see chapter 11.                                 */
```

Maintenance interrupts

```
/* The hypervisor has only N list registers (often 4). A guest
   with more than N interrupts pending needs the hypervisor to
   refill them - but the hypervisor is not running.

   ICH_HCR_EL2 configures a MAINTENANCE INTERRUPT that fires
   when the LR state changes in ways you asked about:      */

   ICH_HCR_EL2.UIE   Underflow: fewer than 2 LRs are valid.
                     "I am running out of queued interrupts,
                      give me more."
   ICH_HCR_EL2.LRENPIE  A list register with EOIcount != 0
                     needs attention.
   ICH_HCR_EL2.NPIE  No pending interrupts.
   ICH_HCR_EL2.VGrp0EIE / VGrp1EIE
                     the guest enabled or disabled a group -
                     the hypervisor may want to know.

/* The maintenance interrupt is a normal physical PPI (KVM
   prints it at boot: "vgic interrupt IRQ9"). When it fires:

     -> exit to EL2
     -> drain completed interrupts out of the LRs
     -> load more pending interrupts in
     -> resume

   With enough LRs and a sane workload this is rare. With 4 LRs
   and an interrupt storm it becomes the dominant exit reason,
   and you will see it in perf as a flood of maintenance
   interrupts. That is the signal to reduce interrupt rate
   (coalescing, NAPI) rather than to tune the hypervisor.   */
```

> **THE DISTRIBUTOR IS EMULATED, AND THAT IS A TRAP YOU WILL HIT**
>
> A guest writing `GICD_ISENABLER`, changing a priority, or re-routing an interrupt causes an MMIO exit into the software vGIC model. Guests that reconfigure interrupts constantly — some RTOSes do this per operation — perform terribly under virtualisation for this reason alone. Configure once at init, as Linux does.

GICv2 versus GICv3 for guests

	GICv2	GICv3
Guest CPU interface	MMIO region (`GICV`) mapped over where the guest expects `GICC`	System registers, redirected by `HCR_EL2.IMO`
Max CPUs	8	Effectively unlimited (affinity routing)
Interrupt IDs	SGI 0–15, PPI 16–31, SPI 32–1019	Adds LPIs (8192+) via the ITS
Cost of guest EOI	Uncached MMIO write, but no trap	System register write — cheaper still
KVM device type	`KVM_DEV_TYPE_ARM_VGIC_V2`	`KVM_DEV_TYPE_ARM_VGIC_V3`
QEMU option	`-machine virt,gic-version=2`	`gic-version=3` (or `host` , or `max`)

```
# Which one is in use?

# On the host:
$ dmesg | grep -i vgic
[    0.512480] kvm [1]: vgic interrupt IRQ9
$ dmesg | grep -i 'GICv'
[    0.000000] GICv3: GIC: Using split EOI/Deactivate mode

# Inside the guest:
$ dmesg | grep -i gic
[    0.000000] GICv3: 288 SPIs implemented
[    0.000000] GICv3: CPU0: found redistributor 0 region 0

$ cat /proc/interrupts
           CPU0       CPU1
  3:       1204       1188   GICv3  27 Level  arch_timer
 25:          0          0   GICv3  33 Level  virtio0
 26:      88104          0   GICv3  34 Level  virtio1

# A guest that shows "GICv2" while the host is GICv3 is running
# a legacy-mode vGIC - possible, and slower. Prefer matching.
```

How it shows up

Symptom	Cause
Guest never receives interrupts at all	`HCR_EL2.IMO` clear, so the virtual interface is not enabled and `ICC_*` is not redirected
Guest receives an interrupt once, then never again	Guest's EOI not reflected back into the hypervisor's model — LRs not synced on exit
Passed-through device stops after one interrupt	`HW` bit not set in the list register, so the physical interrupt was never deactivated
Interrupt storm of maintenance interrupts	More pending interrupts than list registers; guest interrupt rate too high
vCPU in `WFI` never wakes	Injection path marks pending but does not kick the blocked thread
Interrupt delivered to the wrong vCPU	Affinity routing mismatch between the emulated distributor and the vCPU's `VMPIDR_EL2`
Guest boots on GICv2 but not GICv3 (or vice versa)	Guest device tree describes a different GIC version than the one configured
Terrible performance in an RTOS guest	The guest reprograms the distributor per operation; every write is an MMIO exit
Timer interrupt lost when a vCPU migrates	Per-CPU (PPI) state not migrated with the vCPU

Check yourself

- ✓ Explain why the CPU interface is virtualised in hardware while the distributor is emulated.
- ✓ Describe what `HCR_EL2.IMO` does to a guest's `ICC_IAR1_EL1` access.
- ✓ Draw a list register and name the state, HW, pINTID and vINTID fields.
- ✓ Explain exactly what the `HW` bit causes to happen on guest EOI, and why passthrough needs it.
- ✓ Trace an emulated-device interrupt from device model to guest handler, counting exits.
- ✓ Trace a passed-through interrupt the same way and say where the remaining exit is.
- ✓ Explain what a maintenance interrupt is and name two conditions that raise one.

- ✓ Give two reasons a guest might be slow that are visible only in the vGIC.
- ✓ Determine from a running host and guest which GIC version each is using.

LPIs, the ITS and direct injection

The vGIC of the previous chapter still costs one exit per physical interrupt. GICv4 removes even that: a device's message-signalled interrupt can be delivered straight into a running guest with the hypervisor asleep. Getting there requires understanding LPIs, the ITS translation tables, and what "doorbell" means.

LPIs: interrupts as messages

```
The three older interrupt kinds are WIRES:

  SGI   0-15     software generated, core to core
  PPI   16-31    private per CPU (timers, PMU)
  SPI   32-1019  shared peripheral - a physical signal
                 routed into the distributor

Their state lives in distributor registers, one bit per
interrupt. That is fine for 1000 interrupts and hopeless for
a NIC with 512 queues on a 128-core machine.

LPI  8192+       Locality-specific Peripheral Interrupt.
                 NOT a wire. A MEMORY WRITE.

A device raises an LPI by writing an ID to a doorbell
address:

    device -> AXI write of value 0x2A to GITS_TRANSLATER
              (an address inside the ITS)

The ITS looks up "which device is this, what does its
EventID 0x2A mean, which CPU should get it" and delivers.

Consequences:
  * state lives in DDR tables, not in registers -> millions
    of interrupts are affordable
  * routing is per-interrupt and reprogrammable
  * this is exactly PCIe MSI/MSI-X, which is also "a device
    writes a value to an address"
```

The ITS and its tables

```
ITS = Interrupt Translation Service. A little engine that
turns (DeviceID, EventID) into (LPI number, target
redistributor).

  device does an MSI write
       |
       |  DeviceID comes from the interconnect - it is the
       |  same identity the SMMU uses as a StreamID
       v
  +-------------------------------------------------+
  |  ITS                                            |
  |                                                 |
  |  Device Table:  DeviceID -> ITT pointer         |
  |         |                                       |
  |         v                                       |
  |  Interrupt Translation Table (per device):      |
  |         EventID -> (LPI ID, Collection ID)      |
  |         |                                       |
  |         v                                       |
  |  Collection Table: Collection -> Redistributor  |
  +-------------------------------------------------+
       |
       v
  redistributor sets the pending bit in the
  LPI Pending Table (in DDR), then signals the CPU

THREE indirections, all through tables in normal memory that
software allocates and the ITS walks. You program them with
COMMANDS, not register writes:

  MAPD    map a DeviceID to an ITT
  MAPTI   map (DeviceID, EventID) -> (LPI, Collection)
  MAPC    map a Collection -> a redistributor
  INV     invalidate a cached entry after changing config
  SYNC    wait for prior commands to complete
  DISCARD unmap an event
  MOVI    move an interrupt to another collection (i.e.
          another CPU) - this is IRQ affinity for LPIs
```

DEVICEID IS STREAMID

The identity the ITS uses to look up a device is the same bus-level identity the SMMU uses to decide which translation tables apply. One identity, two consumers: the SMMU constrains what the device may read and write, the ITS constrains what it may interrupt. On a well-designed SoC they are configured together, and a device that is passed through to a guest gets both a stage-2 translation and an ITS mapping.

Virtualising the ITS: GICv3

```
/* Under GICv3 the ITS is EMULATED. The guest thinks it owns
   one; KVM models it.                                       */

  guest writes an ITS command (MAPTI) into its command queue
     -> MMIO exit into KVM's vgic-its model
     -> KVM records "guest LPI 8192 belongs to vCPU 3"
     -> if a real device is behind it (passthrough), KVM ALSO
        programs the physical ITS so the real device's MSI
        lands on the host

  device raises the MSI
     -> physical LPI delivered to the HOST
     -> host interrupt handler runs
     -> looks up: this physical LPI maps to guest LPI 8192 on vCPU 3
     -> inject into a list register (chapter 10)
     -> if vCPU 3 is running elsewhere, IPI it to force an exit
     -> vCPU 3 re-enters and sees the interrupt

  COST: one host interrupt + one exit + one entry, per device
  interrupt. For a 10GbE NIC at 300k interrupts/sec that is
  300k exits/sec, and it dominates everything.

/* This is why interrupt coalescing matters so much more in a
   VM than on bare metal, and why NAPI polling wins.        */
```

GICv4: direct injection

```
The insight: if the ITS already knows which vCPU an LPI
belongs to, and the redistributor already knows which vCPU is
RESIDENT on this physical CPU, then the hardware can deliver
straight to the guest.

GICv4 adds:

  * VPE (Virtual Processing Element) - the hardware's notion
    of a vCPU. Each has an ID and a pair of tables:
        Virtual LPI Pending Table
        Virtual LPI Configuration Table
    both in normal memory.

  * New ITS commands:
        VMAPP    map a VPE to a redistributor
        VMAPTI   map (DeviceID,EventID) -> virtual LPI on a VPE
        VMOVP    move a VPE to another redistributor
        VINVALL  invalidate cached virtual LPI config
        VSYNC

  * GICR_VPROPBASER / GICR_VPENDBASER - the redistributor
    registers that say "VPE X is currently resident here"

Then:

  device MSI write
       |
       v
  ITS translates to a VIRTUAL LPI on VPE 3
       |
       +--- is VPE 3 resident on some redistributor?
       |
       |    YES -> set the pending bit in the VIRTUAL pending
       |           table and signal the CPU directly.
       |           The guest takes the interrupt.
       |           ZERO EXITS. The hypervisor never runs.
       |
       |    NO  -> the vCPU is not scheduled. Send a
       |           DOORBELL interrupt: a normal physical LPI
       |           to the host saying "VPE 3 has work".
       v
  host wakes the vCPU thread, makes VPE 3 resident,
  and the pending virtual LPI is delivered on entry.

GICv4.1 adds direct virtual SGIs too, so a guest sending an
IPI from vCPU 0 to vCPU 1 need not exit either.
```

> **THE DOORBELL IS THE WHOLE TRICK**
> Direct injection would be unsafe if the target vCPU were descheduled — the interrupt would sit in memory unnoticed. The doorbell converts exactly that case back into a normal host interrupt. So the fast path costs nothing and the slow path costs what it used to. This "fast path in hardware, slow path via a wake-up signal" pattern shows up again in vhost and in virtio notification suppression.

Finding out what you have

```
# Host: is there an ITS at all?
$ dmesg | grep -i its
[    0.000000] GICv3: GIC: Using split EOI/Deactivate mode
[    0.000000] ITS [mem 0x08080000-0x0809ffff]
[    0.000000] ITS@0x0000000008080000: allocated 65536 Devices
               @880000000 (indirect, esz 8, psz 64K, shr 1)
[    0.000000] ITS: using cache flushing for cmd queue
[    0.000000] GICv4 support enabled                        <-- the line you want

# GICv4.1 will say:
[    0.000000] GICv4.1 support enabled

# Is direct injection actually in use for a given VM?
$ sudo cat /sys/kernel/debug/kvm/*/vgic-state 2>/dev/null | head -30

# Per-interrupt counts inside the guest tell you the rate:
$ cat /proc/interrupts | grep -E 'virtio|mlx|ixgbe'

# Host-side, watch for the exits that direct injection removes:
$ sudo perf stat -e kvm:kvm_exit -a sleep 5
# then compare with and without vfio passthrough of the device.

# QEMU: request an ITS in the guest
$ qemu-system-aarch64 -M virt,gic-version=3,its=on ...
# its=off removes it; some guests then fall back to a wired
# interrupt path, and PCIe MSI-X will not work.
```

Memory the ITS demands of you

```
/* The tables are not optional and their sizes surprise people. */

  Device Table        one entry per DeviceID the ITS can see.
                      GITS_TYPER.Devbits says how wide DeviceID
                      is. 16 bits -> 65536 entries. At 8 bytes
                      each that is 512 KB, contiguous, unless
                      you use the INDIRECT (two-level) form.

  ITT (per device)    one entry per EventID that device can
                      raise. A NIC with 2048 MSI-X vectors needs
                      a 2048-entry ITT.

  LPI Config Table    one BYTE per LPI, shared by all
                      redistributors: priority + enable.
                      1M LPIs -> 1 MB.

  LPI Pending Table   one BIT per LPI, PER REDISTRIBUTOR.
                      1M LPIs x 128 CPUs -> 16 MB.

  Virtual equivalents (GICv4) - per VPE, so multiply by the
  number of vCPUs in the system.

/* And they must be:
     - physically contiguous (or indirect)
     - aligned as GITS_BASER demands (often 64 KB)
     - coherent, or explicitly cleaned - GITS_BASER.InnerCache
       tells you whether the ITS snoops. If it does not, every
       table update needs a DC CVAC before the SYNC command.

   "ITS: using cache flushing for cmd queue" in dmesg means
   exactly that: your ITS is not coherent with the CPU caches. */
```

How it shows up

Symptom	Cause
PCIe device in a guest never receives MSI-X	No ITS in the guest (`its=off`), or the guest's ITS command queue was never enabled
Passthrough NIC works but at terrible packet rates	No GICv4, so every device interrupt costs an exit; enable coalescing or accept the cost
Interrupts arrive on the wrong CPU after affinity change	`MOVI` / `VMOVP` issued without a following `SYNC` , or a stale cached ITS entry (missing `INV`)
ITS silently drops interrupts after config changes	Tables updated but not cleaned to memory on a non-coherent ITS
Boot fails allocating ITS tables	Device table too large for contiguous allocation — needs the indirect two-level form
A vCPU misses interrupts while descheduled	Doorbell not configured, so nothing wakes the vCPU thread
Guest sees interrupts belonging to another guest	DeviceID not isolated — two devices behind one DeviceID, or the SMMU StreamID mapping does not match the ITS mapping
`ITS command queue timeout`	The ITS stalled — usually a command referencing an unmapped device or an unaligned table

Check yourself

- ✓ Explain how an LPI differs from an SPI, mechanically.
- ✓ Describe the three table lookups an ITS performs and what each maps.
- ✓ Name five ITS commands and say what each does.
- ✓ Explain the relationship between DeviceID, StreamID and PCIe requester ID.
- ✓ Count the exits per device interrupt for a passed-through device under GICv3.
- ✓ Explain what a VPE is and which two tables belong to it.
- ✓ Describe direct injection and state precisely when it does not apply.
- ✓ Explain what a doorbell interrupt is and why the design needs one.
- ✓ Estimate the memory required for LPI configuration and pending tables on a 128-CPU system with 1M LPIs.
- ✓ Determine from a host's boot log whether GICv4 is available and in use.

Timer virtualisation

Time is the illusion hardest to maintain, because a guest can measure it against the outside world. ARM's answer is a single 64-bit offset register that shifts a guest's view of the counter, plus a dedicated virtual timer per exception level — and a set of compromises about what happens while a vCPU is not running.

One counter, several views

```
There is exactly ONE physical counter in the system: a
free-running, always-on, fixed-frequency counter, shared by
every core. Software reads it through several windows.

CNTPCT_EL0   physical count   = the counter, raw
CNTVCT_EL0   virtual count    = CNTPCT_EL0 - CNTVOFF_EL2

                                        ^^^^^^^^^^^
                          ONE register, per vCPU, 64-bit,
                          writable only at EL2. That is the
                          entire mechanism.

Timers (comparators) come in matching flavours:

  EL1 physical timer   CNTP_CTL_EL0  CNTP_CVAL_EL0  CNTP_TVAL_EL0
  EL1 virtual timer    CNTV_CTL_EL0  CNTV_CVAL_EL0  CNTV_TVAL_EL0
  EL2 hypervisor timer CNTHP_CTL_EL2 CNTHP_CVAL_EL2
  EL2 virtual timer    CNTHV_*_EL2   (VHE)
  EL3 secure timer     CNTPS_*_EL1

Each has its own interrupt (a PPI):
  30  EL1 physical timer
  27  EL1 virtual timer     <-- the one a KVM guest uses
  26  EL2 hypervisor timer
  29  EL3 secure timer

A guest kernel under KVM is told, via its device tree, to use
the VIRTUAL timer. It then reads CNTVCT_EL0 with no trap at
all, and gets a value shifted by CNTVOFF_EL2.
```

WHY THE OFFSET MUST EXIST

A guest that boots two hours after the host expects its counter to start near zero, not at the host's uptime. More importantly, a guest that is suspended and resumed, or migrated to another machine, must not see time jump backwards or leap forwards — its scheduler, its watchdogs and its TCP stack all assume monotonic, roughly-real time. `CNTVOFF_EL2` lets the hypervisor rebase the guest's clock without touching a single guest instruction.

What the hypervisor does with CNTVOFF

```
/* At VM creation: */
    vcpu->cntvoff = read_cntpct();      /* guest time starts at 0 */

/* On every guest entry: */
    write_sysreg(vcpu->cntvoff, cntvoff_el2);

/* All vCPUs of one VM MUST share the same offset, or the guest
   sees different cores disagreeing about the time - which
   breaks its scheduler, its clocksource watchdog and any
   lock-free algorithm using timestamps.

   KVM enforces this: CNTVOFF is per-VM, not per-vCPU.       */

/* On resume from a host suspend: */
    /* The physical counter kept running (or did not - it is
       "always on" but the SoC may have powered it). Either way
       the guest must not observe a jump. Adjust:            */
    vcpu->cntvoff += (now - suspend_started);

/* On live migration: */
    /* The destination machine's counter has a completely
       different value AND possibly a different frequency.
       CNTFRQ_EL0 is not writable per-guest, which is a real
       architectural gap - migration between machines with
       different counter frequencies is not supported. Check
       CNTFRQ on both ends before you promise migration.     */
```

Which timer belongs to whom

Timer	Used by	Trapped?	Notes
EL1 virtual (`CNTV_*`)	The guest	No	The fast path. Guest programs its own comparator; hardware raises PPI 27; the vGIC delivers it
EL1 physical (`CNTP_*`)	Bare-metal EL1 software; a guest that was misconfigured	**Yes**, via `CNTHCTL_EL2.EL1PCEN`	Must be trapped and emulated, because the physical timer's interrupt is not the guest's to own
EL2 hypervisor (`CNTHP_*`)	The hypervisor	n/a	Preemption timer: how KVM takes a vCPU away when its slice expires
Counter reads (`CNTVCT_EL0`)	Guest user space and kernel	No	Offset in hardware. This is why `clock_gettime()` in a guest is as fast as on bare metal
`CNTPCT_EL0`	Anyone	Optionally, via `CNTHCTL_EL2.EL0PCTEN` / `EL1PCTEN`	Trapping it hides the host's real uptime; leaving it open lets a guest detect virtualisation

```
/* CNTHCTL_EL2 - who may touch what, from EL1 and EL0.       */

  Without VHE (or with TGE=0):
    EL1PCTEN  [0]  EL0/EL1 may read CNTPCT_EL0
    EL1PCEN   [1]  EL0/EL1 may use the EL1 PHYSICAL timer
    EVNTEN    [2]  event stream enable
    EVNTDIR   [3]  event stream edge
    EVNTI     [7:4] which counter bit drives the event stream

/* KVM's normal setting for a guest:

     EL1PCTEN = 1   let the guest read CNTPCT - it is only the
                    raw counter, and hiding it costs a trap on
                    a hot path for very little benefit
     EL1PCEN  = 0   TRAP the physical timer. The guest should be
                    using the virtual one; if it insists on the
                    physical one, KVM emulates it on top of the
                    virtual timer.

   A guest device tree that lists the physical timer interrupt
   instead of the virtual one produces a guest that works but
   traps on every timer programming operation. Symptom: high
   exit count with EC=0x18 on CNTP registers.               */
```

The hard part: time while you are not running

```
   A guest sets a timer for 1 ms from now, then its vCPU is
   descheduled for 20 ms because the host is busy.

   The virtual timer fires - in hardware - while the vCPU is
   not resident. Who notices?

   ANSWER: the hypervisor must arrange to notice. KVM does this
   by putting the guest's timer deadline into a HOST timer
   (an hrtimer) whenever the vCPU is descheduled:

     vCPU blocks / is preempted
        |
        v
     read guest CNTV_CVAL, convert to host time
     arm a host hrtimer for that instant
     save and DISABLE the guest's timer in hardware
        |
        ... host runs other things ...
        |
     hrtimer fires -> mark virtual PPI 27 pending for that vCPU
                   -> wake the vCPU thread
        |
        v
     vCPU is scheduled again
        |
        v
     restore guest timer state, inject the pending interrupt

   The guest observes: "my 1 ms timer fired after 20 ms".
   That is LATE, not WRONG - and lateness is unavoidable when
   you overcommit. But it must never be EARLY, and it must
   never be LOST.
```

> **THE RTOS PROBLEM**
> An RTOS guest with a 100 µs deadline cannot tolerate 20 ms of scheduling delay, and no amount of hypervisor cleverness fixes it — the physical CPU was genuinely doing something else. The answer is not a better timer path; it is to stop sharing that CPU: pin the vCPU, isolate the core (`isolcpus`, `nohz_full`), give it a real-time scheduling class, or use a partitioning hypervisor that never time-shares in the first place.

Steal time: telling the guest the truth

```
/* A guest's own accounting is a lie under overcommit: it
   thinks it used 100 ms of CPU when 60 ms of that was spent
   descheduled. Its load average, its CPU-frequency governor
   and its scheduler all draw wrong conclusions.

   The paravirtual fix: the hypervisor publishes, in a shared
   page, how much time this vCPU spent NOT running.        */

  struct pvclock_vcpu_stolen_time {
          __le32 revision;
          __le32 attributes;
          __le64 stolen_time;      /* nanoseconds, monotonic  */
          /* padded to 64 bytes                              */
  };

/* Discovered via SMCCC:
     HV_PV_TIME_FEATURES  -> is it there?
     HV_PV_TIME_ST        -> give me the IPA of my structure   */

/* In the guest: */
$ cat /proc/stat | head -2
cpu  1204 0 388 90112 22 0 8 1877 0 0
                               ^^^^
                               steal time, in USER_HZ

$ vmstat 1
procs -----------memory---------- ---system-- ------cpu-----

 2  0      0 743210  1122  88240  912 1840 41  6 22  0 31
                                                     ^^
                                          31% stolen - this
                                          guest is starved

/* st consistently above a few percent means the host is
   oversubscribed. It is the single most useful number for
   diagnosing "the VM is slow" complaints, and it points at the
   host, not the guest.                                    */
```

Checking the timer setup

```
# Guest: which timer is it actually using?
$ cat /proc/interrupts | grep timer
  3:      12045      11982   GICv3  27 Level  arch_timer
                                    ^^ 27 = VIRTUAL timer. Good.
                                    30 would be the physical one.

$ cat /sys/devices/system/clocksource/clocksource0/current_clocksource
arch_sys_counter

$ dmesg | grep -i arch_timer
[    0.000000] arch_timer: cp15 timer(s) running at 54.00MHz (virt).
[    0.000000] clocksource: arch_sys_counter: mask: 0xff...
                                                      ^^^^^^
# "(virt)" is what you want. "(phys)" means the guest is on the
# physical timer and every access traps.

# Host: what frequency does the hardware run at?
$ dmesg | grep -i 'arch_timer.*MHz'
# Must match on both ends of a live migration.

# Prove the offset works - guest uptime should not be host uptime:
$ uptime            # in the guest
$ ssh host uptime   # on the host

# Measure timer accuracy inside the guest:
$ cyclictest -t1 -p 80 -n -i 1000 -l 10000
T: 0 ( 1234) P:80 I:1000 C:  10000 Min:     12 Act:   28 Avg:   35 Max:    9812
                                                              ^^^^^^^
# 9.8 ms worst case = the vCPU was descheduled. Pin it and
# re-run; on an isolated core this should drop to tens of us.
```

How it shows up

Symptom	Cause
Guest time is the host's uptime, not zero-based	`CNTVOFF_EL2` never initialised
Guest cores disagree about the time; scheduler misbehaves	Per-vCPU rather than per-VM `CNTVOFF`
Guest time jumps after host suspend/resume	Offset not adjusted across the suspend window
Huge exit rate with `EC=0x18` on `CNTP_*`	Guest using the physical timer — wrong interrupt in its device tree
Guest timers fire late by whole milliseconds	vCPU descheduled; the host hrtimer path is working as designed. Pin and isolate
Guest timer never fires at all	Descheduled-vCPU hrtimer not armed, or the virtual PPI not injected on wake
Guest clocksource watchdog marks the counter unstable	Time observed going backwards — usually an offset updated on one vCPU only
Live migration leaves the guest's clock wrong	Different `CNTFRQ_EL0` on source and destination
Guest reports high load with idle applications	Steal time not exposed, so the guest attributes stolen cycles to itself
`cyclictest` max latency in milliseconds	Overcommitted host; this is a capacity decision, not a bug

Check yourself

- ✓ Write the relationship between `CNTPCT_EL0`, `CNTVCT_EL0` and `CNTVOFF_EL2`.
- ✓ Name the four timer variants and the PPI number each uses.
- ✓ Explain why `CNTVOFF` must be per-VM rather than per-vCPU.
- ✓ Say which timer a KVM guest should use and how it is told.
- ✓ Explain what `CNTHCTL_EL2.EL1PCEN` controls and why KVM clears it.
- ✓ Describe how a guest timer fires while its vCPU is descheduled.
- ✓ Explain why "late" is acceptable but "early" and "lost" are not.
- ✓ Define steal time, say how a guest learns it, and explain what a high value tells you.
- ✓ Explain why counter frequency blocks some live migrations.
- ✓ Verify from inside a guest that it is using the virtual timer.

Trapping MMIO and emulating a device

A device model is a state machine driven by faults. The guest stores to an address that has no memory behind it, the hypervisor decodes what that store meant, updates some software state, and possibly raises an interrupt. This chapter builds one from nothing, and shows why doing it in the fewest possible traps is the entire design problem.

A device is a hole in the address space

```
Guest's view of its own physical memory:

  0x0000_0000  +--------------------+
               |  (nothing)         |
  0x0800_0000  +--------------------+
               |  GIC distributor   |  <- emulated
  0x0801_0000  +--------------------+
               |  GIC redistributor |  <- emulated
  0x0900_0000  +--------------------+
               |  PL011 UART        |  <- emulated
  0x0900_1000  +--------------------+
               |  RTC               |  <- emulated
  0x0a00_0000  +--------------------+
               |  virtio-mmio x32   |  <- emulated
  0x1000_0000  +--------------------+
               |  PCIe ECAM         |  <- emulated
  0x4000_0000  +--------------------+
               |                    |
               |  RAM               |  <- REAL memory,
               |                    |     mapped at stage 2
               +--------------------+

Stage 2 maps the RAM region and leaves EVERYTHING ELSE
unmapped. Every access to a device region therefore takes a
stage-2 translation fault, which is exactly the notification
the hypervisor wants.

In KVM this is expressed as MEMSLOTS: user space registers
"guest physical range X is backed by this host virtual
address". Anything outside a memslot is, by definition, MMIO.
```

The path of one register write

```
/* Guest driver:                                              */
        writel(0x41, uart_base + UARTDR);   /* print 'A'      */

/* 1. STR w0, [x1] where x1 -> IPA 0x0900_0000                */

/* 2. Stage-2 translation fault. ESR_EL2:
        EC   = 0x24  data abort from lower EL
        ISV  = 1     syndrome valid
        SAS  = 0b10  word access
        SRT  = 0      register x0
        WnR  = 1      it was a write
        DFSC = 0b000111  translation fault, level 3

      HPFAR_EL2 gives IPA 0x0900_0000.                       */

/* 3. KVM: is 0x0900_0000 inside a memslot?  No.
      -> it is MMIO. Is there an in-kernel device claiming it?
         (vGIC, arch timer, PV interfaces)  No.
      -> hand it to user space.                              */

/* 4. KVM_RUN returns. kvm_run->exit_reason = KVM_EXIT_MMIO:  */

        struct {
                __u64 phys_addr;   /* 0x09000000             */
                __u8  data[8];     /* 0x41                   */
                __u32 len;         /* 4                      */
                __u8  is_write;    /* 1                      */
        } mmio;

/* 5. QEMU dispatches to the PL011 model, which appends 'A' to
      the character device. If this were a READ, QEMU would
      instead fill kvm_run->mmio.data before re-entering.    */

/* 6. ioctl(KVM_RUN) again. KVM writes the read data into the
      guest's register x0 if needed, ADVANCES THE GUEST PC past
      the faulting instruction, and ERETs.

      Note: skip, not retry. The access was emulated, not
      fixed - the opposite of a memory fault (chapter 6).    */
```

TWO TIERS OF DEVICE MODEL

Devices that are hot and simple live *in the kernel*: the vGIC, the architected timer, the PV interfaces. Their exits never leave `KVM_RUN`, costing single-digit microseconds. Everything else lives in user space, costing ten times that but gaining the ability to be written in ordinary code with files, threads and sockets. Deciding which tier a device belongs in is the main performance lever you have.

Writing a device model

```
/* A minimal PL011 UART model. This is the shape of every
   device model you will ever write: a struct of state, a read
   function, a write function, and an interrupt line.        */

struct pl011 {
        uint32_t dr;          /* data                        */
        uint32_t fr;          /* flags                       */
        uint32_t imsc;        /* interrupt mask              */
        uint32_t ris;         /* raw interrupt status        */
        uint32_t cr;          /* control                     */
        uint8_t  rxfifo[16];
        unsigned rxhead, rxtail;
        int      irq;         /* which vINTID we raise       */
        int      chr_fd;      /* where output goes           */
};

#define UARTDR    0x000
#define UARTFR    0x018
#define UARTIMSC  0x038
#define UARTRIS   0x03c
#define UARTMIS   0x040
#define UARTCR    0x030
#define UARTICR   0x044

#define FR_RXFE   (1u << 4)   /* receive FIFO empty          */
#define FR_TXFF   (1u << 5)   /* transmit FIFO full          */
#define INT_RX    (1u << 4)
#define INT_TX    (1u << 5)

static uint32_t pl011_read(struct pl011 *u, uint64_t off)
{
        switch (off) {
        case UARTDR: {
                uint32_t c = 0;
                if (u->rxhead != u->rxtail) {
                        c = u->rxfifo[u->rxtail++ % 16];
                        if (u->rxhead == u->rxtail)
                                u->fr |= FR_RXFE;
                }
                /* READING CLEARS STATE. This is why speculative
                   reads of device memory are forbidden - see
                   chapter 7.                                  */
                pl011_update_irq(u);
                return c;
        }
        case UARTFR:   return u->fr;

                                         for an unknown offset -
                                         real hardware does not */
        }
}

static void pl011_write(struct pl011 *u, uint64_t off, uint32_t v)
{
        switch (off) {
        case UARTDR: {
                uint8_t c = v & 0xff;
```

```
                write(u->chr_fd, &c, 1);
                u->ris |= INT_TX;       /* transmit completed   */
                pl011_update_irq(u);
                break;
        }
        case UARTIMSC: u->imsc = v; pl011_update_irq(u); break;
        case UARTICR:  u->ris &= ~v;  pl011_update_irq(u); break;
        case UARTCR:   u->cr   = v; break;
        }
}

static void pl011_update_irq(struct pl011 *u)
{
        int level = (u->ris & u->imsc) != 0;
        set_irq_line(u->irq, level);     /* KVM_IRQ_LINE ioctl  */
}

/* Rules this small function already demonstrates:

   1. NEVER fault on an unrecognised offset. Return 0 and log.
      Guests probe. Hardware tolerates probing.
   2. Model side effects of READS explicitly (clear-on-read,
      FIFO pop). Getting these wrong causes lost data that
      looks like a driver bug.
   3. Recompute the interrupt line after any state change, and
      drive it as a LEVEL, not an edge. Level semantics are
      self-correcting; edges get lost.
   4. Handle partial-width accesses. A guest may read a byte of
      a 32-bit register.                                      */
```

The cost, and how to escape it

Path	Typical cost	When it applies
In-kernel device (vGIC, timer)	1–3 µs	Hot, simple, no external I/O
User-space device (QEMU)	10–30 µs	Anything needing files, sockets or complex state
`ioeventfd`	~1 µs, and asynchronous	A write to one address whose *value* does not matter — a doorbell
`irqfd`	~1 µs	Raising an interrupt from another thread or from the kernel without an ioctl
vhost (in-kernel datapath)	Comparable to host I/O	virtio net/blk where the whole datapath moves into the kernel
Passthrough	Zero for MMIO	The guest owns the real device (chapter 16)

```
/* ioeventfd: the single most valuable optimisation for a
   device model, and the reason virtio is fast.             */

  Ordinary path for "kick the queue":
     guest writes QueueNotify
       -> stage-2 fault
       -> exit to EL2
       -> exit to host kernel
       -> exit to QEMU
       -> QEMU decodes, finds the queue, processes
       -> re-enter (4 transitions)

  With ioeventfd:
     QEMU tells KVM in advance:
        "a write to 0x0a000050 of any value means: signal
         eventfd 7. Do not tell me the value. Do not return
         from KVM_RUN."

     guest writes QueueNotify
       -> stage-2 fault
       -> KVM writes eventfd 7 and IMMEDIATELY RE-ENTERS
       -> a separate QEMU thread (or vhost kernel thread)
          wakes on eventfd 7 and does the work CONCURRENTLY
          with the guest continuing to run.

  The guest never waits. The exit is a light one. This is the
  difference between "virtio is fine" and "virtio is fast".  */

/* The registration, in QEMU terms: */
   struct kvm_ioeventfd ke = {
            .addr     = 0x0a000050,
            .len      = 4,
            .fd       = evfd,
            .flags    = 0,     /* KVM_IOEVENTFD_FLAG_DATAMATCH
                                  if you need to distinguish
                                  which queue was kicked      */
   };
   ioctl(vmfd, KVM_IOEVENTFD, &ke);
```

Telling the guest the device exists

```
/* A device model is useless unless the guest is told where it
   is. Two mechanisms; on embedded arm64 it is the device tree. */

/ {
        soc {
                #address-cells = <2>;
                #size-cells    = <2>;

                pl011@9000000 {
                        compatible = "arm,pl011", "arm,primecell";
                        reg = <0x0 0x09000000 0x0 0x1000>;
                        interrupts = <0 1 4>;  /* SPI 1, level  */
                        clocks = <&uartclk>;
                        clock-names = "uartclk";
                };

                virtio_mmio@a000000 {
                        compatible = "virtio,mmio";
                        reg = <0x0 0x0a000000 0x0 0x200>;
                        interrupts = <0 16 1>;
                };
        };
};

/* QEMU GENERATES this device tree at runtime from the machine
   model, which is why -M virt "just works" for any memory size
   and CPU count. To see what your guest was actually given: */

$ qemu-system-aarch64 -M virt,dumpdtb=virt.dtb -nographic ...
$ dtc -I dtb -O dts virt.dtb | less

/* And from inside a running guest: */
$ ls /sys/firmware/devicetree/base/
$ dtc -I fs -O dts /sys/firmware/devicetree/base | less

/* A mismatch between the model's address and the device tree's
   reg property produces a device that is never probed, or a
   guest that faults on a region nothing models. The dumpdtb
   trick resolves this in seconds and is the first thing to
   reach for when "my device does not appear".              */
```

> **NEVER FAULT THE GUEST FOR AN UNKNOWN REGISTER**
> It is tempting to signal an abort when a guest touches an offset you did not implement. Do not. Guests probe hardware, read reserved fields, and read whole register blocks in a loop to dump state. Real silicon returns zero or garbage and carries on. A model that aborts turns a harmless probe into a guest kernel panic, and the panic points at the guest driver rather than at your model.

How it shows up

Symptom	Cause
Guest panics probing a device	Model aborts on an unimplemented offset instead of returning zero
Device never appears in the guest	Device tree `reg` does not match the address the model claims, or `compatible` matches no driver

Symptom	Cause
Guest receives the first interrupt only	Interrupt driven as an edge; the line was never lowered, so the next rise is not seen
Characters lost on an emulated UART	Clear-on-read side effects modelled incorrectly, or the RX FIFO overrun path missing
VM killed: "no valid syndrome"	Guest used `memcpy` / `LDP` on the MMIO region; `ISV=0` (chapter 6)
Throughput far below expectations	Doorbell handled as a full user-space exit instead of an `ioeventfd`
Guest hangs on a byte access to a 32-bit register	Model assumes word-width accesses only
Interrupt raised but guest never runs its handler	`irqfd` / `KVM_IRQ_LINE` targeting the wrong vINTID, or the vGIC not told the line is level-triggered
Device works in TCG but not with KVM	The model relies on ordering QEMU's own emulation provided; real guest CPUs reorder

Check yourself

- ✓ Explain how a hypervisor arranges to be notified of a device access, in terms of stage 2 and memslots.
- ✓ Trace a guest `writel()` to an emulated UART through every layer to the host's terminal.
- ✓ Say whether the guest PC is advanced or not after MMIO emulation, and contrast with a memory fault.
- ✓ Give three rules a device model must follow to survive guest probing.
- ✓ Explain why a device's interrupt should be modelled as a level, not an edge.
- ✓ Describe what `ioeventfd` changes and count the transitions it removes.
- ✓ Describe what `irqfd` is for.
- ✓ Explain how a guest learns a device exists, and how you inspect what it was told.
- ✓ Give the cost ratio between an in-kernel device and a user-space one, and the criterion for choosing.

virtio: the transport and the virtqueue

virtio is what you design when you accept that the guest knows it is a guest. Instead of pretending to be an IDE controller, you build the interface you would have wanted all along: a shared-memory ring where the expensive operation — telling the other side there is work — happens once per batch instead of once per register.

The shape of the thing

```
GUEST                                    HOST

virtio driver                            virtio device
(net, blk, console, ...)                 (QEMU, vhost, or a
     |                                    separate process)
     |                                          |
+----+------------------------------------------+----+
|             ONE OR MORE VIRTQUEUES                  |
|    living in GUEST MEMORY, which the host can       |
|    read and write directly - no copying, no         |
|    per-register traps                               |
+-----------------------------------------------------+
     |                                          |
     | NOTIFY: guest -> device                  |
     |   one MMIO write. This is the ONLY       |
     |   trap in the whole data path.           |
     |                                          |
     | INTERRUPT: device -> guest               |
     |   one virtual interrupt when work is done|

Plus a CONFIGURATION space for the slow path: feature
negotiation, queue setup, device-specific config (MAC
address, disk size, screen resolution). Touched at probe
time and then essentially never.

Split the design in your head:
  CONTROL PLANE  = MMIO registers, traps, rare
  DATA PLANE     = shared memory rings, no traps, constant
```

ONE IDEA, THREE TRANSPORTS

The virtqueue is the same everywhere. Only the way you find it and kick it changes: **virtio-mmio** (a flat register block, used on embedded and by QEMU's `virt` machine), **virtio-pci** (BARs and capabilities, used in clouds), and **virtio-ccw** (s390). Learn the queue once; the transports are packaging.

The split virtqueue

```
   Three arrays, all in guest memory, all agreed in advance.

   DESCRIPTOR TABLE - the buffers themselves
   +----+---------------+--------+-------+-------+
   | id |     addr      |  len   | flags |  next |
   +----+---------------+--------+-------+-------+
   |  0 | 0x4123_0000   |   16   | NEXT  |   1   |  request header
   |  1 | 0x4123_1000   | 4096   | NEXT  |   2   |  data
   |  2 | 0x4123_2000   |    1   | WRITE |   -   |  status byte
   +----+---------------+--------+-------+-------+
        flags: NEXT (chained)  WRITE (device writes it)
               INDIRECT (this descriptor points at a whole
                         table of descriptors)

   AVAILABLE RING - guest -> device.  "please process these"
   +-------+-------+--------------------------+
   | flags | idx=7 | ring[0..N]: 0, 5, 9, ...  |
   +-------+-------+--------------------------+
                ^         each entry is the HEAD descriptor
                |         of a chain
                idx only ever increases, and wraps naturally
                at 16 bits

   USED RING - device -> guest.  "these are done"
   +-------+-------+-------------------------------+
   | flags | idx=5 | ring[0..N]: {id=0,len=4096},  |
   +-------+-------+-------------------------------+
                       each entry says which chain completed
                       and how many bytes were written

   THE PROTOCOL:

     guest:  fill descriptors
             write avail.ring[avail.idx % N] = head
             memory barrier
             avail.idx++
             memory barrier
             NOTIFY (one MMIO write)   <-- the only trap

     device: sees avail.idx moved
             reads the chain, does the work
             writes used.ring[used.idx % N] = {head, len}
             memory barrier
             used.idx++
             raises an interrupt (maybe - see suppression)

     guest:  interrupt handler sees used.idx moved
             reclaims all completed chains in one pass
```

The barriers are not optional

```
/* Both sides are ordinary code on weakly-ordered CPUs, writing
   to shared memory with no lock. Every publication needs a
   barrier, and getting one wrong produces corruption that
   appears once an hour under load.                          */

/* GUEST, adding a buffer (linux/drivers/virtio/virtio_ring.c) */

        vq->split.vring.desc[head] = ...;      /* fill descriptors */

        /* The descriptor contents must be visible BEFORE the
           index that publishes them.                          */
        virtio_wmb(vq->weak_barriers);        /* DMB ISHST      */

        vq->split.vring.avail->idx = cpu_to_virtio16(vdev, new);

        /* And the index must be visible before the notify.    */
        virtio_mb(vq->weak_barriers);         /* DMB ISH        */

        if (vring_need_event(...))
                vq->notify(vq);

/* DEVICE, completing a buffer */

        used->ring[i] = (struct vring_used_elem){ head, len };
        smp_wmb();                            /* entry before idx */
        used->idx = new_idx;
        smp_mb();                             /* idx before irq   */
        raise_interrupt();

/* GUEST, reaping */

        if (vq->last_used_idx == virtio16_to_cpu(vdev, used->idx))
                return NULL;                  /* nothing new      */
        virtio_rmb(vq->weak_barriers);        /* idx before entry */
        elem = &used->ring[vq->last_used_idx % vq->num];

/* The "weak_barriers" flag: when the device is a HOST THREAD
   sharing coherent memory, SMP barriers (DMB ISH) suffice.
   When it is a real PCIe device doing DMA, you need full DMA
   barriers. VIRTIO_F_ORDER_PLATFORM tells the driver which.  */
```

Notification suppression: doing nothing, faster

```
/* An interrupt per completed request is as bad as a trap per
   register. Both sides can say "do not bother me".         */

/* Basic form, in the ring flags:

     avail->flags |= VRING_AVAIL_F_NO_INTERRUPT
         the GUEST is saying: I am polling, do not interrupt me.
         Used while NAPI is active.

     used->flags |= VRING_USED_F_NO_NOTIFY
         the DEVICE is saying: I am already processing, do not
         trap on notify. This is what removes the exit
         entirely while a batch is in flight.                */

/* Better form: VIRTIO_F_EVENT_IDX. Instead of on/off, each
   side publishes the index at which it WANTS to be told.  */

     used_event  = the avail.idx value at which the device
                   should notify the guest
     avail_event = the used.idx value at which the guest
                   should notify the device

/* So a busy device processing a stream of requests sets
   avail_event far ahead, and the guest submits hundreds of
   buffers with ZERO exits. When the device drains the queue it
   moves avail_event to "next one", and the following submit
   traps once to wake it.

   Result on a saturated virtio-net link: the exit rate is
   roughly the number of BATCHES per second, not packets. That
   is the difference between 50k and 3M packets per second.  */

/* This is the same fast-path/doorbell pattern as GICv4 direct
   injection (chapter 11). It recurs because it is the only way
   to make an expensive notification cheap: make it
   conditional on the receiver actually being asleep.        */
```

The packed virtqueue

```
virtio 1.1 replaces three arrays with ONE.

Split ring: descriptor table + avail ring + used ring
            -> three cache lines touched per request,
               in three separate places

Packed ring: a single descriptor ring, where ownership is
             encoded in two flag bits and a wrap counter.

+-----------------------------------------------------+
|  addr  |  len  |  id  |  flags: AVAIL | USED       |
+-----------------------------------------------------+

  driver writes a descriptor with AVAIL == wrap_counter
  device sees it, processes, writes back with
         USED == wrap_counter

Each side keeps its own index and wrap counter, and flips
the counter each time it goes round.

Why it is faster:
  * one cache line per descriptor instead of three
  * the device prefetches sequentially - the ring is read in
    order
  * far friendlier to a hardware implementation, which is
    the real motivation: virtio-net offloaded onto a SmartNIC
    or DPU wants a ring a state machine can walk.

Negotiated with VIRTIO_F_RING_PACKED. Both sides must
support it; the split ring remains the universal fallback.
```

virtio-mmio, concretely

```
/* The register block QEMU's virt machine puts at 0x0a000000,
   0x0a000200, 0x0a000400, ... one per device slot.         */

  0x000  MagicValue        0x74726976  ("virt")
  0x004  Version           2 (modern) or 1 (legacy)
  0x008  DeviceID          1=net 2=blk 3=console 4=entropy
                           16=gpu 18=input 19=vsock 25=fs
                           0 = EMPTY SLOT
  0x00c  VendorID
  0x010  DeviceFeatures    read, 32 bits at a time
  0x014  DeviceFeaturesSel which 32-bit word
  0x020  DriverFeatures
  0x024  DriverFeaturesSel
  0x030  QueueSel          which queue the following apply to
  0x034  QueueNumMax       device's maximum ring size
  0x038  QueueNum          driver's chosen size
  0x044  QueueReady
  0x050  QueueNotify       <-- THE DOORBELL. ioeventfd this.
  0x060  InterruptStatus
  0x064  InterruptACK
  0x070  Status            the handshake state machine
  0x080  QueueDescLow      guest-physical address of the
  0x084  QueueDescHigh     descriptor table
  0x090  QueueDriverLow    ... of the avail ring
  0x094  QueueDriverHigh
  0x0a0  QueueDeviceLow    ... of the used ring
  0x0a4  QueueDeviceHigh
  0x100+ Config            device-specific

/* The Status handshake - every virtio driver does exactly
   this, and a device model must enforce the order:        */

    0                          reset
    |= ACKNOWLEDGE   (1)       "I see a virtio device"
    |= DRIVER        (2)       "I have a driver for it"
    ... read DeviceFeatures, write DriverFeatures ...
    |= FEATURES_OK   (8)       "I accept this feature set"
    ... re-read Status: if FEATURES_OK cleared, the device
        rejected the negotiation and the driver must give up
    ... set up queues, write addresses, QueueReady = 1 ...
    |= DRIVER_OK     (4)       "I am live, you may use the
                                queues"

    FAILED           (128)     something went wrong
    DEVICE_NEEDS_RESET (64)    the device gave up

/* A device that starts processing queues before DRIVER_OK, or
   a driver that touches a queue before QueueReady, produces
   the classic "works most of the time" virtio bug.        */
```

> **LEGACY VERSUS MODERN**
> Version 1 (legacy) virtio-mmio uses guest page numbers rather than addresses, has a different endianness rule, and lacks the `QueueReady` handshake. Mixing a modern driver with a legacy device model gives you a device that probes and then silently transfers nothing. Check register `0x004` first — it is two instructions and saves an afternoon.

Watching it work

```
# Guest: which virtio devices exist and what negotiated?
$ ls /sys/bus/virtio/devices/
virtio0  virtio1  virtio2
$ cat /sys/bus/virtio/devices/virtio1/device       # 0x0002 = blk
$ cat /sys/bus/virtio/devices/virtio1/features
10000000000000000000001100001000000000000000000000000000000000000

$ cat /proc/interrupts | grep virtio
 25:      88104          0     GICv3  34 Level     virtio1

# Host: how many exits is the data path costing?
$ sudo perf stat -e kvm:kvm_mmio -a sleep 5
# Then run a big dd inside the guest and compare. With
# ioeventfd + EVENT_IDX the count should barely move.

# Is vhost carrying the datapath, or QEMU?
$ ps -T -p $(pgrep qemu) -o comm | grep vhost
vhost-4211            # kernel thread -> vhost is in use

# QEMU command line for an mmio virtio-blk on the virt machine:
$ qemu-system-aarch64 -M virt -m 1G \
    -drive file=rootfs.ext4,format=raw,if=none,id=hd0 \
    -device virtio-blk-device,drive=hd0 \
    -netdev user,id=n0 -device virtio-net-device,netdev=n0
# "-device virtio-*-device" = mmio transport
# "-device virtio-*-pci"    = PCI transport (needs a PCIe host
#                             bridge, which -M virt provides)
```

How it shows up

Symptom	Cause
Device probes, then no data ever moves	Legacy/modern mismatch, or queue addresses programmed before `QueueReady`
Rare data corruption under load	A missing barrier between descriptor contents and `avail.idx`, or between `used.idx` and the interrupt
Guest hangs waiting for completions	Notification suppression bug: device slept and the guest's notify was suppressed, so nobody woke
Throughput fine, latency terrible	`EVENT_IDX` thresholds too far ahead — batching at the cost of responsiveness
Enormous MMIO exit count on a busy queue	No `ioeventfd` on `QueueNotify`
Guest driver refuses to attach	Feature negotiation failed — `FEATURES_OK` cleared by the device
Works with QEMU, breaks with vhost	Device model and vhost disagree about which features were negotiated
Works on x86, fails on arm64	Barriers that were free on a strongly-ordered CPU and are not here
Ring wedges after ~65536 requests	Index wrap handled with a comparison instead of modular arithmetic

Check yourself

- ✓ Explain the control-plane/data-plane split and say which one costs exits.
- ✓ Name the three arrays of a split virtqueue and say which direction each carries.

- ✓ Walk a request from descriptor allocation to completion reaping, naming every barrier.
- ✓ Explain why the descriptor contents must be published before `avail.idx`.
- ✓ Describe both forms of notification suppression and what `EVENT_IDX` adds.
- ✓ Explain what the packed ring changes and why hardware implementers wanted it.
- ✓ List the virtio status handshake states in order and say what each asserts.
- ✓ Name the doorbell register in virtio-mmio and the optimisation that should be attached to it.
- ✓ Give two symptoms of a legacy/modern transport mismatch.
- ✓ Determine, from inside a guest, which virtio devices exist and what features they negotiated.

virtio device families and vhost

One queue mechanism, thirty device types, and three places the device implementation can live: in the VMM process, in the host kernel, or in a separate process entirely. Which you choose decides your throughput, your latency and your blast radius when the device model has a bug.

The device families

ID	Device	Queues	What it is for
1	`virtio-net`	RX/TX pair per channel, plus a control queue	Networking. The most optimised of the lot; supports multiqueue, checksum and TSO offload
2	`virtio-blk`	1 or more	Block storage. Simplest useful device — a good first one to implement
3	`virtio-console`	2 per port	Serial ports and the hvc console
4	`virtio-rng`	1	Entropy. Small, and matters more than it looks: a guest with no entropy blocks at boot
5	`virtio-balloon`	2–3	Return guest pages to the host under pressure
9	`virtio-9p`	1	File sharing, largely superseded by virtiofs
16	`virtio-gpu`	2	Display and 3D, with venus/virgl for GPU passthrough of API calls
18	`virtio-input`	2	Keyboard, mouse, touch — evdev over a queue
19	`virtio-vsock`	3	Host↔guest sockets with no network stack. The right answer for an agent inside a VM
22	`virtio-snd`	4	Audio
23	`virtio-fs`	2+	FUSE protocol over a queue, with DAX so the guest can map host page cache directly
25	`virtio-iommu`	1	A paravirtual IOMMU — lets a guest manage DMA mappings for its own passed-through devices
27	`virtio-mem`	1	Memory hotplug at sub-DIMM granularity; supersedes ballooning for most uses

WHICH ONES MATTER ON AN EMBEDDED TARGET

`virtio-blk`, `virtio-net`, `virtio-console` and `virtio-rng` give you a fully functional Linux guest on QEMU's `virt` machine with four command-line options. Everything else is specialisation. Start there, and see the recipes in QEMU chapter 15.

Three places a device can live

```
1. IN THE VMM (userspace, e.g. QEMU)

   guest  --notify-->  KVM  --exit-->  QEMU thread
                                         |
                                       host syscall
   Latency:  ~15-30 us per batch
   Pros:     easy to write, debug and sandbox; full access
             to files, sockets, image formats (qcow2)
   Cons:     two context switches per batch

2. IN THE HOST KERNEL (vhost)

   guest  --notify(ioeventfd)-->  KVM  --wake--> vhost-net
                                                 kernel thread
                                                    |
                                                 net stack
   Latency:  close to host-native
   Pros:     no userspace round trip; the kernel already has
             the socket/block layer right there
   Cons:     device model is kernel code - a bug is a host
             kernel bug. Only exists for net, blk (vhost-blk,
             out of tree), scsi, vsock.

   QEMU still does SETUP: feature negotiation, queue
   addresses, and it hands vhost the memory map and the
   eventfds. Only the DATA PATH moves.

3. IN ANOTHER PROCESS (vhost-user / vhost-vdpa)

   guest  --notify-->  KVM  --> a separate daemon
                                (DPDK, SPDK, virtiofsd,
                                 a rust-vmm device)
   Latency:  can be the best of all - a polling DPDK thread
             never sleeps, so there is no wake-up at all
   Pros:     device crash does not take down the VMM or the
             host kernel; can be written in Rust; can be
             updated independently
   Cons:     the daemon must map ALL of guest memory, so it
             is inside the trust boundary for confidentiality

   The daemon learns the guest memory layout over a UNIX
   socket (the vhost-user protocol) and then accesses the
   rings directly.
```

virtio-net in detail

```
/* Feature bits worth knowing, because they decide performance
   far more than the ring implementation does.              */

  VIRTIO_NET_F_CSUM            device handles checksums; the
                               guest can send unchecksummed
                               packets. Saves a pass over data.
  VIRTIO_NET_F_GUEST_CSUM      the guest will accept them.
  VIRTIO_NET_F_HOST_TSO4/6     device will segment; the guest
                               may send 64 KB "packets".
                               THE big win - one descriptor
                               chain instead of forty.
  VIRTIO_NET_F_GUEST_TSO4/6    guest accepts big receives (GRO).
  VIRTIO_NET_F_MRG_RXBUF       merge several receive buffers
                               into one packet - needed for
                               large receives without wasting
                               memory on small ones.
  VIRTIO_NET_F_MQ              multiqueue: one RX/TX pair per
                               vCPU, so no cross-CPU contention.
  VIRTIO_NET_F_CTRL_VQ         a control queue for MAC filters,
                               VLANs, offload changes.
  VIRTIO_NET_F_MTU             device tells the guest the MTU.

/* The header prepended to every packet: */

struct virtio_net_hdr_v1 {
        __u8  flags;            /* NEEDS_CSUM, DATA_VALID       */
        __u8  gso_type;         /* NONE, TCPV4, UDP, TCPV6      */
        __le16 hdr_len;
        __le16 gso_size;        /* MSS for segmentation         */
        __le16 csum_start;      /* where the checksum field is  */
        __le16 csum_offset;
        __le16 num_buffers;     /* MRG_RXBUF: how many buffers
                                   this packet occupies         */
};

/* Descriptor chain for one transmitted packet:

     desc[0]  the header above          (device reads)
     desc[1]  the packet data           (device reads)
     ...      more fragments if scattered

   For a receive:

     desc[0]  a buffer the DEVICE WRITES, big enough for header
              plus data. With MRG_RXBUF, several such buffers
              may be consumed for one large packet, and
              num_buffers says how many.                    */
```

```
# Turn the knobs and watch what happens.

# Multiqueue, 4 pairs, with vhost:
$ qemu-system-aarch64 -M virt -accel kvm \
   -netdev tap,id=n0,vhost=on,queues=4 \
   -device virtio-net-pci,netdev=n0,mq=on,vectors=10

# vectors = 2*queues + 2 (one per queue direction, plus config
# and control). Too few and the guest silently falls back to
# fewer queues.

# In the guest, confirm:
$ ethtool -l eth0
Channels: Combined: 4

# Which offloads did the guest actually get?
$ ethtool -k eth0 | grep -E 'tx-checksum|tso|gro|gso'
tx-checksumming: on
tcp-segmentation-offload: on
generic-receive-offload: on

# Turning TSO off is the single fastest way to prove it matters:
$ ethtool -K eth0 tso off
$ iperf3 -c host      # expect a large drop
```

virtio-blk, the one to implement first

```
/* Three descriptors per request. That is the whole protocol. */

struct virtio_blk_outhdr {
        __le32 type;       /* IN=0 read, OUT=1 write,
                              FLUSH=4, GET_ID=8, DISCARD=11,
                              WRITE_ZEROES=13                */
        __le32 reserved;
        __le64 sector;     /* in 512-byte units, ALWAYS,
                              regardless of the logical block
                              size the device advertises     */
};

  desc[0]  -> struct virtio_blk_outhdr   (device reads)
  desc[1]  -> the data buffer            (read: device writes
                                          write: device reads)
  desc[2]  -> a single status byte       (device writes)
                VIRTIO_BLK_S_OK      0
                VIRTIO_BLK_S_IOERR   1
                VIRTIO_BLK_S_UNSUPP  2

/* A device model's whole hot path: */

static void blk_handle_request(struct blkdev *d, struct chain *c)
{
        struct virtio_blk_outhdr *h = c->desc[0].addr;
        void   *buf  = c->desc[1].addr;
        size_t  len  = c->desc[1].len;
        uint8_t *st  = c->desc[2].addr;
        off_t   off  = (off_t)le64toh(h->sector) * 512;

        switch (le32toh(h->type)) {
        case VIRTIO_BLK_T_IN:
                *st = (pread(d->fd, buf, len, off) == (ssize_t)len)
                    ? VIRTIO_BLK_S_OK : VIRTIO_BLK_S_IOERR;
                break;
        case VIRTIO_BLK_T_OUT:
                *st = (pwrite(d->fd, buf, len, off) == (ssize_t)len)
                    ? VIRTIO_BLK_S_OK : VIRTIO_BLK_S_IOERR;
                break;
        case VIRTIO_BLK_T_FLUSH:
                *st = fdatasync(d->fd) == 0
                    ? VIRTIO_BLK_S_OK : VIRTIO_BLK_S_IOERR;
                break;
        default:
                *st = VIRTIO_BLK_S_UNSUPP;
        }
        vq_complete(c, len);
}

/* THE FLUSH IS NOT OPTIONAL. A device model that ignores
   VIRTIO_BLK_T_FLUSH will pass every functional test and lose
   the guest's filesystem on the first host power cut, because
   the guest believed its journal was durable. If you take one
   thing from this chapter, take that.                       */
```

CACHE MODES ARE A DURABILITY CONTRACT

QEMU's `cache=` option decides who may lie about durability. `cache=writeback` (the default) lets the host page cache absorb writes and relies on the guest issuing flushes — correct, and fast, *if* your flush path works. `cache=unsafe` discards flushes entirely: excellent for a throwaway build VM, catastrophic for anything you care about. `cache=none` uses O_DIRECT. Choose deliberately, and never leave `unsafe` in a script someone else might reuse.

virtio-vsock: the one people forget

```
/* Host-guest communication without a network. No IP, no
   firewall, no DHCP, no risk of the guest routing somewhere.
   Addresses are (CID, port).                                */

  CID 0  hypervisor
  CID 1  local (loopback)
  CID 2  the HOST, always
  CID 3+ guests, assigned by the VMM

# QEMU:
$ qemu-system-aarch64 ... -device vhost-vsock-pci,guest-cid=42

# Guest, a server:
$ socat VSOCK-LISTEN:1234,fork -
# Host, a client:
$ socat - VSOCK-CONNECT:42:1234

/* In C, it is just sockets: */
    int s = socket(AF_VSOCK, SOCK_STREAM, 0);
    struct sockaddr_vm a = {
            .svm_family = AF_VSOCK,
            .svm_cid    = VMADDR_CID_HOST,   /* 2              */
            .svm_port   = 1234,
    };
    connect(s, (struct sockaddr *)&a, sizeof a);

/* Use it for: guest agents, log shipping, test harnesses,
   debugging a guest with no network configured, and anything
   where giving the guest a network interface would be a
   security decision you do not want to make.               */
```

virtiofs and DAX

```
# Sharing a host directory with a guest, properly.

# Host: run the daemon (a vhost-user device in its own process)
$ /usr/libexec/virtiofsd --socket-path=/tmp/vfs.sock \
      -o source=/srv/shared -o cache=auto

# QEMU: connect to it, and give it shared memory
$ qemu-system-aarch64 -M virt,memory-backend=mem \
   -object memory-backend-file,id=mem,size=4G,\
mem-path=/dev/shm,share=on \
   -chardev socket,id=vfs,path=/tmp/vfs.sock \
   -device vhost-user-fs-pci,chardev=vfs,tag=myfs

# Guest:
$ mount -t virtiofs myfs /mnt

/* Why "share=on" and a file-backed memory object are
   mandatory: virtiofsd is a SEPARATE PROCESS. It must be able
   to map guest memory to read and write the queues. Anonymous
   private memory cannot be shared, so the VM will start and
   the mount will hang.

   DAX goes further: with a DAX window, the guest maps host
   PAGE CACHE PAGES directly into its own address space. A
   read() becomes a memory access with no copy and no exit at
   all. That is why virtiofs beats 9p by an order of magnitude
   on metadata-heavy workloads like a source tree.          */
```

How it shows up

Symptom	Cause
Guest filesystem corrupt after a host crash	Device model ignores `VIRTIO_BLK_T_FLUSH`, or `cache=unsafe`
Network throughput a fraction of the host's	TSO/checksum offload not negotiated — every packet is a separate chain
Multiqueue configured but only one queue active	Too few MSI-X vectors, or the guest never sent the control-queue command to enable the pairs
vhost-user device never starts, VM hangs at boot	Guest memory not shared (`share=on` and a file-backed memory object missing)
Guest blocks for a minute early in boot	No `virtio-rng`; the entropy pool is empty
Large receives dropped or truncated	`MRG_RXBUF` negotiated but `num_buffers` not honoured
Guest sees the wrong disk size after resizing	Config-space change not signalled with a configuration-change interrupt
vsock connection refused from the host	Wrong CID — the guest must connect to CID 2, not to its own
virtiofs mount hangs	Daemon not running, socket path mismatch, or DAX window requested without shared memory
Everything is slow only with `-accel tcg`	Not a virtio problem — emulation is the bottleneck (QEMU chapter 2)

Check yourself

- ✓ Name six virtio device types and what each replaces.
- ✓ Compare the three places a device implementation can live, with a latency figure for each.

- ✓ Explain what vhost moves into the kernel and what QEMU still does.
- ✓ Explain why vhost-user requires shared guest memory.
- ✓ List four virtio-net feature bits and say what each saves.
- ✓ Describe the three-descriptor structure of a virtio-blk request.
- ✓ Explain why ignoring `FLUSH` is a data-loss bug and not a performance choice.
- ✓ Give the vsock CID for the host and describe one good use for vsock.
- ✓ Explain what DAX gives virtiofs over 9p.
- ✓ Diagnose "multiqueue configured but only one queue is busy".

Device passthrough, the SMMU and VFIO

Giving a guest a real device removes every emulation cost at once — and hands an untrusted kernel a DMA engine. The SMMU is what makes that survivable, and VFIO is the interface through which Linux lets user space own a device safely. This chapter is where the isolation track and the virtualisation track meet.

Why passthrough, and what it costs you

	Emulated	virtio	Passthrough
MMIO cost	One exit per register	One exit per batch	**Zero** — the guest maps the real registers
Interrupt cost	Exit to inject	Exit to inject	One exit, or zero with GICv4
Guest driver	Any	Must have a virtio driver	The real vendor driver, unmodified
Live migration	Easy	Easy	**Very hard** — device state is opaque (unless it supports the VFIO migration protocol)
Sharing between guests	Trivial	Trivial	Impossible without SR-IOV
Host visibility	Full	Full	None — the host cannot inspect the traffic
Blast radius of a guest bug	Contained	Contained	The device is compromised

Passthrough is the right answer for a GPU, a 100GbE NIC, an accelerator, or an automotive CAN controller that a partition must own outright. It is the wrong answer whenever you need to migrate, oversubscribe, or inspect. Most real systems mix: virtio for the boot disk and management network, passthrough for the one device whose performance actually matters.

The problem passthrough creates

```
The guest programs the real device:

    "DMA 4 KB from your FIFO to address 0x4200_0000"

The guest means its own IPA 0x4200_0000. But the device does
not go through the CPU's MMU - it issues a bus transaction
with that address directly.

WITHOUT an SMMU:

    device writes PHYSICAL 0x4200_0000
         |
         v
    whatever is there. The host kernel. Another guest.
    Firmware. The guest just wrote to it.

A guest with a passed-through device and no SMMU owns the
entire machine. Not "can crash it" - OWNS it. This is not a
subtle bug; it is the reason IOMMUs exist.

WITH an SMMU:

    device writes IPA 0x4200_0000
         |
         |  SMMU looks up the StreamID of this device,
         |  finds the translation tables the hypervisor
         |  installed for it - THE SAME STAGE-2 TABLES the
         |  guest's CPU accesses use
         v
    real physical address, inside the guest's memory. Or a
    fault, if the guest lied.

The elegance: the device and the vCPU now share one notion
of "guest physical". A guest driver written for bare metal
works unmodified, because its DMA addresses mean the same
thing to the device that they mean to its own CPU.
```

> **STAGE 2 DOES DOUBLE DUTY**
> The same translation tables that constrain the guest's CPU also constrain its devices. That is why StreamID and `VTTBR_EL2` appear together in every passthrough setup: the hypervisor points the device's SMMU context descriptor at the VM's stage-2 tables and its VMID, and isolation follows automatically.

VFIO: owning a device from user space

```
VFIO is how Linux hands a device to a non-kernel owner
safely. QEMU uses it; so does DPDK; so can you.

/dev/vfio/vfio          the container - an address space
/dev/vfio/<group>       an IOMMU group - the unit of
                        assignment

+-------------------------------------------------------+
|  CONTAINER  (one IOMMU address space)                 |
|                                                       |
|   +---------------+     +----------------+          |
|   | GROUP 12      |     | GROUP 13       |          |
|   |  device 0000: |     |  device 0000:  |          |
|   |   03:00.0     |     |   04:00.0      |          |
|   |  device 0000: |     |                |          |
|   |   03:00.1     |     |                |          |
|   +---------------+     +----------------+          |
+-------------------------------------------------------+

THE GROUP IS THE UNIT, AND YOU DO NOT CHOOSE IT.

Two devices share a group when the hardware cannot tell them
apart - they sit behind a PCIe bridge that does not do ACS
(Access Control Services), or they share a StreamID, or they
are functions of one multifunction device that alias.

If they cannot be told apart, they cannot be isolated from
each other, so they must be assigned together. A group
containing your NIC and your disk controller means you
cannot pass through the NIC alone. That is a HARDWARE
limitation and no kernel flag legitimately works around it.
(There is an "ACS override" patch. Using it on a machine you
care about is choosing to believe a device that has told you
it cannot be trusted.)
```

```
# The whole workflow, on a PCIe NIC.

# 1. What group is it in, and who else is in there?
$ lspci -nn | grep -i ethernet
03:00.0 Ethernet controller [0200]: Intel X710 [8086:1572]

$ readlink -f /sys/bus/pci/devices/0000:03:00.0/iommu_group
/sys/kernel/iommu_groups/12

$ ls /sys/kernel/iommu_groups/12/devices/
0000:03:00.0  0000:03:00.1        # both ports - both must go

# 2. Unbind from the host driver, bind to vfio-pci
$ echo 0000:03:00.0 | sudo tee /sys/bus/pci/devices/0000:03:00.0/driver/unbind
$ echo 8086 1572 | sudo tee /sys/bus/pci/drivers/vfio-pci/new_id
# (repeat for 03:00.1)

$ ls -l /dev/vfio/
crw------- 1 root root 241, 0 vfio
crw------- 1 root root 511, 0 12          # the group is now ours

# 3. Hand it to QEMU
$ qemu-system-aarch64 -M virt,iommu=smmuv3 -accel kvm \
    -device vfio-pci,host=0000:03:00.0 \
    -device vfio-pci,host=0000:03:00.1 \
    ...

# 4. In the guest, it is simply the real device:
$ lspci
00:01.0 Ethernet controller: Intel X710
$ dmesg | grep i40e
i40e 0000:00:01.0: fw 6.1.42...
```

Why the guest's memory gets pinned

```
/* The moment a device can DMA into guest memory, that memory
   can no longer be swapped, migrated, or reclaimed - because
   the device holds a translation the kernel cannot revoke
   without the device noticing.

   So VFIO PINS it. All of it.                              */

    ioctl(container, VFIO_IOMMU_MAP_DMA, &(struct vfio_iommu_type1_dma_map){
            .vaddr = host_virtual_address_of_guest_ram,
            .iova  = guest_physical_address,
            .size  = whole_guest_ram,
            .flags = VFIO_DMA_MAP_FLAG_READ | VFIO_DMA_MAP_FLAG_WRITE,
    });

/* Consequences you must plan for:

   * A 16 GB guest with passthrough consumes 16 GB of host RAM,
     immediately and permanently. No ballooning, no overcommit,
     no KSM.

   * You will hit RLIMIT_MEMLOCK. The error is
     "VFIO_MAP_DMA failed: Cannot allocate memory" and it is
     nothing to do with free memory.
         $ ulimit -l
         64            # kilobytes. Nowhere near enough.
     Fix in /etc/security/limits.conf or the systemd unit:
         LimitMEMLOCK=infinity

   * Huge pages help a lot: fewer SMMU table levels, fewer
     entries, better TLB reach on the device side too.

   * Live migration of a pinned, passed-through device requires
     the device itself to implement the VFIO migration region
     so its internal state can be saved. Most do not.        */
```

Interrupts for a passed-through device

```
   The device's real interrupt must become the guest's virtual
   interrupt, and the guest's EOI must deactivate the real one.

     device raises MSI / SPI
        |
        v
     physical interrupt -> host (HCR_EL2.IMO routes to EL2)
        |
        v
     VFIO's handler signals an EVENTFD
        |
        v
     KVM has that eventfd bound as an IRQFD to a vINTID:
        ioctl(vmfd, KVM_IRQFD, {fd, gsi})
        |
        v
     KVM writes a list register with
        HW = 1, pINTID = the real one, vINTID = the guest's
        |
        v
     guest reads ICV_IAR1_EL1, services the device through its
     passed-through MMIO, writes ICV_EOIR1_EL1
        |
        v
     hardware deactivates the PHYSICAL interrupt too, because
     HW = 1. (chapter 10)

   Exits: one, for the physical interrupt. GICv4 removes even
   that by delivering the virtual LPI directly (chapter 11).

   The MSI address problem: a device programmed by the guest
   writes its MSI to an address the GUEST chose - an IPA. The
   SMMU must translate that to the real ITS doorbell, so the
   ITS window has to be mapped in the device's stage-2 tables.
   Linux handles this with "reserved regions"; a mismatch
   produces a device that works for MMIO and never interrupts. */
```

```
# The reserved regions the IOMMU insists you avoid or map:
$ cat /sys/kernel/iommu_groups/12/reserved_regions
0x0000000008080000 0x000000000809ffff msi
0x00000000fee00000 0x00000000feefffff msi

# QEMU refuses to place guest RAM over these, and maps the MSI
# window so the device's doorbell writes land on the real ITS.

# Check the SMMU is actually in the path:
$ dmesg | grep -i smmu
[    1.234567] arm-smmu-v3 arm-smmu-v3.0.auto: ias 44-bit, oas 48-bit
[    1.234599] arm-smmu-v3 arm-smmu-v3.0.auto: allocated 65536 entry CMDQ
[    1.234610] arm-smmu-v3 arm-smmu-v3.0.auto: 2-level strtab only

# And that the group is genuinely isolated, not a passthrough
# fallback:
$ cat /sys/kernel/iommu_groups/12/type
DMA          # good.  "identity" means NO TRANSLATION - the
             # device sees physical addresses. Never pass a
             # device through from an identity-mapped group.
```

> **`IOMMU.PASSTHROUGH=1` AND IDENTITY DOMAINS**
> Some distributions boot with the IOMMU in identity (bypass) mode for performance. A device in an identity domain sees real physical addresses. Passing such a device to a guest gives that guest full write access to host memory, silently — everything appears to work. Always check `/sys/kernel/iommu_groups/N/type` before trusting an assignment.

Platform devices, not just PCIe

```
/* Embedded SoCs have few PCIe devices and many platform
   devices described by device tree. VFIO handles those too,
   with more manual work.                                    */

  vfio-platform      generic platform device passthrough
  vfio-amba          for AMBA/PrimeCell devices

# Bind:
$ echo vfio-platform | sudo tee \
    /sys/bus/platform/devices/ff170000.i2c/driver_override
$ echo ff170000.i2c | sudo tee /sys/bus/platform/drivers/vfio-platform/bind

# QEMU:
$ qemu-system-aarch64 -M virt -accel kvm \
    -device vfio-platform,host=ff170000.i2c

/* Extra work platform passthrough demands and PCIe does not:

   1. YOU must write the guest's device tree node for it -
      there is no enumeration. QEMU can generate one for
      simple cases; anything with clocks, resets, regulators
      or pinmux you do yourself.

   2. RESET. PCIe has FLR (function level reset) as a standard.
      A platform device has whatever the vendor invented. VFIO
      requires a reset driver in the host kernel
      (vfio_platform_reset) or it refuses to bind, because
      handing a guest a device you cannot reset means the next
      guest inherits whatever the last one left running -
      including in-flight DMA.

   3. Shared resources. A clock or power domain shared between
      a passed-through device and a host device means the guest
      can switch off something the host is using. Device tree
      will not stop you; only your partitioning discipline
      will.                                                  */
```

How it shows up

Symptom	Cause
`VFIO_MAP_DMA failed: Cannot allocate memory`	`RLIMIT_MEMLOCK` too low — not a shortage of RAM
Cannot bind: "group is not viable"	Another device in the same IOMMU group is still bound to a host driver
Guest sees the device, MMIO works, no interrupts ever	MSI doorbell window not mapped, or `irqfd` not bound to the right vINTID

Symptom	Cause
Device works once, then not after guest reboot	No reset path — the device kept running with stale DMA
Host memory corruption when the guest starts	IOMMU in identity/passthrough mode, or no SMMU in the path at all
Guest boots, device faults on every DMA	Stage-2 tables not shared with the SMMU context, or the guest's DMA addresses are not IPAs it owns
SMMU fault flood in host `dmesg`	Guest driver programming addresses outside its memory — usually a guest bug the SMMU is correctly catching
Cannot migrate the VM	Passed-through device without VFIO migration support. Expected, not a bug
Guest gets far less memory than requested	Pinning failed partway; check for `hugetlb` availability and memlock limits
Two guests both crash when one uses its device	Devices share a StreamID, so the SMMU cannot tell them apart

Check yourself

- ✓ Give three costs of passthrough and three benefits, and name a workload for each side.
- ✓ Explain precisely what a passed-through device can do to a system with no SMMU.
- ✓ Explain how the SMMU and the vCPU come to agree on what a guest-physical address means.
- ✓ Define an IOMMU group and say why you cannot choose its membership.
- ✓ Walk through binding a PCIe device to `vfio-pci` and handing it to QEMU.
- ✓ Explain why guest memory is pinned and list three consequences.
- ✓ Diagnose `VFIO_MAP_DMA failed: Cannot allocate memory`.
- ✓ Trace a passed-through device's interrupt to the guest handler and back, naming the `HW` bit's role.
- ✓ Explain the MSI doorbell translation problem and how reserved regions solve it.
- ✓ Give three things platform passthrough requires that PCIe passthrough does not.
- ✓ Explain why an identity-domain IOMMU group must never be passed through.

KVM/arm64 internals

Everything in this track so far exists in one directory of the Linux source tree. This chapter is the map: where each mechanism lives, what the ioctl interface looks like from the outside, and how to build a working hypervisor in about two hundred lines so that the abstractions stop being abstract.

The source map

```
arch/arm64/kvm/
|
+-- arm.c              VM and vCPU lifecycle, the run loop.
|                      kvm_arch_vcpu_ioctl_run() is the
|                      function everything passes through.
+-- handle_exit.c      the exit dispatch table, keyed on
|                      ESR_EL2.EC. Start reading here.
+-- sys_regs.c         the emulated system register table -
|                      one entry per trapped register, with
|                      its access function and reset value.
|                      Enormous, and mechanical.
+-- mmu.c              stage-2: memslots, user_mem_abort(),
|                      page table management, dirty logging.
+-- pkvm.c             protected-KVM setup.
+-- psci.c             PSCI: CPU_ON/OFF/SUSPEND, SYSTEM_RESET.
+-- pmu.c pmu-emul.c   virtual PMU.
+-- arch_timer.c       CNTVOFF, the timer save/restore and
|                      the hrtimer used while descheduled.
+-- vgic/
|    +-- vgic-init.c   creation, from the KVM device API
|    +-- vgic-mmio*.c  the emulated distributor/redistributor
|    +-- vgic-v3.c     list registers, the hardware side
|    +-- vgic-its.c    the emulated ITS
|    +-- vgic-v4.c     direct injection
+-- hyp/
     +-- nvhe/         code that runs at EL2 in nVHE mode.
     |                 Compiled separately, its own linker
     |                 script, cannot call ordinary kernel
     |                 functions.
     +-- vhe/          the VHE variants
     +-- include/      shared switch code

virt/kvm/              architecture-independent core:
                       kvm_main.c, eventfd.c (irqfd,
                       ioeventfd), the memslot machinery.

READING ORDER that works:
  1. handle_exit.c  - see every exit reason in one table
  2. arm.c          - the loop around it
  3. mmu.c          - user_mem_abort(), the single most
                      important function in the file
  4. sys_regs.c     - pick one register and follow it
  5. vgic/          - only when you need it
```

The ioctl interface, in order

```
/* This is the entire contract between a VMM and KVM. Every
   VMM - QEMU, crosvm, firecracker, cloud-hypervisor - makes
   these calls in this order.                                */

  int kvm = open("/dev/kvm", O_RDWR);

  ioctl(kvm, KVM_GET_API_VERSION);              /* must be 12  */
  ioctl(kvm, KVM_CHECK_EXTENSION, KVM_CAP_ARM_VM_IPA_SIZE);

  int vm = ioctl(kvm, KVM_CREATE_VM, 40);       /* 40-bit IPA  */

  /* Memory: tell KVM which host memory backs which guest
     physical range. Anything not covered is MMIO.            */
  ioctl(vm, KVM_SET_USER_MEMORY_REGION,
        &(struct kvm_userspace_memory_region){
            .slot            = 0,
            .guest_phys_addr = 0x40000000,
            .memory_size     = 1UL << 30,
            .userspace_addr  = (uint64_t)mmap(...),
        });

  /* The interrupt controller is a "KVM device".              */
  int gic = ioctl(vm, KVM_CREATE_DEVICE,
        &(struct kvm_create_device){
            .type = KVM_DEV_TYPE_ARM_VGIC_V3 });
  ioctl(gic, KVM_SET_DEVICE_ATTR, ...);   /* base addresses    */

  /* vCPUs.                                                   */
  int vcpu = ioctl(vm, KVM_CREATE_VCPU, 0);

  struct kvm_vcpu_init init = {};
  ioctl(vm, KVM_ARM_PREFERRED_TARGET, &init);
  init.features[0] |= 1 << KVM_ARM_VCPU_PSCI_0_2;
  ioctl(vcpu, KVM_ARM_VCPU_INIT, &init);

  /* The shared communication page.                           */
  size_t mmap_sz = ioctl(kvm, KVM_GET_VCPU_MMAP_SIZE, 0);
  struct kvm_run *run = mmap(NULL, mmap_sz, PROT_READ|PROT_WRITE,
                             MAP_SHARED, vcpu, 0);

  /* Registers are set through a generic ID-based interface.  */
  ioctl(vcpu, KVM_SET_ONE_REG, &(struct kvm_one_reg){
            .id   = ARM64_CORE_REG(regs.pc),
            .addr = (uint64_t)&entry_point });

  /* And then, forever:                                       */
  for (;;) {
          ioctl(vcpu, KVM_RUN, 0);
          switch (run->exit_reason) { ... }
  }
```

A hypervisor in two hundred lines

```
/* Runs a tiny AArch64 payload that writes to a UART address we
   model, then halts. Build:
       aarch64-linux-gnu-gcc -static -o tinyvmm tinyvmm.c
   Run on an arm64 host with /dev/kvm.                        */

                                run->exit_reason);
                        return 1;
                }
        }
}
```

```
$ aarch64-linux-gnu-gcc -static -o tinyvmm tinyvmm.c
$ ./tinyvmm
KVM

# Then it sits in WFI forever - because we never created a vGIC,
# so nothing can ever wake it. Ctrl-C.

# That single word of output required: a VM, a memslot, a vCPU,
# an architected reset state, a run loop and an MMIO handler.
# Everything else in QEMU is more of the same, plus device
# models, plus a device tree, plus forty years of compatibility.
```

WHAT THIS PROVES

KVM does not "run virtual machines". It provides a CPU in a box and tells you when the box needs something. Every device, every address-space decision, every piece of firmware and every policy is user space's problem. That is why there are half a dozen VMMs with wildly different characters — firecracker boots in 100 ms because it declines to implement almost everything QEMU does.

The VMMs, and what they optimise for

VMM	Language	Optimises for	Notes
QEMU	C	Completeness	Every device, every architecture, TCG as well as KVM. The reference
Firecracker	Rust	Boot time and attack surface	~5 devices, no PCI, no BIOS. Used for AWS Lambda
crosvm	Rust	Sandboxing	Each device in its own process with seccomp; the basis of ChromeOS and Android VMs
cloud-hypervisor	Rust	Modern cloud workloads	Hotplug, live migration, no legacy emulation
rust-vmm	Rust	Being a library	The shared crates the above are built from; the fastest way to write your own
kvmtool	C	Being readable	~10k lines. The best code to learn from after this chapter

Instrumenting KVM

```
# Per-VM statistics (modern kernels expose them per-fd):
$ sudo ls /sys/kernel/debug/kvm/
$ sudo grep . /sys/kernel/debug/kvm/*/vcpu0/stat/* 2>/dev/null

# Tracepoints - the useful ones:
$ sudo ls /sys/kernel/debug/tracing/events/kvm/
kvm_entry  kvm_exit  kvm_guest_fault  kvm_mmio  kvm_set_irq
kvm_wfx_arm64  kvm_hvc_arm64  kvm_arm_setup_debug  ...

$ sudo perf record -e 'kvm:*' -a -- sleep 5
$ sudo perf script | awk '{print $5}' | sort | uniq -c | sort -rn

# Live summary:
$ sudo perf kvm --host stat live

# Function-level, when you are changing KVM itself:
$ sudo trace-cmd record -p function_graph \
      -g kvm_arch_vcpu_ioctl_run -O nofuncgraph-irqs
$ trace-cmd report | head -50

# Building a KVM with your own printk:
#   CONFIG_KVM=y (not =m, if you are changing hyp code)
#   CONFIG_DEBUG_INFO=y
# Note: in nVHE mode, code under arch/arm64/kvm/hyp/nvhe/
# CANNOT printk. Use the trace buffer or a magic register value
# you read after the exit. In VHE mode, ordinary printk works -
# one more reason VHE made KVM development pleasant.
```

How it shows up

Symptom	Cause
`KVM_CREATE_VM: Permission denied`	Not in the `kvm` group; check `ls -l /dev/kvm`
`KVM_ARM_VCPU_INIT: Invalid argument`	Requested a feature the host does not have — call `KVM_ARM_PREFERRED_TARGET` first and start from that
`KVM_RUN` returns `KVM_EXIT_FAIL_ENTRY` immediately	Illegal `PSTATE` in the initial register set, or PC outside any memslot
Guest runs but produces no output	MMIO handler matching the wrong address, or the payload writing to an address in a memslot (so it never traps)
vCPU never wakes from `WFI`	No vGIC created, so no interrupt can ever be delivered
Works as root, fails as a user	`RLIMIT_MEMLOCK`, or `/dev/kvm` permissions
Exit reason 0 or an unknown number	Kernel newer than your headers — rebuild against the running kernel's `linux/kvm.h`
Guest memory writes not visible to the VMM	Memslot registered with `MAP_PRIVATE` where the device or another process needs `MAP_SHARED`
No `printk` output from hyp code	nVHE mode — that code cannot printk at all

Check yourself

- ✓ Name the file in `arch/arm64/kvm/` that handles each of: exit dispatch, stage-2 faults, system-register emulation, the timer.

- ✓ List the ioctls needed to get from `/dev/kvm` to a running vCPU, in order.
- ✓ Explain what a memslot is and what "outside a memslot" implies.
- ✓ Explain what `kvm_run` is and how the VMM gets access to it.
- ✓ Explain why the tiny VMM's guest never wakes from `WFI`.
- ✓ State the division of responsibility between KVM and the VMM in one sentence.
- ✓ Give two VMMs other than QEMU and say what each optimises for.
- ✓ Name three KVM tracepoints and what each tells you.
- ✓ Explain why hyp code cannot `printk` in nVHE mode.
- ✓ Extend the tiny VMM: add a second MMIO address that returns a counter on read.

Static partitioning: Xen, Jailhouse and safety

Everything so far assumed the hypervisor should share resources cleverly. In safety-critical embedded systems that assumption is inverted: sharing is the hazard, and the hypervisor's job is to divide the machine once, at boot, and then get out of the way — ideally while executing no code at all during normal operation.

The inversion

```
CONSOLIDATING hypervisor (KVM, Xen, VMware)

  goal: run N guests on M cores, N > M
  scheduler: yes, and it is the interesting part
  memory: overcommitted, ballooned, swapped
  devices: emulated or shared
  failure mode: a noisy guest degrades its neighbours
  metric: throughput per watt, density, utilisation

PARTITIONING hypervisor (Jailhouse, Xen dom0-less,
                         Bao, PikeOS, QNX Hypervisor)

  goal: run N guests on N disjoint sets of cores
  scheduler: NONE. A core belongs to one guest, always.
  memory: statically carved, never shared, never reclaimed
  devices: statically assigned, one owner each
  failure mode: a guest can only harm itself
  metric: worst-case latency, certifiability, code size

The partitioning hypervisor is not a worse consolidator.
It is a different product, and asking it to time-share is
asking it to stop being what it is.
```

WHY "NO SCHEDULER" IS THE POINT

If the hypervisor never preempts a guest, then the guest's worst-case execution time is a property of the guest and the hardware alone. You can analyse it, bound it, and put it in a safety case. Add a scheduler and the worst case becomes a property of every other guest in the system — and that is not analysable in any useful sense. Certification does not reward cleverness; it rewards arguments you can finish.

Jailhouse: the minimal case

```
Jailhouse does not boot the machine. Linux does.
Then Linux hands pieces of itself away.

Step 1: Linux boots normally on all 4 cores.
        You reserve memory with the kernel command line:
           memmap=0x4000000$0x3f000000

Step 2: load the hypervisor
           jailhouse enable system-config.cell
        Jailhouse installs itself at EL2 UNDER the running
        Linux, which becomes the "root cell". Linux does not
        notice; it keeps running, now virtualised.

Step 3: take resources away
           jailhouse cell create rtos.cell
           jailhouse cell load rtos 0 rtos.bin
           jailhouse cell start rtos
        Cores 2 and 3 are removed from Linux (offlined
        first), the reserved memory is unmapped from the
        root cell, and the RTOS starts on them.

AFTER THIS POINT:

  +----------------------+   +----------------------+
  | root cell: Linux     |   | cell 1: RTOS         |
  | cores 0-1            |   | cores 2-3            |
  | RAM 0-1 GB           |   | RAM 1.0-1.06 GB      |
  | eth0, sd, usb        |   | CAN, one timer       |
  +----------------------+   +----------------------+
  +-----------------------------------------------------+
  |  Jailhouse at EL2: ~10k lines, no scheduler,       |
  |  no dynamic memory, no drivers, no interrupts      |
  |  of its own. Configures stage 2, the SMMU and the  |
  |  GIC, then ERETs and is essentially never          |
  |  entered again.                                     |
  +-----------------------------------------------------+

The hypervisor's steady-state CPU consumption is ZERO,
because in steady state it does not run.
```

```
/* A Jailhouse cell configuration is a C struct compiled to a
   binary blob. This is the entire interface, and its
   explicitness is deliberate.                                */

struct { ... } config = {

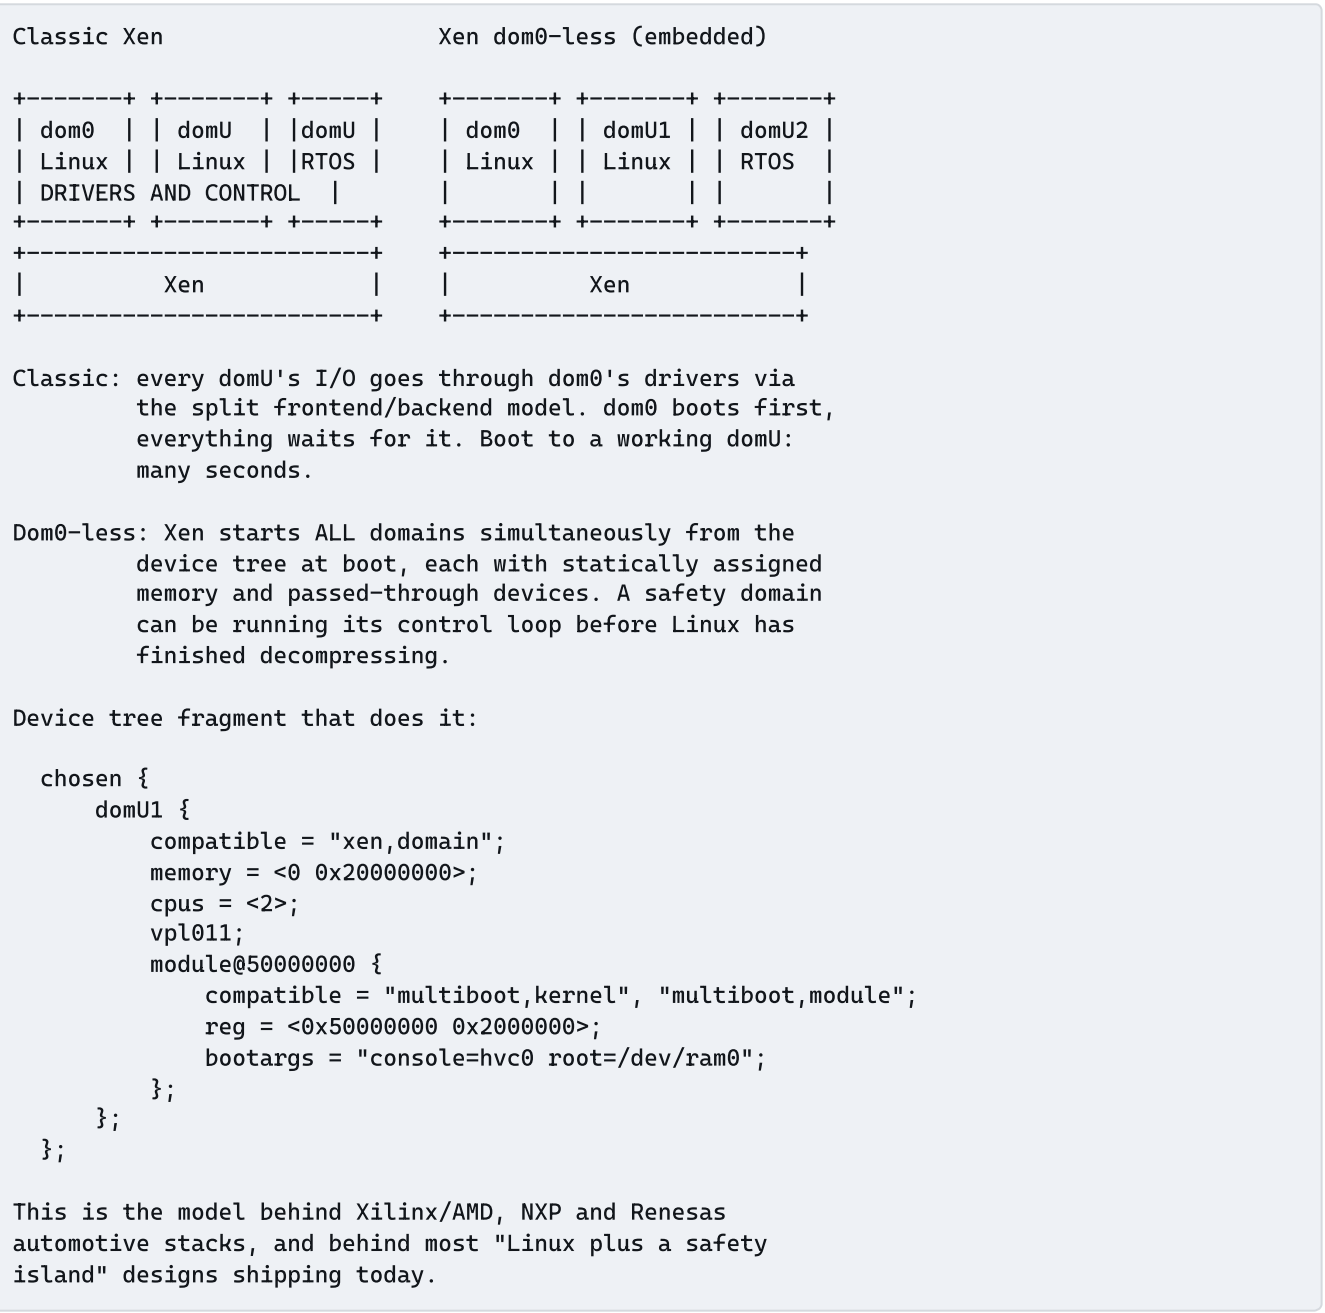
/* Notice what is NOT here: no memory size to grow into, no
   share of CPU time, no priority. Everything is a fixed
   assignment, decided before the system runs, auditable by
   reading one file.                                          */
```

Xen on ARM, and dom0-less



Classic: every domU's I/O goes through dom0's drivers via the split frontend/backend model. dom0 boots first, everything waits for it. Boot to a working domU: many seconds.

Dom0-less: Xen starts ALL domains simultaneously from the device tree at boot, each with statically assigned memory and passed-through devices. A safety domain can be running its control loop before Linux has finished decompressing.

Device tree fragment that does it:

```
  chosen {
      domU1 {
          compatible = "xen,domain";
          memory = <0 0x20000000>;
          cpus = <2>;
          vpl011;
          module@50000000 {
              compatible = "multiboot,kernel", "multiboot,module";
              reg = <0x50000000 0x2000000>;
              bootargs = "console=hvc0 root=/dev/ram0";
          };
      };
  };
```

This is the model behind Xilinx/AMD, NXP and Renesas automotive stacks, and behind most "Linux plus a safety island" designs shipping today.

The part everyone forgets: shared microarchitecture

```
You have partitioned cores, memory and devices. You have
NOT partitioned:

  the last-level cache      a Linux guest streaming data
                            evicts the RTOS's working set

  the memory controller     bandwidth and queueing delay are
                            shared; a DMA-heavy guest adds
                            latency to every other access

  the interconnect          arbitration, and any shared
                            buffering

  shared TLB / prefetchers  on some designs

Consequence: two guests that never share a byte of memory
still interfere in TIME. For a throughput workload this is
noise. For a 100 us control loop it is the difference
between meeting and missing a deadline.

MITIGATIONS, in increasing order of effort:

1. CACHE COLOURING. Allocate each partition only physical
   pages that map to disjoint cache sets. Because the cache
   index comes from physical address bits, choosing pages
   chooses cache regions. Jailhouse and Bao support it;
   you pay in usable memory and in allocator complexity.

2. MPAM (ARMv8.4 Memory System Resource Partitioning and
   Monitoring). Hardware support: tag each request with a
   PARTID, and configure cache-capacity and bandwidth limits
   per PARTID. This is the proper answer, and it is
   appearing in server and automotive silicon now.
     MPAM1_EL1 / MPAM2_EL2 hold the PARTID for each level.

3. MEASURE AND OVER-PROVISION. Run the interference
   benchmark (a deliberately cache-hostile stressor) in the
   Linux partition while measuring the RTOS's worst-case
   latency. Whatever number you get IS your worst case.
   This is what safety cases actually contain.
```

> **INTERFERENCE IS A CERTIFICATION PROBLEM, NOT A BUG**
> ISO 26262 and DO-178C both require you to argue freedom from interference. Partitioning the address space gets you spatial freedom. Temporal freedom needs measurement, and often needs MPAM or colouring. A design review that only shows the memory map has answered half the question.

Choosing

	KVM	Xen dom0-less	Jailhouse	Bao / PikeOS / QNX
Lines of code at EL2	Large (or ~10k for pKVM)	~100k	~10k	~5–50k
Scheduler	Full	Optional (null scheduler)	None	None or partitioned
Boot to first guest	Seconds	Sub-second	Linux first, then instant	Tens of ms

	KVM	Xen dom0-less	Jailhouse	Bao / PikeOS / QNX
Overcommit	Yes	Optional	No	No
Certifiable	Not realistically	Xen has safety-certified variants	Research/ industrial, small enough to try	Yes — that is the product
Best for	Servers, dev boxes, Android VMs	Automotive, mixed criticality	Adding a real-time partition to an existing Linux	Shipping safety systems

Trying it

```
# Jailhouse on QEMU's virt machine is the cheapest way to see
# a partitioning hypervisor work.

$ git clone https://github.com/siemens/jailhouse
$ cd jailhouse
$ make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- \
       KDIR=/path/to/linux
# Configs for qemu-arm64 ship in configs/arm64/

# Boot Linux under QEMU with reserved memory:
$ qemu-system-aarch64 -M virt,gic-version=3 -cpu cortex-a57 \
    -smp 4 -m 1G -nographic \
    -kernel Image -append "console=ttyAMA0 mem=768M" ...

# Inside the guest Linux:
$ insmod jailhouse.ko
$ jailhouse enable qemu-arm64.cell
Initializing Jailhouse hypervisor v0.12 on CPU 0
Code location: 0x0000ffffc0200000
Page pool usage after early setup: mem 39/993, remap 0/131072
...
The Jailhouse is opening.

$ jailhouse cell create qemu-arm64-inmate-demo.cell
$ jailhouse cell load 1 gic-demo.bin
$ jailhouse cell start 1
$ jailhouse cell list
ID      Name                    State             Assigned CPUs
0       qemu-arm64              running           0-2
1       inmate-demo             running           3

# Core 3 is now gone from Linux entirely:
$ nproc
3

# And the demo inmate is printing timer ticks on the second
# UART with a jitter of a few microseconds, regardless of what
# Linux is doing - which is the entire point.
```

How it shows up

Symptom	Cause
`jailhouse enable` fails with "CPU is not in EL2"	Firmware dropped to EL1 — the same prerequisite as KVM (chapter 3)
Cell creation fails: memory region overlaps	The reserved region was not actually reserved from Linux, or two cells claim it
Linux crashes when a cell starts	A device assigned to the cell is still bound to a Linux driver

Symptom	Cause
Guest partition misses deadlines only when Linux is busy	Cache and memory-bandwidth interference; partitioning was spatial only
Interrupts for a cell's device arrive in the root cell	The GIC `pin_bitmap` does not include that SPI, or affinity routes it elsewhere
Cell runs once and cannot be restarted	No reset path for its assigned device; it resumed with stale state
Everything works until you enable the SMMU	Device StreamIDs not listed in the cell config, so its DMA now faults
Worst-case latency good in the lab, bad in the field	The lab never ran the interference workload; measure with a deliberate stressor

Check yourself

- ✓ State the difference in goal between a consolidating and a partitioning hypervisor.
- ✓ Explain why "no scheduler" makes a safety argument tractable.
- ✓ Describe how Jailhouse installs itself beneath a running Linux, in three steps.
- ✓ Read a cell configuration and say which cores, memory and interrupts a partition owns.
- ✓ Explain what dom0-less Xen changes about boot time and why it matters in a car.
- ✓ Name four microarchitectural resources that partitioning does *not* divide.
- ✓ Explain cache colouring and what it costs.
- ✓ Say what MPAM provides and which registers carry the partition identity.
- ✓ Distinguish spatial from temporal freedom from interference.
- ✓ Choose a hypervisor for: an Android phone, a domain controller in a car, and adding a motor-control loop to an existing Linux product — and justify each.

S-EL2, Hafnium and FF-A

TrustZone gave the secure world one privileged OS and no way to isolate its parts from each other. As secure firmware grew — a TEE, a firmware TPM, a DRM stack, a vendor's key manager, all from different suppliers — that became untenable. S-EL2 adds virtualisation *inside* the secure world, and FF-A is the standard that makes the pieces interoperate.

The problem with one secure world

```
BEFORE S-EL2

S-EL0   TA   TA   TA          isolated from each other by
                              the trusted OS's MMU
S-EL1   OP-TEE                ONE trusted OS. Everything
                              privileged in the secure world
                              lives here.
EL3     TF-A

So: a firmware TPM, a vendor keystore, a DRM widevine
implementation and OP-TEE itself all end up either
  (a) as trusted applications, sharing one trusted OS's
      privilege domain and trusting its kernel completely, or
  (b) bolted INTO the trusted OS as pseudo-TAs, which means
      a bug in a vendor's DRM blob is a bug in the most
      privileged non-EL3 software on the phone.

Neither is acceptable when the components come from
different vendors with different assurance levels.

AFTER S-EL2

S-EL0   TA  TA        app          app
S-EL1   OP-TEE     |  fTPM SP   |  vendor SP
                   |            |
S-EL2   HAFNIUM - the Secure Partition Manager.
        Stage-2 translation for the SECURE world. Each
        secure partition gets its own IPA space, its own
        memory, its own devices, and cannot see the others.
EL3     TF-A - now also the SPM Dispatcher, routing FF-A
        calls between worlds.

Same architecture as the normal world, one world across.
Stage 2, VMIDs, traps - all of it, but with NS=0.
```

THE NAMING

In the normal world you say hypervisor, VM, vCPU. In the secure world you say **SPM** (Secure Partition Manager), **SP** (Secure Partition), and **execution context**. The mechanisms are the same; the vocabulary comes from the FF-A specification, and using the wrong one in a review makes conversations harder than they need to be.

FF-A: the Firmware Framework

Arm's Firmware Framework for A-profile defines how partitions discover each other, send messages, and share memory — across the world boundary and within a world. It replaces a decade of incompatible vendor SMC conventions with one ABI.

```
/* FF-A calls are SMCs with function IDs in a reserved range,
   following SMCCC. The ones you will actually use:        */

  SETUP AND DISCOVERY
    FFA_VERSION                 negotiate the version
    FFA_FEATURES                what does this implementation do?
    FFA_ID_GET                  what is my own partition ID?
    FFA_PARTITION_INFO_GET      who else exists, and what UUID?
    FFA_RXTX_MAP                give the SPM my message buffers
    FFA_RXTX_UNMAP

  MESSAGING
    FFA_MSG_SEND_DIRECT_REQ     synchronous call to a partition
    FFA_MSG_SEND_DIRECT_RESP    its reply
    FFA_MSG_WAIT                "I am idle, wake me on a message"
    FFA_RUN                     schedule a partition's context
    FFA_YIELD
    FFA_INTERRUPT               an interrupt arrived for you

  MEMORY MANAGEMENT - the interesting part
    FFA_MEM_DONATE              transfer ownership permanently
    FFA_MEM_LEND                transfer access, keep ownership
    FFA_MEM_SHARE               both parties may access
    FFA_MEM_RETRIEVE_REQ        receiver claims the transfer
    FFA_MEM_RETRIEVE_RESP
    FFA_MEM_RELINQUISH          receiver gives it back
    FFA_MEM_RECLAIM             sender takes it back

  ERROR / SUCCESS
    FFA_SUCCESS   FFA_ERROR

/* A direct request, from a normal-world driver: */

    x0 = FFA_MSG_SEND_DIRECT_REQ_64   /* 0xC400006F          */
    x1 = (sender_id << 16) | receiver_id
    x2 = 0                            /* flags               */
    x3..x7 = up to five 64-bit values of payload
    smc #0

    /* returns in x0 = FFA_MSG_SEND_DIRECT_RESP, x3..x7 = the
       reply. Synchronous, and the caller's context is
       blocked meanwhile.                                    */
```

Memory transfer, done properly

```
The old way: a normal-world driver passes a physical address
in an SMC and the trusted OS trusts it. Every parameter-
validation bug in every TEE ever, in one sentence.

FF-A instead makes the transfer an explicit, mediated
transaction with THREE distinct semantics:

DONATE   ownership moves. The sender can never get it back.
         Used for: handing a buffer to a partition for its
         own permanent use.

LEND     access moves, ownership stays. The sender loses
         access while the loan is outstanding. Exclusive.
         Used for: "process this buffer and give it back" -
         and because the sender loses access, there is no
         time-of-check-to-time-of-use window.

SHARE    both may access concurrently. Cheapest, and the
         one that reintroduces TOCTOU if you are careless.

The protocol:

  sender:   FFA_MEM_LEND with a descriptor listing
            address ranges, receiver ID, and permissions
               -> SPM validates the sender OWNS those pages
               -> SPM returns a HANDLE
  sender:   passes the handle to the receiver (by message)
  receiver: FFA_MEM_RETRIEVE_REQ(handle)
               -> SPM maps the pages into the RECEIVER'S
                  stage-2 tables with the agreed permissions
               -> and UNMAPS them from the sender if LEND
  ...work happens...
  receiver: FFA_MEM_RELINQUISH(handle)
  sender:   FFA_MEM_RECLAIM(handle)
               -> SPM restores the sender's mapping

The SPM is the only component that edits stage-2 tables, and
it validates every claim of ownership. A partition cannot
lend what it does not have.
```

> **LEND VERSUS SHARE IS A SECURITY DECISION**
>
> With `SHARE`, the sender can modify a buffer after the receiver has validated its contents — the classic double-fetch. With `LEND`, the sender's mapping is removed, so it physically cannot. Use `LEND` for anything where the receiver makes a trust decision based on the buffer's contents, and pay the extra unmap cost.

Hafnium

```
/* Hafnium is Arm's reference SPM. Small, C, no dynamic
   allocation, and it is also usable as a normal-world
   hypervisor (that was its original life, as the Android
   "protected VM" hypervisor before pKVM).                  */

  Runs at:      S-EL2   (as an SPM)
                EL2     (as a plain hypervisor)
  Language:     C, ~20k lines
  Scheduling:   cooperative - partitions are RUN by the normal
                world's scheduler via FFA_RUN. Hafnium does not
                have a scheduler of its own, deliberately.
  Memory:       fully static. Every partition's memory comes
                from its manifest, allocated at boot.

/* A secure partition manifest - device tree, compiled into
   the SP package:                                          */

  sp {
      compatible = "arm,ffa-manifest-1.0";
      ffa-version = <0x00010001>;      /* FF-A v1.1          */
      uuid = <0xb476b8a1 0xdcbf474f 0xa4b7a2a1 0x6f0f4d3c>;
      id = <0x8001>;
      execution-ctx-count = <1>;
      exception-level = <2>;           /* S-EL1              */
      execution-state = <0>;           /* AArch64            */
      load-address = <0x6280000>;
      entrypoint-offset = <0x2000>;
      xlat-granule = <0>;              /* 4 KB               */
      boot-order = <0>;
      messaging-method = <3>;          /* direct req + resp  */

      memory-regions {
          compatible = "arm,ffa-manifest-memory-regions";
          rx-buffer { base-address = <0x0 0x7300000>;
                      pages-count = <1>; attributes = <1>; };
          tx-buffer { base-address = <0x0 0x7301000>;
                      pages-count = <1>; attributes = <3>; };
      };

      device-regions {
          compatible = "arm,ffa-manifest-device-regions";
          crypto-accel {
              base-address = <0x0 0x40010000>;
              pages-count = <16>;
              attributes = <3>;        /* read-write          */

              stream-ids = <0x0 0x1>;  /* SMMU isolation too  */
          };
      };
  };

/* Read it as a contract: this is EXACTLY what partition 0x8001
   may touch. Anything else faults. And because it is static,
   a reviewer can check it without running anything.        */
```

Talking to a secure partition from Linux

```
# Linux has an FF-A bus, like any other bus.

$ ls /sys/bus/ffa/devices/
arm-ffa-8001   arm-ffa-8002

$ cat /sys/bus/ffa/devices/arm-ffa-8001/uuid
b476b8a1-dcbf-474f-a4b7-a2a16f0f4d3c

$ dmesg | grep -i ff-a
[    0.812] ARM FF-A: Initialized with version 1.1
[    0.813] ARM FF-A: Partition ID 0x8001 : 1 exec ctx, props 0x3

/* And a driver binds to it exactly as it would to a PCI or
   platform device:                                          */

static const struct ffa_device_id my_sp_ids[] = {
        { UUID_INIT(0xb476b8a1, 0xdcbf, 0x474f,
                    0xa4, 0xb7, 0xa2, 0xa1,
                    0x6f, 0x0f, 0x4d, 0x3c) },
        {}
};

static int my_sp_probe(struct ffa_device *dev)
{
        const struct ffa_ops *ops = dev->ops;
        struct ffa_send_direct_data d = {
                .data0 = MY_CMD_GET_VERSION,
        };

        ops->msg_ops->sync_send_receive(dev, &d);
        dev_info(&dev->dev, "SP version %llu\n", d.data0);
        return 0;
}

static struct ffa_driver my_sp_driver = {
        .name     = "my_sp",
        .probe    = my_sp_probe,
        .id_table = my_sp_ids,
};
module_ffa_driver(my_sp_driver);

/* This is how the upstream fTPM driver will eventually talk to
   an fTPM secure partition, replacing the OP-TEE-specific path
   we build in the OP-TEE track. The TA logic is the same; the
   transport changes.                                          */
```

Realms, in one page

```
ARMv9 Confidential Compute Architecture adds a FOURTH
security state, for a different threat model again:

  Non-secure   normal world - hypervisor and its VMs
  Secure       TrustZone - TEE, secure partitions
  Realm        confidential VMs
  Root         EL3, and the Granule Protection Table

Threat model: protect a guest from the HYPERVISOR and from
the cloud operator. Not from itself; not from the TEE.

  R-EL2   RMM (Realm Management Monitor) - a small, spec'd
          component that manages realms
  Root    Monitor + GPT: hardware-checked ownership of every
          granule of physical memory. GPC (Granule
          Protection Check) happens on EVERY access, in
          addition to stage 1 and stage 2.

The hypervisor still SCHEDULES realms and still allocates
their memory - but it cannot READ it. Attempts fault with a
Granule Protection Fault.

Where it fits with this track: everything you know about
stage 2 and vCPUs still applies. What changes is that the
hypervisor's stage-2 edits must be ratified by the RMM, and
the guest's memory is not in the hypervisor's address space.
The mental model is "pKVM, enforced by hardware rather than
by trusting a small EL2 component".
```

How it shows up

Symptom	Cause
No FF-A devices in `/sys/bus/ffa/`	No SPM in firmware, or TF-A built without the SPM dispatcher
`FFA_ERROR NOT_SUPPORTED` on a direct request	The partition's manifest declares a different `messaging-method`
Memory retrieve fails with `DENIED`	Sender does not own the pages, or the receiver requested different permissions than were offered
Secure partition faults on its device registers	Device region missing from the manifest, or the StreamID not listed so the SMMU blocks its DMA
Partition never runs	Nothing called `FFA_RUN` — Hafnium has no scheduler of its own
Version negotiation fails	Caller and SPM implement different FF-A versions; check `FFA_VERSION` first and downgrade
Double-fetch vulnerability found in review	`SHARE` used where `LEND` was required
Works on one board, not another	Manifest load addresses are physical and board-specific

Check yourself

- ✓ Explain the problem with a single S-EL1 trusted OS when components come from several vendors.
- ✓ Draw the exception levels and security states with an SPM and two secure partitions.
- ✓ Translate hypervisor/VM/vCPU into the FF-A vocabulary.

- ✓ Name the three FF-A memory-transfer semantics and say when each is correct.
- ✓ Explain why `LEND` closes a TOCTOU window that `SHARE` leaves open.
- ✓ Walk through a lend-retrieve-relinquish-reclaim sequence and say who edits the page tables.
- ✓ Read a secure-partition manifest and list exactly what that partition may touch.
- ✓ Explain why Hafnium deliberately has no scheduler.
- ✓ Describe how a Linux driver binds to a secure partition.
- ✓ State the Realm threat model in one sentence and say what a Granule Protection Fault means.

Nested virtualisation

There is one EL2 and two hypervisors that want it. Resolving that — letting a guest believe it owns the virtualisation extensions while the real owner watches — is the most intricate trick in the architecture, and it is why your cloud VM can itself run Docker Desktop, Android emulators and CI runners that expect KVM.

The names, first

```
L0   the real hypervisor, running at real EL2.
     The only software with genuine EL2 privilege.

L1   a GUEST that is itself a hypervisor. It believes it
     runs at EL2. It actually runs at EL1.

L2   L1's guest. It believes it runs at EL1. It actually
     also runs at EL1 - but with L0 having composed L1's
     intentions into the real hardware.

+-------------------------------------------+
|  L2 guest  (thinks: EL1)     really: EL1  |
+-------------------------------------------+
|  L1 hypervisor (thinks: EL2)  really: EL1 |
|     - has "its own" HCR_EL2, VTTBR_EL2 ...|
|       every one of them a value in memory |
+-------------------------------------------+
|  L0 hypervisor            really: EL2     |
|     - owns the actual system registers    |
|     - owns the actual stage-2 tables      |
+-------------------------------------------+
|  hardware                                 |
+-------------------------------------------+

Real-world instances:
  L0 = your cloud provider's KVM
  L1 = the KVM inside your VM
  L2 = the container-in-a-VM, the Android emulator, the
       CI runner's test VM

Or, on a phone:
  L0 = pKVM
  L1 = the Android guest kernel running its own VMs
  L2 = a protected app VM
```

How L0 fakes EL2 for L1

```
/* L1 executes code that only EL2 may execute. Since L1 is
   really at EL1, that traps to L0. L0 then EMULATES an EL2
   for it.                                                  */

  L1 does:  MSR VTTBR_EL2, x0
     -> trap to L0 (EC = 0x18, or a dedicated nested trap)
     -> L0 records: "L1's virtual VTTBR_EL2 = x0"
        It does NOT program the hardware VTTBR_EL2 with it.

  L1 does:  MSR HCR_EL2, x0
     -> trap. L0 records L1's intended trap configuration and
        RECOMPUTES the real HCR_EL2 as roughly
             real = L0's own requirements
                  UNION L1's requirements
        so that anything either hypervisor wanted to trap
        still traps - to L0, which then decides whether the
        trap belongs to L1.

  L1 does:  ERET into L2
     -> trap. L0 switches to "running L2" mode: it loads the
        shadow stage-2 (below), sets the real HCR_EL2 for an
        L2 guest, and ERETs.

  L2 traps (say, an MMIO access)
     -> arrives at L0, because all traps arrive at real EL2.
     -> L0 asks: did L1 ask for this to trap?
          YES -> synthesise an exception INTO L1: set L1's
                 virtual ESR_EL2, ELR_EL2, SPSR_EL2 and enter
                 L1 at its virtual VBAR_EL2.
          NO  -> handle it myself and resume L2 directly.

/* Every EL2 register L1 touches becomes a field in a struct.
   ARMv8.4-NV and 8.4-NV2 help enormously: NV redirects
   _EL2 register accesses at EL1 to trap, and NV2 redirects
   many of them to a MEMORY PAGE instead of trapping at all -
   so L1 writes "VTTBR_EL2" and the value lands in a VNCR page
   that L0 reads later, with no exception taken.            */
```

> **NV2 IS THE DIFFERENCE BETWEEN "POSSIBLE" AND "USABLE"**
>
> Without `ARMv8.4-NV2`, every single EL2 register access by L1 is a trap, and a hypervisor touches those constantly. NV2 gives L1 a page of memory that the hardware treats as the EL2 register file for most registers. L1's ordinary `MSR`/`MRS` become memory accesses; L0 reads the page when it needs to. Nested virtualisation on hardware without NV2 works and is slow enough that few people use it.

Shadow stage-2: two translations, one MMU

```
The hardware has ONE stage-2. Nesting needs two:

  L2 virtual address
     |  L2's stage 1 (L2's own page tables)
     v
  L2 intermediate physical address
     |  L1's stage 2  - L1 built these tables and believes
     |                  they are in force
     v
  L1 intermediate physical address
     |  L0's stage 2  - the real one
     v
  real physical address

The hardware can do one of those. So L0 COMPOSES them:

  shadow_s2[L2_ipa] = L0_s2[ L1_s2[L2_ipa] ]

and programs the shadow into the real VTTBR_EL2 whenever L2
runs. This is exactly the shadow-page-table technique that
stage 2 was invented to eliminate (chapter 2) - it has
returned, one level up.

Maintaining it:
  * L1 edits its stage-2 tables. Those tables live in L1's
    memory, so L0 can write-protect them and catch edits...
    expensive.
  * Better: L1 must issue a TLBI after any change (the
    architecture requires it). L0 traps the TLBI and
    invalidates the corresponding shadow entries. This is
    why nested virt REQUIRES trapping L1's TLB maintenance
    while ordinary virt deliberately does not.
  * The shadow is built lazily: on an L2 fault, walk L1's
    stage 2 in software, then L0's, install one entry.

COST: an L2 stage-2 fault costs a software walk of L1's
tables plus a shadow install - hundreds of times a plain
stage-2 fault. L2's steady-state execution, once the shadow
is warm, is close to native.
```

Interrupts and timers, nested

```
/* The vGIC problem: L1 wants to write list registers. There is
   one set, and L0 is using it.                              */

  L1 writes ICH_LR0_EL2 to inject into L2
     -> trap (or NV2 memory write)
     -> L0 records L1's intended list-register content
     -> when L0 runs L2, it merges:
           interrupts L0 wants to inject into L1
           interrupts L1 wants to inject into L2
        into the real list registers, with the right virtual
        INTIDs for whichever level is executing.

/* GICv4.1 helps: a VPE can be a NESTED vCPU, so an LPI can be
   delivered directly to L2 without either hypervisor running.
   Support for this is recent and not universal.            */

/* Timers: CNTVOFF_EL2 is singular, and now two hypervisors
   want to offset time.

     L1 sets its virtual CNTVOFF_EL2 = A  (to rebase L2)
     L0 has its own CNTVOFF_EL2      = B  (to rebase L1)

   The value the hardware needs while L2 runs is A + B, and L0
   computes it. ARMv8.6-ECV adds CNTPOFF_EL2 and finer control
   precisely because composing offsets by hand was error-prone.

   Symptom of getting it wrong: L2's clock drifts relative to
   L1's, and the guest's clocksource watchdog eventually
   declares the counter unstable.                           */
```

Turning it on

```
# Hardware requirement: FEAT_NV2 in practice. Check:
$ dmesg | grep -i nested
[    0.512] kvm [1]: Nested virtualization is experimental

# Enable in the host kernel (L0):
#   kvm-arm.mode=nested
# and the VM must be created asking for it:

$ qemu-system-aarch64 -M virt -accel kvm -cpu host,el2=on ...

# Inside L1, confirm it believes it has EL2:
$ dmesg | grep -i 'EL2\|kvm'
[    0.000000] CPU: All CPU(s) started at EL2
[    0.498112] kvm [1]: Hyp mode initialized successfully
$ ls -l /dev/kvm

# Then run L2 from inside L1 exactly as normal.

# x86 equivalent, for comparison - the concept is identical:
$ cat /sys/module/kvm_intel/parameters/nested
Y
$ qemu-system-x86_64 -cpu host,+vmx ...

# EXPECTATIONS. Measure, do not assume:
#   L1 CPU-bound work      ~ native
#   L2 CPU-bound work      ~ native
#   L2 I/O and interrupts  noticeably slower - every exit that
#                          L1 must see is two exits
#   L1 booting L2          slow: the shadow stage-2 is cold and
#                          every page is a software walk
```

> **NESTED IS FOR CAPABILITY, NOT PERFORMANCE**
>
> People enable nesting so that something *works* — a CI job that spawns VMs, a developer's Android emulator, a container runtime that wants a VM per container. If L2's performance is on your critical path, the answer is almost always to flatten the stack rather than to tune the nesting.

Where it actually ships

Stack	L0	L1	L2	Why
Cloud CI	Provider KVM	Your VM's KVM	Test VMs	Build and test images that need a real kernel
Android	pKVM	Android kernel	Protected app VMs	Isolate a payment or biometric workload from Android itself
Windows on Arm	Hyper-V	The "root" Windows	WSL2, containers, VBS	Virtualisation-based security means Windows itself is already a guest
Automotive dev	Type-1 hypervisor	Linux domain	Emulated ECUs	Develop and test partitions without the target hardware
Hypervisor development	KVM	The hypervisor you are writing	Its guests	Debug an EL2 payload with gdb instead of a JTAG probe — see QEMU chapter 11

How it shows up

Symptom	Cause
L1 says `HYP mode not available`	The VM was not created with EL2 (`-cpu host,el2=on`), or L0 does not have nesting enabled
L2 boots then hangs at random points	Shadow stage-2 stale — L1's TLBI not trapped or not translated into shadow invalidation
L2 memory corruption under load	Shadow composition bug: permissions not intersected across both stage-2 levels
L2's clock drifts from L1's	Timer offsets not composed (`A + B`)
L2 never receives interrupts	L1's list-register writes recorded but not merged into the real list registers when L2 runs
Extremely slow, hardware supports nesting	No NV2 — every L1 EL2 register access is a trap
L1 crashes with an unexpected exception	L0 synthesised an exception into L1 with an `ESR` encoding L1 does not handle
Works with one vCPU, breaks with several	Shadow tables shared across vCPUs without the locking the real hardware provided implicitly

Check yourself

- ✓ Define L0, L1 and L2 and state the real exception level each runs at.
- ✓ Explain what happens when L1 executes `MSR VTTBR_EL2`.
- ✓ Explain how L0 computes the real `HCR_EL2` from its own needs and L1's.
- ✓ Describe what happens to an L2 trap and how L0 decides whether L1 should see it.
- ✓ Explain shadow stage-2 and write the composition rule.
- ✓ Say why nested virtualisation must trap L1's `TLBI` when ordinary virtualisation must not.
- ✓ Explain what FEAT_NV2 changes and why it matters so much.
- ✓ Explain how two levels of timer offset are combined.
- ✓ Give three real deployments of nested virtualisation and what each needs it for.
- ✓ Predict which of L2's workloads will be near-native and which will not.

Virtualisation performance and how to measure it

Virtualised code runs at native speed until it does not. All the cost is at boundaries — exits, page walks, interrupts, stolen time — and each has a specific measurement that identifies it. This chapter is the diagnostic procedure, in the order that finds problems fastest.

The cost model

```
Guest execution time =

    instructions that just run          (free)
  + stage-2 page walks                  (bounded, cacheable)
  + exits x cost-per-exit               (the big one)
  + time the vCPU was not scheduled     (steal)
  + interference from other guests      (cache, bandwidth)

Every performance problem you will meet is one of the last
four, and they are distinguishable:

  high exit count          -> the guest is asking too often
  high cost per exit       -> the wrong handler tier
  high steal time          -> the host is oversubscribed
  high cache miss rate,    -> a neighbour is thrashing the
    low exits, low steal      shared cache

Diagnose in that order. It is roughly the order of
likelihood, and each test is cheap.
```

Step 1: is it exits?

```
# The single most informative command:
$ sudo perf kvm --host stat live

Analyze events for all VMs, all VCPUs:
   VM-EXIT   Samples  Samples%  Time%  Min Time  Max Time  Avg time
      MMIO     48112    71.20%  44.1%    1.90us  180.11us   9.44us
       WFx     15003    22.20%  51.2%    0.50us   19.98ms   1.44ms
       HVC      3201     4.74%   1.1%    1.20us    9.02us   2.11us
    SYS64      1250     1.85%   3.6%    2.10us   14.44us   4.02us

# Read it as:
#   MMIO dominating      -> device emulation. Which device?
#   WFx dominating       -> the guest is idle, or spinning on a
#                           lock it cannot get (lock-holder
#                           preemption)
#   SYS64 significant    -> a trapped system register in a hot
#                           path; find which one
#   Huge Max Time on WFx -> normal (it is a sleep), ignore

# Which addresses are the MMIO exits hitting?
$ sudo perf record -e kvm:kvm_mmio -a -- sleep 5
$ sudo perf script | grep -o 'gpa 0x[0-9a-f]*' | sort | uniq -c | sort -rn
  41022 gpa 0x0a000050        # a virtio QueueNotify
   4180 gpa 0x08010000        # the GIC redistributor
    900 gpa 0x09000000        # the UART

# 41k exits on a QueueNotify means no ioeventfd. That is a
# one-line fix (chapter 13) worth an order of magnitude.

# Which system registers?
$ sudo perf record -e kvm:kvm_sys_access -a -- sleep 5
$ sudo perf script | head
```

Dominant exit	Usual cause	Fix
MMIO on a virtio notify address	No `ioeventfd`	Register one; enable `EVENT_IDX`
MMIO on the GIC distributor	Guest reprogramming interrupts constantly	Fix the guest driver; configure once at init
MMIO on a legacy device	Emulating an old NIC or IDE controller	Switch to virtio
MMIO scattered across a device's whole register block	A polling driver	Interrupts, or passthrough
WFx with short durations	Lock-holder preemption	Pin vCPUs; stop oversubscribing
WFx with long durations	Guest is idle	Nothing — this is correct
SYS64 on `CNTP_*`	Guest on the physical timer	Fix the guest device tree (chapter 12)
SYS64 on ID registers	Guest probing features in a loop	Rare; usually a guest bug
Guest faults (stage-2)	Memory being populated, or dirty logging active	Pre-fault with huge pages; expected during migration

Step 2: is it steal time?

```
# In the guest:
$ vmstat 1 5
procs -----------memory---------- ---system-- ------cpu-----
 r  b   swpd   free  buff  cache   in   cs us sy id wa st
 4  0      0 512300  2200 120440 1210 3402 52  8  9  0 31
                                                      ^^
# st = 31%. Nearly a third of this guest's time does not exist.
# No amount of guest-side tuning will recover it.

$ mpstat -P ALL 1
# per-vCPU steal - an uneven distribution points at pinning
# problems rather than global oversubscription

# On the host, confirm:
$ vmstat 1
$ cat /proc/pressure/cpu
some avg10=42.11 avg60=38.90 avg300=31.02 total=...
# PSI "some" above ~20 means real contention

# How oversubscribed?
$ echo "vCPUs: $(pgrep -c 'CPU .*KVM')  pCPUs: $(nproc)"

# Fixes, in order of effectiveness:
#  1. reduce vCPU count or VM count (yes, really)
#  2. pin vCPUs to distinct pCPUs
#       $ taskset -cp 4 $(pgrep -f 'CPU 0/KVM')
#     or in libvirt:  <vcpupin vcpu='0' cpuset='4'/>
#  3. isolate the cores the latency-sensitive VM uses
#       isolcpus=4-7 nohz_full=4-7 rcu_nocbs=4-7
#  4. give the vCPU threads a real-time policy - carefully;
#     a runaway RT vCPU thread can wedge the host
#       $ chrt -f -p 10 $(pgrep -f 'CPU 0/KVM')
```

Step 3: is it the page tables?

```
# A two-stage walk can be 24 memory accesses (chapter 5). Huge
# pages at BOTH stages cut it dramatically.

# Host: back guest RAM with huge pages
$ echo 2048 | sudo tee /proc/sys/vm/nr_hugepages
$ qemu-system-aarch64 \
    -object memory-backend-file,id=mem,size=4G,\
mem-path=/dev/hugepages,share=on,prealloc=on \
    -M virt,memory-backend=mem ...

# Or transparent huge pages, which KVM will happily use at
# stage 2 if the host allocation is contiguous:
$ cat /sys/kernel/mm/transparent_hugepage/enabled
[always] madvise never

# Verify KVM actually built large stage-2 blocks:
$ sudo grep -r . /sys/kernel/debug/kvm/*/  2>/dev/null | grep -i huge

# Guest: measure the TLB pressure directly
$ sudo perf stat -e \
    dTLB-load-misses,iTLB-load-misses,instructions,cycles \
    -- ./workload

# A guest with a much worse dTLB-miss rate than the same
# workload on the host is paying for two-stage walks. Huge
# pages are the fix; there is no software workaround.

# prealloc=on matters more than it looks: without it, the guest
# faults every page in on first touch, and a 4 GB guest spends
# its first seconds taking a million stage-2 faults.
```

Step 4: is it a neighbour?

```
# Symptom: low exits, low steal, and still slow. Something
# else on the machine is evicting your cache lines or
# saturating memory bandwidth.

# Measure the shared resources:
$ sudo perf stat -e \
    LLC-loads,LLC-load-misses,cache-misses,cache-references \
    -a -- sleep 10

# arm64 PMU events for memory traffic (names vary by part):
$ sudo perf list | grep -i -E 'bus|l2d|ll_cache'
$ sudo perf stat -e armv8_pmuv3/ll_cache_rd/,armv8_pmuv3/ll_cache_miss_rd/ \
    -a -- sleep 5

# Prove it by removing the neighbour:
#   run your benchmark alone   -> baseline
#   run it with the suspect VM -> the difference IS the
#                                 interference
# That difference is your worst case, and it is what belongs in
# a capacity plan or a safety case (chapter 18).

# If the silicon has MPAM, partition the cache properly:
$ ls /sys/fs/resctrl/ 2>/dev/null
$ cat /sys/fs/resctrl/info/L3/num_closids
# then assign the latency-sensitive VM its own cache portion.

# If it does not, your options are cache colouring (chapter 18)
# or not co-locating those workloads.
```

> **THE MEASUREMENT DISCIPLINE**
> Always measure the same workload three ways: on bare metal, in the VM alone, and in the VM with realistic neighbours. The first two differences tell you the virtualisation cost; the third tells you the co-location cost. Reporting only "the VM is 20% slower" without saying which of those you measured makes the number useless.

A tuning checklist that actually helps

Change	Typical effect	When
`-accel kvm` instead of TCG	10–100x	Always, if the host architecture matches
`-cpu host`	Enables the guest to use every CPU feature	Always, unless you need migration compatibility
virtio + vhost instead of emulated devices	5–50x on I/O	Always
`ioeventfd` on queue notifies	2–10x on I/O	Always (QEMU does it by default; check your own VMM)
Huge pages, preallocated	5–30% on memory-heavy work; large boot-time win	Whenever the guest is big or TLB-sensitive
vCPU pinning	Removes jitter; small mean improvement	Latency-sensitive guests
`isolcpus` / `nohz_full` on the host	Large tail-latency improvement	Real-time guests

Change	Typical effect	When
Multiqueue virtio-net	Scales with vCPUs	Network-heavy guests with several vCPUs
Passthrough	Removes I/O cost entirely	When you can give up migration and sharing
VHE (do not force nVHE)	~2x on exit cost	Never set `kvm-arm.mode=nvhe` without a reason
Fewer vCPUs	Often the largest single win	Whenever steal time is non-trivial

Benchmarks worth running

```
# Exit cost, isolated. A guest loop that only traps:
#    1: hvc #0
#       b 1b
# Time N iterations. This is your floor.

# Memory, in the guest and on the host:
$ sysbench memory --memory-block-size=1M --memory-total-size=20G run
$ stream_c.exe            # if you have STREAM built

# Block I/O - and use O_DIRECT or you measure the page cache:
$ fio --name=r --rw=randread --bs=4k --iodepth=32 --direct=1 \
      --ioengine=libaio --runtime=30 --filename=/dev/vdb

# Network:
$ iperf3 -c host -P 4 -t 30           # throughput
$ netperf -H host -t TCP_RR           # latency, the harder one

# Latency and jitter - the number that matters for embedded:
$ cyclictest -S -p 90 -i 200 -d 0 -m -D 60
T: 0 (  911) P:90 I:200 C: 300000 Min: 6 Act: 11 Avg: 12 Max: 89

# Run cyclictest in the guest WHILE running a stressor in a
# neighbouring guest. The Max column with interference is the
# only latency figure worth quoting.
$ stress-ng --cpu 4 --vm 2 --vm-bytes 1G --cache 4 --timeout 60s
```

How it shows up

Symptom	Cause
Guest 50–100x slower than the host at everything	TCG, not KVM. Check `/dev/kvm` and `-accel`
CPU work fast, I/O terrible	Emulated devices, or missing `ioeventfd`/vhost
Everything fine except one driver	That driver polls a register; every read is an exit
Steal time high, host looks idle	vCPU threads pinned to the same pCPU, or a cgroup CPU quota
Big guest slow for the first minute, then fine	Memory faulted in on demand; use `prealloc=on`
Worse dTLB miss rate than bare metal	Two-stage walks without huge pages
Latency spikes correlate with a neighbour's activity	Cache or memory-bandwidth interference, not a hypervisor problem
Idle guest burning a core	`WFI` not trapped, or a guest spinning
Exit rate fine, cost per exit terrible	Exits reaching user space that should be handled in the kernel

Symptom	Cause
Performance regressed after a kernel update	Check for `kvm-arm.mode=` on the command line and for a mitigation that changed the exit path

Check yourself

- ✓ Write the cost model and name the four terms that are not free.
- ✓ Give the order in which you would test for each, and why that order.
- ✓ Interpret a `perf kvm stat live` table dominated by MMIO, and by WFx.
- ✓ Find which guest-physical addresses are causing the most exits.
- ✓ Explain what steal time measures and name three fixes.
- ✓ Explain why huge pages matter more under virtualisation than on bare metal.
- ✓ Distinguish interference from steal time by measurement.
- ✓ List the five highest-value tuning changes and say when each applies.
- ✓ Describe the three-way measurement discipline and why a single number is not enough.
- ✓ Design an experiment that produces a defensible worst-case latency figure for a guest.

TRACK

QEMU & emulation

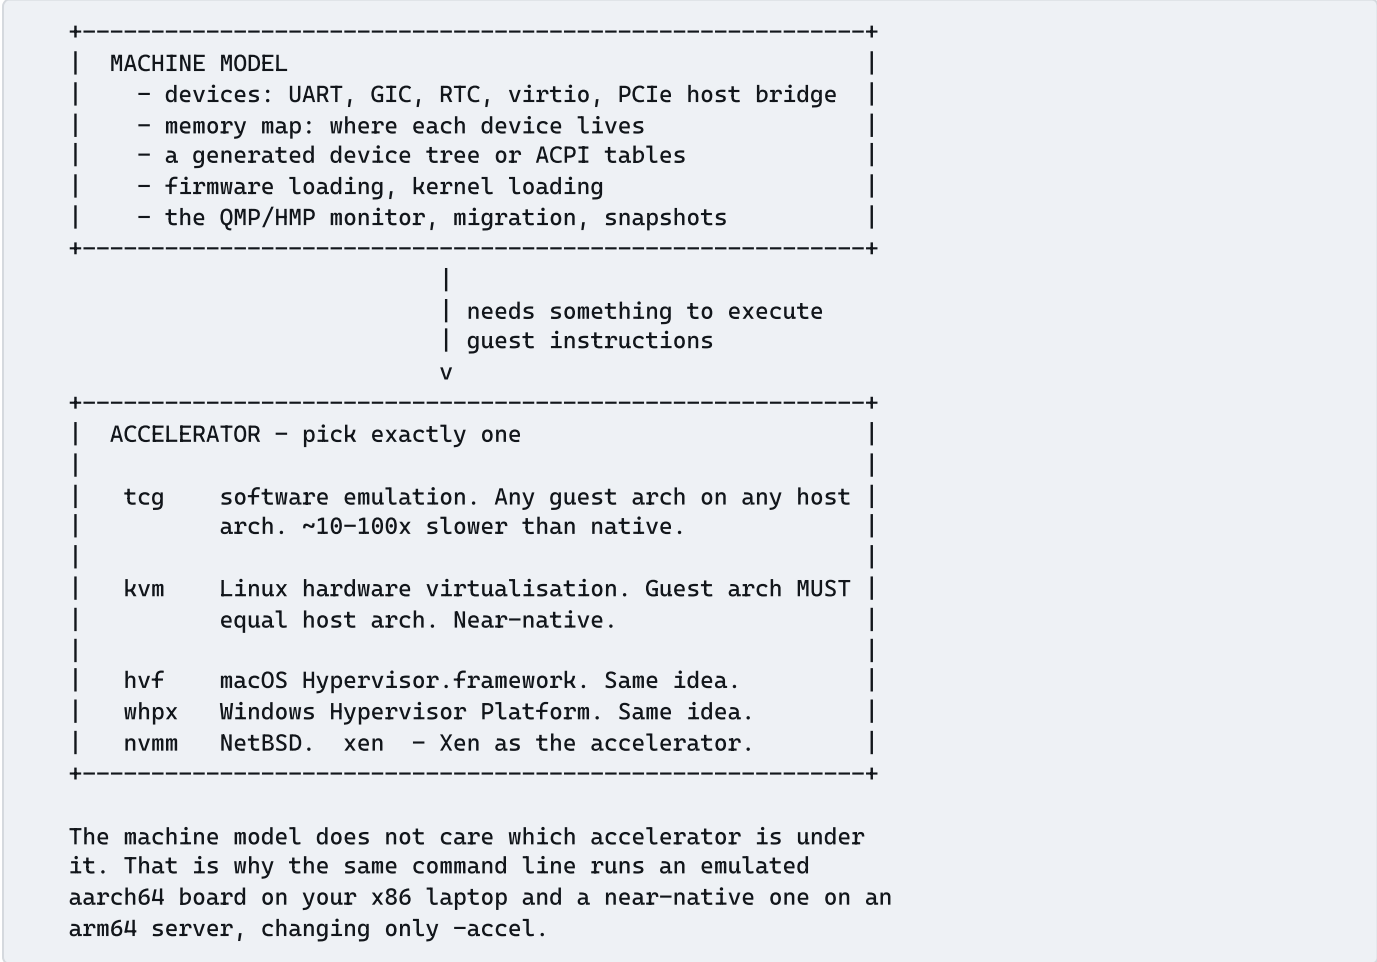
The machine you develop on when the hardware does not exist yet. Building it, booting it, wiring devices into it and debugging through it.

15 chapters

What QEMU is and its four modes

QEMU is two separable things that ship in one binary: a CPU emulator that can execute any supported architecture on any other, and a machine model — devices, buses, firmware, a device tree — that turns a CPU into a computer. Which of those you are using at a given moment decides everything about your speed and your debugging options.

The two halves



The machine model does not care which accelerator is under it. That is why the same command line runs an emulated aarch64 board on your x86 laptop and a near-native one on an arm64 server, changing only `-accel`.

The four ways to run it

Mode	Binary	What it emulates	Use it for
System emulation	`qemu-system-aarch64`	A whole machine: CPU, memory, devices, firmware	Kernels, drivers, bootloaders, OP-TEE, hypervisors — everything in this site
User-mode emulation	`qemu-aarch64`	One Linux process; syscalls are translated to host syscalls	Running a cross-compiled binary or test suite without a VM
Accelerator only	`qemu-system-*` with `-accel kvm`	Nothing — the hardware runs the guest	Production virtualisation
Tools	`qemu-img`, `qemu-nbd`, `qemu-storage-daemon`	Disk images, no CPU involved	Creating, converting and mounting images

```
# System emulation: a whole aarch64 machine, on any host
$ qemu-system-aarch64 -M virt -cpu cortex-a57 -m 1G \
    -kernel Image -append "console=ttyAMA0" -nographic

# User-mode: run ONE aarch64 binary on an x86 host
$ qemu-aarch64 -L /usr/aarch64-linux-gnu ./my-arm-binary
# Or transparently, via binfmt_misc:
$ sudo apt install qemu-user-static binfmt-support
$ ./my-arm-binary          # the kernel invokes qemu-aarch64 for you
# This is how "docker run --platform linux/arm64" works on an
# x86 machine, and it is invaluable for running a cross-compiled
# test suite in CI.

# Tools:
$ qemu-img create -f qcow2 disk.qcow2 8G
$ qemu-img convert -O raw disk.qcow2 disk.raw
$ sudo qemu-nbd --connect=/dev/nbd0 disk.qcow2   # mount it
```

WHY THIS TRACK EXISTS

Every project on this site — a Linux driver, a Windows driver, an OP-TEE trusted application, a bare-metal EL2 payload — can be built and debugged on QEMU without buying hardware. More than that: QEMU gives you things hardware cannot, including a stopped CPU with a GDB stub attached before the first instruction, and a complete trace of every memory access. Learn it properly once and every other track gets cheaper.

What to expect from each accelerator

```
   Same aarch64 guest, same workload, three ways:

   TCG on x86 host          ~10–50x slower than native arm64.
                            Kernel boot: 20–60 seconds.
                            Perfectly usable for driver work.
                            Timing is meaningless.

   TCG on arm64 host        Same. TCG does not shortcut when
                            the architectures match — use KVM.

   KVM on arm64 host        ~1.0–1.05x native for CPU work.
                            Kernel boot: under a second.
                            Timing is roughly meaningful.

   The corollary that catches people out:

     A race condition that reproduces on hardware may NEVER
     reproduce under TCG, because TCG executes one guest
     instruction stream at a time per vCPU and its memory
     ordering is far stronger than real ARM's.

     And a race that reproduces under TCG is real, because TCG
     is a valid (if unusual) execution.

   So: use TCG to find logic bugs and KVM to find timing bugs,
   and never conclude "the lock is fine" from a TCG run.
```

MTTCG and the ordering trap

```
/* Multi-Threaded TCG runs each guest vCPU in its own host
   thread. It is the default where the guest and host memory
   models are compatible.                                    */

$ qemu-system-aarch64 -M virt -smp 4 -accel tcg,thread=multi ...
$ qemu-system-aarch64 -M virt -smp 4 -accel tcg,thread=single ...

/* When emulating a WEAKLY ordered guest (arm64) on a STRONGLY
   ordered host (x86), MTTCG is safe: the host provides more
   ordering than the guest requires, so a guest that forgot a
   barrier still works.

   THAT IS THE PROBLEM. Your code appears correct.

   Emulating a strongly ordered guest on a weakly ordered host
   is the dangerous direction, and QEMU inserts explicit
   barriers to be safe.                                      */

/* Practical rules:

   1. Missing barriers in guest code are INVISIBLE under TCG on
      x86. Test on real arm64 hardware, or under KVM on arm64,
      before believing your lock-free code.

   2. -icount gives you deterministic, reproducible timing:
        -icount shift=5,align=off,sleep=off
      Each guest instruction takes 2^5 virtual ns. The run is
      REPRODUCIBLE - the same input gives the same interleaving
      every time. Invaluable for debugging a heisenbug, and it
      also makes record/replay possible:
        -icount shift=auto,rr=record,rrfile=replay.bin
        -icount shift=auto,rr=replay,rrfile=replay.bin

   3. -singlestep (now -accel tcg,one-insn-per-tb=on) forces
      one instruction per translation block. Very slow, and it
      makes tracing and breakpoints exact.                   */
```

Checking your setup

```
$ qemu-system-aarch64 --version
QEMU emulator version 8.2.2

# Which accelerators were compiled in and are usable here?
$ qemu-system-aarch64 -accel help
Accelerators supported in QEMU binary:
tcg
kvm

# Is KVM actually available?
$ ls -l /dev/kvm
crw-rw---- 1 root kvm 10, 232 /dev/kvm
$ groups | grep -q kvm && echo "you can use it" || \
    echo "run: sudo usermod -aG kvm $USER, then log out and in"

# Which machines does this binary know?
$ qemu-system-aarch64 -M help | head -20
virt                 QEMU 8.2 ARM Virtual Machine
raspi3b              Raspberry Pi 3B
sbsa-ref             QEMU SBSA Reference Platform
vexpress-a15         ARM Versatile Express for Cortex-A15
xlnx-zcu102          Xilinx ZynqMP ZCU102

# Which CPUs?
$ qemu-system-aarch64 -cpu help | head
cortex-a53  cortex-a57  cortex-a72  cortex-a76
neoverse-n1 neoverse-v1
max                  # every feature this QEMU implements
host                 # KVM only: pass the host CPU through

# The two you will use:
#   -cpu max   under TCG - gives you SVE, pointer auth, MTE,
#              every architectural feature, so you can develop
#              against hardware you do not own
#   -cpu host  under KVM - no translation, real features
```

> **`-CPU MAX` IS A SUPERPOWER**
>
> It implements architectural features that shipping silicon may not have: SVE2, MTE, pointer authentication, FEAT_NV2 for nested virtualisation, S-EL2. You can write and debug code for a CPU that does not exist yet. The catch is that `max` tracks the QEMU version, so pin your QEMU version in CI or your feature set moves under you.

How it shows up

Symptom	Cause
Guest boots but takes minutes	TCG. Expected. Use KVM if the architectures match
`Could not access KVM kernel module: Permission denied`	Not in the `kvm` group
`-accel kvm` fails on an x86 host with an arm64 guest	KVM cannot cross architectures. This is not a bug
Lock-free code passes under QEMU, fails on hardware	MTTCG on a strongly ordered host hid a missing barrier
A race never reproduces	Try `-icount` with different shifts, or single-thread TCG

Symptom	Cause
Timing measurements make no sense	TCG time is not real time; use `-icount` for determinism or KVM for realism
Feature present under `-cpu max`, absent on the board	Exactly what `max` is for — check `ID_AA64*` registers on the real part
Machine type not found	Wrong binary — `qemu-system-arm` is 32-bit, `qemu-system-aarch64` is 64-bit

Check yourself

- ✓ Name the two separable halves of QEMU and say which one `-accel` selects.
- ✓ List the four ways to run QEMU and give a use for each.
- ✓ Explain why `-accel kvm` requires matching architectures and TCG does not.
- ✓ Give the approximate slowdown of TCG and say what it does and does not invalidate.
- ✓ Explain why a missing memory barrier can be invisible under TCG on an x86 host.
- ✓ Say what `-icount` buys you and name one thing it enables.
- ✓ Explain the difference between `-cpu max` and `-cpu host`.
- ✓ Determine, on your own machine, which accelerators and machine types are available.
- ✓ Explain how `binfmt_misc` plus user-mode QEMU lets you run foreign binaries transparently.

TCG: how emulation actually works

QEMU does not interpret instructions one at a time — that would be a hundred times slower still. It translates blocks of guest code into host code, caches them, and chains them together so that straight-line guest execution never returns to the translator. Understanding that machinery explains every performance surprise and every debugging limitation you will meet.

Translate, cache, chain

```
guest PC = 0x40080000, nothing cached
     |
     v
+-------------------------------------------------+
| 1. FIND: is there a translation block for this  |
|    (PC, CPU flags, MMU mode)?  No.              |
+-------------------------------------------------+
     |
     v
+-------------------------------------------------+
| 2. TRANSLATE. Decode guest instructions from the |
|    PC until a branch, a system instruction, or a |
|    page boundary. Emit TCG IR - a small, target- |
|    independent RISC-like intermediate language.  |
+-------------------------------------------------+
     |
     v
+-------------------------------------------------+
| 3. OPTIMISE the IR: dead code, constant folding, |
|    liveness. Cheap passes only - translation time|
|    is on the critical path.                      |
+-------------------------------------------------+
     |
     v
+-------------------------------------------------+
| 4. EMIT host machine code into the code cache.   |
+-------------------------------------------------+
     |
     v
+-------------------------------------------------+
| 5. EXECUTE it. Guest registers live in a struct  |
|    (CPUARMState); the emitted code loads and     |
|    stores them.                                  |
+-------------------------------------------------+
     |
     v
+-------------------------------------------------+
| 6. CHAIN. If the block ends in a direct branch   |
|    to a block already translated, PATCH the jump |
|    so it goes straight there next time, without  |
|    returning to the dispatcher at all.           |
+-------------------------------------------------+

A hot loop therefore becomes host code jumping directly to
host code. The translator runs once. That is why TCG is
10-50x slower than native and not 1000x.
```

The intermediate representation

```
# See it for yourself. This is the single most useful QEMU
# debugging flag nobody knows about.

$ qemu-system-aarch64 -M virt -cpu cortex-a57 -nographic \
    -kernel Image -d in_asm,op,out_asm 2>trace.log

# Or, more usefully, on a single small binary:
$ qemu-aarch64 -d in_asm,op,out_asm ./hello 2>trace.log

----------------
IN: main                        <-- the GUEST instructions
0x00400594:  d10083ff  sub sp, sp, #0x20
0x00400598:  a9017bfd  stp x29, x30, [sp, #16]
0x0040059c:  910043fd  add x29, sp, #0x10
0x004005a0:  94000010  bl  #+0x40

OP:                             <-- the TCG IR
 ld_i64 tmp0,env,$0xfffffffffffffd8
 movi_i64 tmp1,$0x20
 sub_i64 tmp0,tmp0,tmp1
 st_i64 tmp0,env,$0xfffffffffffffd8
 ...
 goto_tb $0x0
 exit_tb $0x7f2c14000043

OUT: [size=124]                 <-- the HOST instructions
0x7f2c14000000:  48 8b 6d f0    mov -0x10(%rbp),%rbp
0x7f2c14000004:  48 83 ed 20    sub $0x20,%rbp
...

# The IR is deliberately tiny - about 150 operations. Adding a
# new guest architecture means writing a FRONT END that emits
# this IR; adding a new host means writing a BACK END that
# consumes it. That N+M rather than N*M structure is why QEMU
# supports so many combinations.
```

Flag	Shows	Volume
`-d in_asm`	Guest instructions as they are translated	One line per instruction, once per block
`-d op`	TCG IR before optimisation	Large
`-d op_opt`	IR after optimisation	Large
`-d out_asm`	Emitted host code	Large
`-d exec`	Every block *execution*	Enormous — this is the one that traces control flow
`-d cpu`	Full register dump at each block	Enormous
`-d int`	Every exception and interrupt taken	Modest — extremely useful
`-d mmu`	MMU faults and translation	Modest
`-d guest_errors`	Guest doing something invalid	Small — always turn this on
`-d unimp`	Unimplemented device or CPU features	Small — always turn this on

Helpers: the escape hatch

```
/* Some guest instructions are too complex to express in 150 IR
   operations. For those, TCG emits a CALL to a C function
   called a HELPER.                                           */

/* target/arm/helper.c - a real one, simplified: */

void HELPER(msr_i_daifset)(CPUARMState *env, uint32_t imm)
{
        env->daif |= (imm << 6) & PSTATE_DAIF;
        arm_rebuild_hflags(env);
}

/* And in the translator, target/arm/translate-a64.c: */

    gen_helper_msr_i_daifset(cpu_env, tcg_constant_i32(imm));

/* What becomes a helper:
     - system register access
     - MMU translation (the slow path; the fast path is the
       software TLB, below)
     - floating point and SIMD, mostly
     - cryptographic instructions
     - anything touching CPU mode or exception state

   What stays in IR:
     - arithmetic, logic, shifts
     - loads and stores (fast path)
     - branches

   A helper call costs a real host function call, so an
   instruction that becomes a helper is far slower than one
   that does not. This is why FP-heavy code is
   disproportionately slow under TCG, and why crypto benchmarks
   inside QEMU are meaningless.                               */
```

The software TLB

```
Every guest load and store needs a guest-virtual to
host-virtual translation. Doing a full page-table walk in
software per access would be catastrophic, so TCG keeps a
direct-mapped software TLB and inlines the lookup.

Emitted code for a guest LDR, conceptually:

  index = (guest_addr >> 12) & (CPU_TLB_SIZE - 1)
  entry = env->tlb_table[mmu_idx][index]

  if (entry.addr_read == (guest_addr & TARGET_PAGE_MASK)) {
          /* FAST PATH: a few host instructions            */
          host_addr = guest_addr + entry.addend;
          value = *(uint64_t *)host_addr;
  } else {
          /* SLOW PATH: call a helper that walks the guest
             page tables, fills the TLB entry, and may
             raise a guest fault - or dispatches to a
             DEVICE MODEL if the address is MMIO.          */
          value = helper_ldq_mmu(env, guest_addr, oi, ra);
  }

Consequences you can feel:

* A guest that thrashes its own TLB thrashes QEMU's too, and
  the slow path is a C function call plus a walk.
* MMIO is ALWAYS the slow path, by construction - that is
  how device models get called.
* mmu_idx encodes the exception level and translation
  regime, so a guest that switches EL frequently invalidates
  less than you would fear but still pays.
* Flushing: any guest TLBI causes QEMU to flush its software
  TLB. A guest doing aggressive TLB maintenance is slow
  under TCG for a reason that does not exist on hardware.
```

Self-modifying code and page protection

```
/* The cached translation is only valid while the guest code it
   came from is unchanged. If the guest rewrites its own
   instructions - JIT compilers, bootloaders relocating
   themselves, module loaders - QEMU must notice.

   Mechanism: any guest page that has been translated is
   marked, and writes to it are detected. The affected
   translation blocks are invalidated and retranslated.     */

  Symptoms of a guest that fights this:

    * A JIT (a JVM, V8, or the kernel's BPF JIT) inside a TCG
      guest is dramatically slower than the rest of the guest,
      because it repeatedly invalidates translations.

    * A guest that writes data into the same PAGE as code -
      even not overlapping the code - triggers invalidation.
      Literal pools next to code, or a bootloader keeping
      variables in its text section, do this.

  Tuning the code cache, which matters for large guests:

$ qemu-system-aarch64 -accel tcg,tb-size=512 ...
      # 512 MB of translation cache. Default is smaller and is
      # sized from RAM. A large kernel plus a large userspace
      # can thrash a small cache, and the symptom is a guest
      # that gets SLOWER the longer it runs.

$ qemu-system-aarch64 -accel tcg,one-insn-per-tb=on ...
      # one guest instruction per block. Very slow, but exact:
      # every instruction boundary is a block boundary, so
      # breakpoints, tracing and -d exec become precise.
```

WHAT TCG DOES NOT MODEL

Caches, pipelines, branch prediction, memory latency, DVFS, and real interrupt timing. A cycle count from TCG is not merely inaccurate — it is meaningless. Use TCG to prove that logic is correct and to observe what the guest *did*; use hardware or KVM to find out how long it takes.

TCG plugins

```
# Since QEMU 4.2 you can load a shared library that gets called
# on translation and execution events. This is the closest
# thing to a hardware trace probe that costs nothing.

$ ls /usr/lib/qemu/         # or build them from tests/plugin/
libinsn.so  libmem.so  libhotblocks.so  libhotpages.so
libcache.so libhowvec.so

# Count every instruction executed:
$ qemu-aarch64 -plugin /usr/lib/qemu/libinsn.so -d plugin ./workload
insns: 48120311

# Find the hottest basic blocks:
$ qemu-system-aarch64 -M virt -kernel Image \
    -plugin /usr/lib/qemu/libhotblocks.so -d plugin ...
collected 25011 entries
pc, hits, insns
0x40081234, 1204551, 12
0x40095678,  883012,  8

# Model a cache and count misses - a real one, not a guess:
$ qemu-system-aarch64 ... \
    -plugin /usr/lib/qemu/libcache.so,dcachesize=32768,\
dassoc=4,dblksize=64

# Trace every memory access:
$ qemu-aarch64 -plugin /usr/lib/qemu/libmem.so,inline=on ./prog

# Writing your own is ~100 lines: register callbacks in
# qemu_plugin_install(), then use
#   qemu_plugin_register_vcpu_insn_exec_cb()
#   qemu_plugin_register_vcpu_mem_cb()
# This is how you answer "how many times does my driver touch
# that register?" without changing the driver.
```

How it shows up

Symptom	Cause
Guest gets slower the longer it runs	Code cache thrashing — raise `tb-size`
A JIT inside the guest is pathologically slow	Self-modifying-code invalidation; unavoidable under TCG
FP or crypto benchmarks absurdly slow	Those instructions become helper calls
Breakpoint fires at the wrong instruction	Block-granular execution; use `one-insn-per-tb=on`
`-d exec` produces gigabytes	Working as intended. Filter with `-D file` and a narrow window
Guest hits an instruction QEMU does not implement	`-d unimp` will say so — always enable it during bring-up
Device access silently returns zero	No model at that address; `-d guest_errors` reports it
Timing-dependent code behaves differently every run	Use `-icount` to make runs deterministic
Guest TLB-heavy workload disproportionately slow	Every guest `TLBI` flushes QEMU's software TLB

Check yourself

✓ Describe the six steps from an untranslated guest PC to executing host code.

- ✓ Explain block chaining and why it is the reason TCG is not catastrophically slow.
- ✓ Explain the N+M structure of front ends and back ends around the IR.
- ✓ Define a helper and name three instruction classes that become one.
- ✓ Describe the software TLB fast path and say what always takes the slow path.
- ✓ Explain why a guest JIT is slow under TCG.
- ✓ Name five `-d` flags and say what each is for.
- ✓ List four things TCG does not model, and say what that invalidates.
- ✓ Use a TCG plugin to count instructions or find hot blocks.
- ✓ Explain what `one-insn-per-tb=on` changes and when you would pay for it.

Building QEMU from source

Distribution packages lag, omit machine types, and are built without the debug information you need the first time a device model misbehaves. Building QEMU takes about ten minutes and gives you a tree you can patch — which you will, the first time you add a device model in chapter 13.

When the packaged one is not enough

You need	Because
A newer version	Machine types, CPU features (FEAT_NV2, MTE, S-EL2) and virtio devices land in QEMU long before distributions ship them
Debug symbols and assertions	When a device model asserts, you want a stack trace with line numbers, not `??`
To add or modify a device	Chapter 13
TCG plugins	Often not built or shipped by distributions
A reproducible CI pin	`-cpu max` changes meaning between versions; pin the version
A specific board	Vendor forks (Xilinx, NXP) carry machine models not upstream

Dependencies

```
# Debian / Ubuntu
$ sudo apt update
$ sudo apt install -y \
    git build-essential ninja-build meson pkg-config python3-venv \
    libglib2.0-dev libpixman-1-dev libfdt-dev zlib1g-dev \
    libslirp-dev libcap-ng-dev libattr1-dev \
    libaio-dev libbpf-dev libcurl4-gnutls-dev \
    libgnutls28-dev libnfs-dev libssh-dev \
    libncurses-dev libsdl2-dev libgtk-3-dev \
    libspice-server-dev libusb-1.0-0-dev libusbredirhost-dev \
    libvirglrenderer-dev libepoxy-dev \
    flex bison

# Fedora / RHEL
$ sudo dnf install -y \
    git gcc make ninja-build meson glib2-devel pixman-devel \
    libfdt-devel zlib-devel libslirp-devel libcap-ng-devel \
    libaio-devel gnutls-devel ncurses-devel SDL2-devel \
    gtk3-devel libusbx-devel spice-server-devel flex bison

# Arch
$ sudo pacman -S base-devel git ninja meson glib2 pixman dtc \
    libslirp libcap-ng libaio gnutls sdl2 gtk3 libusb

# macOS (Homebrew) - hvf accelerator, useful on Apple silicon
$ brew install ninja meson glib pixman dtc pkg-config libslirp

# The three that actually matter and are most often missing:
#   libglib2.0-dev   - QEMU will not configure without it
#   libpixman-1-dev  - graphics; required even headless
#   libslirp-dev     - user-mode networking (-netdev user)
#                      Without it, "-netdev user" silently
#                      disappears from the help output and you
#                      will spend an hour wondering why.
```

The build

```
$ git clone https://gitlab.com/qemu-project/qemu.git
$ cd qemu

# Pin a release. Building master is fine for development but a
# terrible idea for anything you want to reproduce later.
$ git checkout v8.2.2
$ git submodule update --init --recursive

# Out-of-tree build. Always.
$ mkdir build && cd build

# Minimal, fast build: only the targets you need.
$ ../configure \
    --target-list=aarch64-softmmu,arm-softmmu,aarch64-linux-user \
    --enable-slirp \
    --enable-debug \
    --enable-debug-info \
    --enable-plugins \
    --prefix=$HOME/opt/qemu

$ ninja -j$(nproc)
$ ninja install

# Building ALL targets takes 20+ minutes and produces 40
# binaries you will never run. --target-list is the single
# most valuable configure flag.

$ ~/opt/qemu/bin/qemu-system-aarch64 --version
QEMU emulator version 8.2.2

# Put it on your PATH ahead of the packaged one:
$ export PATH=$HOME/opt/qemu/bin:$PATH
```

configure flag	Effect
`--target-list=`	Which guest architectures to build. `*-softmmu` = system emulation, `*-linux-user` = user mode
`--enable-debug`	No optimisation, assertions on. Roughly 2x slower; worth it while developing a device
`--enable-debug-info`	Symbols without disabling optimisation — the middle ground
`--enable-plugins`	TCG plugin support (chapter 12)
`--enable-trace-backends=log,ftrace`	Built-in tracepoints
`--enable-slirp`	User-mode networking
`--enable-sanitizers`	ASan/UBSan. Invaluable when your own device model corrupts memory
`--disable-werror`	Needed when building an older QEMU with a newer compiler
`--static`	A binary you can copy to a machine with different libraries
`--enable-kvm`	Usually autodetected; force it to catch a missing header

TWO BUILDS, SIDE BY SIDE

Keep an optimised build for daily use and a `--enable-debug --enable-sanitizers` build for when something breaks. Meson supports several build directories against one source tree, so this costs disk space and nothing else:

```
$ mkdir build-opt build-dbg
$ (cd build-opt && ../configure --target-list=aarch64-softmmu \
      --prefix=$HOME/opt/qemu && ninja)
$ (cd build-dbg && ../configure --target-list=aarch64-softmmu \
      --enable-debug --enable-sanitizers && ninja)

# Run from the build directory without installing - the
# binaries work in place:
$ ./build-dbg/qemu-system-aarch64 -M virt -nographic ...
```

Firmware you will also need

```
# QEMU ships some firmware blobs, but for arm64 work you build
# your own. These are the ones this site's tracks use.

# 1. U-Boot - for a realistic boot chain
$ git clone https://source.denx.de/u-boot/u-boot.git
$ cd u-boot && make qemu_arm64_defconfig
$ make CROSS_COMPILE=aarch64-linux-gnu- -j$(nproc)
# produces u-boot.bin -> qemu -bios u-boot.bin

# 2. EDK2 / UEFI - for an ACPI-based boot, as on servers
$ sudo apt install qemu-efi-aarch64
$ ls /usr/share/AAVMF/AAVMF_CODE.fd
# -drive if=pflash,format=raw,readonly=on,file=AAVMF_CODE.fd

# 3. TF-A - EL3 firmware, needed for the OP-TEE track
$ git clone https://github.com/ARM-software/arm-trusted-firmware
$ cd arm-trusted-firmware
$ make CROSS_COMPILE=aarch64-none-elf- PLAT=qemu \
       BL33=/path/to/u-boot.bin all fip
# produces bl1.bin and fip.bin -> loaded with -bios and -device
# loader; the OP-TEE track's chapter 4 does this properly.

# 4. A cross toolchain, if you do not have one
$ sudo apt install gcc-aarch64-linux-gnu       # Linux userspace
$ sudo apt install gcc-aarch64-none-elf        # bare metal
# or fetch the Arm GNU toolchain:
#   https://developer.arm.com/downloads/-/arm-gnu-toolchain-downloads
```

Verifying the build

```
# 1. Does it run at all?
$ qemu-system-aarch64 -M virt -nographic -kernel /dev/null 2>&1 | head -2

# 2. Are the accelerators there?
$ qemu-system-aarch64 -accel help

# 3. Is slirp present? (the silent-failure one)
$ qemu-system-aarch64 -netdev help | grep -q user && \
    echo "user networking OK" || echo "MISSING libslirp"

# 4. Are plugins enabled?
$ ls build/tests/plugin/*.so

# 5. Run the smoke tests - fast, and they catch a broken build:
$ cd build && ninja check-qtest-aarch64

# 6. The full suite, if you have changed something:
$ ninja check           # unit tests
$ ninja check-qtest     # device-level tests
$ ninja check-tcg       # requires cross compilers

# 7. Boot something real. The definitive test:
$ qemu-system-aarch64 -M virt -cpu cortex-a57 -m 512M -nographic \
    -kernel Image -append "console=ttyAMA0 rdinit=/bin/sh" \
    -initrd initramfs.cpio.gz
```

How it shows up

Symptom	Cause
`ERROR: glib-2.56 gthread-2.0 is required`	`libglib2.0-dev` missing — the runtime library alone is not enough
`-netdev user` not accepted	Built without libslirp. Reconfigure with `--enable-slirp`
`Unsupported machine type`	Wrong target list, or wrong binary (`qemu-system-arm` vs `-aarch64`)
Build fails with new-compiler warnings	Old QEMU, new GCC. Add `--disable-werror`
Meson errors about a stale build directory	`rm -rf build` and reconfigure; meson caches aggressively
Submodule errors during configure	`git submodule update --init --recursive`
Enormous build time	No `--target-list` — you are building every architecture
Binary works locally, not on another machine	Shared-library mismatch; build `--static`
Device model bug with no useful backtrace	Built without `--enable-debug`

Check yourself

- ✓ Give three reasons to build QEMU rather than install it.
- ✓ Name the three most commonly missing build dependencies and what each breaks.
- ✓ Explain what `--target-list` controls and why it matters.
- ✓ Distinguish `--enable-debug` from `--enable-debug-info`.
- ✓ Explain the value of keeping two build directories.
- ✓ Name the four firmware components an arm64 development setup may need.

- ✓ Verify from the command line that user networking and plugins are available.
- ✓ Say why pinning a QEMU version matters for CI.
- ✓ Run the qtest suite for aarch64 and interpret a failure.

The AArch64 virt machine

There is no such board. `virt` is a machine designed to be virtualised: a memory map chosen for convenience, only devices worth emulating, and a device tree generated at runtime to describe whatever you asked for. It is the target for every arm64 exercise on this site, and knowing its map by heart saves an enormous amount of time.

The memory map

```
0x0000_0000  +---------------------------+
             |  flash 0 (secure)  64 MB  |  -bios / pflash
0x0400_0000  +---------------------------+
             |  flash 1           64 MB  |  UEFI vars
0x0800_0000  +---------------------------+
             |  GIC distributor    64 KB |
0x0801_0000  +---------------------------+
             |  GICv2 CPU iface / GICv3  |
             |  redistributors           |
0x0808_0000  +---------------------------+
             |  GICv3 ITS                |
0x0809_0000  +---------------------------+
             |  GICv2m (MSI for v2)      |
0x0900_0000  +---------------------------+
             |  PL011 UART        4 KB   |  ttyAMA0
0x0901_0000  +---------------------------+
             |  PL031 RTC                |
0x0903_0000  +---------------------------+
             |  PL061 GPIO               |
0x0905_0000  +---------------------------+
             |  ACPI GED / power button  |
0x0a00_0000  +---------------------------+
             |  virtio-mmio x 32         |  0x200 apart
             |    slot 0: 0x0a00_0000    |  IRQ 16
             |    slot 1: 0x0a00_0200    |  IRQ 17
             |    ...                    |  ...
             |    slot31: 0x0a003e00     |  IRQ 47
0x0c00_0000  +---------------------------+
             |  platform bus (dynamic)   |  vfio-platform
0x1000_0000  +---------------------------+
             |  PCIe MMIO (32-bit)       |
0x3eff_0000  +---------------------------+
             |  PCIe I/O port window     |
0x3f00_0000  +---------------------------+
             |  PCIe ECAM config space   |
0x4000_0000  +---------------------------+
             |                           |
             |  RAM  - starts here, size |
             |  from -m, grows upward    |
             |                           |
             +---------------------------+
             |  high PCIe MMIO (64-bit)  |  above RAM
             +---------------------------+

TWO ADDRESSES TO MEMORISE:
  0x0900_0000   the UART. Your first printf.
  0x4000_0000   where RAM starts. Where your kernel goes.

Everything else you can look up - and the way to look it up
is dumpdtb, below.
```

The device tree is generated, and you can read it

```
# QEMU builds a device tree describing exactly the machine you
# asked for - your CPU count, your memory size, your devices -
# and places it in memory for the kernel.

$ qemu-system-aarch64 -M virt,dumpdtb=virt.dtb \
    -cpu cortex-a57 -smp 4 -m 2G -nographic
# exits immediately, having written virt.dtb

$ dtc -I dtb -O dts virt.dtb -o virt.dts
$ less virt.dts

/dts-v1/;
/ {
    interrupt-parent = <0x8002>;
    #size-cells = <0x02>;
    #address-cells = <0x02>;
    compatible = "linux,dummy-virt";

    memory@40000000 {
        reg = <0x00 0x40000000 0x00 0x80000000>;

        method = "hvc";
    };
};

# THIS IS THE SINGLE MOST USEFUL DEBUGGING TRICK IN THE TRACK.
# "My device does not appear in the guest" is answered in ten
# seconds by dumping the DTB and looking.

# From inside a running guest, the same information:
$ dtc -I fs -O dts /sys/firmware/devicetree/base | less
```

WHY IT IS GENERATED, NOT FIXED

A real board has a device tree committed to a repository, describing hardware that cannot change. `virt` has no fixed hardware: the number of CPUs, the amount of RAM, the GIC version, whether there is an ITS, and which virtio devices exist are all decided by your command line. Generating the tree at startup is the only way to keep it truthful, and it means you never edit a DTS to change your VM's memory.

The machine options that matter

Option	Values	Effect
`gic-version`	`2`, `3`, `4`, `host`, `max`	Which interrupt controller. `host` matches the hardware under KVM; `max` is the newest QEMU supports
`its`	`on` / `off`	The GICv3 ITS. Needed for PCIe MSI-X (virt chapter 11)
`virtualization`	`on` / `off`	Give the guest EL2, so it can run its own hypervisor
`secure`	`on` / `off`	Give the machine EL3 and a secure world. Required for TF-A and OP-TEE
`mte`	`on` / `off`	Memory Tagging Extension
`iommu`	`smmuv3`	An SMMU, for passthrough and DMA isolation experiments
`highmem`	`on` / `off`	Whether to place devices above 4 GB. Turn off for a 32-bit-limited guest
`acpi`	`on` / `off`	Generate ACPI tables as well as a device tree — the server boot path
`dumpdtb=`	filename	Write the generated device tree and exit
`memory-backend=`	object id	Back RAM with hugetlbfs or shared memory — needed for vhost-user and virtiofs

```
# The configuration this site's ARM and security tracks use:
$ qemu-system-aarch64 \
    -M virt,secure=on,virtualization=on,gic-version=3 \
    -cpu max -smp 2 -m 1G -nographic

# Everything on, for exploring:
$ qemu-system-aarch64 \
    -M virt,gic-version=max,its=on,virtualization=on,secure=on,\
mte=on,iommu=smmuv3,acpi=on \
    -cpu max -smp 4 -m 4G -nographic

# Native speed on an arm64 host:
$ qemu-system-aarch64 -M virt,gic-version=host -cpu host \
    -accel kvm -smp 4 -m 4G -nographic
```

`SECURE=ON` AND `-CPU MAX` TOGETHER

Turning on the secure world changes the boot: the CPU now starts at EL3, and QEMU expects firmware there. With `-kernel` QEMU synthesises a minimal EL3 stub that drops to EL1, which is fine for testing — but the moment you supply real firmware with `-bios`, the stub disappears and your image must handle EL3 itself. This trips up nearly everyone on their first OP-TEE build; see OP-TEE chapter 4.

The other arm64 machines

Machine	Models	Use it when
`virt`	Nothing real	Almost always. Fast, flexible, well-maintained
`sbsa-ref`	An Arm ServerReady platform	Testing UEFI/ACPI firmware as a server would boot it
`raspi3b`, `raspi4b`	Raspberry Pi	Reproducing a Pi-specific issue; slow and partially modelled
`xlnx-zcu102`	Xilinx ZynqMP	ZynqMP driver work — has the real memory map and many real IP blocks
`imx8mp-evk`	NXP i.MX8M Plus	i.MX driver work
`vexpress-a15`	ARM Versatile Express	Legacy 32-bit material
`none`	Nothing at all	Loading a bare-metal ELF with `-device loader` and nothing else

```
# List everything this binary knows:
$ qemu-system-aarch64 -M help

# And what a specific machine accepts:
$ qemu-system-aarch64 -M virt -machine help 2>&1 | head
# or, more reliably, ask QMP (chapter 10):
$ qemu-system-aarch64 -M virt -nographic -S \
    -qmp stdio <<'EOF' | python3 -m json.tool
{"execute":"qmp_capabilities"}
{"execute":"qom-list-properties","arguments":{"typename":"virt-8.2-machine"}}
EOF

# Which devices exist on this machine, at runtime:
# (in the monitor, Ctrl-A c)
(qemu) info qtree
(qemu) info mtree          # the memory map, authoritative
(qemu) info qom-tree
```

info mtree: the memory map, from the machine itself

```
(qemu) info mtree
address-space: memory
  0000000000000000-ffffffffffffffff (prio 0, i/o): system
    0000000000000000-000000007fffffff (prio 0, romd): virt.flash0
    0000000008000000-0000000000800fff (prio 0, i/o): gicv3_dist
    0000000008080000-00000000080bffff (prio 0, i/o): gicv3_its
    0000000009000000-0000000009000fff (prio 0, i/o): pl011
    0000000009010000-0000000009010fff (prio 0, i/o): pl031
    000000000a000000-000000000a0001ff (prio 0, i/o): virtio-mmio
    000000000a000200-000000000a0003ff (prio 0, i/o): virtio-mmio
    ...
    0000000040000000-00000000bfffffff (prio 0, ram): mach-virt.ram

# This is the truth. If your guest faults at an address, find
# it here first: either there is no region (nothing modelled)
# or there is one and your driver is misusing it.

# Regions with "romd" are read-mostly flash; "i/o" are device
# models; "ram" is real backing memory.

# Overlaps are resolved by priority, which is how a boot ROM
# can shadow RAM at address 0 and then be removed.
```

How it shows up

Symptom	Cause
No console output at all	Wrong console in `-append`; it is `console=ttyAMA0` on `virt`, not `ttyS0`
Guest cannot find its root device	virtio device added but the guest's device tree slot differs; check `dumpdtb`
PCIe device gets no MSI-X	`its=off`, or `gic-version=2`
Kernel panics with "no matching CPU" or hangs at "Starting kernel"	Loaded at the wrong address — RAM starts at `0x4000_0000`
Guest cannot run its own hypervisor	`virtualization=on` missing
TF-A or OP-TEE will not start	`secure=on` missing
Boots with `-kernel`, fails with `-bios`	The synthesised EL3 stub is gone; your firmware must handle EL3
virtio device present but never probed	Slot used out of order, or the guest kernel lacks `CONFIG_VIRTIO_MMIO`
Memory map differs from the documentation	The map has changed between QEMU versions — always `dumpdtb` rather than trusting a blog

Check yourself

- ✓ State the addresses of the UART and the start of RAM on `virt`, from memory.
- ✓ Explain why the device tree is generated at runtime rather than committed.
- ✓ Dump the device tree for a machine you configured and find the virtio-mmio slots.
- ✓ Name the machine options that add EL2, EL3, an ITS and an SMMU.
- ✓ Explain what changes when you pass `-bios` on a `secure=on` machine.
- ✓ Give the correct `console=` argument for this machine and say why.
- ✓ Use `info mtree` to determine whether an address is modelled.
- ✓ Choose a machine type for: kernel driver development, server firmware testing, and ZynqMP bring-up.
- ✓ Explain the difference between `gic-version=host` and `gic-version=max`.

Booting a kernel directly

`-kernel` lets you skip the bootloader entirely: QEMU loads your image, synthesises the handoff a bootloader would have performed, and jumps to it. It turns a five-minute build-flash-boot cycle into a two-second one, and it is how you should develop everything until the boot chain itself is the thing you are testing.

What `-kernel` actually does

```
Normally, on real hardware:

  ROM -> BL1 -> BL2 -> BL31 (EL3) -> U-Boot (EL2/EL1)
                                        |
                                        | reads a device tree
                                        | loads Image + initrd
                                        | sets x0 = DTB address
                                        | jumps to the kernel
                                        v
                                      Linux

With -kernel, QEMU IS the bootloader:

  1. Parse the image. An arm64 "Image" has a 64-byte header:
         0x00  code0, code1        (branch instructions)
         0x08  text_offset         (where to load, relative
                                    to the start of RAM)
         0x10  image_size
         0x18  flags
         0x38  magic "ARM\x64"
     QEMU reads text_offset and image_size and places the
     image accordingly - usually 0x4008_0000.

  2. Load the initrd, if given, somewhere above the kernel,
     and record its address and size.

  3. GENERATE the device tree (chapter 4), then PATCH it:
         /chosen/bootargs        = your -append string
         /chosen/linux,initrd-start
         /chosen/linux,initrd-end
     and write it into guest RAM.

  4. Write a tiny boot stub at the start of RAM that:
         sets x0 = DTB address
         x1 = x2 = x3 = 0
         branches to the kernel entry point
     For -smp N, secondary CPUs park in a PSCI-compatible
     wait loop.

  5. Release the CPU at the stub.

The kernel cannot tell the difference, which is the point.
```

The smallest thing that boots

```
# You need three things: a kernel, a console, and a root
# filesystem. Start with only the first two.

$ qemu-system-aarch64 \
    -M virt -cpu cortex-a57 -m 512M -nographic \
    -kernel Image \
    -append "console=ttyAMA0 earlycon"

# It boots, prints, and panics with "No working init found",
# because there is no root filesystem. That panic is SUCCESS:
# it means the kernel ran to the end of its own initialisation.

# Now add an initramfs and you have a usable system:
$ qemu-system-aarch64 \
    -M virt -cpu cortex-a57 -m 512M -nographic \
    -kernel Image -initrd initramfs.cpio.gz \
    -append "console=ttyAMA0 earlycon rdinit=/bin/sh"

# Exit with Ctrl-A x.  (Ctrl-A c switches to the monitor.)

# The four arguments that matter, and why:
#
#   console=ttyAMA0   the PL011 at 0x09000000. WITHOUT THIS you
#                     see nothing after the kernel takes over
#                     its own console. It is the single most
#                     common "it hangs" cause.
#
#   earlycon          console output BEFORE the driver probes.
#                     On virt, the kernel finds the address in
#                     /chosen/stdout-path, so plain "earlycon"
#                     works with no arguments.
#
#   rdinit=/bin/sh    run a shell from the initramfs instead of
#                     looking for /sbin/init.
#
#   -nographic        no window; serial to your terminal.
#                     Implies -serial mon:stdio.
```

> **ALWAYS ADD `EARLYCON` WHILE BRINGING SOMETHING UP**
>
> Without it, the window between "kernel entered" and "console driver probed" is silent — and that window contains the MMU setup, the memory-map parse and the device-tree parse, which is exactly where early boot failures live. With it, you see `Booting Linux on physical CPU 0x0` almost immediately, and a hang after that is a much smaller problem than a hang before it.

Building a kernel worth booting

```
$ git clone --depth=1 -b v6.8 \
    https://git.kernel.org/pub/scm/linux/kernel/git/stable/linux.git
$ cd linux

$ export ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu-
$ make defconfig

# defconfig already includes virtio, PL011 and the GIC. Add the
# things you will want for this site's tracks:
$ scripts/config --enable  DEBUG_INFO_DWARF5 \
                 --enable  GDB_SCRIPTS \
                 --enable  DEBUG_KERNEL \
                 --enable  DYNAMIC_DEBUG \
                 --enable  MAGIC_SYSRQ \
                 --enable  KGDB \
                 --enable  FTRACE \
                 --enable  FUNCTION_TRACER \
                 --enable  KPROBES \
                 --enable  TEE \
                 --enable  OPTEE \
                 --enable  BLK_DEV_INITRD \
                 --set-val CONFIG_RANDOMIZE_BASE n
$ make olddefconfig
$ make -j$(nproc) Image modules

# Result: arch/arm64/boot/Image   (uncompressed - what -kernel
#                                  wants)
#         arch/arm64/boot/Image.gz (what a real board uses)
#         vmlinux                  (with symbols - what GDB
#                                   wants, chapter 11)

# RANDOMIZE_BASE off is deliberate: KASLR moves the kernel
# every boot, and then your GDB symbols are at the wrong
# addresses. Turn it off for debugging, on for realism.
# Alternatively pass "nokaslr" in -append.
```

A root filesystem in thirty seconds

```
# Option 1: busybox, statically linked. Smallest and fastest.

$ wget https://busybox.net/downloads/busybox-1.36.1.tar.bz2
$ tar xf busybox-1.36.1.tar.bz2 && cd busybox-1.36.1
$ make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- defconfig
$ sed -i 's/# CONFIG_STATIC is not set/CONFIG_STATIC=y/' .config
$ make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- -j$(nproc)
$ make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- \
       CONFIG_PREFIX=../rootfs install

$ cd ../rootfs
$ mkdir -p proc sys dev etc/init.d
$ cat > init <<'EOF'
#!/bin/sh
mount -t proc  none /proc
mount -t sysfs none /sys
mount -t devtmpfs none /dev
echo "=== up ==="
exec /bin/sh
EOF
$ chmod +x init
$ find . | cpio -o -H newc | gzip > ../initramfs.cpio.gz

# Boot it:
$ qemu-system-aarch64 -M virt -cpu cortex-a57 -m 512M -nographic \
    -kernel Image -initrd initramfs.cpio.gz \
    -append "console=ttyAMA0 earlycon"

# Option 2: use the host's own aarch64 container image
$ docker create --platform linux/arm64 --name x arm64v8/alpine
$ docker export x | (mkdir -p rootfs && cd rootfs && tar xf -)
$ docker rm x
# ...then cpio it as above, or make it a disk image (chapter 6).
```

Supplying your own device tree

```
# Sometimes you want to modify what QEMU generated - to add a
# node for a device model you are writing, or to change a
# property. The workflow is: dump, edit, feed back.

$ qemu-system-aarch64 -M virt,dumpdtb=virt.dtb -m 1G -smp 2
$ dtc -I dtb -O dts virt.dtb -o virt.dts

# Edit virt.dts - add your node:
#     my-device@c000000 {
#         compatible = "acme,widget";
#         reg = <0x0 0x0c000000 0x0 0x1000>;
#         interrupts = <0x0 0x30 0x4>;
#     };

$ dtc -I dts -O dtb virt.dts -o virt-mod.dtb
$ qemu-system-aarch64 -M virt -m 1G -smp 2 -nographic \
    -kernel Image -dtb virt-mod.dtb -append "console=ttyAMA0"

# CAUTION: -dtb REPLACES the generated tree entirely. If you
# then change -m or -smp, the tree no longer matches the
# machine and the guest will see the OLD memory size. Regenerate
# after any machine change. This causes hours of confusion, so
# script it:

$ cat > boot.sh <<'EOF'
#!/bin/sh
set -e
MEM=${MEM:-1G}; SMP=${SMP:-2}
qemu-system-aarch64 -M virt,dumpdtb=/tmp/base.dtb -m $MEM -smp $SMP
dtc -I dtb -O dts /tmp/base.dtb -o /tmp/base.dts 2>/dev/null
python3 add_my_node.py /tmp/base.dts /tmp/final.dts
dtc -I dts -O dtb /tmp/final.dts -o /tmp/final.dtb 2>/dev/null
exec qemu-system-aarch64 -M virt -m $MEM -smp $SMP -nographic \
    -kernel Image -dtb /tmp/final.dtb -append "console=ttyAMA0 earlycon"
EOF
$ chmod +x boot.sh
```

Choosing the exception level you land at

```
# -kernel normally enters at EL1 (or EL2 with virtualization=on).
# For bare-metal work you often want something else.

# Land at EL2, so you can write a hypervisor:
$ qemu-system-aarch64 -M virt,virtualization=on -cpu max \
    -kernel my-el2-payload.bin -nographic
# Confirm from inside: mrs x0, CurrentEL  -> 0x8 means EL2

# Land at EL3, for firmware work:
$ qemu-system-aarch64 -M virt,secure=on -cpu max \
    -bios my-el3-firmware.bin -nographic
# NOTE: -bios, not -kernel. -bios loads at address 0 and starts
# there with no stub, no device tree patching and no PSCI - you
# are the firmware now.

# Load a raw ELF anywhere, with full control:
$ qemu-system-aarch64 -M virt -cpu max -nographic \
    -device loader,file=payload.elf \
    -device loader,addr=0x40100000,cpu-num=0
# The second loader sets the PC of CPU 0.

# Load several blobs at chosen addresses - the pattern the
# OP-TEE track uses for TF-A + OP-TEE + U-Boot:
$ qemu-system-aarch64 -M virt,secure=on -cpu max -nographic \
    -bios bl1.bin \
    -device loader,file=fip.bin,addr=0x40100000 \
    -semihosting-config enable=on,target=native
```

> **`-KERNEL` VERSUS `-BIOS`**
> `-kernel` means "you are an OS; I will act as your bootloader". `-bios` means "you are the firmware; here is a bare machine". With `-bios` you get no device tree, no `-append`, no initrd loading and no PSCI implementation — QEMU stops helping. Mixing them up produces a payload that runs but finds `x0` pointing at nothing.

How it shows up

Symptom	Cause
Completely silent, no output ever	Missing `console=ttyAMA0`, or `-nographic` omitted so output went to a window
Prints "Booting Linux" then stops	Console handed over from earlycon to the real driver and the real console is wrong
Hangs before any output at all	Add `earlycon`; if still silent, the image is loaded at the wrong address or is the wrong format
`No working init found`	No initrd, or no `/init` in it, or it is not executable, or it is dynamically linked with no libraries
Guest sees the wrong memory size	A stale `-dtb` from a different `-m`
Secondary CPUs never come up	PSCI conduit mismatch, or `-bios` used so there is no PSCI at all
GDB symbols are all wrong	KASLR — add `nokaslr` or disable `RANDOMIZE_BASE`
`Image` rejected or garbage executed	Passed `Image.gz` or `vmlinux` to `-kernel` instead of `Image`
Works with `-kernel`, fails with `-bios`	Expected — no boot stub, no DTB, no PSCI

Symptom	Cause
initramfs unpacks but binaries fail with "not found"	Dynamically linked busybox without its loader; build static

Check yourself

- ✓ List the five things QEMU does on your behalf when you pass `-kernel`.
- ✓ Name the arm64 `Image` header fields QEMU reads and what it does with them.
- ✓ Explain what the kernel finds in `x0` at entry and who put it there.
- ✓ Give the four `-append` arguments needed for a first boot and what each does.
- ✓ Explain why `earlycon` is worth adding during bring-up.
- ✓ Build a static busybox initramfs and boot it.
- ✓ Describe the dump-edit-feed-back workflow for a custom device tree, and its main hazard.
- ✓ State the difference between `-kernel` and `-bios` in terms of what QEMU provides.
- ✓ Show how to land a payload at EL2 and at EL3.
- ✓ Diagnose a completely silent boot in three steps.

Building a root filesystem

A kernel without userspace panics in half a second. This chapter covers the four ways to give it one — an initramfs you assemble by hand, Buildroot, a debootstrap image, and a container image reused as a rootfs — and when each is the right tool.

Choosing

Method	Build time	Size	Use it for
Hand-built initramfs	Seconds	2–5 MB	Driver testing, boot debugging, anything where you want to see everything that runs
Buildroot	15–40 min first time, then incremental	10–100 MB	Realistic embedded userspace, cross-compiled packages, reproducible builds. The right default for this site's projects
debootstrap / mmdebstrap	2–5 min	300 MB–1 GB	You want `apt`, a package archive and a normal distribution
Container image export	Seconds	50–500 MB	You already have the userspace you want as a Docker image
Yocto	Hours	Anything	Product builds. Overkill for learning

Method 1: initramfs, by hand

```
#!/bin/sh
# mkinitramfs.sh - a complete, working root filesystem in one
# script. This is the one to keep.
set -e

BB_VER=1.36.1
ARCH=arm64
CROSS=aarch64-linux-gnu-
ROOT=$PWD/rootfs

# --- busybox, statically linked -----------------------------
if [ ! -d busybox-$BB_VER ]; then
    wget -q https://busybox.net/downloads/busybox-$BB_VER.tar.bz2
    tar xf busybox-$BB_VER.tar.bz2
fi
cd busybox-$BB_VER
make ARCH=$ARCH CROSS_COMPILE=$CROSS defconfig >/dev/null
sed -i 's/# CONFIG_STATIC is not set/CONFIG_STATIC=y/' .config
sed -i 's/CONFIG_TC=y/# CONFIG_TC is not set/' .config
make ARCH=$ARCH CROSS_COMPILE=$CROSS -j$(nproc) >/dev/null
make ARCH=$ARCH CROSS_COMPILE=$CROSS CONFIG_PREFIX=$ROOT install
cd ..

# --- the directory skeleton ---------------------------------
mkdir -p $ROOT/{proc,sys,dev,tmp,run,root,etc/init.d,lib/modules}

# --- init ---------------------------------------------------
cat > $ROOT/init <<'EOF'
#!/bin/sh
mount -t proc     proc     /proc
mount -t sysfs    sysfs    /sys
mount -t devtmpfs devtmpfs /dev
mount -t tmpfs    tmpfs    /tmp
mkdir -p /dev/pts && mount -t devpts devpts /dev/pts

# load any modules we shipped
for m in /lib/modules/*.ko; do
        [ -e "$m" ] && insmod "$m" 2>/dev/null
done

# bring up loopback and the virtio NIC if present
ip link set lo up 2>/dev/null
ip link set eth0 up 2>/dev/null && udhcpc -i eth0 -q 2>/dev/null

echo
echo "=== rootfs up: $(uname -srm) ==="
echo

exec /bin/sh
EOF
chmod +x $ROOT/init

# --- minimal /etc -------------------------------------------
echo "root:x:0:0:root:/root:/bin/sh" > $ROOT/etc/passwd
echo "root:x:0:"                     > $ROOT/etc/group
echo "qemu"                          > $ROOT/etc/hostname
cat > $ROOT/etc/fstab <<'EOF'
proc  /proc  proc  defaults 0 0
sysfs /sys   sysfs defaults 0 0
EOF
```

```
# --- pack ------------------------------------------------
( cd $ROOT && find . -print0 \
  | cpio --null -o --format=newc 2>/dev/null ) | gzip -9 \
  > initramfs.cpio.gz

echo "built: initramfs.cpio.gz ($(du -h initramfs.cpio.gz | cut -f1))"
```

```
$ ./mkinitramfs.sh
built: initramfs.cpio.gz (1.2M)

$ qemu-system-aarch64 -M virt -cpu cortex-a57 -m 512M -nographic \
    -kernel Image -initrd initramfs.cpio.gz \
    -append "console=ttyAMA0 earlycon"
...
=== rootfs up: Linux 6.8.0 aarch64 ===

/ #

# To add YOUR kernel module to the image, drop it in
# rootfs/lib/modules/ before packing. The init script loads
# everything it finds - which is exactly what you want while
# developing a driver (Linux track, chapter 28).
```

WHY STATIC LINKING MATTERS HERE

An initramfs has no dynamic loader unless you put one there, and a dynamically linked busybox fails with `not found` — a message that describes the missing *loader*, not the missing binary, and sends people hunting for the wrong thing. Build static and the problem cannot occur.

Method 2: Buildroot

```
$ git clone --depth=1 -b 2024.02 \
    https://gitlab.com/buildroot.org/buildroot.git
$ cd buildroot

# There is a ready-made config for exactly our target:
$ make qemu_aarch64_virt_defconfig

# Customise:
$ make menuconfig
#   Target packages -> Debugging  -> gdb, strace, ltrace
#   Target packages -> Networking -> openssh, iperf3
#   Target packages -> Hardware   -> optee-client, optee-test
#   Filesystem images -> ext2/3/4 root filesystem
#                     -> cpio the root filesystem (for initramfs)
#   Toolchain -> Build cross gdb for the host
#   Kernel -> (leave off if you build your own)

$ make -j$(nproc)          # 15-40 minutes the first time

$ ls output/images/
Image  rootfs.cpio.gz  rootfs.ext4  start-qemu.sh

# Buildroot even writes the QEMU command line for you:
$ ./output/images/start-qemu.sh
# or run it yourself:
$ qemu-system-aarch64 -M virt -cpu cortex-a53 -m 512M -nographic \
    -kernel output/images/Image \
    -drive file=output/images/rootfs.ext4,if=none,format=raw,id=hd0 \
    -device virtio-blk-device,drive=hd0 \
    -append "console=ttyAMA0 root=/dev/vda rootwait"

# Rebuild just one package after changing it:
$ make optee-client-rebuild
$ make                       # repacks the images

# Buildroot is the right answer for this site's OP-TEE track
# because it already knows how to build optee-client,
# optee-test and the TA development kit, and puts them in the
# right places.
```

Method 3: a real Debian

```
# When you want apt, a package archive, and systemd.

$ sudo apt install debootstrap qemu-user-static
$ mkdir -p rootfs
$ sudo debootstrap --arch=arm64 --foreign bookworm rootfs \
      http://deb.debian.org/debian

# Second stage runs arm64 binaries via binfmt_misc + qemu-user
$ sudo cp /usr/bin/qemu-aarch64-static rootfs/usr/bin/
$ sudo chroot rootfs /debootstrap/debootstrap --second-stage

# Configure it before first boot
$ sudo chroot rootfs /bin/bash <<'EOF'
echo "root:root" | chpasswd
echo qemu > /etc/hostname
apt-get update
apt-get install -y --no-install-recommends \
    systemd-sysv udev iproute2 openssh-server vim less
systemctl enable serial-getty@ttyAMA0.service
cat > /etc/fstab <<'FSTAB'
/dev/vda / ext4 defaults 0 1
FSTAB
EOF

# Turn the directory into a disk image
$ dd if=/dev/zero of=debian.ext4 bs=1M count=4096
$ mkfs.ext4 -F debian.ext4
$ mkdir -p mnt && sudo mount -o loop debian.ext4 mnt
$ sudo cp -a rootfs/. mnt/
$ sudo umount mnt

$ qemu-system-aarch64 -M virt -cpu cortex-a57 -m 2G -nographic \
    -kernel Image \
    -drive file=debian.ext4,if=none,format=raw,id=hd0 \
    -device virtio-blk-device,drive=hd0 \
    -netdev user,id=n0 -device virtio-net-device,netdev=n0 \
    -append "console=ttyAMA0 root=/dev/vda rw rootwait"
```

Method 4: steal a container image

```
# The fastest way to a full userspace you already trust.

$ docker pull --platform linux/arm64 debian:bookworm
$ docker create --platform linux/arm64 --name tmp debian:bookworm
$ mkdir -p rootfs && docker export tmp | tar -C rootfs -xf -
$ docker rm tmp

# Container images have no init and no kernel. Add one:
$ sudo tee rootfs/init >/dev/null <<'EOF'
#!/bin/sh
mount -t proc none /proc
mount -t sysfs none /sys
mount -t devtmpfs none /dev
exec /bin/bash
EOF
$ sudo chmod +x rootfs/init

# Then pack as initramfs, or write into an ext4 image as above.
$ ( cd rootfs && sudo find . -print0 \
    | sudo cpio --null -o --format=newc ) | gzip > initramfs.cpio.gz

# Podman works identically and does not need a daemon:
$ podman pull --arch arm64 alpine
$ podman export $(podman create --arch arm64 alpine) | tar -C rootfs -xf -
```

Making a bootable disk image

```
# A single-partition ext4 image, which is all QEMU needs:
$ truncate -s 2G rootfs.ext4
$ mkfs.ext4 -d rootfs -F rootfs.ext4      # -d populates it
                                          # directly - no
                                          # mounting, no root!

# A partitioned image, closer to a real SD card:
$ truncate -s 4G sd.img
$ sfdisk sd.img <<'EOF'
label: dos
start=2048, size=204800, type=c, bootable
start=206848, type=83
EOF
$ LOOP=$(sudo losetup -Pf --show sd.img)
$ sudo mkfs.vfat -F32 ${LOOP}p1
$ sudo mkfs.ext4 -F ${LOOP}p2
$ sudo mount ${LOOP}p2 /mnt && sudo cp -a rootfs/. /mnt/ \
  && sudo umount /mnt
$ sudo losetup -d $LOOP

# Resize later, without recreating:
$ truncate -s 8G rootfs.ext4
$ e2fsck -f rootfs.ext4 && resize2fs rootfs.ext4

# Inspect an image without mounting - useful in CI:
$ debugfs -R "ls -l /" rootfs.ext4
$ debugfs -R "cat /etc/hostname" rootfs.ext4
```

> **`MKFS.EXT4 -D` IS THE TRICK WORTH REMEMBERING**
> It populates a filesystem image from a directory without mounting anything, which means no `sudo`, no loop devices, and it works inside an unprivileged container. Every CI pipeline that builds an image should use it.

Getting files in and out

```
# 1. virtiofs - best, needs a daemon (virt chapter 15)
$ virtiofsd --socket-path=/tmp/vfs.sock -o source=$PWD/share &
$ qemu-system-aarch64 ... \
    -object memory-backend-file,id=mem,size=2G,mem-path=/dev/shm,share=on \
    -M virt,memory-backend=mem \
    -chardev socket,id=vfs,path=/tmp/vfs.sock \
    -device vhost-user-fs-device,chardev=vfs,tag=share
# guest: mount -t virtiofs share /mnt

# 2. 9p - no daemon, slower, works everywhere
$ qemu-system-aarch64 ... \
    -fsdev local,id=fs0,path=$PWD/share,security_model=none \
    -device virtio-9p-device,fsdev=fs0,mount_tag=share
# guest: mount -t 9p -o trans=virtio,version=9p2000.L share /mnt

# 3. A second disk - simplest, no guest config
$ qemu-img create -f raw scratch.img 1G && mkfs.ext4 -F scratch.img
$ qemu-system-aarch64 ... \
    -drive file=scratch.img,if=none,format=raw,id=s0 \
    -device virtio-blk-device,drive=s0
# guest: mount /dev/vdb /mnt

# 4. SSH over user networking (chapter 8)
$ qemu-system-aarch64 ... \
    -netdev user,id=n0,hostfwd=tcp::2222-:22 \
    -device virtio-net-device,netdev=n0
$ scp -P 2222 file root@localhost:/tmp/
```

How it shows up

Symptom	Cause
`No working init found`	No `/init`, not executable, or the archive was built from the wrong directory
`/init: not found` though the file exists	Dynamically linked binary with no loader — build static, or ship `ld-linux-aarch64.so.1`
`VFS: Unable to mount root fs on unknown-block(0,0)`	Wrong `root=`, or no virtio-blk driver, or missing `rootwait`
Boots to a prompt with no working commands	busybox installed but its symlinks were not created — run `busybox --install -s`
No `/dev` entries	`devtmpfs` not mounted, or `CONFIG_DEVTMPFS` off
Debian image hangs after mounting root	No getty on `ttyAMA0` — `systemctl enable serial-getty@ttyAMA0`
Container-derived rootfs has no `/proc`	Container images omit the pseudo-filesystem mount points; create them
Image full immediately	`truncate` made a sparse file; the filesystem inside is still its original size — `resize2fs`

Symptom	Cause
Buildroot rebuild does not pick up a change	Use `make <pkg>-rebuild`, not `make` alone
9p mount fails with "no such device"	Guest kernel missing `CONFIG_NET_9P_VIRTIO`

Check yourself

- ✓ Give the four rootfs methods and the situation each is best for.
- ✓ Explain why busybox must be statically linked in a hand-built initramfs.
- ✓ Write the minimum `/init` that a kernel will accept, and say what each mount is for.
- ✓ Pack a directory into a `newc` cpio archive and say why that format.
- ✓ Explain what `mkfs.ext4 -d` avoids.
- ✓ Build a Buildroot image for `qemu_aarch64_virt` and boot it from a virtio disk.
- ✓ Explain how `debootstrap --foreign` plus `qemu-user-static` builds a foreign rootfs.
- ✓ Give four ways to move a file between host and guest, ranked.
- ✓ Diagnose `Unable to mount root fs on unknown-block(0,0)`.
- ✓ Add your own kernel module to an initramfs so it loads at boot.

Devices, buses and the command line

QEMU's command line looks arbitrary until you see the object model underneath it. There are three layers — a backend that does real work, a frontend the guest sees, and a bus they plug into — and every confusing option is one of those three. Learn the shape and the syntax stops needing memorisation.

Backend, frontend, bus

```
HOST SIDE                GUEST SIDE
"backend"                "frontend" / device

a file on disk    <---->  virtio-blk-device      on virtio-mmio
a tap interface   <---->  virtio-net-pci         on PCIe
your terminal     <---->  pl011 UART             on the SoC
a unix socket     <---->  virtio-serial port     on virtio
/dev/urandom      <---->  virtio-rng-device

The command line names them SEPARATELY and joins them by id:

  -drive   file=disk.img,if=none,format=raw,id=hd0
           ^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^^  backend
                                     ^^^^  its name

  -device  virtio-blk-device,drive=hd0
           ^^^^^^^^^^^^^^^^^               frontend
                            ^^^^^^^^^      the link

Once you see that, every option follows:

  -netdev   TYPE,id=NAME,...        network backend
  -device   virtio-net-...,netdev=NAME
  -chardev  TYPE,id=NAME,...        character backend
  -device   ...,chardev=NAME
  -blockdev TYPE,node-name=NAME,... modern block backend
  -object   TYPE,id=NAME,...        memory, rng, crypto,
                                    tls credentials

"if=none" means "do not auto-attach this backend to a
default controller - I will attach it myself with -device".
Forgetting it is the most common mistake, and the symptom is
a disk that appears twice or not at all.
```

Which frontend for which bus

Suffix	Bus	Example	Notes
`-device`	virtio-mmio	`virtio-blk-device`	The 32 mmio slots on `virt`. Simple, no PCIe needed. Best for minimal guests
`-pci`	PCIe	`virtio-blk-pci`	Enumerable, hotpluggable, supports MSI-X and multiqueue properly. Best for full guests
`-ccw`	s390 channel	`virtio-blk-ccw`	s390x only

```
# The same disk, three ways:

# 1. virtio-mmio - no PCIe involved
-drive file=d.img,if=none,format=raw,id=hd0 \
-device virtio-blk-device,drive=hd0

# 2. virtio-pci - needs the PCIe host bridge (virt has one)
-drive file=d.img,if=none,format=raw,id=hd0 \
-device virtio-blk-pci,drive=hd0

# 3. The shorthand, which auto-picks a controller.
#    Convenient, and it hides which bus you got.
-drive file=d.img,format=raw,if=virtio

# Prefer the explicit forms. When something does not appear in
# the guest, the explicit form tells you where to look.

# See what you actually built:
$ qemu-system-aarch64 -M virt ... -monitor stdio
(qemu) info qtree
(qemu) info pci
(qemu) info block
```

Character devices: where output goes

```
# Every serial port, console, monitor and debug channel is a
# chardev. This is the layer people fight with most.

# The simple forms:
-nographic                # serial + monitor multiplexed to
                          # stdio. Ctrl-A c switches, Ctrl-A x
                          # quits.
-serial mon:stdio         # exactly what -nographic does
-serial null              # discard
-serial file:boot.log     # write to a file
-serial tcp::4444,server,nowait     # telnet to it
-serial unix:/tmp/sock,server,nowait
-serial pty               # QEMU prints "char device redirected
                          # to /dev/pts/5" - screen or minicom
                          # to it

# Named chardevs, so several devices can each have their own:
-chardev stdio,id=con0,mux=on \
-chardev file,id=log1,path=secure.log \
-chardev socket,id=dbg,path=/tmp/dbg.sock,server=on,wait=off \
-serial chardev:con0 \
-serial chardev:log1

# TWO UARTs, which the OP-TEE track needs (normal world on one,
# secure world on the other):
-serial mon:stdio -serial file:secure-world.log

# The order matters: the first -serial is ttyAMA0, the second
# is ttyAMA1, and so on. On virt only the first is in the
# generated device tree unless the machine adds more.

# Logging everything to a file while still watching it:
$ qemu-system-aarch64 ... -nographic 2>&1 | tee boot.log

# A virtio-serial channel, for a guest agent:
-device virtio-serial-device \
-chardev socket,path=/tmp/agent.sock,server=on,wait=off,id=ag \
-device virtserialport,chardev=ag,name=org.example.agent
# guest sees /dev/virtio-ports/org.example.agent
```

> **CTRL-A IS THE ESCAPE KEY**
> `Ctrl-A c` toggles between the guest console and the QEMU monitor. `Ctrl-A x` quits. `Ctrl-A h` lists the rest. If your terminal multiplexer already uses `Ctrl-A` (screen does), change QEMU's with `-echr 0x05` to use `Ctrl-E` instead.

A tour of devices worth knowing

```
# Storage
-device virtio-blk-device,drive=hd0            # the fast path
-device virtio-scsi-device -device scsi-hd,drive=hd0
-device nvme,drive=hd0,serial=deadbeef         # a real NVMe
                                               # controller model -
                                               # excellent for
                                               # driver work
-device usb-storage,drive=hd0

# Network
-device virtio-net-device,netdev=n0
-device e1000e,netdev=n0                       # Intel NIC model
-device rtl8139,netdev=n0                      # ancient, useful
                                               # for driver
                                               # teaching

# Console and input
-device virtio-serial-device
-device virtio-keyboard-device
-device virtio-tablet-device
-device usb-kbd -device usb-mouse

# Graphics
-device virtio-gpu-device
-device ramfb                                  # a dumb
                                               # framebuffer -
                                               # simplest possible
-device virtio-gpu-gl-device                   # with virgl

# Entropy - add this to every guest
-object rng-random,filename=/dev/urandom,id=rng0 \
-device virtio-rng-device,rng=rng0

# USB
-device qemu-xhci,id=xhci \
-device usb-host,hostbus=1,hostaddr=5          # pass a real
                                               # USB device
                                               # through!

# The one that matters most for this site:
-device loader,file=payload.bin,addr=0x40100000,force-raw=on
-device loader,addr=0x40100000,cpu-num=0       # set the PC
# Loads arbitrary blobs anywhere. This is how TF-A, OP-TEE and
# bare-metal payloads get placed.

# Ask what a device accepts:
$ qemu-system-aarch64 -device virtio-blk-device,help
$ qemu-system-aarch64 -device help | less
```

Hotplug

```
# PCIe devices can be added and removed while the guest runs.
# virtio-mmio devices cannot - the slots are fixed at startup.
# That alone is a reason to prefer -pci for a long-lived guest.

$ qemu-system-aarch64 -M virt -nographic -monitor stdio ...

(qemu) drive_add 0 if=none,file=extra.img,format=raw,id=hd1
(qemu) device_add virtio-blk-pci,drive=hd1,id=blk1
# guest: a new /dev/vdb appears

(qemu) device_del blk1
# guest: the device is unplugged (the guest must cooperate)

(qemu) info block
(qemu) info pci

# The same through QMP, which is what you would automate
# (chapter 10):
{"execute":"device_add",
 "arguments":{"driver":"virtio-blk-pci","drive":"hd1","id":"blk1"}}

# CPU hotplug on arm64 needs the machine to reserve slots:
$ qemu-system-aarch64 -M virt -smp 2,maxcpus=8 ...
(qemu) device_add cortex-a57-arm-cpu,id=cpu2,core-id=2

# Memory hotplug:
$ qemu-system-aarch64 -m 1G,slots=4,maxmem=8G ...
(qemu) object_add memory-backend-ram,id=m1,size=1G
(qemu) device_add pc-dimm,id=d1,memdev=m1
```

Making command lines survivable

```
# A real command line is 20 lines long. Do not retype it.

# 1. A shell script with a variable per concern:
#!/bin/sh
MACHINE="-M virt,gic-version=3,virtualization=on -cpu max -smp 4 -m 2G"
KERNEL="-kernel Image -append 'console=ttyAMA0 earlycon root=/dev/vda'"
DISK="-drive file=rootfs.ext4,if=none,format=raw,id=hd0
      -device virtio-blk-device,drive=hd0"
NET="-netdev user,id=n0,hostfwd=tcp::2222-:22
     -device virtio-net-device,netdev=n0"
DEBUG="-s -S -d guest_errors,unimp -D qemu.log"
exec qemu-system-aarch64 $MACHINE $KERNEL $DISK $NET -nographic "$@"

# 2. -readconfig, a config file QEMU parses itself:
$ cat vm.cfg
[machine]
  type = "virt"
  gic-version = "3"
[memory]
  size = "2G"
[drive "hd0"]
  file = "rootfs.ext4"
  format = "raw"
  if = "none"
[device "blk0"]
  driver = "virtio-blk-device"
  drive = "hd0"

$ qemu-system-aarch64 -readconfig vm.cfg -kernel Image -nographic

# 3. Dump the configuration QEMU derived, to see defaults:
$ qemu-system-aarch64 -M virt -writeconfig - -m 1G 2>/dev/null

# 4. -nodefaults, when you want NOTHING you did not ask for:
$ qemu-system-aarch64 -M virt -nodefaults \
    -serial mon:stdio -device virtio-blk-device,drive=hd0 ...
# Without it QEMU adds a default VGA, a default NIC, a default
# serial and a default parallel port. -nodefaults plus explicit
# devices is how you get a reproducible machine.
```

> **DEFAULTS CHANGE BETWEEN QEMU VERSIONS**
> A machine type is versioned (`virt-8.2`) precisely so that migration and reproducibility work, but `-M virt` means "the newest", which moves. For anything you want to reproduce in six months — CI, a bug report, a test baseline — pin the versioned machine type and use `-nodefaults` .

How it shows up

Symptom	Cause
`Property 'drive' not found`	Frontend name wrong for the bus — `virtio-blk-device` vs `virtio-blk-pci`
Disk appears twice in the guest	Missing `if=none` , so QEMU auto-attached it as well as your `-device`
`Drive 'hd0' is already in use`	Same, or two `-device` lines referencing one drive
Device configured but absent in the guest	Wrong bus for the machine, or the guest kernel lacks the driver. Check `info qtree` then guest `dmesg`

Symptom	Cause
No console output	chardev routed elsewhere; check the `-serial` ordering and `console=`
Cannot escape QEMU	Terminal multiplexer eating `Ctrl-A`; use `-echr`
Hotplug fails on `virt`	Device is on virtio-mmio, which is not hotpluggable — use `-pci`
Guest gets a NIC you did not ask for	Default devices; add `-nodefaults`
Command line works on one machine, not another	Different QEMU version, different defaults
`-device help` lists a device that then fails	Present in the binary but not valid on this machine type

Check yourself

- ✓ Explain the backend/frontend split and how the two are linked on the command line.
- ✓ Say what `if=none` means and what happens without it.
- ✓ Give the three virtio frontend suffixes and the bus each attaches to.
- ✓ Configure two serial ports, one to the terminal and one to a file.
- ✓ Explain how a guest agent gets a private channel with `virtio-serial`.
- ✓ Name the escape key and how to change it.
- ✓ Hotplug a disk from the monitor and explain why it must be PCIe.
- ✓ Explain what `-nodefaults` is for.
- ✓ Say why a versioned machine type matters for CI.
- ✓ Use `info qtree` to determine whether a device was actually created.

Networking

Four backends, each with a different answer to "who can talk to whom". Picking the wrong one is why guests cannot reach the internet, why you cannot SSH in, and why two guests that should see each other do not. This chapter is the decision table plus the exact commands.

The four backends

Backend	Guest → internet	Host → guest	Guest ↔ guest	Root needed
user (SLIRP)	Yes, NAT	Only via `hostfwd`	No	No
tap	Yes, if you route/NAT	Yes	Yes, via a bridge	Yes (or a pre-made tap)
bridge	Yes, as a peer on the LAN	Yes	Yes	Yes (or `qemu-bridge-helper` setuid)
socket / **vde**	No	No	Yes	No
none	No	No	No	No

```
Decide in this order:

Do I just need the guest to reach the internet and to
SSH in?                          -> USER + hostfwd. Done.
                                    No root, no setup, works
                                    on every host including
                                    macOS and Windows.

Do I need the guest to be a real host on my LAN, with its
own IP, reachable by other machines?
                                 -> BRIDGE.

Do I need several guests on a private network, with the host
as a router or observer?
                                 -> TAP + a host bridge.

Do I need two guests to talk to each other and nothing else,
without root?
                                 -> SOCKET.

Am I testing a driver and do not care about connectivity?
                                 -> USER, or none at all.
```

user: the default that is almost always right

```
# SLIRP implements a TCP/IP stack in QEMU's own process. The
# guest gets 10.0.2.15, a gateway at 10.0.2.2 and DNS at
# 10.0.2.3. No configuration on the host at all.

$ qemu-system-aarch64 -M virt ... \
    -netdev user,id=n0 \
    -device virtio-net-device,netdev=n0

# Guest:
$ udhcpc -i eth0          # or: dhclient eth0
$ ip addr show eth0
    inet 10.0.2.15/24
$ ping -c1 10.0.2.2       # the gateway = QEMU itself
$ curl https://example.com   # works, NATted through the host

# SSH IN - this is the option you will use every day:
$ qemu-system-aarch64 ... \
    -netdev user,id=n0,hostfwd=tcp::2222-:22 \
    -device virtio-net-device,netdev=n0
$ ssh -p 2222 root@localhost

# Several forwards at once:
-netdev user,id=n0,hostfwd=tcp::2222-:22,hostfwd=tcp::8080-:80,\
hostfwd=udp::5353-:53

# Bind a forward to one host interface only:
-netdev user,id=n0,hostfwd=tcp:127.0.0.1:2222-:22

# Serve a directory over TFTP, for netbooting the guest:
-netdev user,id=n0,tftp=/srv/tftp,bootfile=/Image

# Give the guest a share over SMB (needs samba on the host):
-netdev user,id=n0,smb=/home/me/share
# guest: mount -t cifs //10.0.2.4/qemu /mnt

# Change the network:
-netdev user,id=n0,net=192.168.76.0/24,host=192.168.76.9,\
dhcpstart=192.168.76.20

# Restrict the guest to only what you forward:
-netdev user,id=n0,restrict=on,hostfwd=tcp::2222-:22
# No internet, no host access except the forward. Good for
# running something you do not trust.
```

> **WHAT USER NETWORKING CANNOT DO**
>
> ICMP from the guest often does not work (SLIRP needs raw sockets or `ping_group_range`), so `ping` failing does not mean the network is broken — test with `curl` instead. Guests cannot see each other. The host cannot initiate a connection except through `hostfwd`. And throughput is limited by SLIRP's userspace stack: expect hundreds of Mbit/s, not tens of Gbit/s.

tap: a real interface on the host

```
# A tap device is a virtual Ethernet interface the kernel
# exposes as a file descriptor. QEMU writes frames into it; the
# host's network stack sees them arriving on an interface.

# 1. Create a persistent tap owned by you (do this once):
$ sudo ip tuntap add dev tap0 mode tap user $USER
$ sudo ip link set tap0 up
$ sudo ip addr add 192.168.100.1/24 dev tap0

# 2. Use it - no root needed now, because you own tap0:
$ qemu-system-aarch64 -M virt ... \
    -netdev tap,id=n0,ifname=tap0,script=no,downscript=no \
    -device virtio-net-device,netdev=n0,mac=52:54:00:12:34:56

# 3. Guest:
$ ip addr add 192.168.100.2/24 dev eth0
$ ip link set eth0 up
$ ip route add default via 192.168.100.1
$ ping 192.168.100.1              # the host. Works.

# 4. Give the guest internet, by NATting on the host:
$ sudo sysctl -w net.ipv4.ip_forward=1
$ sudo iptables -t nat -A POSTROUTING -s 192.168.100.0/24 \
       -o eth0 -j MASQUERADE
$ sudo iptables -A FORWARD -i tap0 -j ACCEPT
$ sudo iptables -A FORWARD -o tap0 -m state \
       --state RELATED,ESTABLISHED -j ACCEPT

# 5. vhost, for near-native throughput (virt chapter 15):
-netdev tap,id=n0,ifname=tap0,script=no,downscript=no,vhost=on

# ALWAYS set an explicit MAC. QEMU's default is the same for
# every guest, so two guests on one bridge collide, and the
# symptom is intermittent packet loss that looks like a driver
# bug.
```

bridge: the guest as a peer on your LAN

```
# The guest gets an address from your real DHCP server and is
# reachable from any machine on the network.

# 1. Build a bridge and move your physical NIC onto it.
#    WARNING: this drops your connection momentarily. Do not do
#    it over SSH without a console.
$ sudo ip link add br0 type bridge
$ sudo ip link set eth0 master br0
$ sudo ip addr flush dev eth0
$ sudo ip link set br0 up
$ sudo dhclient br0

# NetworkManager equivalent, which survives reboots:
$ nmcli con add type bridge ifname br0 con-name br0
$ nmcli con add type ethernet ifname eth0 master br0
$ nmcli con up br0

# 2. Allow QEMU's helper to use it:
$ echo "allow br0" | sudo tee /etc/qemu/bridge.conf
$ sudo chmod u+s /usr/lib/qemu/qemu-bridge-helper

# 3. Run:
$ qemu-system-aarch64 -M virt ... \
    -netdev bridge,id=n0,br=br0 \
    -device virtio-net-device,netdev=n0,mac=52:54:00:aa:bb:cc

# Guest gets a LAN address by DHCP. Colleagues can reach it.
# So can anything else on that network - treat it accordingly.
```

socket: guests talking to each other, no root

```
# A pure userspace virtual switch. Ideal for testing a network
# protocol between two guests on a laptop.

# Guest A listens:
$ qemu-system-aarch64 ... \
    -netdev socket,id=n0,listen=:1234 \
    -device virtio-net-device,netdev=n0,mac=52:54:00:00:00:01

# Guest B connects:
$ qemu-system-aarch64 ... \
    -netdev socket,id=n0,connect=127.0.0.1:1234 \
    -device virtio-net-device,netdev=n0,mac=52:54:00:00:00:02

# More than two, using multicast as a shared bus:
$ qemu-system-aarch64 ... \
    -netdev socket,id=n0,mcast=230.0.0.1:1234 \
    -device virtio-net-device,netdev=n0,mac=52:54:00:00:00:0N

# Then inside each guest, configure static addresses on the
# same subnet. Nothing leaves the host.

# Two NICs in one guest - one for management, one for the test
# network. This is the standard shape for a router or firewall
# under test:
$ qemu-system-aarch64 ... \
    -netdev user,id=mgmt,hostfwd=tcp::2222-:22 \
    -device virtio-net-device,netdev=mgmt,mac=52:54:00:00:00:10 \
    -netdev socket,id=lab,mcast=230.0.0.1:1234 \
    -device virtio-net-device,netdev=lab,mac=52:54:00:00:00:11
```

Capturing traffic

```
# QEMU can write a pcap of everything on a netdev. No tcpdump
# in the guest, no host interface to find - and it captures
# frames the guest never successfully received, which is
# exactly what you want when debugging a NIC driver.

$ qemu-system-aarch64 ... \
    -netdev user,id=n0 \
    -object filter-dump,id=f0,netdev=n0,file=capture.pcap

$ wireshark capture.pcap
$ tcpdump -r capture.pcap -nn

# Attach a dump filter at runtime, from the monitor:
(qemu) object_add filter-dump,id=f1,netdev=n0,file=/tmp/live.pcap
(qemu) object_del f1

# Other filters worth knowing:
-object filter-buffer,id=f1,netdev=n0,interval=1000
      # delay all traffic by 1 ms - test timeout handling
-object filter-mirror,id=f2,netdev=n0,outdev=chr0
      # mirror to a chardev, for a live analyser
-object filter-redirector,...
      # send traffic somewhere else entirely

# On a tap, the host interface is real, so ordinary tools work:
$ sudo tcpdump -i tap0 -nn
$ sudo tcpdump -i br0 -nn 'ether host 52:54:00:12:34:56'
```

Throughput, and what limits it

```
# Measure honestly: run iperf3 in the guest against the host.
$ iperf3 -s                        # host
$ iperf3 -c 10.0.2.2 -t 20         # guest

# Rough expectations on a modern machine:
#   user (SLIRP), TCG guest        50-200 Mbit/s
#   user (SLIRP), KVM guest        0.5-2 Gbit/s   (SLIRP is the
#                                                  bottleneck)
#   tap, no vhost, KVM             2-5 Gbit/s
#   tap + vhost=on, KVM            10-40 Gbit/s
#   tap + vhost + multiqueue       scales with vCPUs
#   passthrough VF (SR-IOV)        line rate

# The three changes that matter, in order:
#  1. -accel kvm            (if the architectures match)
#  2. vhost=on              (tap only; SLIRP cannot use it)
#  3. multiqueue:
-netdev tap,id=n0,ifname=tap0,script=no,downscript=no,\
vhost=on,queues=4 \
-device virtio-net-pci,netdev=n0,mq=on,vectors=10
# vectors = 2*queues + 2. Too few silently reduces the queue
# count.

# Guest side, confirm what you got:
$ ethtool -l eth0
$ ethtool -k eth0 | grep -E 'tso|gso|gro|checksum'
```

How it shows up

Symptom	Cause
Guest has no interface at all	No `-device` for the netdev, or the guest kernel lacks `CONFIG_VIRTIO_NET`
Interface exists, no address	No DHCP client ran; with user networking run `udhcpc` / `dhclient`
`ping` fails but `curl` works	SLIRP and ICMP. Not a problem
Cannot SSH in	No `hostfwd`, or sshd not running, or the guest firewall
Two guests cannot see each other	Both on `user`, which is isolated by design. Use socket, tap or bridge
Intermittent loss with two guests on a bridge	Both using QEMU's default MAC — set them explicitly
`could not open /dev/net/tun`	Tap not created, not owned by you, or no `CAP_NET_ADMIN`
`bridge helper failed`	Bridge not listed in `/etc/qemu/bridge.conf`, or the helper is not setuid
Host loses network when creating a bridge	Expected while the NIC moves; reconfigure `br0`
Throughput far below expectation	SLIRP, or `vhost=on` missing, or TCG
Multiqueue configured, one queue used	`vectors` too small

Check yourself

- ✓ Give the four backends and fill in the connectivity table from memory.
- ✓ Write the `user` networking options that let you SSH into a guest on port 2222.
- ✓ Explain what `restrict=on` does and when you would want it.
- ✓ Create a tap device you own and attach a guest to it without root.
- ✓ Give the host commands that NAT a tap network to the internet.
- ✓ Explain why every guest needs an explicit MAC address on a shared network.
- ✓ Connect two guests with `socket` and say why no root is needed.
- ✓ Capture guest traffic to a pcap without running anything in the guest.
- ✓ List the three changes that most improve throughput, in order.
- ✓ Diagnose "the guest has an interface but no connectivity" in three steps.

Storage and block devices

QEMU's block layer is a stack of filters — format drivers, protocol drivers, caches, throttling, snapshots — that you compose. The command line hides this behind `-drive`, which is convenient until you need a snapshot chain or an overlay, at which point knowing the real structure saves you.

The block stack

```
guest driver  (virtio-blk, nvme, ahci ...)
     |
     v
+-------------------------------------------+
|  FRONTEND     -device virtio-blk-device   |
+-------------------------------------------+
     |
     v
+-------------------------------------------+
|  FILTERS (optional, stackable)            |
|    throttle    - IOPS/bandwidth limits    |
|    copy-on-read                           |
|    blkverify, blkdebug - fault injection  |
+-------------------------------------------+
     |
     v
+-------------------------------------------+
|  FORMAT driver                            |
|    raw    - nothing, byte for byte        |
|    qcow2  - snapshots, compression, backing |
|             files, sparse allocation      |
|    vmdk / vhdx / vdi / vpc - other people's |
|    luks   - encryption                    |
+-------------------------------------------+
     |
     v
+-------------------------------------------+
|  PROTOCOL driver                          |
|    file   - a local file or block device  |
|    nbd    - network block device          |

     |
     v
host storage

-drive collapses all of this into one option. -blockdev
exposes each layer as a named node you can wire together,
which is what libvirt and any serious automation uses.
```

raw versus qcow2

	raw	qcow2
Overhead	None	~5–10% on random writes
Sparse	Only if the host filesystem is	Always
Snapshots	No	Internal and external

	raw	qcow2
Backing files	No	Yes — the basis of overlays
Compression	No	Yes, read-only after write
Encryption	Via the `luks` layer	Built in (LUKS)
Mount on the host	`mount -o loop`	Needs `qemu-nbd`
Use it for	Rootfs images you rebuild often; anything you want to inspect with ordinary tools	Golden images, overlays, snapshot workflows

```
$ qemu-img create -f qcow2 disk.qcow2 20G
Formatting 'disk.qcow2', fmt=qcow2 size=21474836480 ...

$ qemu-img create -f raw disk.raw 20G
$ ls -lh disk.raw          # 20G apparent
$ du -h  disk.raw          # 0 actual - sparse, on ext4/xfs/btrfs

$ qemu-img info disk.qcow2
image: disk.qcow2
file format: qcow2
virtual size: 20 GiB (21474836480 bytes)
disk size: 196 KiB
cluster_size: 65536

$ qemu-img convert -p -O raw disk.qcow2 disk.raw
$ qemu-img convert -p -O qcow2 -c disk.raw compressed.qcow2

$ qemu-img resize disk.qcow2 +10G
# then, in the guest: growpart /dev/vda 1 && resize2fs /dev/vda1

$ qemu-img check disk.qcow2
$ qemu-img map disk.qcow2         # which ranges are allocated
```

Overlays: the workflow that saves the most time

```
# Build a golden image once. Never boot it directly again.
# Every experiment gets a disposable overlay on top.

$ qemu-img create -f qcow2 -b golden.qcow2 -F qcow2 work.qcow2
Formatting 'work.qcow2', fmt=qcow2 backing_file=golden.qcow2 ...

$ ls -lh
-rw-r--r-- 2.1G golden.qcow2
-rw-r--r--  196K work.qcow2        # writes go here only

$ qemu-system-aarch64 ... -drive file=work.qcow2,if=none,id=hd0 \
    -device virtio-blk-device,drive=hd0

# Broke it? Throw the overlay away, make a new one. Two seconds.
$ rm work.qcow2 && qemu-img create -f qcow2 -b golden.qcow2 \
    -F qcow2 work.qcow2

# Even quicker, for a single throwaway run - no overlay file at
# all, all writes go to a temporary file QEMU deletes on exit:
$ qemu-system-aarch64 ... -snapshot -drive file=golden.qcow2,...

# Commit an overlay back into its backing file, when the change
# was one you wanted to keep:
$ qemu-img commit work.qcow2

# Chains are allowed, and useful:
#   base.qcow2  <- installed.qcow2  <- configured.qcow2  <- run.qcow2
$ qemu-img info --backing-chain run.qcow2

# Flatten a chain into one image:
$ qemu-img convert -O qcow2 run.qcow2 flattened.qcow2
```

> **THE SINGLE HABIT WORTH FORMING**
>
> Keep one read-only golden image per project and always boot an overlay. Experiments become free, "it worked yesterday" becomes recoverable, and you stop being afraid of `rm -rf` inside a guest. The whole trick is one `qemu-img create -b` command.

Cache modes: a correctness setting

```
   Three caches sit between the guest and the platter:

     guest page cache -- guest's own, always present
     HOST page cache  -- controlled by cache=
     disk write cache -- controlled by whether flushes reach it

   cache=writeback   (default)
       host page cache USED. Guest flushes are honoured
       (fdatasync). Fast, and SAFE - provided the guest issues
       flushes and your device model implements them.

   cache=none
       O_DIRECT: bypass the host page cache. The guest's own
       cache is the only one. Predictable, avoids double
       caching, required for some migration setups. Needs
       aligned I/O, so it fails on some filesystems (tmpfs).

   cache=writethrough
       every write goes to stable storage before completing.
       Very slow. Safe even for a guest that never flushes.

   cache=unsafe
       FLUSHES ARE IGNORED. Fastest by far. A host crash loses
       arbitrary amounts of guest data, including data the
       guest was told was durable.

   cache=directsync
       O_DIRECT plus writethrough.

   Choose:
     building/throwaway images, CI        -> unsafe   (10x on
                                             installs)
     day-to-day development               -> writeback
     anything holding work you care about -> writeback, and
                                             verify flushes
     production, shared storage           -> none
```

```
# The full modern form. aio=native needs cache=none or
# directsync; aio=io_uring is better where available.
-drive file=disk.qcow2,if=none,id=hd0,format=qcow2,\
cache=none,aio=io_uring,discard=unmap,detect-zeroes=unmap \
-device virtio-blk-device,drive=hd0

#   discard=unmap        guest TRIM shrinks the host image
#   detect-zeroes=unmap  writes of zeroes become holes
#   Together these keep a long-lived image from growing without
#   bound. Add them to every qcow2 you keep.

# Throttling, to simulate slow storage - genuinely useful for
# finding timeout bugs in a driver:
-drive file=disk.img,if=none,id=hd0,\
throttling.iops-total=100,throttling.bps-total=1048576

# Fault injection, to test error paths:
-drive file=blkdebug::disk.img,if=none,id=hd0
# with a config file that fails the Nth read, or corrupts a
# write, or returns EIO after a delay.
```

Reading and writing images from the host

```
# raw, single filesystem - simplest:
$ sudo mount -o loop rootfs.ext4 /mnt

# raw, partitioned:
$ LOOP=$(sudo losetup -Pf --show sd.img)
$ sudo mount ${LOOP}p2 /mnt
$ ... ; sudo umount /mnt ; sudo losetup -d $LOOP

# qcow2 - via NBD:
$ sudo modprobe nbd max_part=8
$ sudo qemu-nbd --connect=/dev/nbd0 disk.qcow2
$ sudo fdisk -l /dev/nbd0
$ sudo mount /dev/nbd0p1 /mnt
$ ... ; sudo umount /mnt ; sudo qemu-nbd --disconnect /dev/nbd0

# WITHOUT ROOT, and without mounting - libguestfs. This is the
# right tool for scripting:
$ sudo apt install libguestfs-tools
$ virt-ls -a disk.qcow2 /etc
$ virt-cat -a disk.qcow2 /etc/hostname
$ virt-copy-out -a disk.qcow2 /var/log/messages ./
$ virt-copy-in -a disk.qcow2 mydriver.ko /lib/modules/
$ virt-customize -a disk.qcow2 \
      --root-password password:secret \
      --install openssh-server \
      --run-command 'systemctl enable serial-getty@ttyAMA0'
$ guestfish -a disk.qcow2 -i        # an interactive shell

# NEVER mount an image read-write while a guest is using it.
# Two writers on one filesystem corrupts it immediately and
# the corruption may not show for hours.
```

Snapshots

```
# INTERNAL snapshots - stored inside a qcow2, include RAM if
# taken from the monitor. This is save-state/load-state.

(qemu) savevm before-experiment
(qemu) info snapshots
ID   TAG                 VM SIZE  DATE                VM CLOCK
1    before-experiment     512MiB 2026-08-22 10:14   00:02:31
(qemu) loadvm before-experiment      # instant time travel
(qemu) delvm before-experiment

# Offline:
$ qemu-img snapshot -l disk.qcow2
$ qemu-img snapshot -c mytag disk.qcow2
$ qemu-img snapshot -a mytag disk.qcow2
$ qemu-img snapshot -d mytag disk.qcow2

# EXTERNAL snapshots - a new overlay, taken live via QMP. This
# is how backups are done without pausing the guest:
{"execute":"blockdev-snapshot-sync",
 "arguments":{"device":"hd0","snapshot-file":"snap1.qcow2",
              "format":"qcow2"}}

# savevm/loadvm is the most underused debugging tool in QEMU.
# Reproducing a bug that takes ten minutes of setup? Snapshot
# just before it, then loadvm as many times as you need. It
# turns a ten-minute iteration into a one-second one.
# (It requires all devices to support migration state; a
# passed-through device will refuse.)
```

How it shows up

Symptom	Cause
Guest filesystem corrupt after a host crash	`cache=unsafe`, or a device model that ignores `FLUSH`
Image grows until the host disk fills	No `discard=unmap`; deleted guest data still occupies clusters
`Could not open backing file`	Overlay moved away from its backing file — the path is stored inside the overlay. Use `qemu-img rebase`
Guest sees a smaller disk than the file	Image resized but the guest partition and filesystem were not
`cache=none` fails to open	Filesystem does not support O_DIRECT (tmpfs, some network filesystems)
`aio=native` rejected	Requires `cache=none` or `cache=directsync`
Both host and guest wrote to an image; it is wrecked	Two writers. There is no recovery; restore from the golden image
`savevm` refuses	A device without migration support — commonly a passed-through device or a non-migratable model
Guest boots from the wrong disk	Ordering; set `bootindex=` on the device
Terrible install performance	Use `cache=unsafe` for the install, then switch back

Check yourself

✓ Name the four layers of the block stack and give an example driver at each.

- ✓ Give three things qcow2 does that raw cannot, and one thing raw does better.
- ✓ Create an overlay on a golden image and explain why this should be your default workflow.
- ✓ Explain what `-snapshot` does without creating a file.
- ✓ Describe each cache mode and say which is a correctness hazard.
- ✓ Explain what `discard=unmap` and `detect-zeroes=unmap` prevent.
- ✓ Mount a qcow2 image on the host, and give a way to read one without mounting.
- ✓ State the rule about writing to an image a guest is using.
- ✓ Use `savevm`/`loadvm` to shorten a debugging loop, and name one thing that blocks it.
- ✓ Explain what `qemu-img rebase` fixes.

The monitor, QMP and snapshots

QEMU has a control channel into a running machine that can inspect memory, dump registers, add and remove devices, and freeze the whole system into a file. Two interfaces expose it: one for humans and one for programs. The human one is the fastest debugging tool in this track.

HMP and QMP

```
HMP - Human Monitor Protocol
    terse, text, tab-completion, stable enough for daily use
    but NOT a stable API.
    Reach it with:  -monitor stdio
                    Ctrl-A c   (with -nographic)
                    -monitor telnet::4444,server,nowait

QMP - QEMU Machine Protocol
    JSON, versioned, introspectable, the actual API. libvirt
    speaks this. Scripts should too.
    Reach it with:  -qmp unix:/tmp/qmp.sock,server,nowait
                    -qmp tcp::4444,server,nowait
                    -qmp stdio

You can have both at once, and usually should:

  -monitor unix:/tmp/hmp.sock,server,nowait \
  -qmp     unix:/tmp/qmp.sock,server,nowait

And you can run an HMP command through QMP when a QMP
equivalent does not exist:

  {"execute":"human-monitor-command",
   "arguments":{"command-line":"info mtree"}}
```

The HMP commands that matter

Command	Shows
`info registers`	Every CPU register, including system registers on arm64. The first thing to run when a guest hangs
`info registers -a`	All CPUs
`info mtree`	The complete memory map — what is modelled where
`info qtree`	The device tree QEMU built, with every property
`info block`	Drives, their backing files, cache modes
`info network`	netdevs and the devices attached
`info pci`	The PCIe topology
`info irq` / `info pic`	Interrupt counts and controller state
`info cpus`	vCPU list, thread ids, halted state
`info roms`	Everything loaded and where
`info snapshots`	Saved VM states

Command	Shows
`x/<fmt> <addr>`	Examine *virtual* memory
`xp/<fmt> <addr>`	Examine *physical* memory
`gva2gpa` / `gpa2hva`	Translate an address through the stages
`stop` / `cont`	Freeze and resume the machine
`system_reset` / `system_powerdown`	Reset; send an ACPI power button
`savevm` / `loadvm` / `delvm`	Snapshot the whole machine
`migrate`	Move or dump the machine state
`dump-guest-memory`	Write an ELF core of guest RAM for crash analysis
`sendkey`	Inject keystrokes, e.g. `sendkey ctrl-alt-f2`
`nmi`	Poke the guest into its panic handler

```
(qemu) info registers
 PC=ffff800008a41234 X00=0000000000000000 X01=ffff0000c1234000
 X02=0000000000001000 ...
 PSTATE=204003c5 --C- EL1h
 SP_EL0=ffff0000c0a1bf00  SP_EL1=ffff800008003e70
 ELR_EL1=ffff800008a41230 ESR_EL1=96000047
 SCTLR_EL1=0000000034d4d91d  TTBR0_EL1=00000000c1122000
 TTBR1_EL1=0000000041c50000  VBAR_EL1=ffff800008010000

# A hung guest, decoded in one command: PSTATE says EL1h,
# ESR_EL1 says data abort (EC=0x25), and ELR_EL1 is the
# faulting instruction. Feed that address to addr2line.

(qemu) x/8i $pc              # disassemble at the PC
(qemu) x/16xg 0xffff0000c1234000
(qemu) xp/32xb 0x09000000    # the UART's registers, physically
(qemu) gva2gpa 0xffff800008a41234
gpa: 0x41234234

# Dump a region of guest memory to a file:
(qemu) pmemsave 0x40000000 0x100000 /tmp/first-mb.bin
(qemu) memsave 0xffff800008000000 0x1000 /tmp/kernel-page.bin

# A full guest core, readable by crash(8) or gdb:
(qemu) dump-guest-memory /tmp/guest.core
$ crash vmlinux /tmp/guest.core
```

> **`INFO REGISTERS` ON A HUNG GUEST**
>
> A guest that stops responding is not a black box. Press `Ctrl-A c`, type `info registers`, and you have the PC, the exception syndrome and the exception link register — which is more than a kernel oops would have given you, and you did not need the guest to be healthy enough to print it.

QMP, properly

```
$ qemu-system-aarch64 -M virt ... \
    -qmp unix:/tmp/qmp.sock,server=on,wait=off

# Talk to it. Every session starts with a greeting, then you
# must leave capabilities negotiation before anything works:
$ socat - UNIX-CONNECT:/tmp/qmp.sock
{"QMP": {"version": {"qemu": {"major": 8, "minor": 2}}, ...}}
{"execute":"qmp_capabilities"}
{"return": {}}
{"execute":"query-status"}
{"return": {"status": "running", "singlestep": false, "running": true}}

# From Python, which is how you should automate it. QEMU ships
# the client library:
$ pip install qemu.qmp
```

```
#!/usr/bin/env python3
"""Wait for a guest to boot, snapshot it, and pull stats."""
import asyncio
from qemu.qmp import QMPClient

async def main():
    qmp = QMPClient('vm')
    await qmp.connect('/tmp/qmp.sock')

    # What can this QEMU do?
    cmds = await qmp.execute('query-commands')
    print(len(cmds), 'commands available')

    # Machine state
    print(await qmp.execute('query-status'))
    print(await qmp.execute('query-cpus-fast'))
    print(await qmp.execute('query-block'))

    # Wait for the guest to signal readiness. Events are the
    # right way to synchronise - never sleep and hope.
    await qmp.execute('cont')
    async for event in qmp.events:
        print('EVENT', event['event'])
        if event['event'] == 'RESET':
            break

    # Snapshot the whole machine
    await qmp.execute('human-monitor-command',
                      {'command-line': 'savevm booted'})

    # Add a disk while it runs
    await qmp.execute('blockdev-add', {
        'node-name': 'extra',
        'driver': 'qcow2',
        'file': {'driver': 'file', 'filename': 'extra.qcow2'},
    })
    await qmp.execute('device_add', {
        'driver': 'virtio-blk-pci', 'drive': 'extra', 'id': 'blk1',
    })

    await qmp.disconnect()

asyncio.run(main())
```

Events: the synchronisation primitive

```
# QMP pushes events asynchronously. Waiting for one is how a
# test harness knows when to act.

{"event": "RESET",          "data": {"guest": true}, ...}
{"event": "SHUTDOWN",       "data": {"guest": true, "reason": "guest-shutdown"}}
{"event": "STOP"}
{"event": "RESUME"}
{"event": "POWERDOWN"}
{"event": "GUEST_PANICKED",  "data": {"action": "pause"}}
{"event": "DEVICE_TRAY_MOVED"}
{"event": "BLOCK_IO_ERROR",  "data": {"device": "hd0", "operation": "write"}}
{"event": "MIGRATION",       "data": {"status": "completed"}}
{"event": "VSERPORT_CHANGE"}

# A CI harness in eight lines of shell + socat:
$ (echo '{"execute":"qmp_capabilities"}'; cat) \
  | socat - UNIX-CONNECT:/tmp/qmp.sock \
  | while read -r line; do
        case "$line" in
          *GUEST_PANICKED*) echo "FAIL: guest panicked"; exit 1;;
          *SHUTDOWN*)       echo "PASS: clean shutdown";  exit 0;;
        esac
    done

# Make a panic detectable rather than a hang:
$ qemu-system-aarch64 ... -no-reboot \
    -device pvpanic-pci
# The guest's panic handler writes to the pvpanic device, QEMU
# emits GUEST_PANICKED, and your harness fails fast instead of
# waiting for a timeout.
```

Migration, and its offline uses

```
# Migration serialises the entire machine. That is useful even
# when you are not moving anything anywhere.

# 1. Save a machine to a file and restore it later:
(qemu) migrate "exec:gzip -c > state.gz"
# start a NEW qemu with identical arguments plus -incoming:
$ qemu-system-aarch64 ...same args... \
    -incoming "exec:gzip -dc state.gz"

# 2. Move a running guest to another machine:
#    destination:
$ qemu-system-aarch64 ...same args... -incoming tcp:0:4444
#    source:
(qemu) migrate -d tcp:dest-host:4444
(qemu) info migrate
capabilities: xbzrle: off  postcopy-ram: off
Migration status: completed
total time: 4213 ms
downtime: 87 ms

# 3. Requirements people trip over:
#    - IDENTICAL command line on both ends, including the
#      versioned machine type (virt-8.2, not virt)
#    - the same QEMU version, or a compatible one
#    - shared or replicated storage, unless you use
#      --copy-storage-all
#    - NO passed-through devices (virt chapter 16)
#    - the same CPU model; -cpu host will refuse across
#      different silicon

# 4. Tuning, when it will not converge:
(qemu) migrate_set_parameter max-bandwidth 1G
(qemu) migrate_set_parameter downtime-limit 300
(qemu) migrate_set_capability auto-converge on   # throttle the
                                                 # guest until
                                                 # it converges
(qemu) migrate_set_capability postcopy-ram on    # switch over
                                                 # first, fault
                                                 # pages after
```

> **SNAPSHOT BEFORE THE HARD PART**
> Reproducing a bug that needs ten minutes of setup is the most wasteful thing in embedded debugging. `savevm` just before the interesting moment turns every subsequent attempt into `loadvm` plus one second. Combine it with `-icount` (chapter 2) and the replay is deterministic too.

How it shows up

Symptom	Cause
QMP commands all return an error	`qmp_capabilities` not sent first
Cannot reach the monitor with `-nographic`	Use `Ctrl-A c`; the monitor is multiplexed onto the same terminal
`savevm` fails: "state blocked by non-migratable device"	A passed-through or non-migratable device is present

Symptom	Cause
`loadvm` restores but the guest immediately breaks	Different command line — the device model must match exactly
Migration never completes	Guest dirties memory faster than the link copies it; enable `auto-converge` or postcopy
Migration completes, guest is broken	Unversioned machine type, so the two ends built different machines
A guest panic looks like a hang in CI	No `pvpanic` device and no `-no-reboot`
`x` shows garbage	Used `x` (virtual) where you wanted `xp` (physical), or the MMU is off
HMP output changed and broke a script	HMP is not an API. Use QMP

Check yourself

- ✓ Distinguish HMP from QMP and say which a script should use.
- ✓ Show how to run an HMP command through QMP.
- ✓ Given a hung guest, use the monitor to obtain the PC, the fault syndrome and the exception level.
- ✓ Explain the difference between `x` and `xp`, and when each is meaningful.
- ✓ Translate a guest virtual address to a guest physical one from the monitor.
- ✓ Write the QMP handshake and one query command.
- ✓ Name four QMP events and say what a test harness would do with each.
- ✓ Explain what `pvpanic` plus `-no-reboot` buys a CI pipeline.
- ✓ List four requirements for a successful migration.
- ✓ Describe how `savevm` shortens a debugging loop and one thing that prevents it.

Debugging through QEMU with GDB

QEMU has a built-in GDB stub, which means you can stop a machine before its first instruction, single-step through a bootloader, set a watchpoint on a hardware register, and inspect an EL3 exception handler — with no JTAG probe, no cost, and none of the ways a real debug port can interfere with the system it is debugging.

The two flags

```
  -s        shorthand for -gdb tcp::1234
  -S        do NOT start the CPU; wait for the debugger

$ qemu-system-aarch64 -M virt -cpu cortex-a57 -m 1G -nographic \
    -kernel Image -append "console=ttyAMA0 nokaslr" \
    -s -S

# In another terminal:
$ gdb-multiarch vmlinux
(gdb) target remote :1234
Remote debugging using :1234
0x0000000040000000 in ?? ()

# You are now stopped at the very first instruction the machine
# will execute, before any firmware, before the kernel header,
# before anything. No real debug hardware gives you this.

(gdb) break start_kernel
(gdb) continue
Breakpoint 1, start_kernel () at init/main.c:936

# Other ports/transports:
-gdb tcp::4321                   # different port
-gdb unix:/tmp/gdb.sock,server=on
-gdb stdio                       # pipe it

# The right GDB:
#   gdb-multiarch                (Debian/Ubuntu)
#   aarch64-linux-gnu-gdb        (from the cross toolchain)
#   aarch64-none-elf-gdb         (bare metal)
#   lldb also speaks the protocol: (lldb) gdb-remote 1234
#
# Plain x86 gdb will connect and then produce nonsense, because
# it does not know the target architecture. If registers look
# absurd, this is why. Force it:
(gdb) set architecture aarch64
```

Debugging a Linux kernel

```
# Build with symbols and without KASLR (chapter 5), then:

$ gdb-multiarch vmlinux
(gdb) target remote :1234

# Linux ships GDB scripts. They are excellent and nobody uses
# them.
(gdb) source /path/to/linux/vmlinux-gdb.py
(gdb) lx-symbols               # load module symbols too
(gdb) lx-dmesg                 # the kernel ring buffer, even
                               # if the console is broken
(gdb) lx-ps                    # every task
(gdb) lx-lsmod
(gdb) lx-device-tree
(gdb) lx-mounts

# You may need:
$ echo "add-auto-load-safe-path /path/to/linux" >> ~/.gdbinit

# Breakpoints in a MODULE. The module is not loaded yet when
# you connect, so:
(gdb) lx-symbols /path/to/module/build/dir
# after insmod in the guest, run lx-symbols again - it finds
# the load address from the kernel's module list and relocates.

(gdb) break my_driver_probe
(gdb) continue
# in the guest: insmod mydriver.ko
Breakpoint 2, my_driver_probe (pdev=0xffff0000c1234000) ...
(gdb) bt
(gdb) p *pdev
(gdb) p pdev->dev.of_node->name

# Per-CPU variables and the current task:
(gdb) p $lx_current().comm
(gdb) p $lx_per_cpu("runqueues", 1)

# Physical memory, when the MMU is off or you do not trust it:
(gdb) monitor xp/16xg 0x40000000
# "monitor" passes the command to QEMU's HMP - so every command
# from chapter 10 is available from inside GDB.
```

> **`MONITOR` IS THE BRIDGE**
>
> Anything you can do in the QEMU monitor, you can do from the GDB prompt by prefixing it with `monitor`. `monitor info registers`, `monitor info mtree`, `monitor savevm x`. That combination — a source-level debugger plus full machine introspection — is strictly more than a JTAG probe offers.

Exception levels and the multi-image problem

```
A full arm64 boot has four separate binaries at three
exception levels, and GDB only knows about symbols you have
told it about.

  bl1.bin / bl2 / bl31.elf     EL3   TF-A
  tee.elf / tee-pager.elf      S-EL1 OP-TEE
  u-boot                       EL2/1 bootloader
  vmlinux                      EL1   Linux

Load them all, at their link addresses:

  (gdb) file bl31.elf
  (gdb) add-symbol-file tee.elf   0x0e100000
  (gdb) add-symbol-file u-boot    0x60000000
  (gdb) add-symbol-file vmlinux

Now a backtrace resolves whichever image the PC is in.

Which EL are we in right now?

  (gdb) p $cpsr
  (gdb) monitor info registers | grep PSTATE
  PSTATE=204003c9 --C- EL3h
                      ^^^^ there it is

Breakpoints across an EL switch: QEMU's stub uses SOFTWARE
breakpoints by default, which need writable memory. Code in
ROM or in a region the current stage cannot write needs a
HARDWARE breakpoint:

  (gdb) hbreak *0x0e100000
  (gdb) watch *(int *)0x09000000       # software watchpoint
  (gdb) rwatch *(int *)0x09000018      # break on READ of a
                                       # device register -
                                       # this is the killer
                                       # feature for driver
                                       # work
```

Bare-metal and early boot

```
# A payload with no OS. This is the OP-TEE and TF-A workflow.

$ aarch64-none-elf-gcc -g -O0 -nostdlib -Wl,-Ttext=0x40100000 \
      -o payload.elf start.S main.c

$ qemu-system-aarch64 -M virt -cpu max -nographic \
    -kernel payload.elf -s -S

$ aarch64-none-elf-gdb payload.elf
(gdb) target remote :1234
(gdb) break _start
(gdb) continue
(gdb) layout asm            # a disassembly window
(gdb) layout regs           # registers alongside
(gdb) si                    # step one instruction
(gdb) info registers sctlr_el1 ttbr0_el1 vbar_el1

# System registers ARE exposed by QEMU's stub on aarch64:
(gdb) p $sctlr_el1
(gdb) p/x $esr_el1
(gdb) p $currentel

# Stepping through MMU enable - the moment that breaks most
# bare-metal code:
(gdb) break *enable_mmu
(gdb) si
(gdb) p/x $sctlr_el1        # watch bit 0 flip
(gdb) x/4i $pc              # are we still executing sane code?

# If the CPU vanishes after enabling the MMU, the identity
# mapping for the code itself is missing. GDB shows you exactly
# which instruction it died on, which a hardware debugger often
# cannot because it loses the connection at the same moment.
```

Multiple CPUs

```
# Each vCPU is a GDB "thread".

(gdb) info threads
  Id   Target Id      Frame
* 1    Thread 1 (CPU#0 [running])  cpu_do_idle () at ...
  2    Thread 2 (CPU#1 [halted ])  0x0000000000000000 in ?? ()

(gdb) thread 2
(gdb) bt

# By default GDB stops ALL CPUs when one hits a breakpoint,
# which is what you want. Non-stop mode lets the others run:
(gdb) set non-stop on          # before connecting

# Break only on a specific CPU:
(gdb) break my_func if $_thread == 2

# A race between two CPUs is best caught with -icount (chapter
# 2), which makes the interleaving deterministic and therefore
# repeatable:
$ qemu-system-aarch64 ... -icount shift=5,align=off,sleep=off -s -S
```

Techniques worth stealing

```
# 1. Script the whole session. Stop retyping.
$ cat > debug.gdb <<'EOF'
target remote :1234
source /work/linux/vmlinux-gdb.py
lx-symbols
break panic
break die
break my_driver_probe
commands 3
  bt
  p *pdev
  continue
end
continue
EOF
$ gdb-multiarch vmlinux -x debug.gdb

# 2. Catch a fault before it becomes an oops:
(gdb) break do_mem_abort
(gdb) break __do_kernel_fault

# 3. Watch a hardware register be touched, and by whom:
(gdb) awatch *(volatile unsigned int *)0x09000018
Hardware access (read/write) watchpoint 1
Value = 0x90
0xffff800008a41234 in pl011_console_write ()
# THIS is how you find the code that is banging on a register
# it should not.

# 4. Change guest state to test an error path you cannot
#    otherwise reach:
(gdb) p $x0 = -12            # make an allocation "fail"
(gdb) return -ENOMEM
(gdb) set var some_flag = 1

# 5. Combine with savevm: snapshot at the interesting point,
#    then loadvm and try a different intervention each time.
(gdb) monitor savevm probe-entry
(gdb) monitor loadvm probe-entry

# 6. Reverse debugging, with record/replay:
$ qemu-system-aarch64 ... -icount shift=auto,rr=record,rrfile=rr.bin -s -S
$ qemu-system-aarch64 ... -icount shift=auto,rr=replay,rrfile=rr.bin -s -S
(gdb) reverse-continue
(gdb) reverse-step
# Stepping BACKWARDS from a crash to its cause. It has
# limitations (no external input during replay) but when it
# works it is unmatched.
```

KASLR WILL WASTE YOUR AFTERNOON

If breakpoints do not hit and symbols point at nonsense, the kernel relocated itself. Add `nokaslr` to `-append` or turn off `CONFIG_RANDOMIZE_BASE`. The same applies to modules — always re-run `lx-symbols` after `insmod`, because until then GDB has no idea where the module landed.

How it shows up

Symptom	Cause
GDB connects, registers are nonsense	Wrong GDB architecture — use `gdb-multiarch` or `set architecture aarch64`
Breakpoints never hit	KASLR, or symbols from a different build than the running image
Breakpoint in a module never hits	`lx-symbols` not re-run after `insmod`
`Cannot insert breakpoint`	Target memory is read-only (ROM, or another EL's region) — use `hbreak`
Guest runs away immediately	Forgot `-S`
Connection refused	QEMU not started, wrong port, or `-s` missing
Everything freezes when you step	Normal — the whole machine is stopped, including its timers
Guest network connections time out while debugging	Also normal; the guest's clock stopped but the world's did not
Symbols resolve for the kernel but not for firmware	Need `add-symbol-file` at the firmware's link address
Race disappears under GDB	Use `-icount` for determinism, or you are observing a genuine timing dependency

Check yourself

- ✓ Explain what `-s` and `-S` do, separately.
- ✓ Name the correct GDB binary for an aarch64 target and what happens if you use the wrong one.
- ✓ Load the Linux GDB scripts and name four `lx-` commands.
- ✓ Explain how to get a breakpoint into a kernel module.
- ✓ Explain what `monitor` does at the GDB prompt and give two uses.
- ✓ Load symbols for four images at three exception levels and determine the current EL.
- ✓ Say when you need `hbreak` instead of `break`.
- ✓ Set a watchpoint that fires when a device register is *read*.
- ✓ Describe how vCPUs appear to GDB and how to inspect a specific one.
- ✓ Explain how to make a race reproducible under the debugger.

Tracing, logging and TCG plugins

Three separate observation systems ship in QEMU and they answer different questions: `-d` tells you what the guest did, `--trace` tells you what QEMU did, and plugins let you write your own instrumentation over every instruction and memory access. Together they give you visibility no real board can match.

Which one answers which question

Question	Tool
What instructions did the guest execute?	`-d in_asm,exec`
What exceptions did it take?	`-d int`
Why did that access fault?	`-d mmu,guest_errors`
Is the guest touching something I have not modelled?	`-d unimp,guest_errors`
What did my device model receive?	`--trace 'mydev_*'`
Which virtqueue operations happened?	`--trace 'virtio_*'`
How many times is that register read?	a TCG plugin
What is the guest's cache miss rate?	`libcache.so` plugin
Which basic blocks are hot?	`libhotblocks.so` plugin

-d: guest-side logging

```
# Always write to a file. -d output to a terminal is unusable.
$ qemu-system-aarch64 -M virt -nographic -kernel Image \
    -d guest_errors,unimp,int -D qemu.log

# The four to enable by default during bring-up. They are cheap
# and they catch real problems:
#   guest_errors  the guest did something invalid
#   unimp         you hit an unimplemented feature or register
#   int           every exception and interrupt taken
#   mmu           translation faults

$ qemu-system-aarch64 -M virt -nographic -kernel Image \
    -d int -D int.log
$ head -20 int.log
Taking exception 5 [IRQ]
...from EL1 to EL1
...with ESR 0x0/0x0
...with ELR 0xffff800008a41234
...to EL1 PC 0xffff800008010480 PSTATE 0x3c5

Taking exception 3 [Prefetch Abort]
...from EL1 to EL1
...with ESR 0x21/0x86000004
...with FAR 0x0000000000000000

# That last one is a NULL instruction fetch - the guest jumped
# through a null function pointer, and you have the ELR to find
# out from where. -d int is the highest-value flag in QEMU and
# almost nobody enables it.

# The heavyweight ones - use with a narrow window:
$ qemu-system-aarch64 ... -d exec,cpu -D trace.log
# every block execution, plus a full register dump. Gigabytes
# per second. Combine with a breakpoint:
#   run under gdb, break where you care, then
#   (gdb) monitor log exec,cpu
#   (gdb) stepi 1000
#   (gdb) monitor log none

# Toggle logging at runtime, which is how you keep it usable:
(qemu) log int,mmu
(qemu) log none
(qemu) logfile /tmp/window.log

# List everything available:
$ qemu-system-aarch64 -d help
```

> **`-D INT` IS THE ONE TO REMEMBER**
>
> A guest that hangs, resets in a loop, or dies silently is almost always taking an exception it cannot handle. `-d int` prints every exception with its ESR, ELR and FAR — the same three registers you would decode by hand — for the entire boot, at negligible cost. Reach for it before anything else.

--trace: QEMU-side tracepoints

```
# QEMU's own code is instrumented with thousands of static
# tracepoints. They are compiled in but disabled by default.

$ qemu-system-aarch64 -M virt --trace help 2>&1 | wc -l
4127

$ qemu-system-aarch64 -M virt --trace 'virtio_*' -D trace.log ...
virtio_queue_notify   vdev 0x5555 n 0 vq 0x5556
virtio_notify_irqfd   vdev 0x5555 vq 0x5556
virtblk_handle_write  req 0x5557 sector 2048 nsectors 8

$ qemu-system-aarch64 -M virt \
    --trace 'pl011_*' --trace 'gicv3_*' -D trace.log ...
pl011_read      addr 0x18 value 0x90
pl011_write     addr 0x00 value 0x4b
gicv3_icc_iar1_read  cpu 0 value 0x21
gicv3_icc_eoir_write cpu 0 value 0x21

# Many patterns at once, from a file:
$ cat > events.txt <<'EOF'
virtio_*
virtqueue_*
kvm_run_exit
memory_region_ops_read
memory_region_ops_write
EOF
$ qemu-system-aarch64 ... --trace events=events.txt -D trace.log

# THE TWO MOST USEFUL, and they work for ANY device including
# one you just wrote:
--trace 'memory_region_ops_read'
--trace 'memory_region_ops_write'
# Every MMIO access QEMU dispatched, with the region name,
# offset, value and size. "Is my device being accessed at all?"
# answered definitively.

# Toggle at runtime:
(qemu) trace-event virtio_queue_notify on
(qemu) trace-event pl011_* off
(qemu) info trace-events | head

# Into the host's ftrace, so guest and host events interleave
# on one timeline (needs --enable-trace-backends=ftrace):
$ echo 1 | sudo tee /sys/kernel/debug/tracing/tracing_on
$ qemu-system-aarch64 ... --trace 'virtio_*'
$ sudo cat /sys/kernel/debug/tracing/trace
```

Adding a tracepoint to your own device

```
# If you are writing a device model (chapter 13), instrument it
# the way QEMU does rather than with printf.

# 1. hw/misc/trace-events
mydev_read(uint64_t offset, uint64_t value, unsigned size) \
    "offset 0x%" PRIx64 " value 0x%" PRIx64 " size %u"
mydev_write(uint64_t offset, uint64_t value, unsigned size) \
    "offset 0x%" PRIx64 " value 0x%" PRIx64 " size %u"
mydev_irq(int level) "level %d"
mydev_reset(void) ""

# 2. In your source:
#include "trace.h"

static uint64_t mydev_read(void *opaque, hwaddr off, unsigned sz)
{
        MyDevState *s = opaque;
        uint64_t v = do_read(s, off);
        trace_mydev_read(off, v, sz);
        return v;
}

# 3. Use it:
$ qemu-system-aarch64 ... --trace 'mydev_*' -D mydev.log

# Zero cost when disabled (a branch on a flag), full formatting
# when enabled, works with every backend, and does not clutter
# stdout. There is no reason to use printf in a device model.
```

TCG plugins: instrumentation you write

```
# Plugins are shared libraries called back on translation and
# execution events. They work under TCG only (not KVM), and
# they see EVERYTHING.

$ ls build/tests/plugin/
libbb.so  libempty.so  libinsn.so  libmem.so  libhotblocks.so
libhotpages.so  libhowvec.so  libcache.so  libsyscall.so

# Count instructions - a deterministic "cycle" count for
# comparing two implementations:
$ qemu-system-aarch64 ... -plugin build/tests/plugin/libinsn.so \
    -d plugin -D insn.log
cpu 0 insns: 148291043

# Hot basic blocks:
$ qemu-system-aarch64 ... \
    -plugin build/tests/plugin/libhotblocks.so,count=20 -d plugin
collected 154321 entries in the hash table
pc, hits, insns
0x0000ffff80081234, 4092211, 14
0x0000ffff80095678, 2881100,  6

# Hot pages - shows the guest's memory access distribution:
$ qemu-system-aarch64 ... -plugin build/tests/plugin/libhotpages.so \
    -d plugin

# A real cache model - miss rates for a configuration you
# choose, on real guest execution:
$ qemu-system-aarch64 ... -plugin build/tests/plugin/libcache.so,\
dcachesize=32768,dassoc=4,dblksize=64,icachesize=32768 -d plugin
core #, data accesses, data misses, dmiss rate, insn accesses, ...
0       12043221       401223      3.33%       48120311  ...
```

```
/* Your own plugin. ~80 lines for something genuinely useful:
   count every access to one MMIO address.                  */

#include <qemu-plugin.h>
#include <stdio.h>
#include <inttypes.h>

    -d plugin
region 0x9000000: 41022 reads, 8813 writes

# "My driver is slow - how much is it touching the hardware?"
# answered exactly, without modifying the driver, without a
# logic analyser, and with a number you can put in a commit
# message.
```

How it shows up

Symptom	Cause
`-d` produces nothing	Output went to stderr and was swallowed — add `-D file`
`-d exec` fills the disk	Working as intended. Narrow the window with the monitor's `log` command
Plugin fails to load	QEMU built without `--enable-plugins`, or an ABI mismatch between plugin and binary
Plugin produces no output	`-d plugin` missing, or the plugin writes with `qemu_plugin_outs` which needs it
Plugin sees nothing under `-accel kvm`	Plugins are a TCG feature. There is no instruction stream to instrument under KVM
`--trace` pattern matches nothing	Check the exact name with `--trace help`; patterns are glob, not regex
Tracepoint added but never fires	`trace-events` not in the directory's `meson.build`, or `trace.h` not included
Guest behaves differently with tracing on	Logging slows the guest enough to change timing — expected, and sometimes informative
Instruction counts differ between runs	Non-determinism from I/O; add `-icount`

Check yourself

- ✓ Say which of the three systems answers "what did the guest execute", "what did QEMU do", and "how many times".
- ✓ Name the four `-d` flags worth enabling by default and what each catches.
- ✓ Read a `-d int` entry and extract the exception type, ESR, ELR and FAR.
- ✓ Narrow `-d exec` to a small window using the monitor.
- ✓ Name the two `--trace` events that work for any device model.
- ✓ Add a tracepoint to a device model and say why it beats `printf`.
- ✓ Use a stock plugin to find the hottest basic blocks in a guest.
- ✓ Explain why plugins do not work under KVM.
- ✓ Write a plugin that counts accesses to one address range.
- ✓ Explain how to make instruction counts reproducible between runs.

Writing a QEMU device model

When the silicon does not exist yet, you write the device first and the driver against it. This chapter builds a complete, working QEMU device — registers, interrupt, device tree node, migration state — and then a Linux driver for it, so you have the full loop that hardware bring-up teams actually use.

Why you would do this

Situation	What the model buys you
Silicon is six months away	The driver is written, reviewed and tested before tape-out. This is the normal way large SoC drivers are developed
The board is on someone else's desk	Every engineer gets a target
You need to test an error path	Make the model return the error. No fault injector on real hardware can do this as precisely
CI must run driver tests	No board farm required
You are learning	Writing the device teaches you what the driver's assumptions actually are

QOM: QEMU's object model, in one page

```
Every device is a QOM object. Three things to declare:

1. A STATE struct - your instance data, beginning with the
   parent's state struct.

     struct MyDevState {
             SysBusDevice parent_obj;   <- MUST be first
             MemoryRegion iomem;
             qemu_irq     irq;
             uint32_t     regs[8];
     };

2. A TYPE registration - name, parent, sizes, class init.

     static const TypeInfo mydev_info = {
             .name          = TYPE_MYDEV,
             .parent        = TYPE_SYS_BUS_DEVICE,
             .instance_size = sizeof(MyDevState),
             .instance_init = mydev_init,
             .class_init    = mydev_class_init,
     };

3. LIFECYCLE callbacks:

     instance_init  object created. Set defaults only.
     realize        properties are set; NOW create memory
                    regions, allocate, connect IRQs. This is
                    where the real work goes.
     reset          system reset. Restore register defaults.
     unrealize      teardown.

Parent classes you will use:
     TYPE_SYS_BUS_DEVICE   memory-mapped, on the system bus
     TYPE_PCI_DEVICE       a PCIe function
     TYPE_VIRTIO_DEVICE    a virtio device
     TYPE_DEVICE           anything else
```

A complete device

```
/* hw/misc/acme-widget.c
   A device with an ID register, a scratch register, a counter
   that increments on read, and an interrupt you can trigger. */

#include "qemu/osdep.h"
#include "hw/sysbus.h"
#include "hw/irq.h"
#include "hw/qdev-properties.h"
#include "migration/vmstate.h"
#include "qemu/log.h"
#include "qom/object.h"
#include "trace.h"

#define TYPE_ACME_WIDGET "acme-widget"
OBJECT_DECLARE_SIMPLE_TYPE(AcmeWidgetState, ACME_WIDGET)

/* Register map - document it here, it is the contract. */

Wiring it into the build and the machine

```
# 1. hw/misc/trace-events - add your tracepoints
acme_widget_read(uint64_t off, uint64_t val, unsigned sz) \
    "off 0x%" PRIx64 " val 0x%" PRIx64 " size %u"
acme_widget_write(uint64_t off, uint64_t val, unsigned sz) \
    "off 0x%" PRIx64 " val 0x%" PRIx64 " size %u"
acme_widget_irq(int level) "level %d"

# 2. hw/misc/Kconfig
config ACME_WIDGET
    bool
    default y if TEST_DEVICES

# 3. hw/misc/meson.build
system_ss.add(when: 'CONFIG_ACME_WIDGET',
              if_true: files('acme-widget.c'))

# 4. configs/devices/aarch64-softmmu/default.mak
CONFIG_ACME_WIDGET=y

# 5. Rebuild
$ ninja -C build

# 6. Instantiate it. The dynamic sysbus lets you do this from
#    the command line without touching the machine code:
$ qemu-system-aarch64 -M virt -cpu cortex-a57 -m 512M -nographic \
    -kernel Image -append "console=ttyAMA0" \
    -device acme-widget \
    --trace 'acme_widget_*' -D acme.log

# Confirm it exists:
(qemu) info qtree
    dev: acme-widget, id ""
      id = 2900361217 (0xace00001)
      mmio 000000000c000000/0000000000001000
(qemu) info mtree | grep acme
      000000000c000000-000000000c000fff (prio 0, i/o): acme-widget

# Poke it from the monitor, before writing any driver at all:
(qemu) xp/1xw 0x0c000000
000000000c000000: 0xace00001
(qemu) xp/1xw 0x0c000010
000000000c000010: 0x00000000
(qemu) xp/1xw 0x0c000010
000000000c000010: 0x00000001      # the counter increments
```

TEST THE MODEL BEFORE WRITING THE DRIVER

`xp` from the monitor exercises every register without a single line of guest code. If the ID register does not read back, the problem is in your model; if it does, every later failure is in the driver. That separation saves hours, and it is only available because you are on QEMU.

The device tree node

```
/* A dynamic sysbus device gets an auto-generated node with a
   generic compatible string, which no driver will match. For a
   real device you add it to the machine.                     */

/* hw/arm/virt.c, in the machine's device creation: */

static void create_acme_widget(const VirtMachineState *vms)
{
        hwaddr base = 0x0c000000;
        int    irq  = 48;
        DeviceState *dev;
        MachineState *ms = MACHINE(vms);
        char *nodename;

        dev = qdev_new(TYPE_ACME_WIDGET);
        sysbus_realize_and_unref(SYS_BUS_DEVICE(dev), &error_fatal);
        sysbus_mmio_map(SYS_BUS_DEVICE(dev), 0, base);
        sysbus_connect_irq(SYS_BUS_DEVICE(dev), 0,
                           qdev_get_gpio_in(vms->gic,
                                            irq));

        nodename = g_strdup_printf("/acme-widget@%" PRIx64, base);
        qemu_fdt_add_subnode(ms->fdt, nodename);
        qemu_fdt_setprop_string(ms->fdt, nodename,
                                "compatible", "acme,widget-1.0");
        qemu_fdt_setprop_sized_cells(ms->fdt, nodename, "reg",
                                     2, base, 2, 0x1000);
        qemu_fdt_setprop_cells(ms->fdt, nodename, "interrupts",
                               GIC_FDT_IRQ_TYPE_SPI, irq,
                               GIC_FDT_IRQ_FLAGS_LEVEL_HI);
        g_free(nodename);
}

/* Verify it landed: */
$ qemu-system-aarch64 -M virt,dumpdtb=v.dtb ... && \
  dtc -I dtb -O dts v.dtb | grep -A5 acme
```

# did. No hardware exists and none is needed.
```

LEVEL, NOT PULSE

Model the interrupt as a level that you recompute from state (`qemu_set_irq(irq, level)`), never as a pulse. A pulse can be lost, and worse, it hides driver bugs: a driver that forgets to clear the interrupt source works fine against a pulse model and locks the machine up on real hardware. The model should be as unforgiving as the silicon.

How it shows up

Symptom	Cause
Device does not appear in `info qtree`	Not in `meson.build`, or `CONFIG_` not enabled, or not rebuilt
Driver never probes	`compatible` string mismatch — check the dumped DTB
Reads return zero	Wrong base address, or the region size is smaller than the offset you are reading
Guest hangs on the first access	`valid.min_access_size` excludes the access the driver made
Interrupt storm	Level modelled but the driver's clear path does not actually lower it
Interrupt fires once, never again	Modelled as a pulse, or `acme_update_irq` not called after a state change
Registers wrong after `loadvm`	No `VMStateDescription`, or a field missing from it
Byte access from the guest behaves oddly	`impl` and `valid` access sizes inconsistent
Guest kernel panics probing your device	Model faulting on an unknown offset instead of logging and returning zero
Works in `-device` form, not on the machine	The dynamic sysbus node has a generic `compatible`; add a proper node in the machine

Check yourself

- ✓ Give three situations where writing the device model comes before the driver.
- ✓ Name the three things a QOM type declaration needs and the four lifecycle callbacks.
- ✓ Explain why the parent state struct must be the first member.
- ✓ Say what belongs in `instance_init` and what belongs in `realize`.
- ✓ Explain the difference between `valid` and `impl` access sizes.
- ✓ Explain why an unknown register offset must not fault.
- ✓ Explain why the interrupt must be modelled as a level, and what bug a pulse model hides.
- ✓ Say what `VMStateDescription` is for and what breaks without it.
- ✓ Test a device model from the QEMU monitor before writing any driver.
- ✓ Add a device tree node so a real driver's `compatible` string matches.

QEMU with KVM on real hardware

Switching from TCG to KVM changes one flag and everything else: speed goes up a hundredfold, timing becomes meaningful, and every debugging tool that depended on QEMU seeing each instruction stops working. This chapter covers the switch, what you gain, what you lose, and how to set up a machine that serves both.

Making the switch

```
# The requirement: guest architecture == host architecture, and
# the CPU must have reached EL2 at boot (virt chapter 3).

$ ls -l /dev/kvm
crw-rw---- 1 root kvm 10, 232 /dev/kvm
$ sudo usermod -aG kvm $USER      # then log out and back in

$ dmesg | grep -i kvm
[    0.512430] kvm [1]: Hyp mode initialized successfully
[    0.512461] kvm [1]: VHE mode initialized successfully

# TCG, for reference:
$ qemu-system-aarch64 -M virt -cpu cortex-a57 -m 2G -nographic \
    -kernel Image -append "console=ttyAMA0"

# KVM. Three changes:
$ qemu-system-aarch64 -M virt,gic-version=host -cpu host \
    -accel kvm -smp 4 -m 2G -nographic \
    -kernel Image -append "console=ttyAMA0"

#   -accel kvm            use the hardware
#   -cpu host             pass the real CPU through. Any other
#                         -cpu value under KVM either fails or
#                         silently gives you the host CPU anyway
#                         - KVM cannot emulate a different core.
#   gic-version=host      match the real interrupt controller.
#                         A mismatch fails at startup.

# Fall back automatically, for a script that must work on both:
-accel kvm -accel tcg
# QEMU tries them in order and uses the first that initialises.
```

What you gain and lose

	TCG	KVM
Speed	10–50x slower than native	Near native
Cross-architecture	Yes	No
`-d in_asm`, `-d exec`, `-d cpu`	Works	**Nothing** — QEMU never sees the instructions
TCG plugins	Works	**Unavailable**
`-icount`, record/replay, reverse debugging	Works	**Unavailable**

	TCG	KVM
GDB stub	Full	Works, but breakpoints use hardware debug registers and are limited in number
Watchpoints	Unlimited, software	Limited to the CPU's watchpoint registers
`-d int`, `-d mmu`	Full detail	Only what KVM traps
`--trace` on device models	Works	Works — device models still run in QEMU
Monitor `info registers`, `x`, `savevm`	Works	Works
Timing realism	Meaningless	Roughly meaningful
Race reproduction	Poor — ordering is too strong	Real
Emulated CPU features	`-cpu max` gives you anything	Only what the silicon has

USE BOTH, DELIBERATELY

Develop under TCG on your laptop, where `-d exec`, plugins and reverse debugging exist and where you can pretend to have an SoC that does not. Validate under KVM on real arm64 hardware, where timing is real and races reproduce. A bug found only under KVM is a timing bug; a bug found only under TCG is usually a logic bug you got lucky about on hardware. Both are worth finding.

Setting up an arm64 host

```
# Options, cheapest first:
#   Raspberry Pi 5 / Orange Pi 5 - works, slow-ish, ~$80
#   Apple silicon Mac + Asahi Linux or a Linux VM under
#      Virtualization.framework (nested, see below)
#   An Ampere/Graviton cloud instance - the easiest path;
#      c7g/t4g on AWS, or Oracle's free-tier Ampere
#   Any arm64 server board

# 1. Confirm EL2. THIS IS THE ONE THAT FAILS.
$ dmesg | grep -i 'CPU.*started at'
[    0.000000] CPU: All CPU(s) started at EL2       # good
[    0.000000] CPU: All CPU(s) started at EL1       # no KVM,
                                                     # ever
# On a Raspberry Pi, EL2 requires:
$ grep -q '^arm_64bit=1' /boot/firmware/config.txt
$ echo 'arm_control=0x200' | sudo tee -a /boot/firmware/config.txt
# (older firmwares; newer ones start at EL2 by default)

# 2. Packages
$ sudo apt install qemu-system-arm qemu-utils \
      bridge-utils libvirt-daemon-system virtinst

# 3. Permissions
$ sudo usermod -aG kvm,libvirt $USER

# 4. Hugepages, worth doing (virt chapter 21)
$ echo 2048 | sudo tee /proc/sys/vm/nr_hugepages
$ echo 'vm.nr_hugepages=2048' | sudo tee -a /etc/sysctl.conf

# 5. Memlock limit, needed for passthrough
$ sudo tee /etc/security/limits.d/kvm.conf <<'EOF'
@kvm  soft  memlock  unlimited
@kvm  hard  memlock  unlimited
EOF

# 6. Verify end to end
$ qemu-system-aarch64 -M virt,gic-version=host -cpu host \
    -accel kvm -smp 2 -m 1G -nographic \
    -kernel Image -append "console=ttyAMA0"
# Kernel boot in under a second = KVM is working. Twenty
# seconds = you are still on TCG.
```

Nesting, so you can develop hypervisors

```
# To run KVM INSIDE a guest (virt chapter 20), the guest needs
# EL2:

$ qemu-system-aarch64 -M virt,virtualization=on \
    -cpu host,el2=on -accel kvm -smp 4 -m 4G ...

# Inside that guest:
$ dmesg | grep -i 'started at'
[    0.000000] CPU: All CPU(s) started at EL2
$ ls /dev/kvm
# ...and you can run a third-level VM.

# On the HOST, nested support must be enabled:
#   kernel command line: kvm-arm.mode=nested
# and the hardware needs FEAT_NV2 for it to be usable rather
# than merely possible.

# Under TCG there is no such restriction - -cpu max always has
# EL2, and nested virtualisation "works" at TCG speed. That is
# often the right way to develop a hypervisor: correctness
# under TCG with full tracing, performance under KVM later.

$ qemu-system-aarch64 -M virt,virtualization=on,secure=on \
    -cpu max -accel tcg -smp 2 -m 2G -nographic \
    -kernel my-hypervisor.elf -s -S
# EL3, EL2, S-EL2, single-steppable, fully traceable, on a
# laptop. No hardware in the world gives you that.
```

libvirt, when you have more than a couple of VMs

```
# Hand-written command lines stop scaling around the third VM.
# libvirt gives you persistence, autostart, networking and a
# stable API - and it is just generating the same QEMU command
# line underneath.

$ virt-install \
    --name test-arm64 \
    --memory 2048 --vcpus 4 \
    --arch aarch64 --machine virt \
    --cpu host-passthrough \
    --boot uefi \
    --disk path=/var/lib/libvirt/images/test.qcow2,size=20 \
    --network network=default,model=virtio \
    --graphics none --console pty,target_type=serial \
    --os-variant debian12 \
    --location http://deb.debian.org/debian/dists/bookworm/main/installer-arm64/

$ virsh list --all
$ virsh start test-arm64
$ virsh console test-arm64          # Ctrl-] to leave
$ virsh edit test-arm64             # the XML
$ virsh dumpxml test-arm64

# See the command line libvirt actually built - useful when you
# need to reproduce something by hand:
$ virsh domxml-to-native qemu-argv --domain test-arm64

# Pin vCPUs, for latency work:
$ virsh vcpupin test-arm64 0 4
$ virsh emulatorpin test-arm64 8-11

# Hugepages, in the XML:
#   <memoryBacking><hugepages/></memoryBacking>
```

Confirming you are actually getting KVM speed

```
# The three-second check: boot time.
$ time qemu-system-aarch64 -M virt,gic-version=host -cpu host \
    -accel kvm -smp 4 -m 2G -nographic -kernel Image \
    -append "console=ttyAMA0 panic=1" -no-reboot
# under a second to userspace = KVM

# Confirm from inside the guest:
$ dmesg | grep -i 'paravirt\|hypervisor\|KVM'
$ lscpu | grep -i hypervisor
Hypervisor vendor:  KVM

# Exit rate - the number that predicts performance (virt
# chapter 21):
$ sudo perf kvm --host stat live

# Compare like for like:
$ sysbench cpu --threads=4 run          # in the guest
$ sysbench cpu --threads=4 run          # on the host
# Within 5% = KVM working properly. 50x slower = TCG.

# The most common cause of "KVM is slow": it is not KVM.
$ ps aux | grep qemu | grep -o 'accel [a-z]*'
```

MIGRATION AND `-CPU HOST`

`-cpu host` exposes the exact silicon, so a VM started on one CPU model cannot migrate to another. If migration matters, choose a named CPU model that both machines support and accept the lost features. If it does not — which is the case for all development work — use `host` and get everything.

How it shows up

Symptom	Cause
`Could not access KVM kernel module: Permission denied`	Not in the `kvm` group, or you did not log out after being added
`KVM not supported for this target`	Guest and host architectures differ
`kvm [1]: HYP mode not available`	Booted at EL1; firmware consumed EL2
Startup fails with a GIC error	`gic-version` does not match the host — use `host`
Guest is slow despite `-accel kvm`	Check it actually initialised; QEMU may have fallen back to TCG if you listed both
`-d exec` produces nothing	Expected under KVM. Switch to TCG for that investigation
Plugins fail to load	Also expected under KVM
Too many breakpoints	KVM uses hardware debug registers; there are only a handful
Guest cannot see a CPU feature	Under KVM you get the real silicon only; use TCG with `-cpu max`
Migration refused	`-cpu host` across dissimilar machines, or a passed-through device
Nested KVM unavailable in a guest	`virtualization=on` and `el2=on` missing, or host nesting not enabled

Check yourself

- ✓ Give the three command-line changes needed to move from TCG to KVM.
- ✓ Explain why `-cpu host` is effectively mandatory under KVM.
- ✓ List five debugging capabilities you lose under KVM.
- ✓ Give a rule for which accelerator to use for which class of bug.
- ✓ Determine whether an arm64 machine can run KVM at all, and say what to check first.
- ✓ Explain what `-accel kvm -accel tcg` does.
- ✓ Configure a guest that can itself run KVM.
- ✓ Explain why developing a hypervisor under TCG can be better than under KVM.
- ✓ Verify in three ways that a running guest is actually accelerated.
- ✓ Explain the trade-off `-cpu host` imposes on migration.

Recipes: one command line per track

A reference card. Each recipe is a complete, working command line for one kind of work on this site, with the reason for every non-obvious option. Copy, adjust the paths, run.

ASSUMPTIONS

All recipes assume `qemu-system-aarch64` 8.x or newer, a cross toolchain, and an `Image` plus `initramfs.cpio.gz` built as in chapter 5 and chapter 6. Add `-accel kvm -cpu host -M virt,gic-version=host` on an arm64 host to any of them.

ARM architecture track: exception levels and system registers

```
#!/bin/sh
# Bare-metal payload, all exception levels available, stopped
# for the debugger.
qemu-system-aarch64 \
  -M virt,secure=on,virtualization=on,gic-version=3 \
  -cpu max \
  -smp 1 -m 512M -nographic \
  -kernel payload.elf \
  -d int,mmu,guest_errors,unimp -D qemu.log \
  -s -S

#   secure=on         EL3 exists -> you can write monitor code
#   virtualization=on EL2 exists -> you can write hypervisor code
#   -cpu max          every architectural feature: SVE, MTE,
#                     pointer auth, FEAT_NV2, S-EL2
#   -d int            EVERY exception, with ESR/ELR/FAR. This is
#                     the flag that makes this track teachable.
#   -s -S             stopped, GDB on :1234

# then:
$ aarch64-none-elf-gdb payload.elf \
    -ex 'target remote :1234' -ex 'layout regs' -ex 'break _start'
```

Linux kernel and driver track

```
#!/bin/sh
# Kernel plus initramfs, module loading, GDB, and a shared
# directory so you can rebuild a module without repacking.
KDIR=${KDIR:-$HOME/work/linux}

qemu-system-aarch64 \
  -M virt -cpu cortex-a57 -smp 2 -m 1G -nographic \
  -kernel $KDIR/arch/arm64/boot/Image \
  -initrd initramfs.cpio.gz \
  -append "console=ttyAMA0 earlycon nokaslr root=/dev/ram0 rw" \
  -fsdev local,id=fs0,path=$PWD/share,security_model=none \
  -device virtio-9p-device,fsdev=fs0,mount_tag=share \
  -netdev user,id=n0,hostfwd=tcp::2222-:22 \
  -device virtio-net-device,netdev=n0 \
  -object rng-random,filename=/dev/urandom,id=rng0 \
  -device virtio-rng-device,rng=rng0 \
  -d guest_errors,unimp -D qemu.log \
  -s

#   nokaslr           so GDB symbols match (chapter 11)
#   9p share          rebuild a module on the host, insmod it in
#                     the guest, no repacking
#   virtio-rng        without it, early boot blocks on entropy

# In the guest:
#   mount -t 9p -o trans=virtio,version=9p2000.L share /mnt
#   insmod /mnt/mydriver.ko
# On the host:
#   gdb-multiarch $KDIR/vmlinux -ex 'target remote :1234' \
#     -ex "source $KDIR/vmlinux-gdb.py" -ex 'lx-symbols'
```

Virtualisation track: nested, with everything visible

```
#!/bin/sh
# A guest that can itself run KVM, under TCG so that every
# instruction is traceable.
qemu-system-aarch64 \
  -M virt,virtualization=on,gic-version=3,its=on \
  -cpu max \
  -smp 4 -m 4G -nographic \
  -kernel Image \
  -append "console=ttyAMA0 earlycon kvm-arm.mode=nested" \
  -drive file=rootfs.ext4,if=none,format=raw,id=hd0 \
  -device virtio-blk-device,drive=hd0 \
  -netdev user,id=n0,hostfwd=tcp::2222-:22 \
  -device virtio-net-device,netdev=n0 \
  --trace 'kvm_*' --trace 'virtio_*' -D trace.log

#   -cpu max provides FEAT_NV2 even though no laptop has it
#   its=on   needed for PCIe MSI-X inside the guest

# On an arm64 host, the fast version:
#   -M virt,virtualization=on,gic-version=host \
#   -cpu host,el2=on -accel kvm
```

OP-TEE and TrustZone track

```
#!/bin/sh
# TF-A at EL3, OP-TEE at S-EL1, Linux at EL1, with the secure
# world's console on a second UART.
qemu-system-aarch64 \
  -M virt,secure=on,virtualization=on,gic-version=3 \
  -cpu max -smp 2 -m 1G -nographic \
  -bios bl1.bin \
  -device loader,file=fip.bin,addr=0x40100000 \
  -semihosting-config enable=on,target=native \
  -serial mon:stdio \
  -serial file:secure-world.log \
  -netdev user,id=n0 -device virtio-net-device,netdev=n0

#   -bios bl1.bin     TF-A's first stage. NOT -kernel: we are
#                     the firmware now (chapter 5)
#   fip.bin           the Firmware Image Package: BL2, BL31,
#                     BL32 (OP-TEE) and BL33 (U-Boot/Linux)
#   semihosting       TF-A on QEMU uses it to load the FIP
#   two -serial       first = ttyAMA0 = normal world
#                     second = the SECURE world's console. Every
#                     TA panic and trace line lands there.

# The OP-TEE build system generates this for you:
#   cd optee/build && make run
# and the two consoles appear in separate windows. See the
# OP-TEE track's chapter 4 for the full build.
```

Device-model development

```
#!/bin/sh
# Your own QEMU build, your own device, full tracing on both
# sides of the boundary.
QEMU=$HOME/opt/qemu/bin/qemu-system-aarch64

$QEMU \
  -M virt -cpu cortex-a57 -m 512M -nographic \
  -kernel Image -initrd initramfs.cpio.gz \
  -append "console=ttyAMA0 earlycon" \
  -device acme-widget \
  --trace 'acme_widget_*' \
  --trace 'memory_region_ops_read' \
  --trace 'memory_region_ops_write' \
  -d guest_errors,unimp -D dev.log \
  -s

#   memory_region_ops_* traces EVERY MMIO access QEMU
#   dispatched, for every device - so "is my device being
#   touched at all" is answered without any device-specific
#   instrumentation (chapter 12).
```

Fast iteration: overlay plus snapshot

```
#!/bin/sh
# Golden image untouched; every run disposable; snapshot before
# the expensive setup.
[ -f work.qcow2 ] || \
  qemu-img create -f qcow2 -b golden.qcow2 -F qcow2 work.qcow2

qemu-system-aarch64 \
  -M virt -cpu cortex-a57 -smp 4 -m 2G -nographic \
  -kernel Image \
  -drive file=work.qcow2,if=none,id=hd0,cache=unsafe \
  -device virtio-blk-device,drive=hd0 \
  -append "console=ttyAMA0 root=/dev/vda rw" \
  -monitor unix:/tmp/hmp.sock,server=on,wait=off \
  -qmp unix:/tmp/qmp.sock,server=on,wait=off

#   cache=unsafe   10x faster and safe HERE because the overlay
#                  is disposable. Never on anything you keep.

# Reset to pristine:  rm work.qcow2 && rerun
# Snapshot:  echo savevm ready | socat - UNIX-CONNECT:/tmp/hmp.sock
# Restore:   echo loadvm ready | socat - UNIX-CONNECT:/tmp/hmp.sock
```

CI: boot, run a test, exit with a status

```
#!/bin/sh
# Headless, bounded, detects panics, returns a real exit code.
set -e
timeout 300 qemu-system-aarch64 \
  -M virt -cpu cortex-a57 -smp 2 -m 1G \
  -nographic -no-reboot \
  -kernel Image -initrd test-initramfs.cpio.gz \
  -append "console=ttyAMA0 panic=-1 rdinit=/run-tests.sh" \
  -device pvpanic-pci \
  -serial mon:stdio \
  | tee test.log

grep -q "ALL TESTS PASSED" test.log || { echo "FAIL"; exit 1; }
grep -q "Kernel panic"     test.log && { echo "PANIC"; exit 1; }
echo OK

#   -no-reboot      a reset ends the run instead of looping
#   panic=-1        panic reboots immediately -> with -no-reboot,
#                   QEMU exits. A panic becomes a fast failure
#                   rather than a 300-second timeout.
#   pvpanic-pci     QEMU emits a GUEST_PANICKED QMP event too
#   timeout 300     the outer bound. Always have one.

# The test script inside the initramfs ends with:
#   echo "ALL TESTS PASSED"
#   poweroff -f
```

User-mode: run one cross-compiled binary

```
# No VM, no kernel, no rootfs. The fastest way to run an
# aarch64 test suite on an x86 machine.

$ qemu-aarch64 -L /usr/aarch64-linux-gnu ./my-test

# Transparently, via binfmt:
$ sudo apt install qemu-user-static binfmt-support
$ ./my-test              # the kernel routes it to qemu-aarch64

# Under GDB:
$ qemu-aarch64 -g 1234 -L /usr/aarch64-linux-gnu ./my-test &
$ gdb-multiarch ./my-test -ex 'target remote :1234'

# With instruction counting, to compare two implementations
# deterministically:
$ qemu-aarch64 -plugin libinsn.so -d plugin ./my-test

# Emulate a CPU with features your host lacks:
$ qemu-aarch64 -cpu max ./sve-test
```

The flag cheat sheet

Flag	Reach for it when
`-nographic`	Always, for headless work. Ctrl-A c for the monitor, Ctrl-A x to quit
`-s -S`	You want to debug from instruction zero
`-d int`	The guest hangs, resets, or dies silently. *Start here*
`-d guest_errors,unimp`	Always, during bring-up
`-D file`	Every time you use `-d`
`--trace 'memory_region_ops_*'`	"Is my device being accessed?"
`-M virt,dumpdtb=x.dtb`	"Why is my device not probing?"
`-monitor stdio` / Ctrl-A c	Anything is wrong and you want `info registers`
`-snapshot`	You are about to break the disk image
`-icount shift=5`	A race that will not reproduce
`-no-reboot -no-shutdown`	You need to inspect the machine after it dies
`-nodefaults`	You want exactly the machine you specified and nothing more
`-accel kvm -cpu host`	Same architecture and you want speed
`-cpu max`	You need a feature no hardware you own has
`-semihosting-config enable=on`	Bare-metal code that wants host file or console access

How it shows up

Symptom	First thing to try
No output at all	Add `earlycon`; check `console=ttyAMA0` and `-nographic`
Hangs somewhere in boot	`-d int -D log` and read the last exception

Symptom	First thing to try
Device not probing	`dumpdtb` and check the `compatible` and `reg`
Cannot quit QEMU	Ctrl-A x; if the terminal eats Ctrl-A, add `-echr 0x05`
Guest dies and takes the evidence with it	`-no-reboot -no-shutdown`, then `info registers`
Breakpoints never hit	`nokaslr`, and check the symbols match the running build
Painfully slow	You are on TCG. Expected on a foreign architecture
Works today, not tomorrow	Unversioned machine type or an unpinned QEMU; pin both

Check yourself

- ✓ Write, from memory, the command line for a Linux kernel plus initramfs with GDB attached.
- ✓ Give the two machine options that provide EL3 and EL2, and say which track needs each.
- ✓ Explain why the OP-TEE recipe uses `-bios` rather than `-kernel`.
- ✓ Explain what the second `-serial` is for in the OP-TEE recipe.
- ✓ Give the three flags that turn a hung CI job into a fast failure.
- ✓ Explain why `cache=unsafe` is correct in the overlay recipe and nowhere else.
- ✓ Name the first flag to reach for when a guest hangs, and why.
- ✓ Set up a 9p share and use it to iterate on a kernel module without repacking.
- ✓ Run a cross-compiled binary under user-mode emulation, with a debugger.

TRACK

OP-TEE & trusted applications

The open trusted OS, end to end: boot flow, core internals, the two GlobalPlatform APIs, and three projects ending in a firmware TPM with its own client.

25 chapters

What OP-TEE is and what it is for

OP-TEE is a small operating system that runs in the ARM secure world and hosts isolated applications. Its purpose is narrow and worth stating precisely: to keep a handful of operations correct even when the main operating system running beside it has been completely compromised.

The threat model, stated properly

```
WHAT OP-TEE DEFENDS AGAINST

  a compromised Linux kernel
  a compromised bootloader (after the point of measurement)
  a malicious or buggy application with root
  an attacker with a debugger on the normal world
  someone reading the eMMC out of a dead phone

WHAT IT DOES NOT DEFEND AGAINST

  physical attacks on the SoC - decapping, laser fault
    injection, microprobing
  a compromised EL3 (TF-A). EL3 is above OP-TEE.
  a compromised boot ROM or fused-in keys
  side channels it has not been hardened against -
    cache timing, power analysis, Spectre-class leaks
  a bug in your own trusted application. A TA is
    PRIVILEGED code; a bug there is worse than a bug in
    Linux, not better.

The last one is the important one. Moving code into the
secure world does not make it secure. It makes it
PRIVILEGED. If the code is wrong, you have moved the
vulnerability somewhere harder to patch and more valuable
to attack.
```

THE RULE FOR WHAT BELONGS IN A TA

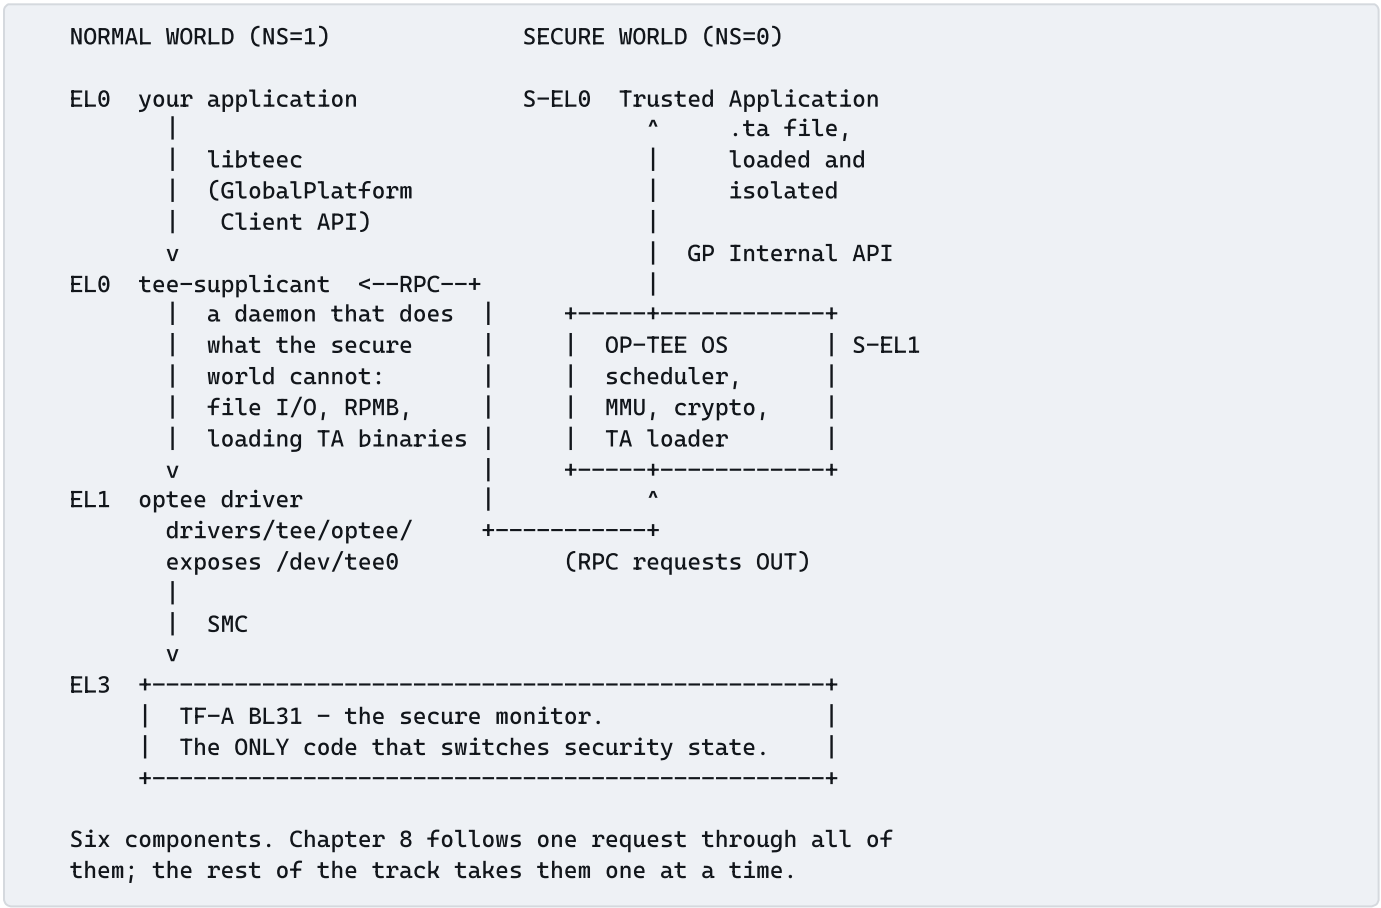
Put in the secure world only what must be protected from the normal world, and as little of it as possible. A key that must never leave: yes. The policy that decides when to use it: yes, if the policy is security-relevant. The parsing of an untrusted network protocol: absolutely not — parse in Linux and pass a validated, fixed-size structure across.

What it actually does for you

Use	What the secure world holds	Real product
Device key storage	A private key that never exists in normal-world memory	Android Keymint, device attestation
Secure boot continuation	Verification keys and the measurement chain	Every phone
Firmware TPM	A full TPM 2.0 in software, with its own NV storage	Windows on ARM, Microsoft's fTPM — chapter 22
Payment and biometrics	The fingerprint template and the matching decision	Samsung Pay, Android BiometricPrompt

Use	What the secure world holds	Real product
DRM	Content keys and the decrypt path	Widevine L1, PlayReady SL3000
Secure display and input	A framebuffer and touch panel Linux cannot see	Transaction confirmation screens
Anti-rollback	Monotonic counters in RPMB	Firmware version enforcement
Automotive / industrial	Key material for CAN authentication, immobilisers	SHE/HSM replacements

The stack, named



OP-TEE among its peers

TEE	Origin	API	Notes
OP-TEE	Linaro, open source	GlobalPlatform	The one to learn on. Upstream Linux driver, runs on QEMU, well documented
Trusty	Google / Android	Its own	C++ and Rust TAs. Keymint and Gatekeeper on Pixel
QSEE / QTEE	Qualcomm	Proprietary	The largest deployed base by volume
TEEGRIS	Samsung	Proprietary	Exynos, replacing Kinibi
Kinibi	Trustonic	Proprietary	Long history on Samsung
Hafnium	Arm, open source	FF-A	Not a TEE — an S-EL2 partition manager that *hosts* TEEs (virt chapter 19)

They differ in API and TA packaging. The *architecture* — a normal-world driver, a monitor, a trusted OS, isolated applications, and RPC back to a supplicant — is identical in all of them. Learn it once here and the proprietary ones become readable.

What this track builds

```
Chapters 2–4    get it RUNNING. Boot flow, build system,
                OP-TEE on QEMU with xtest passing.

Chapters 5–10   how it WORKS. Core architecture, secure
                memory, shared memory, the SMC ABI, RPC,
                the Linux driver.

Chapters 11–14  how you PROGRAM it. Both GlobalPlatform
                APIs, TA lifecycle, building and signing.

Chapters 15–20  what makes it USEFUL and SAFE. Secure
                storage, crypto, rollback protection,
                pseudo TAs, debugging, and how to write a
                TA that survives a hostile client.

Chapters 21–23  THREE PROJECTS:
                  21  a secure key store – a client and a
                      TA you write from nothing
                  22  a firmware TPM as a trusted
                      application – architecture and build
                  23  driving that fTPM from Linux, with
                      PCRs, sealing and attestation

Chapter 24      porting OP-TEE to hardware that is not QEMU.

Prerequisites: TrustZone from the isolation and platform
security track, chapters 8–13, and enough QEMU to
run a two-console machine (QEMU chapter 4).
```

> **READ `SEC-08` TO `SEC-13` FIRST IF TRUSTZONE IS NEW**
>
> This track assumes you know what the NS bit is, what EL3 does, and roughly what an SMC is. The isolation and platform security track covers that ground; chapters 8 through 13 there are the exact prerequisite, and chapter 12 is a compressed version of the stack diagram above.

Four things people get wrong

Belief	Reality
"Code in a TA is secure"	Code in a TA is *privileged*. A buffer overflow there is exploitable at S-EL0 with access to key material
"The TEE protects against physical attack"	Only as far as the SoC's own countermeasures go. TrustZone is not a secure element
"TAs are fast because they are close to the hardware"	Every invocation is a world switch and an SMC. TAs are for infrequent, valuable operations
"OP-TEE can be added to a product later"	It needs a secure memory carve-out, a TZASC configuration, a signing key infrastructure and a boot chain. It is a platform decision, not a feature

How it shows up

Symptom	Cause
A design review asks "why is this in the TEE?"	Usually the right question. If the answer is not "it must be protected from a compromised kernel", it belongs in Linux

Symptom	Cause
The TA is enormous	Something that should have been parsed or filtered in the normal world was moved wholesale
Throughput requirement cannot be met	Per-invocation world-switch cost; batch the work or move the bulk data path out
Vendor TEE has no documentation	Expected. The architecture is the same — map it onto the OP-TEE model in this chapter
Security team rejects the TA	Usually parameter validation (chapter 20) or a rollback gap (chapter 17)

Check yourself

- ✓ State what OP-TEE defends against and name three things it does not.
- ✓ Explain why "in the secure world" and "secure" are not the same claim.
- ✓ Give the rule for deciding whether code belongs in a TA.
- ✓ Name the six components of the stack and what each contributes.
- ✓ Give three shipping products built on a TEE and say what each protects.
- ✓ Name three TEEs other than OP-TEE and say what they have in common architecturally.
- ✓ Explain why Hafnium is not a TEE.
- ✓ Say why adding a TEE to an existing product is a platform decision.

The boot flow: TF-A, BL32 and the handover

OP-TEE does not boot itself. It is loaded, verified and started by ARM Trusted Firmware as one stage of a chain that begins in mask ROM and ends in Linux. Understanding which stage owns what — and which one you are debugging — is the difference between a productive afternoon and a wasted one.

The chain

```
POWER ON
   |
   v
+-----------------------------------------------------+
| BL1   boot ROM, or TF-A's BL1 stage.        EL3     |
|       In mask ROM on real silicon - IMMUTABLE.      |
|       Contains the root of trust: a hash of the public  |
|       key that signs everything after it.           |
|       Loads and VERIFIES BL2.                       |
+-----------------------------------------------------+
   |
   v
+-----------------------------------------------------+
| BL2   trusted boot firmware.                EL1 (S)   |
|       Initialises DRAM. Parses the FIP. Loads and       |
|       verifies BL31, BL32 and BL33 into their places.   |
|       Builds the parameter structures each will need.   |
|       Then hands control to BL31.                   |
+-----------------------------------------------------+
   |
   v
+-----------------------------------------------------+
| BL31  EL3 RUNTIME FIRMWARE - the secure monitor.  EL3   |
|       This one NEVER EXITS. It stays resident for the   |
|       life of the system, and every world switch, every |
|       PSCI call and every SMC goes through it.          |
|                                                         |
|       Its boot job: initialise the GIC, install the     |
|       SMC vector table, then run each "runtime service" |
|       initialiser - including the OP-TEE dispatcher     |
|       (opteed), which starts BL32.                      |
+-----------------------------------------------------+
   |
   +--> BL32 = OP-TEE OS                        S-EL1
   |         initialises: MMU, secure memory pools, the
   |         crypto library, the TA loader, its own
   |         console. Registers its entry vectors with
   |         BL31. Returns "I am ready".
   |
   v
+-----------------------------------------------------+
| BL33  NON-SECURE bootloader - U-Boot or UEFI.  EL2/EL1 |
|       The normal world starts here. From this moment    |
|       the secure world only runs when called.           |
+-----------------------------------------------------+
   |
   v
Linux -> optee driver probes -> /dev/tee0 appears
      -> tee-supplicant starts
      -> your client can open a session
```

> **BL31 IS THE ONE THAT STAYS**
> BL1 and BL2 run once and are gone. BL33 hands off to an OS. **BL31 and BL32 remain resident for ever.** Every SMC your client issues, for the rest of the machine's uptime, enters BL31 and is routed by it. When something goes wrong at the world boundary, BL31 is where it goes wrong.

The FIP: how the images travel together

```
# A Firmware Image Package is a simple container: a header, a
# table of contents keyed by UUID, and the images.

$ fiptool info fip.bin
Trusted Boot Firmware BL2: offset=0xB0, size=0x54D8, cmdline="--tb-fw"
EL3 Runtime Firmware BL31: offset=0x5588, size=0xC1C8, cmdline="--soc-fw"
Secure Payload BL32 (Trusted OS): offset=0x11750, size=0x3E000, cmdline="--tos-fw"
Secure Payload BL32 Extra1: offset=0x4F750, size=0x5A000, cmdline="--tos-fw-extra1"
Secure Payload BL32 Extra2: offset=0xA9750, size=0x21000, cmdline="--tos-fw-extra2"
Non-Trusted Firmware BL33: offset=0xCA750, size=0x9B240, cmdline="--nt-fw"

# The three BL32 entries are OP-TEE's three parts:
#   tos-fw         tee-header_v2.bin   - the header
#   tos-fw-extra1  tee-pager_v2.bin    - the pageable part
#   tos-fw-extra2  tee-pageable_v2.bin - the rest
# (see chapter 5 for why OP-TEE is split this way)

# Building one:
$ fiptool create \
    --tb-fw         bl2.bin \
    --soc-fw        bl31.bin \
    --tos-fw        tee-header_v2.bin \
    --tos-fw-extra1 tee-pager_v2.bin \
    --tos-fw-extra2 tee-pageable_v2.bin \
    --nt-fw         u-boot.bin \
    fip.bin

# Unpack one you were given, to see what a vendor shipped:
$ fiptool unpack fip.bin --out ./extracted/

# TF-A's own build does this for you:
$ make -C arm-trusted-firmware PLAT=qemu \
       BL32=$OPTEE/out/arm-plat-vexpress/core/tee-header_v2.bin \
       BL32_EXTRA1=.../tee-pager_v2.bin \
       BL32_EXTRA2=.../tee-pageable_v2.bin \
       BL33=$UBOOT/u-boot.bin \
       SPD=opteed all fip
```

SPD: how BL31 learns about OP-TEE

```
/* SPD = Secure Payload Dispatcher. A TF-A runtime service that
   knows how to talk to a particular trusted OS. Build TF-A
   with SPD=opteed and you get the OP-TEE one.               */

  services/spd/opteed/
      opteed_main.c     initialisation and the SMC handler
      opteed_common.c   context save/restore
      teesmc_opteed.h   the private ABI between TF-A and OP-TEE

/* At boot: */

  1. BL31 runs its runtime service initialisers.
  2. opteed_setup() finds BL32's entry point from the
     parameters BL2 left behind.
  3. It builds a secure execution context and ERETs into
     OP-TEE's entry point, at S-EL1.
  4. OP-TEE initialises, then calls back:
         SMC(TEESMC_OPTEED_RETURN_ENTRY_DONE, vectors_addr)
     handing BL31 a table of entry points:
         fast_smc_entry     std_smc_entry
         cpu_on_entry       cpu_off_entry
         cpu_resume_entry   cpu_suspend_entry
         fiq_entry          system_off_entry  system_reset_entry
  5. opteed records them and returns to BL2's caller, which
     proceeds to BL33.

/* At RUNTIME, every OP-TEE SMC from the normal world: */

     normal world executes SMC
        -> EL3 vector table
        -> BL31 decodes the function ID
        -> it is in the Trusted OS range -> opteed
        -> opteed SAVES the non-secure context
        -> restores the secure context
        -> ERETs to std_smc_entry in OP-TEE
        ... OP-TEE does the work ...
        -> OP-TEE executes SMC(TEESMC_OPTEED_RETURN_CALL_DONE)
        -> opteed restores the non-secure context
        -> ERET back to the normal world

/* Two SMCs and two full context switches per invocation. That
   is the floor on TA call latency, and it is why TAs are for
   valuable operations rather than hot loops.               */
```

Verified boot: what "chain of trust" means concretely

```
Each stage verifies the next BEFORE executing it.

BL1  holds ROTPK_HASH in ROM or eFuses  (immutable)
  |    reads the Trusted Key certificate from the FIP
  |    checks: SHA256(public key in cert) == ROTPK_HASH
  |    checks: cert signature verifies with that key
  |    -> now the trusted world key is trusted
  v
BL2  its hash is in a certificate signed by that key
  |    BL2 in turn verifies BL31, BL32 and BL33 the same way
  v
BL31, BL32, BL33

Turn it on:  make ... TRUSTED_BOARD_BOOT=1 GENERATE_COT=1 \
                      ARM_ROTPK_LOCATION=devel_rsa \
                      ROT_KEY=plat/arm/board/common/rotpk/arm_rotprivk_rsa.pem

MEASURED boot is different and complementary:
  each stage HASHES the next and EXTENDS the hash into a
  PCR (a TPM register, or OP-TEE's own measurement store)
  before running it. Nothing is blocked; instead the record
  of what ran can later be attested.

  Verified boot  : refuses to run unexpected software
  Measured boot  : runs it, but records what it was

Chapter 22's fTPM is where measured boot lands: the PCRs
that record the boot chain live inside a trusted
application.
```

> **DEVELOPMENT KEYS ARE DEVELOPMENT KEYS**
> Every OP-TEE and TF-A tree ships a test signing key, and every tutorial uses it — including this one. It is public. A device shipped with the default key can have arbitrary trusted applications loaded onto it by anyone. Key management is covered in chapter 14; the short version is that the private key belongs in an HSM and never in a repository.

Watching the boot

```
$ qemu-system-aarch64 -M virt,secure=on,virtualization=on \
    -cpu max -smp 2 -m 1057 -nographic \
    -bios bl1.bin \
    -semihosting-config enable=on,target=native \
    -serial mon:stdio -serial file:secure.log

NOTICE:  Booting Trusted Firmware
NOTICE:  BL1: v2.10.0(release)
NOTICE:  BL1: Booting BL2
NOTICE:  BL2: v2.10.0(release)
NOTICE:  BL1: Booting BL31
NOTICE:  BL31: v2.10.0(release)
I/TC: Reserved shared memory is enabled
I/TC: Dynamic shared memory is enabled
I/TC: Normal World virtualization support is disabled
I/TC: Asynchronous notifications are disabled
I/TC: OP-TEE version: 4.1.0
I/TC: Primary CPU switching to normal world boot
U-Boot 2024.01
...
[    2.114] optee: probing for conduit method.
[    2.115] optee: revision 4.1 (0e3e9c9d)
[    2.118] optee: dynamic shared memory is enabled
[    2.130] optee: initialized driver

# The "I/TC:" lines are OP-TEE's own console - Trusted Core.
# With two -serial they go to secure.log; with one they
# interleave with everything else, which is confusing but
# occasionally useful for ordering.

# Prefixes you will see all track long:
#   I/TC:  info,  trusted core (OP-TEE OS)
#   E/TC:  error, trusted core
#   D/TC:  debug, trusted core
#   I/TA:  from inside a trusted application
#   F/TC:  flow tracing (very verbose)
```

How it shows up

Symptom	Cause
Stops after `BL1: Booting BL2`	BL2 missing from the FIP, or DRAM init failed, or a verification failure with `TRUSTED_BOARD_BOOT`
No `I/TC:` lines at all	TF-A built without `SPD=opteed`, or BL32 not in the FIP
`BL31: Error initializing runtime service opteed_fast`	BL32 entry point wrong, or OP-TEE built for a different platform
OP-TEE prints then the machine hangs	Secure memory carve-out overlaps normal-world RAM (chapter 6)
Linux boots but `/dev/tee0` is absent	`CONFIG_OPTEE` off, or no `optee` node in the device tree, or OP-TEE never registered
`optee: api uid mismatch`	Linux driver and OP-TEE versions incompatible
Verified boot fails on a rebuilt image	The certificate chain was not regenerated — `GENERATE_COT=1`
Works with `-kernel`, not with `-bios`	Different worlds entirely; with `-bios` you supply everything (QEMU chapter 5)

Symptom	Cause
Secondary CPUs hang	PSCI handled by BL31, but OP-TEE's `cpu_on_entry` not registered

Check yourself

- ✓ Name the five boot stages, the exception level each runs at, and which two stay resident.
- ✓ Say what BL2 does that BL31 does not.
- ✓ Explain what a FIP is and list the entries an OP-TEE build puts in one.
- ✓ Explain what an SPD is and how BL31 learns OP-TEE's entry points.
- ✓ Count the SMCs and context switches in one TA invocation.
- ✓ Distinguish verified boot from measured boot, and say which one blocks.
- ✓ Explain the risk of shipping with the default signing key.
- ✓ Identify from a boot log whether OP-TEE initialised, and where its console output goes.
- ✓ Name three reasons `/dev/tee0` might be missing after a successful OP-TEE boot.

The source tree and the build system

An OP-TEE build is nine git repositories, three toolchains and a makefile that coordinates them. The `repo` manifest exists because assembling that by hand is unreasonable — but you should know what it assembled, because the day something breaks you will be building one component alone.

The nine repositories

Repository	What it is	Runs at
`optee_os`	The trusted OS itself. The core of everything in this track	S-EL1
`optee_client`	`libteec` and `tee-supplicant`	Normal world EL0
`optee_test`	`xtest` — the GlobalPlatform conformance suite plus OP-TEE's own tests	Both worlds
`optee_examples`	Small, complete CA+TA pairs. Copy these to start a project	Both worlds
`trusted-firmware-a`	BL1, BL2, BL31 — the monitor	EL3
`u-boot` or `edk2`	BL33, the normal-world bootloader	EL2/EL1
`linux`	The kernel, with `drivers/tee/optee/`	EL1
`buildroot`	Builds the normal-world root filesystem and packages the client tools	host
`build`	The makefiles that tie all of the above together, one `.mk` per platform	host

Getting the tree

```
$ sudo apt install -y \
    android-tools-adb android-tools-fastboot autoconf automake \
    bc bison build-essential ccache cscope curl device-tree-compiler \
    expect flex ftp-upload gdisk git libattr1-dev libcap-ng-dev \
    libfdt-dev libftdi-dev libglib2.0-dev libgmp3-dev libhidapi-dev \
    libmpc-dev libncurses5-dev libpixman-1-dev libslirp-dev \
    libssl-dev libtool make mtools netcat ninja-build python3-cryptography \
    python3-pip python3-pyelftools python3-serial python-is-python3 \
    rsync unzip uuid-dev xdg-utils xterm xz-utils zlib1g-dev

$ pip3 install --user pycryptodome pyelftools cryptography

# repo, Google's multi-repository tool
$ mkdir -p ~/bin
$ curl https://storage.googleapis.com/git-repo-downloads/repo > ~/bin/repo
$ chmod a+x ~/bin/repo && export PATH=~/bin:$PATH

$ mkdir -p ~/optee && cd ~/optee
$ repo init -u https://github.com/OP-TEE/manifest.git -m qemu_v8.xml
$ repo sync -j$(nproc) --no-clone-bundle

# Other manifests, for other targets:
#   qemu_v8.xml     QEMU AArch64 virt   <-- this track
#   qemu.xml        QEMU AArch32
#   rpi3.xml        Raspberry Pi 3
#   hikey.xml  hikey960.xml  imx.xml  stm32mp1.xml  rockpi4.xml
#   default.xml     everything

# Pin a release, so the tree does not move under you:
$ repo init -u https://github.com/OP-TEE/manifest.git \
       -m qemu_v8.xml -b 4.1.0
$ repo sync -j$(nproc)

$ repo forall -c 'echo "$REPO_PATH $(git describe --always)"'
optee_os        4.1.0
optee_client    4.1.0
trusted-firmware-a  v2.10.0
linux           v6.6
...
```

Building

```
$ cd ~/optee/build

# 1. Toolchains - downloads aarch64 and arm cross compilers
$ make toolchains -j2

# 2. Everything. First build: 20-60 minutes.
$ make -j$(nproc)

# 3. Run it. Opens three windows.
$ make run
# or, if you have no X display:
$ make run-only CFG_TEE_CORE_LOG_LEVEL=2

# In the QEMU console that appears:
(qemu) c

# In the "Normal World" window, log in as root, then:
# ls /dev/tee*
/dev/tee0  /dev/teepriv0
# xtest -t regression 1001
# optee_example_hello_world
```

Make target	Does
`make`	Build everything and assemble the images
`make run`	Build if needed, then launch QEMU with three consoles
`make run-only`	Launch without rebuilding
`make optee-os`	Just the trusted OS
`make optee-client`	Just libteec and tee-supplicant
`make optee-examples`	Just the example CA/TA pairs
`make buildroot`	Repack the root filesystem — needed after changing anything that lands in it
`make arm-tf`	Just TF-A
`make linux`	Just the kernel
`make optee-os-clean`	Clean one component
`make -n run`	Print the QEMU command line without running it — *very* useful

> **THE REBUILD TRAP THAT COSTS EVERYONE AN HOUR**
>
> Changing a TA or a client and running `make optee-examples` is not enough. The binaries live in the root filesystem image, which must be repacked:

```
# The correct incremental cycle after editing a TA or CA:
$ make optee-examples
$ make buildroot          # <-- repacks rootfs.cpio.gz
$ make run-only

# Or in one line, which is what you should alias:
$ make optee-examples buildroot run-only

# Same for the trusted OS itself:
$ make optee-os
$ make run-only           # OP-TEE is in the FIP, not the
                          # rootfs, so no buildroot needed

# Prove which binary is actually running - the timestamp is in
# the boot log:
I/TC: OP-TEE version: 4.1.0-12-gabc1234 (gcc version 12.2.0)
      #1 Fri Aug 22 10:14:02 UTC 2026 aarch64
```

The configuration flags that matter

```
# OP-TEE is configured with CFG_ variables, passed on the make
# command line or set in the platform's conf.mk.

$ make CFG_TEE_CORE_LOG_LEVEL=3 \
       CFG_TEE_TA_LOG_LEVEL=4 \
       CFG_CORE_ASLR=n \
       CFG_UNWIND=y \
       DEBUG=1

#   CFG_TEE_CORE_LOG_LEVEL   0 none 1 error 2 info 3 debug 4 flow
#   CFG_TEE_TA_LOG_LEVEL     the same, for TAs
#   CFG_CORE_ASLR=n          turn off ASLR so addresses in a
#                            panic dump match your ELF
#   CFG_UNWIND=y             stack traces on panic
#   DEBUG=1                  -O0 and assertions
#   CFG_CORE_SANITIZE_UNDEFINED=y   UBSan inside OP-TEE
#   CFG_CORE_SANITIZE_KADDRESS=y    KASAN inside OP-TEE

# Feature flags you will meet:
#   CFG_RPMB_FS=y            secure storage in RPMB (ch. 15)
#   CFG_RPMB_TESTKEY=y       use a test RPMB key - DEV ONLY
#   CFG_REE_FS=y             secure storage via the normal world
#   CFG_WITH_PAGER=y         demand-paged OP-TEE (ch. 5)
#   CFG_WITH_LPAE=y          large physical addresses
#   CFG_NS_VIRTUALIZATION=y  OP-TEE aware of normal-world VMs
#   CFG_SECURE_DATA_PATH=y   secure buffers for media
#   CFG_TA_ASLR=y            ASLR inside TAs
#   CFG_ATTESTATION_PTA=y    remote attestation pseudo-TA

# See everything a platform defines:
$ make -C optee_os PLATFORM=vexpress-qemu_armv8a \
       CFG_TEE_CORE_LOG_LEVEL=2 -n | head -40
$ cat optee_os/core/arch/arm/plat-vexpress/conf.mk
```

Where things end up

```
~/optee/
  build/                          the makefiles you invoke

    core/                         the trusted OS
      arch/arm/plat-vexpress/     the QEMU platform
      arch/arm/kernel/            entry, exceptions, boot
      arch/arm/mm/                the MMU and memory maps
      kernel/                     scheduler, TA loading, threads
      drivers/                    OP-TEE's own device drivers
      pta/                        pseudo TAs (ch. 18)
      crypto/                     the crypto layer
      tee/                        the GP Internal API
    ldelf/                        the TA loader/linker
    ta/                           the TA development kit
    lib/libutee/                  the GP Internal API library
    out/arm-plat-vexpress/
      core/tee.elf                <-- the OP-TEE binary, with
                                      symbols. Point GDB here.
      core/tee-header_v2.bin      the FIP pieces
      core/tee-pager_v2.bin
      core/tee-pageable_v2.bin
      export-ta_arm64/            <-- THE TA DEV KIT. Your own
                                      TA builds against this.
  optee_client/out/export/
      usr/lib/libteec.so
      usr/sbin/tee-supplicant
      usr/include/tee_client_api.h
  optee_examples/                 copy one of these to start
  out/                            assembled images
      bin/                        Image, rootfs.cpio.gz
  out-br/                         buildroot's tree
      target/lib/optee_armtz/     <-- WHERE .ta FILES GO
                                      <uuid>.ta, loaded on
                                      demand by tee-supplicant

# The two paths to remember:
#   optee_os/out/arm-plat-vexpress/export-ta_arm64/
#       the dev kit your TA Makefile includes
#   /lib/optee_armtz/ on the TARGET
#       where a signed .ta must be installed to be found
```

Building one component alone

```
# When you are iterating on the trusted OS, the top-level make
# is slow. Go direct:

$ cd ~/optee/optee_os
$ make -j$(nproc) \
    PLATFORM=vexpress-qemu_armv8a \
    CFG_ARM64_core=y \
    CROSS_COMPILE=aarch64-linux-gnu- \
    CROSS_COMPILE_core=aarch64-linux-gnu- \
    CROSS_COMPILE_ta_arm64=aarch64-linux-gnu- \
    CFG_TEE_CORE_LOG_LEVEL=3 \
    DEBUG=1

# The client library alone:
$ cd ~/optee/optee_client
$ cmake -B build -DCMAKE_INSTALL_PREFIX=./out/export \
        -DCMAKE_C_COMPILER=aarch64-linux-gnu-gcc
$ cmake --build build && cmake --install build

# A TA on its own, against the dev kit (ch. 14):
$ export TA_DEV_KIT_DIR=~/optee/optee_os/out/arm-plat-vexpress/export-ta_arm64
$ export CROSS_COMPILE=aarch64-linux-gnu-
$ make -C my_ta

# Find every CFG_ that affects the build:
$ grep -rn "CFG_MY_FEATURE" optee_os/ | head
```

How it shows up

Symptom	Cause
`repo sync` fails	Network, or a manifest branch that no longer exists. Pin a release tag
Build fails on a Python module	`pycryptodome`, `pyelftools` or `cryptography` missing from `pip3`
Changes to a TA have no effect	`make buildroot` not run — the old `.ta` is still in the image
Changes to OP-TEE core have no effect	Stale FIP; run the top-level `make` or rebuild the FIP
`make run` opens nothing	No X display; use `make run-only` and read `make -n run` for the command line
TA build cannot find headers	`TA_DEV_KIT_DIR` unset or pointing at the wrong architecture
Two toolchains, wrong one used	Three separate `CROSS_COMPILE*` variables — core, TA arm32, TA arm64
Panic addresses do not match the ELF	ASLR — rebuild with `CFG_CORE_ASLR=n`
Out of disk	A full tree with objects is 20–30 GB

Check yourself

- ✓ Name the nine repositories and what each contributes.
- ✓ Explain what `repo` does and why a manifest is pinned to a tag.
- ✓ Give the correct incremental build cycle after editing a TA, and say why.
- ✓ Give the cycle after editing the trusted OS, and say why it differs.
- ✓ Name five `CFG_` flags and what each changes.

- ✓ Say where a signed `.ta` must be installed on the target.
- ✓ Say what `TA_DEV_KIT_DIR` points at and why a TA build needs it.
- ✓ Build `optee_os` alone with debug logging enabled.
- ✓ Determine from a boot log exactly which build is running.

Bringing OP-TEE up on QEMU

This is the chapter to get right before any other. A working QEMU setup with two consoles — one per world — and a passing `xtest` is the foundation for everything that follows, and every later failure is much easier to diagnose when you have seen the system work once.

The fast path

```
$ cd ~/optee/build
$ make -j$(nproc)
$ make run

# Three windows appear:
#   1. QEMU's own monitor
#   2. "Normal World" - Linux
#   3. "Secure World" - OP-TEE's console
#
# In window 1:
(qemu) c

# In window 2, after Linux boots (login: root, no password):
buildroot login: root
# ls /dev/tee*
/dev/tee0  /dev/teepriv0
# ps | grep supplicant
  123 root     tee-supplicant
# optee_example_hello_world
Invoking TA to increment 42
TA incremented value to 43

# WATCH WINDOW 3 while that runs. You will see the TA load and
# print. That split - one console per world - is the single
# most useful property of this setup, and the reason to invest
# in getting it working.

# The full conformance suite:
# xtest
Test ID: ...
...
23807 subtests of which 0 failed
78 test cases of which 0 failed
0 test case was skipped
TEE test application done!

# A quick subset, when you only want a sanity check:
# xtest -l 0
# xtest -t regression 1001 1004 1013
```

Without a graphical display

```
# make run needs X for the three xterms. On a headless machine
# or over SSH, drive QEMU yourself.

$ cd ~/optee/build
$ make -n run-only | tr ' ' '\n' | grep -v '^$' | head -40
# ...prints the exact qemu invocation. Adapt it:

$ cd ~/optee
$ qemu-system-aarch64 \
    -nographic \
    -serial mon:stdio \
    -serial file:secure.log \
    -smp 2 \
    -machine virt,secure=on,mte=off,gic-version=3,virtualization=false \
    -cpu max,sve=off \
    -d unimp -semihosting-config enable=on,target=native \
    -m 1057 \
    -bios bl1.bin \
    -initrd rootfs.cpio.gz \
    -kernel Image -no-acpi \
    -append 'console=ttyAMA0,38400 keep_bootcon root=/dev/vda2'

# The two -serial lines are the point:
#   first  -> ttyAMA0 -> the NORMAL world, on your terminal
#   second -> the SECURE world's console -> secure.log
#
# Watch the secure console live in another terminal:
$ tail -f secure.log

# To have both on one screen without X, use tmux:
$ tmux new-session -d 'cd ~/optee/build && make run-only'
$ tmux split-window -h 'tail -f ~/optee/secure.log'
$ tmux attach
```

> **TWO CONSOLES OR NOTHING**
>
> OP-TEE reports TA panics, parameter errors, allocation failures and its own assertions on the secure console — never on the normal-world one. A client that returns `TEEC_ERROR_GENERIC` tells you nothing; the secure console tells you exactly which assertion failed and where. If you set up only one thing from this chapter, set up the second serial port.

Reading the boot log

```
# Secure world (secure.log):
I/TC:
I/TC: Non-secure external DT found
I/TC: Reserved shared memory is enabled
I/TC: Dynamic shared memory is enabled
I/TC: Normal World virtualization support is disabled
I/TC: Asynchronous notifications are disabled
I/TC: OP-TEE version: 4.1.0 (gcc version 12.3.0) #1 ... aarch64
I/TC: WARNING: This OP-TEE configuration might be insecure!
I/TC: WARNING: Please check https://optee.readthedocs.io/...
I/TC: Primary CPU initializing
I/TC: Primary CPU switching to normal world boot

# That WARNING is not noise: it means the build has development
# keys, test RPMB keys, or debug features enabled. Every
# tutorial build shows it. A product build must not.

# Normal world:
[    1.883] optee: probing for conduit method.
[    1.884] optee: revision 4.1 (0e3e9c9d)
[    1.891] optee: dynamic shared memory is enabled
[    1.904] optee: initialized driver

# Four lines, four things confirmed:
#   "probing for conduit method"  the DT has an optee node
#   "revision 4.1"                the SMC handshake worked -
#                                 Linux talked to OP-TEE
#   "dynamic shared memory"       buffer registration will work
#   "initialized driver"          /dev/tee0 now exists

# If any of the four is missing, stop and fix it before writing
# a client.
```

The device tree node

```
/* Linux finds OP-TEE through the device tree. On QEMU the node
   is added by TF-A/QEMU; on real hardware you write it.     */

    firmware {
        optee {
            compatible = "linaro,optee-tz";
            method = "smc";
        };
    };

# Confirm it is there, from inside the guest:
$ ls /proc/device-tree/firmware/optee/
compatible  method  name
$ cat /proc/device-tree/firmware/optee/method
smc

# method = "smc"  bare metal - the driver issues SMC directly
# method = "hvc"  running under a hypervisor that forwards

# Kernel config required:
#   CONFIG_TEE=y
#   CONFIG_OPTEE=y
#   CONFIG_ARM_PSCI_FW=y
$ zcat /proc/config.gz | grep -E 'CONFIG_(TEE|OPTEE)='
CONFIG_TEE=y
CONFIG_OPTEE=y
```

tee-supplicant

```
# Without it, sessions fail with TEEC_ERROR_ITEM_NOT_FOUND,
# because nothing can load the .ta file from the filesystem.
# It is a normal-world daemon (chapter 9 explains why it must
# exist at all).

# Is it running?
$ ps aux | grep [t]ee-supplicant
root  123  tee-supplicant /dev/teepriv0

# Start it by hand:
$ tee-supplicant -d          # daemonise
$ tee-supplicant -f          # foreground, so you see its errors

# Where it looks for trusted applications:
$ ls /lib/optee_armtz/
8aaaf200-2450-11e4-abe2-0002a5d5c51b.ta   # hello_world
f4e750bb-1437-4fbf-8785-8d3580c34994.ta   # aes
...

# The filename IS the UUID. A TA whose UUID does not match its
# filename will never be found.

# systemd unit, on a real distribution:
$ systemctl status tee-supplicant
$ systemctl enable --now tee-supplicant
```

Your first client, from nothing

```
// hello.c - the smallest complete client. Links against
// libteec, talks to the hello_world TA that ships with
// optee_examples.
#include <stdio.h>
#include <string.h>
#include <tee_client_api.h>

#define TA_HELLO_WORLD_UUID \
    { 0x8aaaf200, 0x2450, 0x11e4, \
      { 0xab, 0xe2, 0x00, 0x02, 0xa5, 0xd5, 0xc5, 0x1b} }
#define TA_HELLO_WORLD_CMD_INC_VALUE 0

int main(void)
{
        TEEC_Context   ctx;
        TEEC_Session   sess;
        TEEC_Operation op;
        TEEC_UUID      uuid = TA_HELLO_WORLD_UUID;
        uint32_t       err_origin;
        TEEC_Result    res;

        res = TEEC_InitializeContext(NULL, &ctx);
        if (res != TEEC_SUCCESS) {
                printf("InitializeContext failed 0x%x\n", res);
                return 1;
        }

        res = TEEC_OpenSession(&ctx, &sess, &uuid,
                               TEEC_LOGIN_PUBLIC, NULL, NULL,
                               &err_origin);
        if (res != TEEC_SUCCESS) {
                printf("OpenSession failed 0x%x origin 0x%x\n",
                       res, err_origin);
                TEEC_FinalizeContext(&ctx);
                return 1;
        }

        memset(&op, 0, sizeof op);
        op.paramTypes = TEEC_PARAM_TYPES(TEEC_VALUE_INOUT,
                                         TEEC_NONE,
                                         TEEC_NONE,
                                         TEEC_NONE);
        op.params[0].value.a = 42;

        res = TEEC_InvokeCommand(&sess, TA_HELLO_WORLD_CMD_INC_VALUE,
                                 &op, &err_origin);
        if (res != TEEC_SUCCESS)
                printf("InvokeCommand failed 0x%x origin 0x%x\n",
                       res, err_origin);
        else
                printf("TA returned %u\n", op.params[0].value.a);

        TEEC_CloseSession(&sess);
        TEEC_FinalizeContext(&ctx);
        return 0;
}
```

```
$ aarch64-linux-gnu-gcc -o hello hello.c \
    -I ~/optee/optee_client/out/export/usr/include \
    -L ~/optee/optee_client/out/export/usr/lib \
    -lteec

# Get it into the guest. Easiest: put it in the rootfs and
# repack (chapter 3), or use the shared 9p mount:
$ cp hello ~/optee/out-br/target/root/
$ cd ~/optee/build && make buildroot run-only

# In the guest:
# ./hello
TA returned 43

# And the secure console shows:
D/TC:0 0 tee_ta_init_user_ta_session:1035 Lookup user TA ELF
       8aaaf200-2450-11e4-abe2-0002a5d5c51b (Secure Storage TA)
I/TA: has been called
I/TA: Got value: 42 from NW
I/TA: Increase value to: 43
```

The bring-up checklist

```
Work through these in order. Each one depends on the last.

[ ] 1. TF-A prints "BL31: v2.x"
       -> if not: FIP or build problem (ch. 2)

[ ] 2. Secure console shows "I/TC: OP-TEE version:"
       -> if not: SPD=opteed missing, or BL32 not in the FIP

[ ] 3. Secure console shows "switching to normal world boot"
       -> if not: OP-TEE init failed. Read the lines above it.

[ ] 4. Linux boots to a shell
       -> ordinary kernel debugging (QEMU ch. 5)

[ ] 5. dmesg | grep optee shows all four driver lines
       -> if not: device tree node, or CONFIG_OPTEE

[ ] 6. /dev/tee0 exists
       -> follows from 5

[ ] 7. tee-supplicant is running
       -> if not: start it, check /lib/optee_armtz exists

[ ] 8. optee_example_hello_world works
       -> if not: the .ta is missing, or signed with the
          wrong key

[ ] 9. xtest -l 0 passes
       -> broad sanity

[ ] 10. xtest passes completely
       -> you have a working system. STOP HERE and commit
          the exact versions you used.

Do not start writing your own TA before step 10 passes. A
failure at step 11 with steps 1-10 unverified is
unattributable, and you will spend the afternoon looking in
the wrong place.
```

How it shows up

Symptom	Cause
No secure-world output anywhere	Only one `-serial`; add a second
`make run` does nothing	No X display — use `make run-only` and `make -n run`
QEMU sits doing nothing	It starts paused; type `c` in the monitor
`/dev/tee0` missing	Device tree node absent, `CONFIG_OPTEE` off, or OP-TEE never initialised
`TEEC_ERROR_ITEM_NOT_FOUND` (0xFFFF0008)	TA not in `/lib/optee_armtz`, or `tee-supplicant` not running
`TEEC_ERROR_SECURITY` (0xFFFF000F) on load	TA signed with a key OP-TEE does not trust
`TEEC_ERROR_COMMUNICATION`	`/dev/tee0` exists but the SMC path is broken — check the secure console
Client links but fails at runtime with a missing library	`libteec.so` not in the rootfs; static-link or copy it

Symptom	Cause
Everything works, then stops after a rebuild	`make buildroot` not run — old binaries in the image
`WARNING: This OP-TEE configuration might be insecure`	Expected in development. Never acceptable in a product

Check yourself

- ✓ Get `xtest` passing on QEMU and record the exact versions.
- ✓ Explain what each of the three `make run` windows shows.
- ✓ Set up two serial ports without X and explain why the second one matters.
- ✓ Name the four `optee:` lines in `dmesg` and what each confirms.
- ✓ Write the device tree node OP-TEE needs and say what `method` selects.
- ✓ Explain what `tee-supplicant` does and what fails without it.
- ✓ Say where `.ta` files live and how their filename relates to the UUID.
- ✓ Write and run a client that opens a session and invokes one command.
- ✓ Work through the ten-step bring-up checklist and say why the order matters.
- ✓ Explain what the "might be insecure" warning is telling you.

OP-TEE OS architecture

OP-TEE is a small preemptible kernel with a fixed pool of threads, its own MMU regime, a demand pager, and a strict rule that it never runs unless the normal world asked it to. Those four properties explain almost every behaviour you will observe, including the deadlock in the last section.

The shape of it

```
S-EL0    TA        TA        TA
         |         |         |
         |  SVC (the GP Internal API is a syscall
         |       interface, exactly like Linux's)
         v
+-----------------------------------------------------+
|  OP-TEE CORE                                S-EL1   |
|                                                     |
|   thread pool     N threads, N fixed at build time  |
|   TA manager      load, verify, map, session state  |
|   MMU             one address space per TA          |
|   pager           optional demand paging of core    |
|   crypto          libtomcrypt / mbedTLS, plus       |
|                   hardware accelerator drivers      |
|   drivers         GIC, timer, RNG, RPMB, i2c...     |
|   pseudo TAs      services built into the core      |
|   RPC             asking the normal world for help  |
+-----------------------------------------------------+
         |
         |  SMC
         v
EL3      TF-A BL31

Things OP-TEE deliberately does NOT have:

  no scheduler of its own in the usual sense - the NORMAL
    world schedules it, by choosing when to make an SMC
  no interrupts it services on its own behalf, except its
    own timer and secure interrupts
  no dynamic memory beyond fixed pools
  no filesystem - it asks the normal world (chapter 9)
  no network, no USB, no display, unless a platform adds one

It is closer to a very careful library with an MMU than to
an operating system, and that is deliberate: a small
trusted computing base is the entire product.
```

The thread pool

```
/* OP-TEE has a FIXED number of threads, set at build time:   */

    CFG_NUM_THREADS = 8      /* typical; sometimes 2 or 4      */

/* One thread is occupied for the ENTIRE duration of a normal-
   world call. From the SMC that enters OP-TEE until the SMC
   that returns, that thread belongs to that caller.          */

  normal world calls in       -> a thread is allocated
     TA runs
     TA does secure storage   -> RPC out to tee-supplicant.
                                 THE THREAD IS STILL HELD - it
                                 is suspended waiting for the
                                 normal world to answer.
     TA finishes
  return to normal world      -> thread freed

/* Consequences:

   1. At most CFG_NUM_THREADS concurrent TA invocations,
      system-wide. The 9th caller gets
      TEEC_ERROR_BUSY / OPTEE_SMC_RETURN_ETHREAD_LIMIT and
      libteec retries.

   2. A TA that blocks holds a thread. A TA that blocks
      FOR EVER holds it for ever.

   3. Thread stacks are statically allocated:
        CFG_STACK_THREAD_SIZE   default 8192 bytes
        CFG_STACK_TMP_SIZE      the temporary/abort stack
      8 threads x 8 KB is 64 KB of your secure memory budget,
      before any TA runs.

   4. TA stack size is separate and per-TA:
        TA_STACK_SIZE in the TA's user_ta_header_defines.h    */
```

THE THREAD-EXHAUSTION DEADLOCK

All `CFG_NUM_THREADS` threads are inside OP-TEE, each waiting on an RPC to `tee-supplicant`. `tee-supplicant` is a normal-world process; to service any of them it must be scheduled by Linux. If `tee-supplicant` itself needs to enter OP-TEE — or if the Linux thread that would run it is itself blocked in an OP-TEE call — nothing can make progress. The system hangs with no error anywhere.

Avoid it by: never calling into the TEE from a thread that services the TEE; keeping RPC use out of hot paths; and raising `CFG_NUM_THREADS` so transient bursts do not saturate the pool. It is a design constraint, not a bug to be fixed later.

How a call enters

```
/* core/arch/arm/kernel/thread_spmc.c and entry_a64.S       */

  BL31 ERETs into OP-TEE's vector table at one of:

    fast_smc_entry        a "fast" call - runs to completion
                          with interrupts masked, on the
                          temporary stack, no thread allocated.
                          Used for: version queries, memory
                          config, cache maintenance requests.

    std_smc_entry         a "standard" call - allocates a
                          THREAD, can be preempted by a
                          non-secure interrupt, can make RPCs.
                          Used for: everything that runs a TA.

    fiq_entry             a secure interrupt arrived while the
                          normal world was running

    cpu_on/off/suspend/resume_entry
                          PSCI events forwarded by BL31 so
                          OP-TEE can save and restore per-CPU
                          state

/* The distinction matters. A fast call cannot:
     - allocate memory
     - call a TA
     - make an RPC
     - be interrupted
   It must be short and self-contained. Trying to do real work
   in a fast call is a classic porting mistake and produces
   hangs with interrupts masked.                            */

/* Foreign (non-secure) interrupt handling: while a standard
   call is running, an interrupt destined for the NORMAL world
   causes OP-TEE to save the thread's state and return to the
   normal world with OPTEE_SMC_RETURN_RPC_FOREIGN_INTR. Linux
   services the interrupt, then RESUMES the same thread. The TA
   never notices. This is why a long-running TA does not block
   Linux's timekeeping.                                      */
```

Memory layout

```
TEE_RAM  - OP-TEE's own memory. Secure, and never mapped
           into any TA.
   TEE_RAM_RX   code, read+execute
   TEE_RAM_RW   data, heap, thread stacks
   TEE_RAM_RO

TA_RAM   - the pool TA memory is allocated from. Each TA
           gets its own mapping; TAs cannot see each other.

SHM      - non-secure shared memory. The ONLY region both
           worlds can touch. Chapter 7.

+-----------------------------------------------+
|  TEE_RAM      core code + data      SECURE     |
+-----------------------------------------------+
|  TA_RAM       TA code + data        SECURE     |
+-----------------------------------------------+
|  SHM          shared buffers        NON-SECURE |
+-----------------------------------------------+

Each TA runs at S-EL0 with its own translation tables. A TA
cannot:
  read another TA's memory
  read TEE_RAM
  read normal-world memory except a buffer explicitly
    passed to it
  execute anything it did not bring

The isolation between TAs is exactly the isolation between
Linux processes, implemented by the same hardware. That is
the point of running TAs at S-EL0 rather than linking them
into the core.
```

The pager

```
/* CFG_WITH_PAGER=y makes OP-TEE demand-page its own code.   */

  Why: secure on-chip SRAM is small - often 128-256 KB - and
  OP-TEE plus crypto plus drivers does not fit. But external
  DRAM is not trustworthy: an attacker with bus access could
  read or modify it.

  Solution: keep a small resident part in SRAM, and page the
  rest in from DRAM, where it is stored ENCRYPTED and
  AUTHENTICATED.

     +--------------------------+
     |  SRAM (secure, on-chip)  |
     |    unpaged core          |
     |    the pager itself      |
     |    page tables           |
     |    a pool of page frames |
     +--------------------------+
              ^  page fault
              |  decrypt + verify + map
              v
     +--------------------------+
     |  DRAM                    |
     |    encrypted pages, each |
     |    with an authentication|
     |    tag                   |
     +--------------------------+

  Cost: a page fault inside OP-TEE now involves AES and a MAC
  check. Measurable, and worth it when the alternative is not
  fitting.

  On QEMU there is plenty of secure DRAM, so the pager is
  usually off. On real SoCs with small secure SRAM it is
  essential. tee-pager_v2.bin and tee-pageable_v2.bin in the
  FIP (chapter 2) are exactly this split.                   */
```

TAs, pseudo TAs and early TAs

	User-mode TA	Pseudo TA	Early TA
Runs at	S-EL0	**S-EL1, inside the core**	S-EL0
Isolated from the core	Yes, by the MMU	**No**	Yes
Where it lives	`/lib/optee_armtz/<uuid>.ta`	Linked into `tee.elf`	Linked into `tee.elf`, extracted at boot
Loaded by	`tee-supplicant`, on demand	Nothing — always there	The core, at boot
Needs the normal world to load	Yes	No	No
Can be updated separately	Yes	No — rebuild OP-TEE	No
A bug means	A crashed TA	**A compromised trusted OS**	A crashed TA

	User-mode TA	Pseudo TA	Early TA
Use when	Almost always	You need core services or must run before the normal world can help	You must work before `tee-supplicant` exists

Default to a user-mode TA. A pseudo TA runs with the trusted OS's full privilege and no memory isolation; the only good reasons are needing a core API that is not exposed to S-EL0, or needing to run before the normal world can load anything. Chapter 18 covers the cases where it is genuinely right.

Reading the source

```
# The files that repay reading, in order:

optee_os/core/arch/arm/kernel/
    entry_a64.S            the vector table. Where every call
                           arrives. Read this first.
    thread.c               the thread pool, suspend/resume
    thread_spmc.c          the SMC-side protocol
    boot.c                 initialisation order

optee_os/core/kernel/
    tee_ta_manager.c       sessions, TA lifecycle, the locking
    ree_fs_ta.c            loading a TA from the normal world
    pseudo_ta.c
    scall.c                the S-EL0 syscall dispatch - the
                           other side of the GP Internal API

optee_os/core/mm/
    core_mmu.c  core_mmu_lpae.c   the core's own mappings
    vm.c                   per-TA address spaces
    pgt_cache.c            page table allocation
    tee_pager.c            the pager

optee_os/core/tee/
    tee_svc*.c             the syscall implementations
    tee_fs*.c              secure storage
    tee_rpmb_fs.c          RPMB

optee_os/ldelf/            the loader that maps a TA - it runs
                           in the TA's own address space,
                           which is an unusual and elegant
                           design

# Find where a GP function is implemented:
$ grep -rn "TEE_AllocateOperation" optee_os/lib/libutee/
$ grep -rn "syscall_cryp_obj_alloc" optee_os/core/
```

How it shows up

Symptom	Cause
Calls fail with `TEEC_ERROR_BUSY` under load	Thread pool exhausted; raise `CFG_NUM_THREADS` or reduce concurrency
Whole system hangs, no error	Thread-exhaustion deadlock — every thread waiting on an RPC that cannot be serviced
TA crashes with a stack dump on the secure console	`TA_STACK_SIZE` too small, or a genuine bug

Symptom	Cause
Core panics with a stack overflow	`CFG_STACK_THREAD_SIZE` too small for deep crypto call chains
Everything hangs with interrupts masked	Real work attempted in a fast SMC
Out of secure memory as TAs are added	Fixed pools; see chapter 6
A pseudo TA bug takes down the whole TEE	By design — it runs at S-EL1 with no isolation
A TA works, then fails only when another TA is busy	Shared thread pool
Paged build is slow	Every fault decrypts and authenticates a page

Check yourself

- ✓ Name the components of the OP-TEE core and three things it deliberately lacks.
- ✓ Explain the fixed thread pool and what happens to the ninth concurrent caller.
- ✓ Explain precisely how the thread-exhaustion deadlock occurs and how to avoid it.
- ✓ Distinguish a fast SMC from a standard one and list what a fast call cannot do.
- ✓ Explain what happens when a normal-world interrupt arrives during a TA invocation.
- ✓ Name the three memory regions and say who can access each.
- ✓ Explain why the pager exists and what it costs.
- ✓ Compare user-mode TAs, pseudo TAs and early TAs across privilege, isolation and update.
- ✓ Give two legitimate reasons to write a pseudo TA.
- ✓ Locate, in the source tree, where an SMC first arrives and where a GP syscall is dispatched.

Secure memory: carve-outs, TZASC and pools

The secure world's memory is secure because a hardware filter in the interconnect refuses non-secure transactions to it. Configuring that filter correctly — and making sure the normal world never believes it owns the same addresses — is the single most common cause of a board that boots on QEMU and dies on real silicon.

What makes memory secure

```
Every bus transaction on an ARM SoC carries an extra signal:
AxPROT[1], the NS bit. 0 = secure, 1 = non-secure.

  CPU at S-EL1  -> issues transactions with NS=0
  CPU at EL1    -> NS=1
  a DMA master  -> whatever the SMMU/interconnect assigns it

A filter in the path enforces a region policy:

  TZASC / TZC-400   for DRAM
  TZPC              for peripherals
  vendor XPU / RPU  the same idea, different name
                    (see the isolation track, ch. 17-20)

+--------+     +---------------------+     +-----------+
|  CPU   |---->|  TZC-400            |---->|   DRAM    |
| NS bit |     |  region 0: 0-1GB    |     |           |
+--------+     |    NS read/write OK |     +-----------+
               |  region 1: 1GB-1.5GB|
               |    SECURE ONLY      |
               |    NS access ->     |
               |    DECERR or RAZ/WI |
               +---------------------+

A non-secure read of a secure region returns zeros or an
external abort, depending on how the filter is configured.
It NEVER returns the data.

Crucially: this is enforced in the INTERCONNECT, not in the
CPU. So it also stops a DMA-capable peripheral that the
normal world programmed. That is the whole reason it exists
rather than relying on the MMU.
```

WHO PROGRAMS THE FILTER

Early secure firmware — BL2 or BL31 — configures the TZASC before any non-secure code runs, and then *locks* it. If the normal world could reconfigure it, the protection would be worthless. On a real port, the TZASC setup lives in your platform's TF-A code and is one of the first things to get right.

The memory map, concretely

```
/* optee_os/core/arch/arm/plat-vexpress/platform_config.h    */

#define TZDRAM_BASE   0x0e100000     /* secure DRAM starts     */
#define TZDRAM_SIZE   0x03000000     /* 48 MB                  */

#define TEE_RAM_START      TZDRAM_BASE
#define TEE_RAM_VA_SIZE    (4 * 1024 * 1024)    /* core: 4 MB  */

#define TA_RAM_START  (TEE_RAM_START + TEE_RAM_VA_SIZE)
#define TA_RAM_SIZE   (TZDRAM_SIZE - TEE_RAM_VA_SIZE)
                                    /* TAs: the remaining
                                       44 MB                  */

#define TEE_SHMEM_START  0x42000000  /* NON-secure shared      */
#define TEE_SHMEM_SIZE   0x00200000  /* 2 MB                   */

/* Which produces:

   0x40000000  +--------------------------+
               |  normal-world DRAM       |  Linux lives here
   0x0e100000  +--------------------------+  <- must NOT
               |  TEE_RAM   4 MB SECURE   |     overlap!
   0x0e500000  +--------------------------+
               |  TA_RAM   44 MB SECURE   |
   0x11100000  +--------------------------+
   ...
   0x42000000  +--------------------------+
               |  SHM  2 MB NON-SECURE    |  both worlds
   0x42200000  +--------------------------+

   THE INVARIANT: the normal world's device tree must describe
   its RAM as excluding every secure region, and the TZASC must
   protect exactly the regions OP-TEE claims. Three descriptions
   of the same memory - platform_config.h, the TZASC
   programming, and the non-secure device tree - and all three
   must agree.

   Disagreement produces:
     DT includes secure RAM -> Linux allocates there -> reads
        return zeros -> random corruption, unattributable
     TZASC protects less than OP-TEE claims -> the secure world
        is NOT actually protected, and everything appears to
        work perfectly
     TZASC protects more -> OP-TEE or Linux takes an external
        abort on a legitimate access                          */
```

```
# Confirm the normal world's view excludes secure regions:
$ cat /proc/iomem | head
40000000-41ffffff : System RAM
42200000-7fffffff : System RAM
# note the gap at 0x42000000-0x421fffff - that is the shared
# memory carve-out, correctly excluded.

$ dtc -I fs -O dts /sys/firmware/devicetree/base | grep -A3 'memory@'
    memory@40000000 {
        reg = <0x00 0x40000000 0x00 0x40000000>;
        device_type = "memory";
    };

# And reserved regions:
$ ls /sys/firmware/devicetree/base/reserved-memory/
$ cat /proc/device-tree/reserved-memory/*/reg | xxd

# The definitive test on real hardware: from Linux, try to read
# an address OP-TEE claims. It must return zeros or fault, not
# data.
$ sudo devmem2 0x0e100000 w
# /dev/mem access to a secure address should not show you
# OP-TEE's code. If it does, the TZASC is not configured.
```

The allocation pools

```
/* OP-TEE has no general heap. It has a small number of pools,
   each sized at build time, each for one purpose.           */

  TEE_RAM        the core's own .text/.data/.bss plus
                 - thread stacks: CFG_NUM_THREADS x
                                  CFG_STACK_THREAD_SIZE
                 - the core heap: CFG_CORE_HEAP_SIZE
                                  (default 65536 bytes)
                   used by malloc() inside the core

  TA_RAM         one region per loaded TA, containing its
                 code, data, stack and heap. Sized per TA by
                 its own header:
                     TA_STACK_SIZE
                     TA_DATA_SIZE
                 A TA is mapped here when loaded and unmapped
                 when the last session closes.

  SHM            the non-secure shared memory pool. Chapter 7.

  SDP            secure data path buffers, if
                 CFG_SECURE_DATA_PATH=y - for media pipelines
                 where a decoder must write into memory the
                 normal world cannot read.

/* Budgeting, worked:

     TZDRAM_SIZE                          48 MB
   - TEE_RAM (core code+data+heap+stacks)  4 MB
   = TA_RAM                               44 MB

     one TA with TA_DATA_SIZE = 1 MB, TA_STACK_SIZE = 32 KB,
     plus its code, mapped with 4 KB granularity
       -> roughly 1.2 MB resident while a session is open

     so ~35 concurrent TA instances before TA_RAM is exhausted.

   In practice you hit CFG_NUM_THREADS (8 concurrent calls)
   long before you hit TA_RAM - but a TA that leaks sessions
   will find this limit, and the error is
   TEE_ERROR_OUT_OF_MEMORY at session open.                  */
```

```
# Watch memory usage. Requires CFG_WITH_STATS=y.
$ xtest --stats

TEE stats:
  Pool: TEE_RAM
    Allocated: 1048576, Max allocated: 1187840, Size: 4194304
  Pool: TA_RAM
    Allocated: 2097152, Max allocated: 4194304, Size: 46137344

# "Max allocated" is the high-water mark - the number that
# tells you whether you are close to the limit. Watch it
# during a stress run, not at idle.

# From the secure console, with debug logging:
D/TC:0   tee_mm_alloc:...  0x0e500000 size 0x120000
D/TC:0   tee_mm_free:...
```

> **SIZING IS A PLATFORM DECISION MADE ONCE**
> `TZDRAM_SIZE` must be chosen before the TZASC is programmed and before the non-secure device tree is written. Growing it later means changing firmware, the device tree and possibly a signed boot image in lockstep. Size it generously at the start of a project — secure DRAM is cheap; a field update to three components is not.

Secure data path, briefly

```
/* The problem: a DRM video pipeline decodes protected content.
   The decoded frames must reach the display without the normal
   world ever being able to read them - but the decoder and the
   display controller are normal-world-programmed hardware.

   The answer: buffers in SECURE memory, with those two
   specific DMA masters permitted to access them by the SMMU
   and the TZASC, while the CPU in the normal world is not.

     CFG_SECURE_DATA_PATH=y
     CFG_TEE_SDP_MEM_BASE / CFG_TEE_SDP_MEM_SIZE

   Linux allocates from a dmabuf heap backed by that region;
   the buffers can be passed to the decoder and the display but
   never mapped by an application.

   $ ls /dev/dma_heap/
   linux,cma  system  sdp

   This is the mechanism behind Widevine L1 and PlayReady
   SL3000, and it is the reason "secure playback" requires
   platform support rather than just a TA.                  */
```

How it shows up

Symptom	Cause
Boots on QEMU, random corruption on hardware	Non-secure device tree includes secure RAM; Linux allocated in it
Linux reads zeros from a region it thinks it owns	Same — the TZASC is doing its job
Everything works but a security review fails	TZASC not configured at all; the "secure" region is readable from Linux
External abort during OP-TEE boot	TZASC protects a region OP-TEE needs to access as non-secure, or vice versa
`TEE_ERROR_OUT_OF_MEMORY` opening a session	TA_RAM exhausted — leaked sessions, or `TZDRAM_SIZE` too small
Core panics allocating in a deep call chain	`CFG_CORE_HEAP_SIZE` too small
TA panics with a stack overflow under load	`TA_STACK_SIZE` too small
Works with one TA, fails when a second is loaded	TA_RAM budget
Secure playback shows a black screen	SDP region not configured, or the display controller's StreamID not permitted
TZASC settings lost after suspend/resume	Not restored on resume — the filter is per-boot state that PSCI resume must re-establish

Check yourself

- ✓ Explain what physically makes a region of DRAM secure, and where the enforcement happens.
- ✓ Say why enforcement in the interconnect matters more than enforcement in the MMU.
- ✓ Name who programs the TZASC and why it must be locked.
- ✓ Name the three descriptions of memory that must agree, and give a failure for each disagreement.
- ✓ Draw the QEMU memory map with TEE_RAM, TA_RAM and SHM.
- ✓ Name the four allocation pools and what each holds.
- ✓ Budget TA_RAM for a given `TZDRAM_SIZE` and TA footprint.
- ✓ Explain why "max allocated" is the number to watch.
- ✓ Verify from Linux that a secure region is genuinely inaccessible.
- ✓ Explain what a secure data path is for and why it needs platform support.

Shared memory across the boundary

Every byte that crosses between worlds crosses through non-secure shared memory, because the normal world cannot be given a pointer into secure memory and the secure world will not trust a pointer the normal world chose. How that buffer is allocated, registered and validated is the security-critical seam of the whole design.

Why it must be non-secure

```
Consider the two alternatives and why both fail.

1. The TA writes directly into normal-world memory at an
   address the client supplied.

   -> The client controls the address. It can name kernel
      memory, another process's memory, a device register,
      or OP-TEE's own memory. The TA, running with secure
      privilege, would perform the write.
   -> This is the single most dangerous class of TEE bug,
      and it is why every address must be VALIDATED, not
      merely used.

2. The client reads from secure memory the TA allocated.

   -> Impossible. The TZASC refuses (chapter 6).

So: a third region, non-secure, agreed by both sides.

  +--------------------+
  |  SHM               |  NS=1, so:
  |  non-secure        |    normal world: read/write
  |  shared memory     |    secure world: read/write
  +--------------------+

The secure world can read and write non-secure memory - it
is more privileged, not less. The restriction is one-way.

And therefore: ANYTHING IN SHM IS ATTACKER-CONTROLLED. The
client can change it at any moment, including between the
TA's validation of a value and the TA's use of it.
```

THE DOUBLE-FETCH RULE

Shared memory can change under you. A TA that reads a length field, checks it, and then reads it again to use it has a time-of-check-to-time-of-use bug: the client can change the value in between, from another thread, and defeat the check. **Copy everything you will act on into secure memory first, then validate the copy, then use only the copy.** This is elaborated in chapter 20 and it is the rule that matters most in this entire track.

Two kinds of shared memory

	Static / reserved SHM	Dynamic SHM
Where it comes from	A carve-out declared at build time; OP-TEE tells Linux the physical range	Ordinary kernel pages, registered with OP-TEE on demand
Contiguity	Physically contiguous	Scattered pages, described by a page list
Size limit	Fixed at build time (often 2 MB)	Whatever the kernel can pin
Registration cost	None	An SMC per registration
Enabled by	Always	`CFG_CORE_DYN_SHM=y` and driver support
Best for	Small, frequent transfers	Large buffers, or buffers the application already has

```
# Which do you have? The driver says so at probe:
$ dmesg | grep optee
optee: dynamic shared memory is enabled

# Static-only systems say nothing about dynamic, and
# TEEC_RegisterSharedMemory on an arbitrary pointer will fail.
```

Three ways a client provides a buffer

```
/* 1. ALLOCATE - let the TEE choose the memory. Simplest,
      always works, always contiguous.                      */

    TEEC_SharedMemory shm = {
            .size  = 4096,
            .flags = TEEC_MEM_INPUT | TEEC_MEM_OUTPUT,
    };
    res = TEEC_AllocateSharedMemory(&ctx, &shm);
    memcpy(shm.buffer, data, len);

    op.paramTypes = TEEC_PARAM_TYPES(TEEC_MEMREF_WHOLE,
                                     TEEC_NONE, TEEC_NONE,
                                     TEEC_NONE);
    op.params[0].memref.parent = &shm;
    /* ... invoke ... */
    TEEC_ReleaseSharedMemory(&shm);

/* 2. REGISTER - hand the TEE memory you already have. Avoids
      a copy; needs dynamic SHM.                            */

    void *mybuf = malloc(65536);          /* or mmap, or a
                                             dmabuf           */
    TEEC_SharedMemory shm = {
            .buffer = mybuf,
            .size   = 65536,
            .flags  = TEEC_MEM_INPUT,
    };
    res = TEEC_RegisterSharedMemory(&ctx, &shm);
    /* the kernel pins the pages and sends OP-TEE a page list */

/* 3. TEMPORARY - a pointer passed inline; libteec allocates,
      copies in, invokes, copies out, frees. Convenient and it
      COPIES TWICE.                                         */

    op.paramTypes = TEEC_PARAM_TYPES(TEEC_MEMREF_TEMP_INPUT,
                                     TEEC_MEMREF_TEMP_OUTPUT,
                                     TEEC_NONE, TEEC_NONE);
    op.params[0].tmpref.buffer = input;
    op.params[0].tmpref.size   = inlen;
    op.params[1].tmpref.buffer = output;
    op.params[1].tmpref.size   = sizeof output;

/* Use TEMP for small parameters and control messages. Use
   REGISTER for anything large or repeated - a 1 MB buffer
   copied twice per call, at 60 calls a second, is 120 MB/s of
   pure waste.                                              */
```

The parameter model

```
/* Four slots per invocation. Each is a VALUE (two 32-bit
   numbers) or a MEMREF (a buffer), each with a direction.  */

    TEEC_NONE
    TEEC_VALUE_INPUT           a, b: two uint32_t in
    TEEC_VALUE_OUTPUT          two uint32_t out
    TEEC_VALUE_INOUT
    TEEC_MEMREF_TEMP_INPUT     an inline buffer
    TEEC_MEMREF_TEMP_OUTPUT
    TEEC_MEMREF_TEMP_INOUT
    TEEC_MEMREF_WHOLE          all of a registered shm
    TEEC_MEMREF_PARTIAL_INPUT  part of a registered shm
    TEEC_MEMREF_PARTIAL_OUTPUT
    TEEC_MEMREF_PARTIAL_INOUT

    op.paramTypes = TEEC_PARAM_TYPES(TEEC_VALUE_INPUT,
                                     TEEC_MEMREF_TEMP_OUTPUT,
                                     TEEC_NONE,
                                     TEEC_NONE);

/* On the TA side the same four slots arrive, and the TA MUST
   check that it got what it expected: */

TEE_Result TA_InvokeCommandEntryPoint(void *sess, uint32_t cmd,
                                      uint32_t ptypes,
                                      TEE_Param params[4])
{
        uint32_t exp = TEE_PARAM_TYPES(TEE_PARAM_TYPE_VALUE_INPUT,
                                       TEE_PARAM_TYPE_MEMREF_OUTPUT,
                                       TEE_PARAM_TYPE_NONE,
                                       TEE_PARAM_TYPE_NONE);
        if (ptypes != exp)
                return TEE_ERROR_BAD_PARAMETERS;   /* MANDATORY */
        ...
}

/* Skip that check and a client can pass a VALUE where you
   expect a MEMREF. You then read params[1].memref.buffer -
   which is now an arbitrary 64-bit integer the attacker chose,
   dereferenced by code running with secure privilege.

   This is the most common OP-TEE TA vulnerability class, and
   it is prevented by four lines.                            */
```

What the TA must do with a buffer

```
/* The four rules, in order of importance.                    */

/* RULE 1: check the parameter types. Above. */

/* RULE 2: check that the memory is really where it claims. */

    res = TEE_CheckMemoryAccessRights(
                TEE_MEMORY_ACCESS_READ |
                TEE_MEMORY_ACCESS_ANY_OWNER,
                params[1].memref.buffer,
                params[1].memref.size);
    if (res != TEE_SUCCESS)
            return res;

/* This asks OP-TEE: is this pointer, for this length, actually
   a buffer this session was given? It catches a client that
   passed a length larger than the buffer it registered.    */

/* RULE 3: copy before you use. */

    if (params[0].memref.size > MAX_INPUT)
            return TEE_ERROR_SHORT_BUFFER;

    uint8_t local[MAX_INPUT];
    /* ONE read of the shared memory. */
    memcpy(local, params[0].memref.buffer, params[0].memref.size);

    /* validate the COPY, act on the COPY */
    if (!looks_sane(local, params[0].memref.size))
            return TEE_ERROR_BAD_PARAMETERS;
    do_work(local, params[0].memref.size);

/* RULE 4: write output once, at the end, and only on success. */

    if (params[1].memref.size < needed) {
            params[1].memref.size = needed;   /* tell them how
                                                 much          */
            return TEE_ERROR_SHORT_BUFFER;
    }
    memcpy(params[1].memref.buffer, result, needed);
    params[1].memref.size = needed;
    return TEE_SUCCESS;

/* Writing partial results into the output buffer as you go
   leaks intermediate state to the client on the error path -
   and for a crypto TA, intermediate state is often the
   secret.                                                    */
```

THE SHORT-BUFFER PROTOCOL

GlobalPlatform's convention: if the output buffer is too small, set `memref.size` to the size you need and return `TEE_ERROR_SHORT_BUFFER`. The client sees the required size, reallocates and retries. Clients rely on this, so implement it — and note that it means writing to `memref.size` even on the error path, which is the one output write that *is* allowed before success.

Cache and coherency

```
/* Shared memory is Normal, cacheable memory on both sides, and
   the interconnect is coherent on any SoC that runs OP-TEE. So
   ordinarily NO cache maintenance is required.

   Where it does bite:

   1. CFG_CORE_UNMAP_CORE_AT_EL0 / different mapping
      attributes on the two sides. If OP-TEE maps SHM
      non-cacheable and Linux maps it cacheable, you have a
      mismatched-attribute alias (virtualisation chapter 7) and
      the behaviour is architecturally unpredictable.

   2. A non-coherent DMA master reading the buffer. Then
      whoever set it up must clean/invalidate:
          TEE_CacheClean(buf, len);
          TEE_CacheInvalidate(buf, len);
          TEE_CacheFlush(buf, len);
      These are OP-TEE extensions, available only if
      CFG_CACHE_API=y - they are not standard GlobalPlatform.

   3. Suspend/resume, where a cache may be powered down with
      dirty lines.

   The normal case needs nothing. If you find yourself adding
   cache maintenance to make a bug go away, you probably have
   an attribute mismatch instead - fix that.               */
```

How it shows up

Symptom	Cause
`TEEC_ERROR_BAD_PARAMETERS`	`paramTypes` disagree between client and TA — the check is working
`TEEC_ERROR_OUT_OF_MEMORY` allocating shared memory	Static SHM pool exhausted; use dynamic SHM or a smaller buffer
`TEEC_RegisterSharedMemory` fails	Dynamic SHM not enabled on this platform
TA panics dereferencing a pointer	Missing `paramTypes` or `TEE_CheckMemoryAccessRights` check — this is the vulnerability, caught late
Intermittent wrong results under concurrency	Double-fetch: the TA read shared memory twice and the client changed it in between
Client sees partial output after an error	TA wrote into the output buffer before it succeeded
Client's retry loop never terminates	Short-buffer protocol not implemented — the TA did not set `memref.size`
Throughput far below expectations	`TEMP` memrefs copying large buffers twice per call
Data corruption only with a DMA-capable accelerator	Non-coherent master with no cache maintenance
Works on QEMU, corrupts on hardware	Mismatched cacheability attributes between the two worlds' mappings

Check yourself

- ✓ Explain why the shared region must be non-secure, and why the restriction is one-way.
- ✓ State the double-fetch rule and the three-step pattern that avoids it.

- ✓ Compare static and dynamic shared memory across contiguity, size and cost.
- ✓ Give the three ways a client supplies a buffer and say when each is right.
- ✓ List the parameter types and explain what `TEEC_PARAM_TYPES` packs.
- ✓ Write the four lines that check `paramTypes` in a TA and explain what they prevent.
- ✓ Explain what `TEE_CheckMemoryAccessRights` verifies.
- ✓ State the four rules for handling a client buffer, in order.
- ✓ Implement the short-buffer protocol and say why it is the one early output write allowed.
- ✓ Say when cache maintenance is genuinely needed and what a need for it usually indicates instead.

The SMC ABI and the OP-TEE message protocol

Everything the two worlds say to each other travels as an `SMC` instruction with eight register arguments, plus a message structure in shared memory. This chapter is the wire format — enough to read a trace, debug a handshake, or implement the normal-world side yourself.

SMCCC: the calling convention

```
SMC #0 with a function ID in w0. The ID is structured:

 31  30      29 28        24 23    16 15                  0
+---+----------+-------------+--------+--------------------+
|FST| SMC64    |  reserved   | OWNER  |   function number  |
+---+----------+-------------+--------+--------------------+

bit 31    0 = yielding (may be preempted, may make RPCs)
          1 = fast (runs to completion, interrupts masked)
bit 30    0 = SMC32 (32-bit arguments)
          1 = SMC64 (64-bit arguments)
[29:24]   must be zero
[23:16]   OWNER - who handles this call:
             0x00  Arm architecture calls
             0x01  CPU service calls
             0x02  SiP (silicon partner) calls
             0x03  OEM calls
             0x04  Standard Secure Service - PSCI lives here
             0x05  Standard Hypervisor Service
             0x06  Vendor Hypervisor Service
             0x30-0x31  TRUSTED APPLICATION calls
             0x32-0x3F  TRUSTED OS calls  <-- OP-TEE
[15:0]    the function itself

Arguments in x1-x7 (or w1-w7 for SMC32), results in x0-x3.

Examples:
  0x84000000  PSCI_VERSION      fast, SMC32, owner 4
  0xC4000003  PSCI_CPU_ON       fast, SMC64, owner 4
  0xB2000000  OPTEE_SMC_CALLS_UID
  0x32000004  OPTEE_SMC_CALL_WITH_ARG   yielding, owner 0x32
```

The handshake at probe

```
/* Before it will use OP-TEE, the Linux driver asks four
   questions. Reading this sequence tells you exactly where a
   broken bring-up failed.                                    */

  1. "Who are you?"
       SMC(OPTEE_SMC_CALLS_UID)              = 0xBF00FF01
     returns four words - a UUID. Must equal
       384fb3e0-e7f8-11e3-af63-0002a5d5c51b
     Anything else: not OP-TEE, or not a TEE at all. The
     driver gives up quietly.

  2. "What revision?"
       SMC(OPTEE_SMC_CALLS_REVISION)         = 0xBF00FF03
     returns major, minor. The driver checks compatibility.
       -> dmesg: "optee: revision 4.1"

  3. "What memory can we share?"
       SMC(OPTEE_SMC_GET_SHM_CONFIG)         = 0xB2000007
     returns the physical base, size and settings of the
     static shared memory pool.

  4. "What do you support?"
       SMC(OPTEE_SMC_EXCHANGE_CAPABILITIES)  = 0xB2000009
     the driver sends what IT can do:
       OPTEE_SMC_NSEC_CAP_UNIPROCESSOR
     OP-TEE replies with what it can do:
       OPTEE_SMC_SEC_CAP_HAVE_RESERVED_SHM
       OPTEE_SMC_SEC_CAP_DYNAMIC_SHM
       OPTEE_SMC_SEC_CAP_MEMREF_NULL
       OPTEE_SMC_SEC_CAP_ASYNC_NOTIF
       OPTEE_SMC_SEC_CAP_VIRTUALIZATION
       -> dmesg: "optee: dynamic shared memory is enabled"

  Then, if all four succeed:
       -> "optee: initialized driver", /dev/tee0 appears.

/* drivers/tee/optee/smc_abi.c - optee_probe(). Worth reading
   once; it is about 200 lines and it is the whole
   negotiation.                                               */
```

The message structure

```
/* Registers carry only the call type and a pointer. The real
   request lives in shared memory as an optee_msg_arg.       */

struct optee_msg_arg {
        uint32_t cmd;           /* OPEN_SESSION, INVOKE_COMMAND ... */
        uint32_t func;          /* the TA's command ID              */
        uint32_t session;       /* which session                    */
        uint32_t cancel_id;
        uint32_t pad;
        uint32_t ret;           /* TEE_Result out                   */
        uint32_t ret_origin;    /* who failed: API, comms, TEE, TA  */
        uint32_t num_params;
        struct optee_msg_param params[];   /* flexible array        */
};

struct optee_msg_param {
        uint64_t attr;          /* type + direction                 */
        union {
                struct { uint64_t a, b, c; } value;
                struct { uint64_t offs, size; uint64_t shm_ref; } rmem;
                struct { uint64_t buf_ptr, size, shm_ref; } tmem;
        } u;
};

/* attr values: */
#define OPTEE_MSG_ATTR_TYPE_NONE            0x0
#define OPTEE_MSG_ATTR_TYPE_VALUE_INPUT     0x1
#define OPTEE_MSG_ATTR_TYPE_VALUE_OUTPUT    0x2
#define OPTEE_MSG_ATTR_TYPE_VALUE_INOUT     0x3
#define OPTEE_MSG_ATTR_TYPE_RMEM_INPUT      0x5  /* registered  */
#define OPTEE_MSG_ATTR_TYPE_RMEM_OUTPUT     0x6
#define OPTEE_MSG_ATTR_TYPE_RMEM_INOUT      0x7
#define OPTEE_MSG_ATTR_TYPE_TMEM_INPUT      0x9  /* temporary   */
#define OPTEE_MSG_ATTR_TYPE_TMEM_OUTPUT     0xa
#define OPTEE_MSG_ATTR_TYPE_TMEM_INOUT      0xb

/* Commands: */
#define OPTEE_MSG_CMD_OPEN_SESSION          0
#define OPTEE_MSG_CMD_INVOKE_COMMAND        1
#define OPTEE_MSG_CMD_CLOSE_SESSION         2
#define OPTEE_MSG_CMD_CANCEL                3
#define OPTEE_MSG_CMD_REGISTER_SHM          4
#define OPTEE_MSG_CMD_UNREGISTER_SHM        5
#define OPTEE_MSG_CMD_DO_BOTTOM_HALF        6
#define OPTEE_MSG_CMD_STOP_ASYNC_NOTIF      7
```

One invocation, register by register

```
Client calls TEEC_InvokeCommand(sess, 5, &op, &origin).

1. libteec fills a struct tee_ioctl_invoke_arg and calls
     ioctl(fd, TEE_IOC_INVOKE, &arg)

2. The kernel driver allocates an optee_msg_arg in shared
   memory and fills it:
     cmd        = OPTEE_MSG_CMD_INVOKE_COMMAND
     func       = 5
     session    = the session id
     num_params = 4
     params[0].attr = OPTEE_MSG_ATTR_TYPE_VALUE_INPUT
     params[0].u.value.a = ...
     params[1].attr = OPTEE_MSG_ATTR_TYPE_TMEM_OUTPUT
     params[1].u.tmem.buf_ptr = physical address
     params[1].u.tmem.size    = length
     params[1].u.tmem.shm_ref = cookie

3. The driver issues:
     x0 = OPTEE_SMC_CALL_WITH_ARG   (0x32000004)
     x1 = upper 32 bits of the msg_arg physical address
     x2 = lower 32 bits
     x3-x7 = 0
     SMC #0

4. EL3 (opteed) saves the non-secure context, restores the
   secure one, ERETs into OP-TEE's std_smc_entry.

5. OP-TEE allocates a thread, reads the msg_arg from shared
   memory, translates the parameters, finds the session,
   and calls the TA's TA_InvokeCommandEntryPoint.

6. The TA runs. If it needs the normal world (to read a
   file, to get the time, to load another TA) it makes an
   RPC - which RETURNS through this same path with a
   "please do this for me" code, and the call is later
   resumed. Chapter 9.

7. The TA returns. OP-TEE writes ret and ret_origin into
   the msg_arg, frees the thread, and executes
     SMC(TEESMC_OPTEED_RETURN_CALL_DONE)

8. EL3 restores the non-secure context. The driver's SMC
   returns with:
     x0 = OPTEE_SMC_RETURN_OK      (0)
   or
     x0 = OPTEE_SMC_RETURN_ETHREAD_LIMIT  - retry later
     x0 = OPTEE_SMC_RETURN_RPC_*          - do this first

9. The driver reads ret/ret_origin out of the msg_arg and
   returns them up through the ioctl to libteec.
```

Return origin: who actually failed

```
/* Every failure carries an ORIGIN, and it is the most
   under-used debugging aid in the whole API.              */

  TEEC_ORIGIN_API          0x1  libteec itself rejected it -
                                bad arguments in your client
  TEEC_ORIGIN_COMMS        0x2  the transport failed - driver,
                                SMC, or the message never
                                arrived
  TEEC_ORIGIN_TEE          0x3  OP-TEE core rejected it - no
                                such session, TA not found,
                                out of memory, bad params
  TEEC_ORIGIN_TRUSTED_APP  0x4  YOUR TA returned this. The
                                value is whatever your TA
                                returned.

/* So:
     res = 0xFFFF0006, origin = 3  -> OP-TEE says bad params.
                                      Your paramTypes disagree.
     res = 0xFFFF0006, origin = 4  -> your TA returned
                                      TEE_ERROR_BAD_PARAMETERS.
                                      Different bug entirely.
     res = 0x00000001, origin = 4  -> your TA's own error code.
                                      Nothing standard about it.

   Always print both. A client that prints only the result
   throws away half the information.                       */

  printf("failed: res=0x%08x origin=%u\n", res, origin);
```

```
/* The standard result codes worth recognising on sight: */

#define TEEC_SUCCESS                    0x00000000
#define TEEC_ERROR_GENERIC              0xFFFF0000
#define TEEC_ERROR_ACCESS_DENIED        0xFFFF0001

#define TEEC_ERROR_ACCESS_CONFLICT      0xFFFF0003
#define TEEC_ERROR_EXCESS_DATA          0xFFFF0004
#define TEEC_ERROR_BAD_FORMAT           0xFFFF0005
#define TEEC_ERROR_BAD_PARAMETERS       0xFFFF0006
#define TEEC_ERROR_BAD_STATE            0xFFFF0007
#define TEEC_ERROR_ITEM_NOT_FOUND       0xFFFF0008  /* TA not
                                                       found   */
#define TEEC_ERROR_NOT_IMPLEMENTED      0xFFFF0009
#define TEEC_ERROR_NOT_SUPPORTED        0xFFFF000A
#define TEEC_ERROR_NO_DATA              0xFFFF000B
#define TEEC_ERROR_OUT_OF_MEMORY        0xFFFF000C
#define TEEC_ERROR_BUSY                 0xFFFF000D
#define TEEC_ERROR_COMMUNICATION        0xFFFF000E
#define TEEC_ERROR_SECURITY             0xFFFF000F  /* signature
                                                       check
                                                       failed  */
#define TEEC_ERROR_SHORT_BUFFER         0xFFFF0010
#define TEEC_ERROR_TARGET_DEAD          0xFFFF3024  /* the TA
                                                       PANICKED */
```

> **`TEEC_ERROR_TARGET_DEAD` MEANS READ THE SECURE CONSOLE**
> 0xFFFF3024 is OP-TEE telling you the TA panicked — dereferenced a bad pointer, failed an assertion, or called `TEE_Panic()`. The client cannot know why. The secure console printed a stack dump at the moment it happened. This is the single strongest argument for the two-console setup in chapter 4.

Watching the traffic

```
# The Linux driver has tracepoints and dynamic debug:
$ echo 'module optee +p' | sudo tee /sys/kernel/debug/dynamic_debug/control
$ dmesg -w

# Under QEMU, trace every SMC that reaches EL3 by building TF-A
# with debug:
$ make -C arm-trusted-firmware PLAT=qemu DEBUG=1 LOG_LEVEL=50 ...

# OP-TEE's own view, at flow level:
$ make CFG_TEE_CORE_LOG_LEVEL=4
# secure console then shows every entry and exit:
F/TC:0 0 thread_alloc_and_run:...
F/TC:0 0 tee_ta_open_session:...
F/TC:0 0 tee_ta_invoke_command:...

# And from the guest, the ioctl layer:
$ strace -e trace=ioctl ./my_client
ioctl(3, TEE_IOC_VERSION, ...)     = 0
ioctl(3, TEE_IOC_OPEN_SESSION, ...) = 0
ioctl(3, TEE_IOC_INVOKE, ...)      = 0
ioctl(3, TEE_IOC_CLOSE_SESSION, ...) = 0

# The ioctl numbers, if you ever implement a client without
# libteec:
#   TEE_IOC_VERSION        get driver capabilities
#   TEE_IOC_SHM_ALLOC      allocate shared memory, returns a fd
#   TEE_IOC_SHM_REGISTER   register your own memory
#   TEE_IOC_OPEN_SESSION
#   TEE_IOC_INVOKE
#   TEE_IOC_CANCEL
#   TEE_IOC_CLOSE_SESSION
#   TEE_IOC_SUPPL_RECV     tee-supplicant only
#   TEE_IOC_SUPPL_SEND
```

How it shows up

Symptom	Cause
Driver does not probe, no error	The UID call returned something else — OP-TEE is not there
`optee: api uid mismatch`	Something answered the SMC but is not OP-TEE
`optee: unsupported revision`	Kernel driver and OP-TEE versions too far apart
`TEEC_ERROR_COMMUNICATION`	The SMC path failed — check EL3 built with `SPD=opteed`
`TEEC_ERROR_TARGET_DEAD`	The TA panicked. The reason is on the secure console
`TEEC_ERROR_BUSY` under load	`ETHREAD_LIMIT` — the thread pool is full (chapter 5)
Same error code, two different bugs	You are ignoring the origin. Print it
Client hangs forever in an invoke	The TA is blocked, or a thread-exhaustion deadlock

Symptom	Cause
Works with small buffers, fails with large	Static SHM pool size, or a temporary memref larger than the pool
Registered memory rejected	`DYNAMIC_SHM` not in the exchanged capabilities

Check yourself

- ✓ Decode an SMC function ID into fast/yielding, 32/64-bit and owner.
- ✓ Name the four questions the Linux driver asks at probe and what each confirms.
- ✓ Describe `optee_msg_arg` and say where it lives.
- ✓ Explain how a buffer parameter is expressed in `optee_msg_param`.
- ✓ Trace one `TEEC_InvokeCommand` from ioctl to TA entry point and back, naming both SMCs.
- ✓ Explain `OPTEE_SMC_RETURN_ETHREAD_LIMIT` and what the driver does about it.
- ✓ Name the four return origins and give a case where the same result code means two different things.
- ✓ Say what `TEEC_ERROR_TARGET_DEAD` means and where to look next.
- ✓ Recognise `0xFFFF0008`, `0xFFFF000F` and `0xFFFF0010` on sight.
- ✓ Enable driver, TF-A and OP-TEE tracing simultaneously and correlate one call across all three.

RPC and tee-supplicant

The secure world has no filesystem, no network and no way to allocate normal-world memory. So when it needs those things it asks — by returning from the very SMC that invoked it, with "not finished, do this first". That inversion is elegant, it is why OP-TEE stays small, and it is the source of the deadlock in chapter 5.

Returning in order to ask

```
The secure world cannot CALL the normal world. There is no
such instruction: SMC goes up in privilege, never down.

So OP-TEE uses the only channel it has - the return value of
the call it is currently servicing.

  normal world:   SMC(CALL_WITH_ARG, msg)
                       |
                       v
  OP-TEE:         thread allocated, TA runs
                  TA calls TEE_OpenPersistentObject()
                       |
                       |  "I need a file. I cannot open
                       |   files."
                       v
                  SAVE the thread's full state
                  write an RPC request into shared memory
                  return to the normal world with
                     x0 = OPTEE_SMC_RETURN_RPC_CMD
                       |
                       v
  driver:         "this is not a result, it is a request"
                  hand it to tee-supplicant
                       |
                       v
  tee-supplicant: open("/data/tee/...")
                  read the data into shared memory
                  reply
                       |
                       v
  driver:         SMC(CALL_RETURN_FROM_RPC, thread_id, ...)
                       |
                       v
  OP-TEE:         find the saved thread, RESTORE it,
                  TEE_OpenPersistentObject() returns
                  TA continues as if nothing happened
                       |
                       ... eventually ...
                       v
                  return OPTEE_SMC_RETURN_OK

The TA sees an ordinary blocking function call. Underneath,
control left the secure world entirely and came back.

THE THREAD IS HELD THROUGHOUT. That is the whole design
constraint (chapter 5).
```

The RPC requests

Return code	Meaning	Serviced by
`RPC_ALLOC`	Allocate shared memory for me	The kernel driver
`RPC_FREE`	Free it	The kernel driver
`RPC_FOREIGN_INTR`	A normal-world interrupt is pending; go and service it	The kernel, implicitly
`RPC_CMD`	A real request — see the command table below	Mostly `tee-supplicant`

```
/* The RPC_CMD sub-commands: */

#define OPTEE_RPC_CMD_LOAD_TA         0  /* read a .ta file    */
#define OPTEE_RPC_CMD_RPMB            1  /* an RPMB frame      */
#define OPTEE_RPC_CMD_FS              2  /* REE filesystem op  */
#define OPTEE_RPC_CMD_GET_TIME        3  /* wall-clock time    */
#define OPTEE_RPC_CMD_NOTIFICATION    4  /* wait/wake a thread */
#define OPTEE_RPC_CMD_SUSPEND         5  /* sleep              */
#define OPTEE_RPC_CMD_SHM_ALLOC       6
#define OPTEE_RPC_CMD_SHM_FREE        7
#define OPTEE_RPC_CMD_SQL_FS          8
#define OPTEE_RPC_CMD_GPROF           9
#define OPTEE_RPC_CMD_SOCKET         10  /* network!            */
#define OPTEE_RPC_CMD_BENCH_REG      20
#define OPTEE_RPC_CMD_FTRACE         21
#define OPTEE_RPC_CMD_I2C_TRANSFER   22

/* Two of these deserve a second look.

   LOAD_TA - the secure world asks the normal world to give it
   a trusted application. The normal world is untrusted. So
   OP-TEE VERIFIES THE SIGNATURE of whatever it receives
   (chapter 14). An attacker who substitutes a different .ta
   gets TEEC_ERROR_SECURITY, not code execution. This is the
   design pattern: accept data from an untrusted source, then
   verify it yourself.

   SOCKET - yes, a TA can open a TCP connection, tunnelled
   through tee-supplicant. Whether it SHOULD is another
   question: the normal world sees and can modify every byte
   unless you run TLS end-to-end inside the TA.            */
```

> **THE SECURITY PATTERN THAT MAKES THIS SAFE**
>
> Every RPC hands work to an untrusted party. The rule that keeps it sound: **the secure world never trusts the result**. TA binaries are signature-checked. Secure storage is encrypted and authenticated, so a modified file fails its MAC. RPMB frames are MACed with a key the normal world does not have. Time is explicitly labelled untrusted. Where verification is impossible — as with wall-clock time — the API says so, and chapter 17 covers what to do instead.

tee-supplicant

```
/* A normal user-space daemon, ~2000 lines. Its whole life:  */

int main(void)
{
        int fd = open("/dev/teepriv0", O_RDWR);

        for (;;) {
                struct tee_ioctl_supp_recv_arg arg;

                /* Blocks until OP-TEE needs something. */
                ioctl(fd, TEE_IOC_SUPPL_RECV, &arg);

                switch (arg.func) {
                case OPTEE_RPC_CMD_LOAD_TA:
                        load_ta(&arg);      /* read
                                               /lib/optee_armtz/
                                               <uuid>.ta      */
                        break;
                case OPTEE_RPC_CMD_FS:
                        tee_supp_fs(&arg);  /* open/read/write/
                                               unlink under
                                               /data/tee/      */
                        break;
                case OPTEE_RPC_CMD_RPMB:
                        rpmb_process(&arg); /* ioctl to the
                                               eMMC             */
                        break;
                case OPTEE_RPC_CMD_GET_TIME:
                        get_time(&arg);
                        break;
                case OPTEE_RPC_CMD_I2C_TRANSFER:
                        i2c_transfer(&arg);
                        break;
                ...
                }

                ioctl(fd, TEE_IOC_SUPPL_SEND, &arg);
        }
}

/* Where it keeps things: */
    /lib/optee_armtz/<uuid>.ta    trusted applications
    /data/tee/                    secure storage files
                                  (encrypted; the normal world
                                   can delete them but not read
                                   or forge them)

/* Running it: */
$ tee-supplicant -d              # daemonise
$ tee-supplicant -f              # foreground, prints errors
$ tee-supplicant -f /dev/teepriv0
$ systemctl status tee-supplicant

/* WITHOUT IT:
     TEEC_OpenSession -> TEEC_ERROR_ITEM_NOT_FOUND, because
     nothing can load the TA binary.
   And a TA already loaded that tries to use secure storage
   will BLOCK, holding a thread, until the supplicant returns
   or the call is cancelled.                                  */
```

Asynchronous notification

```
/* A problem the RPC model does not solve: the secure world
   needs to tell the normal world something when it is NOT
   servicing a call. A secure interrupt arrived; a background
   task finished.

   With plain RPC there is no channel - OP-TEE only runs when
   called.

   CFG_CORE_ASYNC_NOTIF=y adds one:

     OP-TEE raises a dedicated non-secure interrupt.
       |
       v
     Linux's optee driver takes it, and issues
       SMC(OPTEE_SMC_GET_ASYNC_NOTIF_VALUE)
       to ask what happened.
       |
       v
     OP-TEE returns a notification value.
       |
       v
     The driver wakes whatever was waiting, or schedules
       OPTEE_MSG_CMD_DO_BOTTOM_HALF so OP-TEE can run
       deferred work.

   Confirm it:
     $ dmesg | grep optee
     optee: Asynchronous notifications enabled

   Without it, a TA that wants to wait for a secure interrupt
   must poll, holding a thread - which is exactly the pattern
   that exhausts the pool.                                  */
```

The deadlock, in full

```
CFG_NUM_THREADS = 4. Four application threads each invoke a
TA that writes to secure storage.

  thread 1  in OP-TEE, blocked on RPC_CMD_FS
  thread 2  in OP-TEE, blocked on RPC_CMD_FS
  thread 3  in OP-TEE, blocked on RPC_CMD_FS
  thread 4  in OP-TEE, blocked on RPC_CMD_FS

All four OP-TEE threads are held. Every one is waiting for
tee-supplicant.

tee-supplicant CAN service them - one at a time - and
normally does, and everything is merely slow.

It deadlocks when tee-supplicant itself cannot run:

  * tee-supplicant's own thread tries to invoke a TA
    (never do this)
  * the storage it must write to is on a filesystem that is
    itself waiting on something blocked in the TEE
  * an out-of-memory condition stops it being scheduled
  * a single-threaded supplicant is servicing a request that
    blocks on a device that is unresponsive

Symptom: total silence. No error, no timeout, no log line.
Every client hangs in ioctl(). The secure console shows
nothing because OP-TEE is not running.

DIAGNOSING IT:
  $ cat /proc/<client-pid>/stack        # blocked in optee
  $ cat /proc/<supplicant-pid>/stack    # what is IT waiting
                                          for?
  $ echo t > /proc/sysrq-trigger        # all task stacks

AVOIDING IT:
  * never call into the TEE from a process that services the
    TEE
  * set CFG_NUM_THREADS comfortably above your peak
    concurrency
  * keep RPC-using operations (secure storage) off hot paths
  * give tee-supplicant a favourable scheduling class if it
    is on a loaded system
  * cancel long operations with TEEC_RequestCancellation
    from a watchdog thread
```

How it shows up

Symptom	Cause
`TEEC_ERROR_ITEM_NOT_FOUND` on every session	`tee-supplicant` not running
Everything hangs with no error	Thread-exhaustion deadlock; check the supplicant's own stack
Secure storage operations extremely slow	Every one is an RPC round trip through a user-space daemon. Expected — batch them
TA works, then fails after the supplicant restarts	Sessions holding state the supplicant was mid-way through servicing

Symptom	Cause
`TEEC_ERROR_SECURITY` loading a TA	The supplicant delivered a binary whose signature did not verify — working as designed
Secure storage file deleted, TA still works	Deletion is possible from the normal world; confidentiality and integrity are protected, availability is not
Time from a TA is wrong or moves backwards	`TEE_GetREETime` comes from the normal world and is not trustworthy
A TA cannot wait for a secure interrupt without spinning	Async notification not enabled
Deadlock only under load	`CFG_NUM_THREADS` too small for peak concurrency

Check yourself

- ✓ Explain why the secure world cannot call the normal world, and what it does instead.
- ✓ Trace a `TEE_OpenPersistentObject` call out to `tee-supplicant` and back.
- ✓ Say what happens to the OP-TEE thread during an RPC.
- ✓ Name six RPC commands and who services each.
- ✓ Explain why loading a TA from an untrusted source is safe, and what makes it so.
- ✓ State the general pattern that makes every RPC safe, and name one case where it cannot apply.
- ✓ Describe what `tee-supplicant` does and the two directories it owns.
- ✓ Explain what asynchronous notification adds and what it replaces.
- ✓ Describe the thread-exhaustion deadlock precisely and give four ways to avoid it.
- ✓ Diagnose a total hang: name the two `/proc` files you would read first.

The Linux TEE subsystem

Linux has a generic TEE framework — `drivers/tee/` — with OP-TEE as one back end, AMD-TEE and Trusty as others. It gives user space a stable ioctl interface and gives kernel code a way to use a TA directly, which is how the fTPM driver in chapter 23 works.

The subsystem

```
drivers/tee/
  tee_core.c        the generic layer: device nodes, the
                    ioctl interface, contexts, sessions
  tee_shm.c         shared memory objects, dmabuf export
  tee_shm_pool.c    the allocators
  optee/
    core.c          probe, device registration
    smc_abi.c       the SMC transport (chapter 8)
    ffa_abi.c       the FF-A transport - for OP-TEE running
                    as a secure partition under an SPM
                    (virt chapter 19)
    call.c          building and issuing optee_msg_arg
    rpc.c           servicing RPC returns
    supp.c          the tee-supplicant queue
    device.c        enumerating TAs as kernel devices
  amdtee/  tstee/   other back ends

Two device nodes per TEE:

  /dev/tee0       for ordinary clients
  /dev/teepriv0   privileged - tee-supplicant uses this one

Kernel config:
  CONFIG_TEE=y
  CONFIG_OPTEE=y
  CONFIG_OPTEE_INSECURE_LOAD_IMAGE  (n; for loading OP-TEE
                                     itself from Linux - a
                                     development feature)
```

The user-space interface

```
/* include/uapi/linux/tee.h - this is the whole ABI, and
   libteec is a thin wrapper over it.                        */

  TEE_IOC_VERSION          what implementation, what caps
  TEE_IOC_SHM_ALLOC        allocate shared memory; returns a
                           file descriptor you mmap
  TEE_IOC_SHM_REGISTER     register memory you already have
  TEE_IOC_OPEN_SESSION     open a session to a TA by UUID
  TEE_IOC_INVOKE           invoke a command
  TEE_IOC_CANCEL           cancel an in-flight invocation
  TEE_IOC_CLOSE_SESSION
  TEE_IOC_SUPPL_RECV       (privileged) wait for an RPC
  TEE_IOC_SUPPL_SEND       (privileged) answer it

/* A client without libteec, to show there is no magic: */

    int fd = open("/dev/tee0", O_RDWR);

    struct tee_ioctl_version_data ver;
    ioctl(fd, TEE_IOC_VERSION, &ver);
    /* ver.impl_id  = TEE_IMPL_ID_OPTEE
       ver.gen_caps = TEE_GEN_CAP_GP | TEE_GEN_CAP_REG_MEM   */

    /* Shared memory is a file descriptor you mmap. */
    struct tee_ioctl_shm_alloc_data shm = { .size = 4096 };
    int shm_fd = ioctl(fd, TEE_IOC_SHM_ALLOC, &shm);
    void *buf = mmap(NULL, shm.size, PROT_READ | PROT_WRITE,
                     MAP_SHARED, shm_fd, 0);

    /* Open a session. */
    struct {
            struct tee_ioctl_open_session_arg arg;
            struct tee_ioctl_param params[4];
    } req = {0};
    memcpy(req.arg.uuid, uuid, 16);
    req.arg.clnt_login = TEE_IOCTL_LOGIN_PUBLIC;
    req.arg.num_params = 4;

    struct tee_ioctl_buf_data bd = {
            .buf_ptr = (uintptr_t)&req,
            .buf_len = sizeof(req),
    };
    ioctl(fd, TEE_IOC_OPEN_SESSION, &bd);
    /* req.arg.session is now valid; req.arg.ret and
       req.arg.ret_origin carry the result (chapter 8).      */

/* The shm-as-a-file-descriptor design is deliberate: it makes
   shared memory a first-class object that can be passed
   between processes with SCM_RIGHTS, exported as a dmabuf, and
   reclaimed automatically when the last reference goes.     */
```

Using a TA from kernel code

```
/* The interesting capability, and the one the fTPM depends on.
   A kernel driver can be a TEE client.                       */

#include <linux/tee_drv.h>

static const uuid_t my_ta_uuid =
        UUID_INIT(0x12345678, 0x1234, 0x1234,
                  0x12, 0x34, 0x12, 0x34, 0x12, 0x34, 0x12, 0x34);

/* Used to find an OP-TEE context among possibly several TEEs. */
static int optee_match(struct tee_ioctl_version_data *ver,
                       const void *data)
{
        return ver->impl_id == TEE_IMPL_ID_OPTEE;
}

struct my_private {
        struct tee_context *ctx;
        u32                 session;
        struct tee_shm     *shm;
};

static int my_tee_init(struct device *dev, struct my_private *p)
{
        struct tee_ioctl_open_session_arg sess_arg = {0};
        int rc;

        /* 1. Get a context. */
        p->ctx = tee_client_open_context(NULL, optee_match,
                                         NULL, NULL);
        if (IS_ERR(p->ctx))
                return PTR_ERR(p->ctx);   /* -ENOENT if no TEE  */

        /* 2. Open a session. */
        export_uuid(sess_arg.uuid, &my_ta_uuid);
        sess_arg.clnt_login = TEE_IOCTL_LOGIN_REE_KERNEL;
        sess_arg.num_params = 0;

        rc = tee_client_open_session(p->ctx, &sess_arg, NULL);
        if (rc < 0 || sess_arg.ret != 0) {

        if (IS_ERR(buf))
                return PTR_ERR(buf);

        memcpy(buf, in, inlen);

        param[0].attr = TEE_IOCTL_PARAM_ATTR_TYPE_MEMREF_INOUT;
        param[0].u.memref.shm      = p->shm;
        param[0].u.memref.size     = inlen;
        param[0].u.memref.shm_offs = 0;

        rc = tee_client_invoke_func(p->ctx, &arg, param);
        if (rc < 0 || arg.ret != 0)
                return -EIO;

        *outlen = param[0].u.memref.size;
        memcpy(out, buf, *outlen);
        return 0;
}

static void my_tee_exit(struct my_private *p)
{
        tee_shm_free(p->shm);
        tee_client_close_session(p->ctx, p->session);
        tee_client_close_context(p->ctx);
}

/* This is, almost exactly, drivers/char/tpm/tpm_ftpm_tee.c.
   Chapter 23 builds on it.                                  */
```

LOGIN TYPES MATTER

`TEE_IOCTL_LOGIN_REE_KERNEL` tells the TA that the caller is the kernel, not a user-space process. A TA can act on that — refusing to serve user space, or applying different policy. Other logins are `PUBLIC` (anyone), `USER` and `GROUP` (the client's uid/gid is hashed into the login identity, so a TA can bind stored data to a specific caller). This is how per-application secure storage works; see chapter 15.

Enumerating TAs as devices

```
/* drivers/tee/optee/device.c asks OP-TEE for the list of TAs
   that want a kernel driver, and registers a device for each.
   A kernel driver then binds by UUID, exactly like PCI.     */

$ ls /sys/bus/tee/devices/
optee-ta-be2dc9a0-02b4-4b33-ba81-9cce8a6c1e1c   # fTPM
optee-ta-e33b0e0e-6e2a-4f3b-8f2f-3e8a5a1a2b3c

$ ls /sys/bus/tee/drivers/
optee-ta-be2dc9a0-02b4-4b33-ba81-9cce8a6c1e1c

/* And a driver: */

static const struct tee_client_device_id my_id_table[] = {
        { UUID_INIT(0xbe2dc9a0, 0x02b4, 0x4b33,
                    0xba, 0x81, 0x9c, 0xce,
                    0x8a, 0x6c, 0x1e, 0x1c) },
        { }
};
MODULE_DEVICE_TABLE(tee, my_id_table);

static struct tee_client_driver my_driver = {
        .id_table = my_id_table,
        .driver = {
                .name  = "my-ta-driver",
                .bus   = &tee_bus_type,
                .probe = my_probe,
                .remove = my_remove,
        },
};
module_driver(my_driver, driver_register, driver_unregister);

/* The TA must declare that it wants this, by setting
   TA_FLAG_DEVICE_ENUM in its properties (chapter 13). Without
   that flag it exists but no device node appears, and a kernel
   driver has nothing to bind to. That is a common and
   confusing failure.                                        */
```

Debugging the driver

```
# Dynamic debug across the whole subsystem:
$ echo 'module optee +p'    | sudo tee /sys/kernel/debug/dynamic_debug/control
$ echo 'module tee +p'      | sudo tee /sys/kernel/debug/dynamic_debug/control
$ dmesg -w

# What did probe conclude?
$ dmesg | grep -E 'optee|tee:'
optee: probing for conduit method.
optee: revision 4.1 (0e3e9c9d)
optee: dynamic shared memory is enabled
optee: initialized driver

# Who has the TEE open?
$ sudo lsof /dev/tee0 /dev/teepriv0
$ sudo fuser -v /dev/tee0

# Where is a hung client blocked?
$ sudo cat /proc/$(pgrep my_client)/stack
[<0>] optee_do_call_with_arg+0x...
[<0>] optee_invoke_func+0x...
[<0>] tee_ioctl+0x...
# In optee_do_call_with_arg = waiting on the secure world.
# Now check tee-supplicant's stack (chapter 9).

# Trace the ioctls a client makes:
$ strace -e trace=ioctl,openat ./my_client

# ftrace the driver's own functions:
$ cd /sys/kernel/debug/tracing
$ echo 'optee_*' | sudo tee set_ftrace_filter
$ echo function | sudo tee current_tracer
$ sudo cat trace_pipe
```

How it shows up

Symptom	Cause
No `/dev/tee0`	`CONFIG_OPTEE` off, device tree node missing, or the probe handshake failed (chapter 8)
`tee_client_open_context` returns `-ENOENT`	No TEE registered yet — the driver probed after yours. Defer with `-EPROBE_DEFER`
No device under `/sys/bus/tee/devices/`	TA missing `TA_FLAG_DEVICE_ENUM`
Kernel driver's session opens, user space's fails	The TA is checking the login type and refusing user space — possibly deliberately
Client blocked in `optee_do_call_with_arg`	Waiting on the secure world; look at `tee-supplicant` next
`tee_shm_alloc` fails	Static SHM pool exhausted; free shared memory or enable dynamic SHM
Works in user space, fails from the kernel	Kernel buffers must come from `tee_shm_alloc_kernel_buf`, not `kmalloc`
Session leaks after a driver unload	Missing `tee_client_close_session` / `close_context` in the remove path
Different behaviour under a hypervisor	The FF-A transport is in use rather than the SMC one

Check yourself

- ✓ Name the generic layer and three back ends, and say what the generic layer provides.
- ✓ Explain the difference between `/dev/tee0` and `/dev/teepriv0`.
- ✓ List the ioctls and say which two are privileged.
- ✓ Explain why shared memory is exposed as a file descriptor.
- ✓ Write the kernel-side sequence to open a context, open a session and invoke a command.
- ✓ Explain what login types exist and what a TA can do with them.
- ✓ Say what `TA_FLAG_DEVICE_ENUM` enables and what fails without it.
- ✓ Bind a kernel driver to a TA by UUID.
- ✓ Determine, for a hung client, whether it is blocked in the secure world.
- ✓ Explain why a kernel client must not pass a `kmalloc` buffer directly.

The Client API in depth

Eleven functions, defined by GlobalPlatform, implemented by `libteec`, and identical across every compliant TEE. Learn them here and your client code moves to Kinibi or QSEE unchanged. This chapter is the complete surface, with the lifecycle rules that the specification states and everyone violates anyway.

The whole API

Function	Does
`TEEC_InitializeContext`	Connect to a TEE. Opens `/dev/tee0`
`TEEC_FinalizeContext`	Disconnect
`TEEC_OpenSession`	Start talking to a TA, identified by UUID
`TEEC_CloseSession`	Stop
`TEEC_InvokeCommand`	Ask the TA to do something
`TEEC_RequestCancellation`	Ask for an in-flight operation to stop
`TEEC_RegisterSharedMemory`	Give the TEE memory you already own
`TEEC_AllocateSharedMemory`	Have the TEE allocate it
`TEEC_ReleaseSharedMemory`	Give it back
`TEEC_RegisterSharedMemoryFileDescriptor`	OP-TEE extension: share a dmabuf
`TEEC_PARAM_TYPES`	A macro that packs four parameter types into one word

The lifecycle, and what it costs

```
   TEEC_InitializeContext
      opens /dev/tee0, queries the driver
      COST: an open() and an ioctl. Cheap-ish.
      |
      v
   TEEC_OpenSession
      -> SMC -> OP-TEE looks up the UUID
      -> if the TA is not resident: RPC to tee-supplicant to
         read the .ta file, then VERIFY ITS SIGNATURE, then
         allocate TA_RAM, map it, run TA_CreateEntryPoint
      -> then TA_OpenSessionEntryPoint
      COST: THE EXPENSIVE ONE. Several milliseconds the first
      time - signature verification of a 100 KB binary is real
      work.
      |
      v
   TEEC_InvokeCommand    (many times)
      -> SMC -> TA_InvokeCommandEntryPoint
      COST: two world switches plus your TA's work. Tens of
      microseconds of overhead.
      |
      v
   TEEC_CloseSession
      -> TA_CloseSessionEntryPoint
      -> if this was the LAST session: TA_DestroyEntryPoint,
         and the TA is unloaded from TA_RAM (unless it is a
         singleton that keeps its instance alive)
      |
      v
   TEEC_FinalizeContext

   THE PERFORMANCE RULE THAT FOLLOWS:

     open the session ONCE, at start-up, and keep it.

   A client that opens and closes a session around every
   operation pays the load-and-verify cost every time. This is
   the single most common OP-TEE performance mistake, and it
   can be a 100x difference.
```

A complete, correct client

```
/* keystore_client.c - the error handling and cleanup are the
   point. Copy this shape.                                    */

        size_t  siglen = sizeof sig;

        if (tee_init(&t, 4096))
                return 1;

        /* Many invocations, ONE session. */
        for (int i = 0; i < 1000; i++) {
                if (tee_sign(&t, "hello", 5, sig, &siglen) < 0)
                        break;
                siglen = sizeof sig;
        }

        tee_fini(&t);
        return 0;
}
```

> **ALLOCATE SHARED MEMORY ONCE**
> `TEEC_AllocateSharedMemory` is not free — it goes to the kernel and possibly to OP-TEE. Allocating a buffer per invocation, in a loop, doubles your overhead for no benefit. Allocate one buffer at start-up, big enough for your largest transfer, and use `TEEC_MEMREF_PARTIAL_INPUT` / `OUTPUT` with offsets to carve it up.

Login types and connection data

```
/* The fifth argument to TEEC_OpenSession says WHO is calling.
   The TA can see it, and OP-TEE derives per-caller storage
   keys from it (chapter 15).                                  */

  TEEC_LOGIN_PUBLIC        no identity claimed. Anyone.
  TEEC_LOGIN_USER          the caller's uid, hashed in by the
                           kernel driver - the client CANNOT
                           forge it
  TEEC_LOGIN_GROUP         a gid, supplied in connectionData
  TEEC_LOGIN_APPLICATION   an application identity
  TEEC_LOGIN_USER_APPLICATION
  TEEC_LOGIN_GROUP_APPLICATION
  TEEC_LOGIN_REE_KERNEL    the caller is the kernel (ch. 10)

    uint32_t gid = 1000;
    res = TEEC_OpenSession(&ctx, &sess, &uuid,
                           TEEC_LOGIN_GROUP, &gid,
                           NULL, &origin);

/* Why it matters: with LOGIN_USER, two different users opening
   sessions to the same TA get DIFFERENT secure storage. The
   TA writes to "my key" and each caller gets their own. That
   separation is enforced by OP-TEE, using an identity the
   client cannot choose.

   With LOGIN_PUBLIC there is one shared storage space for
   everyone. For a multi-user or multi-app system that is
   almost certainly wrong.                                     */
```

Cancellation

```
/* A long-running TA operation can be asked to stop. It is
   COOPERATIVE - the TA must check.                          */

/* Client, from another thread: */
    TEEC_RequestCancellation(&op);

/* TA side: */
    if (TEE_GetCancellationFlag()) {
            cleanup();
            return TEE_ERROR_CANCEL;
    }

    /* A TA can also mask cancellation while in a critical
       section, and must restore it: */
    bool old = TEE_MaskCancellation();
    do_something_uninterruptible();
    if (old) TEE_MaskCancellation(); else TEE_UnmaskCancellation();

/* Uses:
     a watchdog thread that cancels after a timeout
     a UI "cancel" button on a slow key generation
     shutdown

   Limits:
     the TA must poll the flag. A TA blocked in an RPC will
     not see it until the RPC returns.
     There is NO way to forcibly kill a TA invocation. If your
     TA can loop for ever, you have created an unkillable
     thread (chapter 5).                                    */
```

Thread safety

```
/* The GlobalPlatform rules, which OP-TEE follows:

   TEEC_Context   may be shared between threads.
   TEEC_Session   may be shared, BUT concurrent
                  TEEC_InvokeCommand calls on ONE session are
                  serialised by the TA's own instance/session
                  flags (chapter 13). Whether they run
                  concurrently depends on TA_FLAG_*.
   TEEC_Operation must NOT be shared. One per in-flight call.
   TEEC_SharedMemory may be shared, but you are responsible
                  for not having two calls write the same
                  region.

   The practical pattern for a multithreaded client:

     one TEEC_Context           process-wide
     one TEEC_Session           process-wide, if the TA is
                                multi-session capable
     one TEEC_Operation         per call, on the stack
     one TEEC_SharedMemory      per thread, allocated once

   If the TA is TA_FLAG_SINGLE_INSTANCE without
   TA_FLAG_MULTI_SESSION, your threads will serialise inside
   OP-TEE no matter what the client does. Know which your TA
   is.                                                      */
```

How it shows up

Symptom	Cause
Every operation takes milliseconds	Session opened and closed per call — the TA is being loaded and verified each time
`TEEC_ERROR_ITEM_NOT_FOUND` on `OpenSession`	TA not installed, or `tee-supplicant` not running
`TEEC_ERROR_BUSY` intermittently	Thread pool exhausted; libteec retries but concurrency is capped
Corruption with multiple threads	A `TEEC_Operation` or a shared buffer used by two calls at once
Client cannot cancel a stuck TA	Cancellation is cooperative; the TA is not polling the flag
Two users see each other's stored data	`TEEC_LOGIN_PUBLIC` where `LOGIN_USER` was needed
Retry loop on `SHORT_BUFFER` never ends	The TA does not set `memref.size` to the required length
Memory grows over time	Shared memory or sessions not released on the error path
Works alone, fails under concurrency	TA flags serialise sessions; see chapter 13

Check yourself

- ✓ Name the eleven Client API functions and what each does.
- ✓ Describe the lifecycle and identify the expensive step.
- ✓ State the performance rule about sessions and quantify why.
- ✓ Explain why shared memory should be allocated once and carved with partial memrefs.
- ✓ Write a client with correct cleanup on every error path.
- ✓ Implement the short-buffer retry.
- ✓ Name the login types and explain what changes with `LOGIN_USER`.
- ✓ Explain why the client cannot forge its uid.
- ✓ Describe cancellation, what the TA must do, and its two limits.
- ✓ State which Client API objects may be shared between threads and which may not.

The TA Internal Core API in depth

Inside a trusted application there is no libc, no filesystem, no sockets and no `printf` — there is one specified API covering memory, cryptography, storage, time and arithmetic. It is deliberately small and deliberately awkward in places; this chapter is the whole of it, organised by what you actually reach for.

The five entry points

```
/* Every TA implements exactly these. They are the TA's whole
   interface to the world.                                    */

TEE_Result TA_CreateEntryPoint(void)
{
        /* Called ONCE, when the TA is loaded into memory,
           before any session exists. Initialise global state.
           Returning an error prevents the TA loading at all. */
        DMSG("has been called");
        return TEE_SUCCESS;
}

void TA_DestroyEntryPoint(void)
{
        /* Called once, when the last session closes and the TA
           is unloaded. Free global state. Cannot fail.       */
}

TEE_Result TA_OpenSessionEntryPoint(uint32_t param_types,
                                    TEE_Param params[4],
                                    void **sess_ctx)
{
        /* Once per client session. Allocate per-session state
           and store the pointer in *sess_ctx - it comes back
           on every later call for this session.

           params[] are whatever the client passed to
           TEEC_OpenSession. Check param_types here too.      */
        struct my_session *s = TEE_Malloc(sizeof *s, 0);
        if (!s)
                return TEE_ERROR_OUT_OF_MEMORY;
        *sess_ctx = s;
        return TEE_SUCCESS;
}

void TA_CloseSessionEntryPoint(void *sess_ctx)
{
        TEE_Free(sess_ctx);
}

TEE_Result TA_InvokeCommandEntryPoint(void *sess_ctx,
                                      uint32_t cmd_id,
                                      uint32_t param_types,
                                      TEE_Param params[4])
{
        /* THE REAL WORK. One switch on cmd_id.              */
        switch (cmd_id) {
        case CMD_SIGN:   return do_sign(sess_ctx, param_types, params);
        case CMD_VERIFY: return do_verify(sess_ctx, param_types, params);
        default:         return TEE_ERROR_NOT_SUPPORTED;
        }
}
```

Memory

```
void *TEE_Malloc(size_t size, uint32_t hint);
void *TEE_Realloc(void *buffer, uint32_t newSize);
void  TEE_Free(void *buffer);

/* hint:
     TEE_MALLOC_FILL_ZERO   (0)  zeroed. The default, and what
                                 you almost always want.
     TEE_USER_MEM_HINT_NO_FILL_ZERO   uninitialised, faster   */

void TEE_MemMove(void *dest, const void *src, uint32_t size);
int32_t TEE_MemCompare(const void *b1, const void *b2, uint32_t size);
void TEE_MemFill(void *buf, uint32_t x, uint32_t size);

/* TEE_MemCompare is NOT constant time. For comparing a MAC or
   a password against a stored value, that is a timing oracle.
   Write your own:                                            */

static bool ct_equal(const uint8_t *a, const uint8_t *b, size_t n)
{
        uint8_t diff = 0;
        for (size_t i = 0; i < n; i++)
                diff |= a[i] ^ b[i];
        return diff == 0;
}

/* Validating a pointer the client gave you: */
TEE_Result TEE_CheckMemoryAccessRights(uint32_t accessFlags,
                                       void *buffer, uint32_t size);
    TEE_MEMORY_ACCESS_READ
    TEE_MEMORY_ACCESS_WRITE
    TEE_MEMORY_ACCESS_ANY_OWNER    /* it may be shared memory  */
    TEE_MEMORY_ACCESS_SECURE       /* it must be secure memory */

/* Giving up: */
void TEE_Panic(TEE_Result panicCode);   /* never returns. The
                                           session dies, the
                                           client gets
                                           TEEC_ERROR_TARGET_DEAD,
                                           and a stack dump
                                           appears on the secure
                                           console.            */
```

Cryptography

```
/* The pattern is always the same: allocate an OPERATION,
   allocate and populate an OBJECT for the key, attach one to
   the other, then init/update/final.                        */

/* Note TEE_FreeTransientObject on the key: the key material is
   wiped when the object is freed. Never keep raw key bytes in
   a local array longer than necessary, and TEE_MemFill(0) any
   you do keep.                                                 */
```

HANDLES ARE OPAQUE AND MUST BE FREED ON EVERY PATH

`TEE_OperationHandle` and `TEE_ObjectHandle` are allocations inside OP-TEE. A TA that leaks them exhausts its own heap and eventually fails with `TEE_ERROR_OUT_OF_MEMORY` — after running correctly for hours. Initialise every handle to `TEE_HANDLE_NULL` and use a single `goto out` cleanup path, as above; the free functions accept NULL precisely so this pattern works.

Persistent storage

```
TEE_Result TEE_CreatePersistentObject(uint32_t storageID,
                                      const void *objectID,
                                      uint32_t objectIDLen,
                                      uint32_t flags,
                                      TEE_ObjectHandle attributes,

```

Tracing from inside a TA

```
/* There is no printf. There are these, from
   lib/libutee/include/trace.h - they go to the SECURE console. */

    EMSG("error: %d", x);      /* always shown                 */
    IMSG("info: %s", s);       /* CFG_TEE_TA_LOG_LEVEL >= 2    */
    DMSG("debug: %p", p);      /* >= 3                          */
    FMSG("flow");              /* >= 4                          */

    EMSG_RAW("no prefix\n");
    DHEXDUMP(buf, len);        /* a hex dump - very useful     */

/* Output:
     E/TA: do_sign:112 error: -1
     I/TA: something happened
   with the function name and line number added for you.

   NEVER log key material. DHEXDUMP of a buffer that might be a
   key is a habit that ships. If you need it during
   development, guard it:
     #ifdef DEBUG_SECRETS
     DHEXDUMP(key, keylen);
     #endif
   and make sure DEBUG_SECRETS cannot be defined in a release
   build.                                                    */
```

How it shows up

Symptom	Cause
TA works for hours then fails with out-of-memory	Leaked operation or object handles on an error path
`TEEC_ERROR_TARGET_DEAD`	`TEE_Panic`, a bad pointer, or an assertion. Read the secure console
`TEE_ERROR_BAD_PARAMETERS` from a crypto call	Algorithm and key type mismatch, or key size outside the operation's `maxKeySize`
`TEE_ERROR_NOT_SUPPORTED`	That algorithm is not compiled in — check the `CFG_CRYPTO_*` flags
MAC verification is a timing oracle	Used `TEE_MemCompare` instead of `TEE_MACCompareFinal`
Expiry check defeated trivially	Used `TEE_GetREETime`, which the attacker controls
Storage works for one user, collides for another	Login type and storage scoping — see chapter 15
Key material found in a memory dump	Raw key bytes left in a local buffer; wipe with `TEE_MemFill`
A TA hangs the system	`TEE_Wait` or a long loop holding a thread
Secrets in the log	`DHEXDUMP` of key material left in a release build

Check yourself

- ✓ Name the five entry points and say exactly when each is called.
- ✓ Explain what `sess_ctx` is for and where it is allocated and freed.
- ✓ Write the allocate-populate-attach-use pattern for a symmetric cipher.
- ✓ Explain why every handle must be freed on every path, and give the pattern that ensures it.
- ✓ Say why `TEE_MemCompare` is unsafe for MAC verification and what to use instead.

- ✓ Name the three time sources and rank them by trustworthiness.
- ✓ Explain how a TA discovers who its client is, and why that identity cannot be forged.
- ✓ Give the four trace macros and the log level each needs.
- ✓ Explain what `TEE_Panic` does to the session and what the client sees.
- ✓ List the persistent-storage flags and say which one is needed to delete an object.

TA lifecycle, properties and flags

Four flags in a header file decide whether your TA can serve several clients at once, whether it keeps state between them, and whether the kernel can see it. Choosing them wrongly produces bugs that only appear under concurrency, which is the worst kind to find late.

The header that configures everything

```
/* ta/include/user_ta_header_defines.h - every TA has one.   */

#ifndef USER_TA_HEADER_DEFINES_H
#define USER_TA_HEADER_DEFINES_H

#include "my_ta.h"      /* where TA_MY_UUID is defined        */

#define TA_UUID  TA_MY_UUID

#define TA_FLAGS            (TA_FLAG_SINGLE_INSTANCE | \
                             TA_FLAG_MULTI_SESSION | \
                             TA_FLAG_INSTANCE_KEEP_ALIVE)

#define TA_STACK_SIZE       (2 * 1024)      /* per session     */
#define TA_DATA_SIZE        (32 * 1024)     /* the TA's heap   */

#define TA_CURRENT_TA_EXT_PROPERTIES \
    { "gp.ta.description", USER_TA_PROP_TYPE_STRING, \
      "My example TA" }, \
    { "gp.ta.version", USER_TA_PROP_TYPE_U32, &(const uint32_t){ 0x0100 } }

#endif
```

The flags

Flag	Meaning	Consequence
`TA_FLAG_SINGLE_INSTANCE`	One copy of the TA serves all clients	Global state is shared between sessions. Without it, each client gets its own instance and its own globals
`TA_FLAG_MULTI_SESSION`	The instance accepts more than one session at a time	Without it, a second client waits until the first closes
`TA_FLAG_INSTANCE_KEEP_ALIVE`	The instance survives when the last session closes	Global state and `TA_CreateEntryPoint` work persist. Costs TA_RAM permanently
`TA_FLAG_DEVICE_ENUM`	Advertise this TA to the Linux TEE bus	Required for a kernel driver to bind (chapter 10)
`TA_FLAG_SECURE_DATA_PATH`	May receive secure-memory buffers	For media pipelines
`TA_FLAG_CACHE_MAINTENANCE`	May call `TEE_Cache*`	Only with `CFG_CACHE_API=y`

```
The four combinations that matter, and what each is for.

1. SINGLE_INSTANCE | MULTI_SESSION | KEEP_ALIVE
   One instance, always resident, many concurrent clients,
   shared global state.
   -> A SERVICE. The fTPM is exactly this: one TPM, whose
      PCRs and NV storage are global, serving anyone.
   -> You are now responsible for thread safety of your own
      globals. OP-TEE does NOT serialise for you.

2. SINGLE_INSTANCE | MULTI_SESSION       (no keep-alive)
   Same, but unloaded when idle. Saves TA_RAM; pays the
   load-and-verify cost on the next first session.
   -> A frequently-but-not-constantly used service.

3. SINGLE_INSTANCE only
   One instance, ONE session at a time. Clients serialise.
   -> The safe default when you have shared state and do
      not want to think about locking. Simple and slow.

4. neither SINGLE_INSTANCE nor MULTI_SESSION
   A fresh instance per client, each with its own globals
   and its own TA_RAM allocation.
   -> Perfect isolation between clients, at the cost of
      memory. Good for a per-application key handler.

THE TRAP: combination 1 with global variables and no
locking. Two clients invoke concurrently, both touch a
global, and you have a data race inside the secure world.
It will not show up in testing with one client.
```

> **`MULTI_SESSION` MEANS YOU MUST LOCK**
>
> With `SINGLE_INSTANCE | MULTI_SESSION`, OP-TEE will run two `TA_InvokeCommandEntryPoint` calls concurrently on different threads, in the same address space, over the same globals. There is no implicit mutex. If your TA has mutable global state — a PCR bank, a key cache, a counter — you must protect it yourself. If you would rather not, drop `MULTI_SESSION` and accept serialisation.

Where state lives

```
THREE scopes, three lifetimes.

GLOBAL VARIABLES
    lifetime: from TA_CreateEntryPoint to
              TA_DestroyEntryPoint
    shared:   between all sessions, IF SINGLE_INSTANCE
    lost on:  TA unload (unless KEEP_ALIVE), reboot
    use for:  a service's shared state; caches

SESSION CONTEXT (*sess_ctx)
    lifetime: TA_OpenSessionEntryPoint to
              TA_CloseSessionEntryPoint
    shared:   only within that session
    lost on:  session close, TA panic, client death
    use for:  per-client keys, cursors, in-progress
              operations

PERSISTENT OBJECTS
    lifetime: until explicitly deleted
    shared:   per-TA, and per-client if the login type
              scopes it (chapter 15)
    lost on:  explicit delete, factory reset, or a normal
              world that deletes the backing file
    use for:  keys, counters, anything that must survive
              reboot

A common design error: keeping a key in a global "for
performance" in a SINGLE_INSTANCE TA, so that client B can
use the key client A loaded. Put per-client material in the
session context.
```

A TA with all three

```
#include <tee_internal_api.h>
#include <tee_internal_api_extensions.h>
#include <string.h>
#include "my_ta.h"

/* --- GLOBAL: shared, needs locking under MULTI_SESSION --- */
static uint32_t g_invocations;
static bool     g_initialised;

/* --- SESSION: per client --- */
struct session {
        TEE_ObjectHandle key;     /* this client's key         */
        uint32_t         counter;
        uint8_t          nonce[12];
};

TEE_Result TA_CreateEntryPoint(void)
{
        DMSG("TA loaded");
        g_invocations = 0;
        g_initialised = true;
        return TEE_SUCCESS;
}

void TA_DestroyEntryPoint(void)
{
        DMSG("TA unloaded after %u invocations", g_invocations);
        g_initialised = false;
}

TEE_Result TA_OpenSessionEntryPoint(uint32_t ptypes,
                                    TEE_Param params[4],
                                    void **sess_ctx)
{
        struct session *s;

        /* Even here, check the types. */
        if (ptypes != TEE_PARAM_TYPES(TEE_PARAM_TYPE_NONE,
                                      TEE_PARAM_TYPE_NONE,
                                      TEE_PARAM_TYPE_NONE,
                                      TEE_PARAM_TYPE_NONE))
                return TEE_ERROR_BAD_PARAMETERS;

Sizing stack and heap

```
#define TA_STACK_SIZE  (2 * 1024)    /* PER SESSION            */
#define TA_DATA_SIZE   (32 * 1024)   /* the TA's whole heap    */

/* TA_STACK_SIZE: the C stack for TA code. 2 KB is the common
   default and it is small. Things that overflow it:
       - a large local buffer  (uint8_t buf[4096];)
       - deep recursion
       - a crypto call chain with its own locals
   Symptom: a panic with a stack dump, often in an unrelated
   function, and often only for large inputs.

   Do not put big buffers on the stack. TEE_Malloc them, or
   raise TA_STACK_SIZE deliberately.                          */

/* TA_DATA_SIZE: everything TEE_Malloc returns, plus the
   internal allocations OP-TEE makes on the TA's behalf -
   operation handles, object handles, key material.
   Symptom of running out: TEE_ERROR_OUT_OF_MEMORY, usually
   after a leak rather than a genuine shortage.              */

/* Measuring: build with CFG_TA_STATS=y and ask.             */
$ xtest --stats
TA stats:
  <uuid>
    Heap: allocated 8192, max allocated 20480, size 32768
    Stack: max used 1152, size 2048

/* "max used" is the number that matters. 1152 of 2048 is
   comfortable; 1900 of 2048 is a crash waiting for a longer
   input.                                                     */
```

Properties

```
/* Declared in the header, readable by the TA and, for some,
   by the client.                                          */

#define TA_CURRENT_TA_EXT_PROPERTIES \
    { "gp.ta.description", USER_TA_PROP_TYPE_STRING, \
      "Secure key store" }, \
    { "gp.ta.version", USER_TA_PROP_TYPE_U32, \
      &(const uint32_t){ 0x0102 } }, \
    { "com.example.max-keys", USER_TA_PROP_TYPE_U32, \
      &(const uint32_t){ 16 } }

/* Read them: */
    uint32_t maxkeys;
    TEE_GetPropertyAsU32(TEE_PROPSET_CURRENT_TA,
                         "com.example.max-keys", &maxkeys);

/* Standard properties every TA has: */
    gpd.ta.appID            this TA's UUID
    gpd.ta.singleInstance   bool, from the flags
    gpd.ta.multiSession     bool
    gpd.ta.instanceKeepAlive bool
    gpd.ta.dataSize         TA_DATA_SIZE
    gpd.ta.stackSize        TA_STACK_SIZE

/* About the TEE itself: */
    gpd.tee.apiversion
    gpd.tee.internalCore.version
    gpd.tee.trustedos.implementation.version
    gpd.tee.deviceID        a per-device identifier derived
                            from the hardware unique key -
                            useful, and privacy-sensitive

/* About the caller: */
    gpd.client.identity     login type + uuid (chapter 12)
```

How it shows up

Symptom	Cause
Works with one client, corrupts with two	`MULTI_SESSION` with unprotected global state
Second client blocks until the first finishes	`MULTI_SESSION` not set — this may be what you wanted
Global state lost between clients	No `INSTANCE_KEEP_ALIVE`; the TA unloaded when the last session closed
Each client sees its own globals	`SINGLE_INSTANCE` not set
No device under `/sys/bus/tee/devices/`	`TA_FLAG_DEVICE_ENUM` missing
Panic with a stack dump on large inputs	`TA_STACK_SIZE` too small — a big local buffer
`TEE_ERROR_OUT_OF_MEMORY` after long uptime	Leaked handles or allocations; `TA_DATA_SIZE` exhausted
One client can use another's key	Key held in a global rather than the session context
Session context is NULL in a callback	`*sess_ctx` not set, or set after an early error return
Secrets recovered from TA heap	Session structure freed without being wiped

Check yourself

- ✓ Name the TA flags and say what each changes.
- ✓ Give the four useful flag combinations and a use case for each.
- ✓ Explain what `SINGLE_INSTANCE | MULTI_SESSION` obliges you to do.
- ✓ Name the three state scopes, their lifetimes, and what belongs in each.
- ✓ Explain why a per-client key must not live in a global.
- ✓ Say what `TA_STACK_SIZE` and `TA_DATA_SIZE` control and how to measure usage.
- ✓ Give two things that overflow a 2 KB TA stack.
- ✓ Declare a custom property and read it from the TA.
- ✓ Explain why session state should be wiped before it is freed.
- ✓ Say which flag a TA needs for a kernel driver to bind to it.

Building, signing and packaging a TA

A trusted application is delivered as a signed binary sitting in the normal world's filesystem, where an attacker can replace it at will. The signature is the only thing that makes that acceptable, and understanding the format, the build and the key management is what separates a demo from something shippable.

The project layout

```
   Copy optee_examples/hello_world and rename. Every OP-TEE
   project has this shape and there is no reason to invent
   another.

   my_project/
     Makefile              builds both halves
     host/
       Makefile
       main.c              the client (chapter 11)
     ta/
       Makefile            2 lines - includes the dev kit
       sub.mk              lists the source files
       user_ta_header_defines.h    flags, sizes, UUID (ch. 13)
       my_ta.c             the five entry points (ch. 12)
       include/
         my_ta.h           SHARED between host and TA:
                           the UUID and the command IDs
     README.md

   my_ta.h is the interface contract. Both sides include it, so
   a command ID can never drift between them:

     #define TA_MY_UUID \
        { 0x12345678, 0x1234, 0x1234, \
          { 0x12, 0x34, 0x12, 0x34, 0x12, 0x34, 0x12, 0x34 } }

     #define TA_CMD_SIGN     0
     #define TA_CMD_VERIFY   1
     #define TA_CMD_GEN_KEY  2
```

```
# Generate a UUID. Never invent one by hand, and never reuse
# an example's - two TAs with the same UUID cannot coexist.
$ uuidgen
7f2e9c1a-3b4d-4e5f-8a9b-0c1d2e3f4a5b

# In the C form OP-TEE wants:
$ python3 - <<'EOF'
import uuid
u = uuid.uuid4()
b = u.bytes
print(u)
print("#define TA_MY_UUID \\")
print("\t{ 0x%08x, 0x%04x, 0x%04x, \\" % (u.time_low, u.time_mid,
      u.time_hi_version))
print("\t  { " + ", ".join("0x%02x" % c for c in b[8:]) + " } }")
EOF
```

The makefiles

```
# ta/Makefile - genuinely this short. All the work is in the
# dev kit.
CFG_TEE_TA_LOG_LEVEL ?= 3
CPPFLAGS += -DCFG_TEE_TA_LOG_LEVEL=$(CFG_TEE_TA_LOG_LEVEL)

BINARY = 7f2e9c1a-3b4d-4e5f-8a9b-0c1d2e3f4a5b

-include $(TA_DEV_KIT_DIR)/mk/ta_dev_kit.mk

ifeq ($(wildcard $(TA_DEV_KIT_DIR)/mk/ta_dev_kit.mk), )
clean:
        @echo 'TA_DEV_KIT_DIR is not correctly defined' && false
endif

# BINARY must be the UUID. The output is $(BINARY).ta and
# OP-TEE looks it up by that name. A mismatch between BINARY
# and TA_UUID in the header means the file exists and is never
# found.

# ta/sub.mk
global-incdirs-y += include
srcs-y += my_ta.c
srcs-y += crypto_helpers.c
# cflags-my_ta.c-y += -Wno-unused-parameter

# host/Makefile
CC      ?= $(CROSS_COMPILE)gcc
CFLAGS  += -Wall -I../ta/include -I$(TEEC_EXPORT)/include
LDADD   += -lteec -L$(TEEC_EXPORT)/lib

BINARY = my_client
OBJS = main.o

.PHONY: all clean
all: $(BINARY)

$(BINARY): $(OBJS)
        $(CC) -o $@ $< $(LDADD)

%.o: %.c
        $(CC) $(CFLAGS) -c $< -o $@

clean:
        rm -f $(OBJS) $(BINARY)

# Top-level Makefile
export V ?= 0
OUTPUT_DIR := $(CURDIR)/out

.PHONY: all
all: ta host

.PHONY: ta
ta:
        $(MAKE) -C ta CROSS_COMPILE=$(TA_CROSS_COMPILE) \
                LDFLAGS=""
```

```
.PHONY: host
host:
	$(MAKE) -C host CROSS_COMPILE=$(HOST_CROSS_COMPILE) \
		--no-builtin-variables

.PHONY: clean
clean:
	$(MAKE) -C ta clean
	$(MAKE) -C host clean
```

```
# Build it.
$ export TA_DEV_KIT_DIR=$HOME/optee/optee_os/out/arm-plat-vexpress/export-ta_arm64
$ export TEEC_EXPORT=$HOME/optee/optee_client/out/export/usr
$ export TA_CROSS_COMPILE=aarch64-linux-gnu-
$ export HOST_CROSS_COMPILE=aarch64-linux-gnu-
$ make

$ ls ta/*.ta host/my_client
ta/7f2e9c1a-3b4d-4e5f-8a9b-0c1d2e3f4a5b.ta
host/my_client

# Install into the image:
$ cp ta/*.ta   ~/optee/out-br/target/lib/optee_armtz/
$ cp host/my_client ~/optee/out-br/target/usr/bin/
$ cd ~/optee/build && make buildroot run-only

# Or, better, add it to the OP-TEE build as a buildroot
# package so it is rebuilt automatically. See
# optee_examples/ for the pattern.
```

What a .ta file is

```
+-----------------------------------------------------------+
|  shdr - the signed header                                 |
|    magic       0x4f545348  "OTSH"                         |
|    img_type    SHDR_TA / SHDR_BOOTSTRAP_TA /              |
|                SHDR_ENCRYPTED_TA                          |
|    img_size                                               |
|    algo        e.g. RSASSA_PKCS1_PSS_MGF1_SHA256          |
|    hash_size                                              |
|    sig_size                                               |
+-----------------------------------------------------------+
|  hash          SHA-256 of everything below                |
+-----------------------------------------------------------+
|  signature     RSA/ECDSA over that hash                   |
+-----------------------------------------------------------+
|  (bootstrap TA only) the UUID and TA version              |
+-----------------------------------------------------------+
|  the ELF - the actual TA, linked against the dev kit      |
+-----------------------------------------------------------+

VERIFICATION, inside OP-TEE, before a single instruction of
the TA runs:

  1. tee-supplicant delivers the file (chapter 9).
  2. OP-TEE reads shdr and checks magic and sizes.
  3. It hashes the ELF and compares with hash.
  4. It verifies the signature over that hash, using a
     public key COMPILED INTO OP-TEE.
  5. For a bootstrap TA, it checks the UUID inside matches
     the UUID that was requested - so a valid TA cannot be
     substituted for a different valid TA.
  6. Only then is the ELF loaded and mapped.

Failure at any step: TEEC_ERROR_SECURITY (0xFFFF000F).

NOTE WHAT IS NOT PROTECTED: confidentiality. A plain .ta is
readable by anyone with the filesystem. If the TA's code is
itself sensitive, you need SHDR_ENCRYPTED_TA.
```

Signing, and the key problem

```
# The default: every OP-TEE tree ships one key, and it signs
# every TA built in that tree.
$ ls -l optee_os/keys/default_ta.pem
-rw-r--r-- 1 user user 1704 default_ta.pem

# THIS KEY IS PUBLIC. It is in the git repository. A device
# whose OP-TEE trusts it will load any TA anyone builds.

# Use your own:
$ openssl genrsa -out my_ta_key.pem 2048
$ openssl rsa -in my_ta_key.pem -pubout -out my_ta_pub.pem

$ make -C optee_os TA_SIGN_KEY=$PWD/my_ta_key.pem ...
# OP-TEE embeds the PUBLIC half; the private half signs TAs.

# Sign an existing unsigned ELF by hand:
$ python3 optee_os/scripts/sign_encrypt.py sign \
    --key my_ta_key.pem \
    --uuid 7f2e9c1a-3b4d-4e5f-8a9b-0c1d2e3f4a5b \
    --in ta.elf --out ta.ta

# Inspect one you were given:
$ python3 optee_os/scripts/sign_encrypt.py display --in some.ta

# THE PRODUCTION PATTERN: the private key never leaves an HSM.
# sign_encrypt.py supports a two-step flow for exactly this:
#
#   1. produce the digest to be signed
$ python3 scripts/sign_encrypt.py digest \
    --key my_ta_pub.pem --uuid $UUID --in ta.elf --dig ta.dig
#   2. sign the digest elsewhere - HSM, signing service, an
#      air-gapped machine
$ openssl pkeyutl -sign -inkey my_ta_key.pem \
    -in ta.dig -out ta.sig \
    -pkeyopt digest:sha256 -pkeyopt rsa_padding_mode:pss \
    -pkeyopt rsa_pss_saltlen:digest
#   3. staple the signature on
$ python3 scripts/sign_encrypt.py stitch \
    --key my_ta_pub.pem --uuid $UUID \
    --in ta.elf --sig ta.sig --out ta.ta

# The build machine never holds the private key. This is the
# difference between a signing story and a signing key sitting
# in CI's environment variables.
```

> **THREE WAYS TA SIGNING GOES WRONG IN THE FIELD**
>
> **Shipping with the default key** — anyone can load a TA. **Key in the repository** — same, once the repository leaks. **No revocation plan** — the public key is compiled into OP-TEE, which is in a signed boot image, so rotating it means a firmware update. Decide the rotation story before the first device ships, not after a key is compromised.

Encrypted TAs

```
# When the TA's own code is the secret - a proprietary
# algorithm, an anti-tamper routine, an obfuscated licence
# check.

$ make -C optee_os \
    CFG_ENCRYPT_TA=y \
    TA_ENC_KEY=0123456789abcdef0123456789abcdef

$ python3 scripts/sign_encrypt.py sign \
    --key my_ta_key.pem --enc-key $TA_ENC_KEY \
    --enc-key-type SHDR_ENC_KEY_DEV_SPECIFIC \
    --uuid $UUID --in ta.elf --out ta.ta

# Key types:
#   SHDR_ENC_KEY_DEV_SPECIFIC   derived from the device's
#                               hardware unique key. The .ta is
#                               then bound to ONE device and
#                               cannot be moved.
#   SHDR_ENC_KEY_CLASS_WIDE     a key shared by a product
#                               class. Convenient; one
#                               extracted key breaks the whole
#                               class.

# The TA is encrypted at rest and decrypted inside OP-TEE
# during load. It is still in cleartext in TA_RAM while
# running, so this defends against extraction from the
# filesystem, not against an attacker who has already
# compromised the secure world.

# Weigh it honestly: encryption complicates your build and
# your field-update story, and it protects only against
# reverse engineering. Most TAs do not need it. Signing is
# mandatory; encryption is a business decision.
```

Confirming it worked

```
# On the target:
$ ls -l /lib/optee_armtz/
-rw-r--r-- 1 root root 24576 7f2e9c1a-3b4d-4e5f-8a9b-0c1d2e3f4a5b.ta

# Filename MUST equal the UUID. Check:
$ python3 sign_encrypt.py display --in /path/to/ta.ta
uuid: 7f2e9c1a-3b4d-4e5f-8a9b-0c1d2e3f4a5b
img_type: SHDR_BOOTSTRAP_TA
algo: TEE_ALG_RSASSA_PKCS1_PSS_MGF1_SHA256
size: 22016

# Run the client and watch the secure console:
D/TC:0 0 ree_fs_ta_open:...  TA 7f2e9c1a-... loaded
D/TC:0 0 shdr_verify_signature:...  OK
I/TA:  my TA started

# A signature failure looks like:
E/TC:0 0 shdr_verify_signature:...  Signature verification failed
E/TC:0 0 ree_fs_ta_open:...  TEE_ERROR_SECURITY
# and the client sees 0xFFFF000F.
```

How it shows up

Symptom	Cause
`TEEC_ERROR_ITEM_NOT_FOUND`	Filename does not match the UUID, wrong directory, or `tee-supplicant` not running
`TEEC_ERROR_SECURITY`	Signed with a key OP-TEE does not trust — usually a rebuilt OP-TEE with a different `TA_SIGN_KEY`
TA builds but the file is empty or tiny	`BINARY` in `ta/Makefile` does not match, or `sub.mk` lists no sources
`TA_DEV_KIT_DIR is not correctly defined`	Dev kit path wrong, or built for a different architecture (`arm32` vs `arm64`)
Changes have no effect	Old `.ta` still in the image — `make buildroot`
Two TAs conflict	Copied an example without changing the UUID
Client links but cannot find `libteec.so`	Library not in the target rootfs
Works on your build, not on a colleague's	Different `TA_SIGN_KEY`; the TA must be signed by the key that *their* OP-TEE embeds
Cannot rotate a compromised key	The public key is inside a signed boot image; this needed planning
Encrypted TA fails to load on a second device	`DEV_SPECIFIC` key — bound to one device by design

Check yourself

- ✓ Lay out a TA project and say what belongs in the shared header.
- ✓ Explain why `BINARY` in the TA Makefile must be the UUID.
- ✓ Generate a UUID and put it in the C form OP-TEE expects.
- ✓ Describe the `.ta` file format and the six verification steps.
- ✓ Explain what a bootstrap TA's embedded UUID prevents.
- ✓ Say what signing does *not* protect.
- ✓ Explain the risk of the default signing key.
- ✓ Describe the digest-sign-stitch flow and why production needs it.
- ✓ Explain when an encrypted TA is worth the cost, and what it does not defend against.
- ✓ Diagnose `TEEC_ERROR_SECURITY` and `TEEC_ERROR_ITEM_NOT_FOUND` apart.

Secure storage: REE FS and RPMB

The secure world has no flash of its own. It stores data by encrypting it and handing it to the normal world, or by writing it to a partition of the eMMC that authenticates every access. The two approaches protect different things, and knowing which property you are missing is the whole point of this chapter.

Two back ends, different guarantees

Property	REE FS	RPMB
Confidentiality	**Yes** — AES-GCM with a device key	**Yes**
Integrity	**Yes** — authenticated encryption	**Yes** — HMAC in hardware
Rollback protection	**No** — an old ciphertext still verifies	**Yes** — a monotonic write counter
Availability	No — the normal world can delete the file	No — but it cannot silently substitute
Needs hardware	No	eMMC or UFS with an RPMB partition
Typical size	Whatever the filesystem has	128 KB – 16 MB
Speed	RPC per operation; moderate	RPC plus an eMMC transaction; slow
Build flag	`CFG_REE_FS=y`	`CFG_RPMB_FS=y`

```
THE ROLLBACK GAP, which is the whole reason RPMB exists.

REE FS:
  TA writes "failed_attempts = 3"
    -> encrypted, authenticated, written to /data/tee/xyz
  Attacker copies that file.
  TA writes "failed_attempts = 4", then 5, then locks out.
  Attacker restores the copied file.
    -> it decrypts correctly
    -> it authenticates correctly
    -> the TA reads "failed_attempts = 3"

  Nothing was forged. An OLD, GENUINE state was replayed,
  and encryption cannot detect that.

RPMB:
  Every write carries a monotonically increasing counter,
  and the eMMC itself enforces it. A replayed frame has a
  stale counter and the eMMC rejects it. The counter lives
  in the flash controller, not in software, and cannot be
  rewound.

So: use REE FS for things where replay does not matter (a
key, a certificate - old is as good as new). Use RPMB for
anything COUNTED or REVOKED: attempt counters, firmware
anti-rollback versions, licence state, revocation lists.
```

Using it

```
/* The API is the same regardless of back end - only the
   storageID changes.                                          */

#define OBJ_ID  "my-signing-key-v1"

static TEE_Result store_key(const uint8_t *key, size_t len)
{
        TEE_ObjectHandle obj = TEE_HANDLE_NULL;
        TEE_Result res;
        uint32_t flags = TEE_DATA_FLAG_ACCESS_READ  |
                         TEE_DATA_FLAG_ACCESS_WRITE |
                         TEE_DATA_FLAG_ACCESS_WRITE_META |
                         TEE_DATA_FLAG_OVERWRITE;

        res = TEE_CreatePersistentObject(TEE_STORAGE_PRIVATE,
                                         OBJ_ID, sizeof(OBJ_ID) - 1,
                                         flags,
                                         TEE_HANDLE_NULL,   /* no
                                            attributes - raw data */
                                         key, len,
                                         &obj);
        if (res != TEE_SUCCESS) {
                EMSG("create failed 0x%08x", res);
                return res;

        /* This CLOSES the handle as well - do not close it
           again.                                              */
        return TEE_CloseAndDeletePersistentObject1(obj);
}
```

STORING A KEY OBJECT, NOT RAW BYTES

`TEE_CreatePersistentObject`'s `attributes` parameter takes a `TEE_ObjectHandle`. Pass a populated key object there and OP-TEE stores the key *as a key* — you can reopen it and pass it straight to `TEE_SetOperationKey` without the raw material ever appearing in a buffer you manage. For key storage that is strictly better than storing bytes and re-populating.

```
/* The better pattern for keys: */

    TEE_ObjectHandle key = TEE_HANDLE_NULL, persistent = TEE_HANDLE_NULL;

    TEE_AllocateTransientObject(TEE_TYPE_AES, 256, &key);
    TEE_GenerateKey(key, 256, NULL, 0);   /* never leaves the TEE */

    TEE_CreatePersistentObject(TEE_STORAGE_PRIVATE,
                               OBJ_ID, sizeof(OBJ_ID) - 1,
                               flags,
                               key,          /* <-- the object   */
                               NULL, 0,      /* no extra data     */
                               &persistent);

    /* Later, in another session or after a reboot: */
    TEE_OpenPersistentObject(TEE_STORAGE_PRIVATE,
                             OBJ_ID, sizeof(OBJ_ID) - 1,
                             TEE_DATA_FLAG_ACCESS_READ, &persistent);
    TEE_SetOperationKey(op, persistent);    /* use it directly    */

    /* The raw key bytes existed only inside OP-TEE, ever. */
```

The key hierarchy

```
HUK - the Hardware Unique Key
  Burned into fuses or derived from a PUF. Readable only by
  secure-world code, often only through a hardware key
  derivation block that never exposes it. Different on every
  device.
    |
    |  KDF, with a fixed string
    v
SSK - Secure Storage Key
  huk_derive(HUK, "onlinesecurestorage")
    |
    |  KDF, with the TA's UUID
    v
TSK - TA Storage Key
  hmac(SSK, TA_UUID)
    |
    |  and, if the login type scopes it, the client identity
    v
FEK - File Encryption Key
  A FRESH RANDOM key per file, encrypted with the TSK and
  stored in the file's own header.
    |
    v
the file contents, AES-GCM under the FEK

What each level buys:

  HUK per device      one device's storage cannot be read on
                      another, and a stolen image is useless
  TSK per TA          TA A cannot read TA B's objects. This
                      is enforced by key derivation, not by
                      access control - even a compromised
                      TA A does not have TA B's key.
  per-client scoping  with LOGIN_USER, two users of the same
                      TA get different storage
  FEK per file        one file's key does not compromise
                      another; and rewriting a file uses a
                      new FEK

On QEMU there are no fuses, so the HUK is a hardcoded test
value and every "device" has the same one. That is fine for
development and is exactly what the "might be insecure"
warning is about (chapter 4).
```

RPMB in practice

```
# RPMB is a special eMMC partition. Every read and write is
# authenticated with an HMAC-SHA256 key that is PROGRAMMED ONCE
# and can never be read back or changed.

$ ls /dev/mmcblk0*
/dev/mmcblk0  /dev/mmcblk0boot0  /dev/mmcblk0boot1  /dev/mmcblk0rpmb

$ sudo mmc rpmb read-counter /dev/mmcblk0rpmb
Counter value: 0x00001a2f

# Build OP-TEE for it:
$ make CFG_RPMB_FS=y CFG_RPMB_WRITE_KEY=y CFG_RPMB_TESTKEY=n

#   CFG_RPMB_FS=y         use RPMB for secure storage
#   CFG_RPMB_WRITE_KEY=y  allow OP-TEE to PROGRAM the key if it
#                         is not yet set. ONE-WAY. Enable
#                         deliberately, in manufacturing.
#   CFG_RPMB_TESTKEY=y    use a fixed test key. Development
#                         only, and it makes RPMB pointless.

# Under QEMU there is no real eMMC, so tee-supplicant emulates
# one in a file:
$ tee-supplicant -r          # emulated RPMB
$ ls -l /var/lib/optee/rpmb_emu*
# Useful for developing the logic; provides no real rollback
# protection, because the emulation file can be restored.

# From a TA, force RPMB explicitly:
    TEE_CreatePersistentObject(TEE_STORAGE_PRIVATE_RPMB, ...)
```

> **THE RPMB KEY IS WRITTEN ONCE, FOR EVER**
>
> Programming the RPMB authentication key is irreversible. Get it wrong in manufacturing — wrong key, key not recorded, key derived from something you later change — and those devices can never use RPMB again. There is no reset, no factory tool, no vendor override. Decide the key derivation before the first production run and test the whole flow on sacrificial hardware.

What the normal world can still do

```
# REE FS storage is just files:
$ ls -la /data/tee/
drwx------ 2 root root  4096 .
-rw------- 1 root root  4096 0
-rw------- 1 root root   512 1
-rw------- 1 root root  4096 dirf.db

$ xxd /data/tee/0 | head -3
00000000: a3f1 8c2e 44b9 7710 ...   # ciphertext. Unreadable.

# The normal world CAN:
#   delete these files      -> the TA's data is GONE
#   restore an old copy     -> rollback, unless RPMB
#   fill the filesystem     -> writes fail
#   corrupt them            -> reads fail authentication

# The normal world CANNOT:
#   read the plaintext
#   forge a valid file
#   move the data to another device and use it

# So: AVAILABILITY IS NOT PROTECTED, on either back end. A TA
# must handle its storage vanishing:
#
#   res = TEE_OpenPersistentObject(...);
#   if (res == TEE_ERROR_ITEM_NOT_FOUND) {
#           /* First run, OR someone deleted it. You usually
#              cannot tell the difference. Decide, at design
#              time, which of these your TA does:
#                - regenerate and carry on   (a cache)
#                - refuse to operate         (a licence)
#                - re-provision from a server (a credential)
#              "Regenerate silently" for something that was
#              supposed to be counted is how rollback
#              protection gets lost.                        */
#   }
```

How it shows up

Symptom	Cause
`TEE_ERROR_ITEM_NOT_FOUND` on first run	Normal. Handle it as a create-if-absent case
All stored data lost after a filesystem wipe	REE FS lives in `/data/tee`; nothing protects availability
Attempt counter can be reset	REE FS has no rollback protection — this needs RPMB
`TEE_ERROR_MAC_INVALID` or `CORRUPT_OBJECT`	File modified or truncated by the normal world — authentication working
Storage works on one device, not another	Per-device HUK. This is the intended behaviour
Storage lost after a firmware update	HUK derivation changed, or the TA's UUID changed, so the TSK differs
RPMB operations fail with `TEE_ERROR_TIME_NOT_SET`-like errors	RPMB key not programmed, or the wrong key
RPMB writes fail after a while	Partition full — RPMB is small; store counters, not blobs
Storage is very slow	Every operation is an RPC plus an eMMC transaction. Cache in the session context and write rarely

Symptom	Cause
Two users share stored data	`TEEC_LOGIN_PUBLIC`; use `LOGIN_USER` (chapter 11)

Check yourself

- ✓ Compare REE FS and RPMB across confidentiality, integrity, rollback and availability.
- ✓ Explain the rollback attack against REE FS in concrete steps.
- ✓ Say which kinds of data require RPMB and give three examples.
- ✓ Write a create-read-delete cycle for a persistent object with correct error handling.
- ✓ Explain why storing a key object beats storing raw bytes.
- ✓ Draw the key hierarchy from HUK to file, and say what each level isolates.
- ✓ Explain how one TA is prevented from reading another's storage.
- ✓ Say what the RPMB write counter protects and where it lives.
- ✓ Explain why programming the RPMB key is a manufacturing decision.
- ✓ List what the normal world can and cannot do to secure storage, and say how a TA should handle its data disappearing.

Cryptography inside a TA

The whole reason a TA exists is usually to hold a key. This chapter covers the algorithms OP-TEE offers, how keys are generated and derived so that raw material never crosses the boundary, where the hardware accelerator fits, and the handful of mistakes that turn a correct algorithm into a broken system.

The rule that shapes every design

```
A key that crosses into the normal world is not protected.
Design so it never has to.

BAD                          GOOD

client: generate key         client: "generate a key for me"
client -> TA: here is the      TA: TEE_GenerateKey()
    key, please sign               store it persistently
TA: sign with it                   return only a HANDLE/ID
TA -> client: signature       client: "sign this, with key 7"
                               TA: load key 7, sign, return
                                   the signature

In the second design the key material exists only inside
OP-TEE, from generation to destruction. There is no moment
at which a compromised kernel could read it.

The client's interface becomes:
    create_key()  -> key_id
    sign(key_id, digest) -> signature
    get_public_key(key_id) -> public key
    delete_key(key_id)

That is exactly the shape of Android Keymint, of a PKCS#11
token, and of the project in chapter 21. It is not a
coincidence: it is the only shape that works.
```

What OP-TEE offers

Class	Algorithms	Notes
Hashes	MD5, SHA-1, SHA-224/256/384/512, SHA3-*, SM3	MD5 and SHA-1 exist for legacy interop only
Symmetric	AES (ECB, CBC, CTR, CTS, XTS, CBC-MAC), DES, 3DES, SM4	Do not use ECB. Ever. It is there for building other things
AEAD	AES-GCM, AES-CCM	The default choice for encrypting anything
MAC	HMAC-*, AES-CMAC, AES-CBC-MAC	Verify with `TEE_MACCompareFinal`
Asymmetric	RSA (PKCS#1 v1.5, PSS, OAEP), DSA, ECDSA, Ed25519, SM2	PSS over v1.5 for new designs
Key agreement	DH, ECDH, X25519	Followed by a KDF — never use the raw shared secret as a key
Derivation	HKDF, PBKDF2, Concat KDF	Availability depends on `CFG_CRYPTO_*`
Random	`TEE_GenerateRandom`	Backed by a hardware TRNG where the platform has one

```
# Which are actually compiled in? They are individually
# selectable, and a missing one gives TEE_ERROR_NOT_SUPPORTED
# at runtime rather than a build error.

$ grep -E '^CFG_CRYPTO' optee_os/core/crypto/sub.mk | head -20
CFG_CRYPTO_AES ?= y
CFG_CRYPTO_GCM ?= y
CFG_CRYPTO_ECC ?= y
CFG_CRYPTO_RSA ?= y
CFG_CRYPTO_SHA512 ?= y
CFG_CRYPTO_HKDF ?= y
CFG_CRYPTO_SM2_PKE ?= n
...

# Turn off what you do not need - it is code in your trusted
# computing base:
$ make CFG_CRYPTO_MD5=n CFG_CRYPTO_DES=n CFG_CRYPTO_DSA=n

# And confirm from a TA, at runtime, rather than assuming:
    res = TEE_AllocateOperation(&op, TEE_ALG_AES_GCM,
                                TEE_MODE_ENCRYPT, 256);
    if (res == TEE_ERROR_NOT_SUPPORTED)
            /* this build does not have GCM */
```

Generating and keeping a key

```
/* An ECDSA P-256 signing key that is generated inside the TEE,
   stored persistently, and never exported.                   */

static TEE_Result create_signing_key(const char *id, size_t idlen)
{
        TEE_ObjectHandle key  = TEE_HANDLE_NULL;
        TEE_ObjectHandle pobj = TEE_HANDLE_NULL;
        TEE_Attribute    attr;
        TEE_Result       res;

        res = TEE_AllocateTransientObject(TEE_TYPE_ECDSA_KEYPAIR,
                                          256, &key);
        if (res) goto out;

        /* The curve must be given as a generation parameter. */
        TEE_InitValueAttribute(&attr, TEE_ATTR_ECC_CURVE,
                               TEE_ECC_CURVE_NIST_P256, 0);

        res = TEE_GenerateKey(key, 256, &attr, 1);
        if (res) goto out;

        /* Persist it AS AN OBJECT. */
        res = TEE_CreatePersistentObject(
                TEE_STORAGE_PRIVATE, id, idlen,
                TEE_DATA_FLAG_ACCESS_READ |
                TEE_DATA_FLAG_ACCESS_WRITE_META |
                TEE_DATA_FLAG_OVERWRITE,
                key, NULL, 0, &pobj);
out:
        TEE_FreeTransientObject(key);
        if (pobj != TEE_HANDLE_NULL)
                TEE_CloseObject(pobj);
        return res;
}

/* Exporting ONLY the public half - which is safe and
   necessary, because someone must verify the signatures.   */

static TEE_Result export_public(const char *id, size_t idlen,
                                uint8_t *x, size_t *xlen,
                                uint8_t *y, size_t *ylen)
{
        TEE_ObjectHandle pobj = TEE_HANDLE_NULL;
        TEE_Result res;
        uint32_t l;

        res = TEE_OpenPersistentObject(TEE_STORAGE_PRIVATE,
                                       id, idlen,
                                       TEE_DATA_FLAG_ACCESS_READ,
                                       &pobj);
        if (res) return res;

        l = *xlen;
        res = TEE_GetObjectBufferAttribute(pobj,
                        TEE_ATTR_ECC_PUBLIC_VALUE_X, x, &l);
        if (res) goto out;
        *xlen = l;

        l = *ylen;
        res = TEE_GetObjectBufferAttribute(pobj,
```

```
                        TEE_ATTR_ECC_PUBLIC_VALUE_Y, y, &l);
        if (res == TEE_SUCCESS)
                *ylen = l;
out:
        TEE_CloseObject(pobj);
        return res;
}

/* Asking for TEE_ATTR_ECC_PRIVATE_VALUE on a generated key
   returns TEE_ERROR_ACCESS_DENIED. That refusal is the
   guarantee: the private half is structurally unexportable,
   not merely undocumented.                                  */
```

DERIVE, DO NOT STORE

A TA that needs many keys does not have to store many keys. Derive them from one root plus a label: `key_i = HKDF(root, "purpose" || i)`. Storage holds one secret; the derived keys exist only while in use. Fewer persistent objects, no per-key storage failure, and rotating the root rotates everything at once.

Key derivation

```
/* HKDF: the right tool for turning one secret into many. */

static TEE_Result derive(TEE_ObjectHandle root,
                         const char *label, size_t labellen,
                         TEE_ObjectHandle out)
{
        TEE_OperationHandle op = TEE_HANDLE_NULL;
        TEE_Attribute params[2];
        TEE_Result res;

        res = TEE_AllocateOperation(&op,
                        TEE_ALG_HKDF_SHA256_DERIVE_KEY,
                        TEE_MODE_DERIVE, 256);
        if (res) goto out;

        res = TEE_SetOperationKey(op, root);
        if (res) goto out;

        TEE_InitRefAttribute(&params[0], TEE_ATTR_HKDF_INFO,
                             label, labellen);
        TEE_InitRefAttribute(&params[1], TEE_ATTR_HKDF_SALT,
                             SALT, sizeof SALT);

        TEE_DeriveKey(op, params, 2, out);
out:
        TEE_FreeOperation(op);
        return res;
}

/* ECDH, and the mistake everyone makes: */

    /* WRONG: use the shared secret directly as an AES key.
       The X coordinate of an ECDH result is NOT uniformly
       distributed and has algebraic structure. */

    /* RIGHT: */
    TEE_AllocateOperation(&op, TEE_ALG_ECDH_DERIVE_SHARED_SECRET,
                          TEE_MODE_DERIVE, 256);
    TEE_SetOperationKey(op, my_keypair);
    TEE_InitRefAttribute(&p[0], TEE_ATTR_ECC_PUBLIC_VALUE_X,
                         peer_x, sizeof peer_x);
    TEE_InitRefAttribute(&p[1], TEE_ATTR_ECC_PUBLIC_VALUE_Y,
                         peer_y, sizeof peer_y);
    TEE_DeriveKey(op, p, 2, shared);       /* a GENERIC_SECRET */
    /* ...then run HKDF over `shared` to get the actual AES key */
```

The hardware unique key

```
/* Every device has a different HUK (chapter 15). A TA can
   derive from it, which gives you a secret that:
     - is different on every device
     - never existed anywhere else
     - needs no storage at all                              */

#include <tee_internal_api_extensions.h>

    uint8_t key[32];
    TEE_Result res = TEE_GetHUKDerivedKey(
                        (const uint8_t *)"my-ta-purpose-v1", 16,
                        key, sizeof key);
    /* NOT standard GlobalPlatform - an OP-TEE extension,
       available when CFG_HUK_SUBKEY is enabled.            */

/* Uses:
     - encrypting something without a persistent key object
     - a device-binding value, so data cannot move devices
     - a per-device seed for a deterministic key

   Cautions:
     - the derivation label is part of the contract. Change it
       and every previously derived key is gone. Version it.
     - on QEMU the HUK is a fixed test value, so every
       "device" derives the same key. Do not conclude from a
       QEMU test that device binding works.
     - wipe the buffer when you are done:
           TEE_MemFill(key, 0, sizeof key);                 */
```

Hardware acceleration

```
/* Most SoCs have a crypto accelerator. OP-TEE abstracts it
   behind the same API, so a TA does not change - but the
   performance difference is large.                          */

  core/drivers/crypto/
    caam/       NXP i.MX
    se050/      NXP secure element
    stm32/      ST
    hisilicon/  HiSilicon
    versal/     AMD/Xilinx
    aspeed/     ASPEED

  Enabled per platform, e.g.:
    CFG_NXP_CAAM=y
    CFG_NXP_CAAM_SHA_DRV=y
    CFG_NXP_CAAM_CIPHER_DRV=y

/* Rough figures - measure your own part:
     AES-256-GCM, software (libtomcrypt)   ~20-60 MB/s
     AES-256-GCM, CAAM/SAHARA             ~200-800 MB/s
     RSA-2048 sign, software              ~10-40 ms
     RSA-2048 sign, accelerator           ~1-5 ms
     ECDSA P-256 sign, software           ~2-10 ms

   The fixed cost of a TA invocation (chapter 5) is tens of
   microseconds, so for small operations the world switch
   dominates and the accelerator barely shows. For bulk data
   it is the whole story.

   The design consequence: BATCH. One invocation that signs 100
   digests beats 100 invocations that sign one each, by a large
   factor, regardless of the accelerator.                    */
```

The mistakes that matter

Mistake	Why it is fatal	Do this
Reusing a GCM nonce with the same key	Recovers the authentication key; forgeries become trivial	Counter, or 96 bits of `TEE_GenerateRandom`, and never repeat
Comparing MACs with `TEE_MemCompare`	Timing oracle	`TEE_MACCompareFinal`, or a constant-time loop
Using an ECDH shared secret as a key	Not uniform; has structure	Run it through HKDF
AES-ECB	Identical plaintext blocks give identical ciphertext	GCM
RSA PKCS#1 v1.5 encryption	Padding-oracle attacks	OAEP, or better, don't use RSA encryption
Decrypt-then-check	Acting on unauthenticated plaintext	AEAD, which does it in the right order for you
Key material in a local buffer	Left on the TA heap or stack after use	Key objects, and `TEE_MemFill(0)` anything raw
Trusting `TEE_GetREETime` for expiry	The attacker sets the clock	Chapter 17
Logging a key with `DHEXDUMP`	It ships	Never; guard it out of release builds
Rolling your own primitive	You will get it wrong	Use the API; it is there

How it shows up

Symptom	Cause
`TEE_ERROR_NOT_SUPPORTED`	Algorithm not compiled in — check the `CFG_CRYPTO_*` flags
`TEE_ERROR_BAD_PARAMETERS` on `AllocateOperation`	Key size outside the declared maximum, or algorithm/mode mismatch
`TEE_ERROR_ACCESS_DENIED` reading a private attribute	Working as designed — private key material is not exportable
`TEE_ERROR_MAC_INVALID` on decrypt	Wrong key, wrong nonce, or genuinely tampered data
Works, then fails after hours	Leaked operation or object handles
Signature verifies in the TA, fails in OpenSSL	Format mismatch — ECDSA raw r‖s versus DER, or a digest applied twice
Slow despite a hardware accelerator	Per-invocation overhead dominates; batch
Different results on QEMU and hardware	Accelerator driver differences, or the HUK being a fixed test value on QEMU
Key lost after a firmware update	HUK derivation label or TA UUID changed

Check yourself

- ✓ State the rule about keys crossing the boundary and give the client interface it implies.
- ✓ Generate an ECDSA keypair inside a TA and store it as an object.
- ✓ Explain what happens when you ask for the private attribute, and why that is the guarantee.
- ✓ Explain the derive-do-not-store pattern and its advantages.
- ✓ Say why an ECDH shared secret must not be used directly as a key.
- ✓ Describe `TEE_GetHUKDerivedKey`, two uses, and two cautions.
- ✓ Explain why batching matters more than hardware acceleration for small operations.
- ✓ Name five cryptographic mistakes from the table and the correct alternative for each.
- ✓ Explain what GCM nonce reuse costs you.
- ✓ Determine at runtime whether an algorithm is available in the current build.

Time, counters and rollback protection

Two things the secure world cannot get for itself: what time it is, and whether the state it just read is the newest one. Both are supplied by an adversary. Everything in this chapter is about designing around that, because no amount of cryptography fixes a system that believes an old, correctly signed answer.

Three clocks, three trust levels

Source	What it is	Trust
`TEE_GetSystemTime`	Monotonic since boot, from the secure timer	**Trusted for intervals.** Resets on reboot; not wall clock
`TEE_GetREETime`	Wall-clock time from the normal world	**Untrusted.** The attacker sets it to whatever they like
`TEE_GetTAPersistentTime`	A per-TA time that survives reboot, kept in secure storage	**Conditionally trusted** — and it tells you which condition applies

```
/* Persistent time is the interesting one, because it reports
   its own reliability.                                       */

    TEE_Time t;
    TEE_Result res = TEE_GetTAPersistentTime(&t);

    switch (res) {
    case TEE_SUCCESS:
            /* Set, and OP-TEE believes it has not been
               tampered with. Usable.                        */
            break;
    case TEE_ERROR_TIME_NOT_SET:
            /* Never initialised on this device. First run.  */
            break;
    case TEE_ERROR_TIME_NEEDS_RESET:
            /* It was set, but something happened - a battery
               loss, a storage inconsistency. DO NOT TRUST IT.*/
            break;
    case TEE_ERROR_OVERFLOW:
            /* Ran past its representable range. */
            break;
    }

    /* Setting it - the value comes from somewhere you trust,
       which usually means a signed timestamp from a server,
       not from TEE_GetREETime.                              */
    TEE_SetTAPersistentTime(&t);

/* THE ANTI-PATTERN, and it is everywhere:

       TEE_Time now;
       TEE_GetREETime(&now);
       if (now.seconds > licence_expiry)
               return TEE_ERROR_ACCESS_DENIED;

   Defeated with `date -s 2020-01-01`. The check is not weak;
   it is absent, because the attacker supplies the input.  */
```

> **THE GENERAL PRINCIPLE**
> Anything an attacker supplies is not a security input, however carefully you compare it. To bound *something* in time you need a counter you control (below), a signed timestamp from a party you trust, or an online check. If none of those is available, the honest answer is that you cannot enforce expiry offline — and it is better to say so at design time than to ship a check that looks like one.

The rollback problem

```
Encryption and authentication answer: "is this data
genuine?"

They do not answer: "is this the LATEST genuine data?"

Attack, step by step:

  1. TA writes state v1: failed_attempts = 0
     Encrypted, MACed, stored.
  2. Attacker COPIES the file.  (It is in /data/tee - the
     normal world owns that filesystem.)
  3. Legitimate use: 3 failed attempts. TA writes v2, v3, v4.
     After 5 the TA locks out for ever.
  4. Attacker restores their copy of v1.
  5. TA opens it. Decrypts: correct. MAC: correct. Reads
     failed_attempts = 0.

Nothing was forged. The TA has no way to know that a newer
version ever existed - it has no memory outside the storage
it just read.

AFFECTED BY THIS: anything counted, revoked, or versioned.
    PIN attempt counters
    firmware anti-rollback versions
    one-time-use tokens
    licence consumption
    revoked certificate lists
    monotonic nonces

NOT AFFECTED: things where an old value is as good as a new
one.
    a long-lived signing key
    a device certificate
    a configuration blob that never changes
```

Monotonic counters

```
/* The fix: a counter that hardware guarantees can only go up.
   Then every stored blob carries the counter value it was
   written at, and a replayed blob is detectable.            */

/* --- Source 1: RPMB (chapter 15) --- */
/* The eMMC maintains a write counter it will never decrement,
   and authenticates every access with a key the normal world
   does not have. Restore an old RPMB frame and the device
   rejects it: the counter is stale.

   With CFG_RPMB_FS=y, storing to TEE_STORAGE_PRIVATE_RPMB
   gives you rollback protection for free - this is the
   simplest correct answer where the hardware exists.       */

/* --- Source 2: TA persistent time --- */
/* TEE_GetTAPersistentTime is itself backed by secure storage,
   so it inherits whatever protection that storage has. On an
   RPMB-backed system it is monotonic; on REE FS it is not.  */

/* --- Source 3: a fuse or OTP counter --- */
/* Some SoCs have burnable counters. Genuinely monotonic,
   genuinely limited - typically tens of increments in total.
   Reserve them for irreversible events: "firmware version 3
   has been installed, never accept version 2 again."       */

/* --- Source 4: an external secure element --- */
/* An SE05x, an ATECC, a TPM. A separate chip with its own
   monotonic counters and its own tamper resistance. This is
   what you use when the SoC has nothing and the requirement
   is real.                                                 */

/* --- Source 5: an online server --- */
/* The counter lives elsewhere. Correct and simple, and it
   requires connectivity, which is usually why it is
   rejected.                                                */
```

```
/* Using a counter, concretely: */

struct protected_state {
        uint32_t counter;          /* the value it was written
                                      at                       */
        uint32_t failed_attempts;
        uint8_t  data[64];
};

static TEE_Result read_state(struct protected_state *st)
{
        uint32_t hw_counter;
        TEE_Result res;

        res = read_monotonic_counter(&hw_counter);   /* RPMB, SE */
        if (res) return res;

        res = read_object("state", st, sizeof *st);
        if (res) return res;

        /* THE CHECK. A restored old blob has a lower counter. */
        if (st->counter != hw_counter) {
                EMSG("rollback detected: blob %u, hw %u",
                     st->counter, hw_counter);
                return TEE_ERROR_SECURITY;
        }
        return TEE_SUCCESS;
}

static TEE_Result write_state(struct protected_state *st)
{
        uint32_t hw_counter;
        TEE_Result res;

        /* Increment FIRST, then write. If we crash between the
           two, the counter is ahead of the blob and the next
           read fails safe - it refuses rather than accepting
           an old state.                                       */
        res = increment_monotonic_counter(&hw_counter);
        if (res) return res;

        st->counter = hw_counter;
        return write_object("state", st, sizeof *st);
}

/* The ordering matters and the failure mode must be chosen
   deliberately. "Increment then write" fails CLOSED: a crash
   makes the state unreadable, which for a PIN counter is the
   safe direction. "Write then increment" fails OPEN: a crash
   leaves a valid old state that the attacker can trigger on
   purpose.                                                  */
```

COUNTERS ARE A FINITE RESOURCE

RPMB's write counter is 32 bits and the partition wears out. Fuse counters have tens of increments, total. Do not increment on every operation — increment when the *protected state* changes, and cache reads in the session context. A PIN counter that increments on every successful login as well as every failure burns through its budget for no security benefit.

Firmware anti-rollback

```
The most important use, and the one with a standard shape.

Problem: version 1.0 has a known vulnerability. 1.1 fixes
it. An attacker installs 1.0 again and exploits it.
The 1.0 image is genuine and correctly signed, so signature
verification does not help at all.

Solution: a version counter in fuses or RPMB.

  each image carries a MONOTONIC VERSION NUMBER, distinct
  from its marketing version:
      v1.0 -> nv_counter 1
      v1.1 -> nv_counter 2      (security fix)
      v1.2 -> nv_counter 2      (features only - no bump)
      v2.0 -> nv_counter 3      (another security fix)

  at boot, BL2 checks:
      if (image.nv_counter < fuse.nv_counter) REFUSE
  after a successful boot of a newer image:
      fuse.nv_counter = image.nv_counter    (irreversible)

Bump the counter only for security-relevant fixes: every
bump permanently burns a fuse and permanently forecloses a
downgrade path, including a downgrade you might one day
want because a release was bad.

In TF-A this is TRUSTED_BOARD_BOOT with the
trusted/non-trusted NV counters, and the platform hooks
plat_get_nv_ctr() / plat_set_nv_ctr().
```

Replay of messages, not just storage

```
/* The same problem appears in protocols. A client replays a
   previously valid request; the TA cannot tell.            */

/* WRONG: */
    /* client sends {command, signature} */
    if (verify(sig, command)) do_it();
    /* replayable for ever */

/* RIGHT - a challenge the TA chooses: */

    /* 1. client asks for a challenge */
    case CMD_GET_CHALLENGE:
            TEE_GenerateRandom(sess->challenge,
                               sizeof sess->challenge);
            sess->challenge_valid = true;
            memcpy(out, sess->challenge, sizeof sess->challenge);
            return TEE_SUCCESS;

    /* 2. client signs {challenge || command} */
    case CMD_EXECUTE:
            if (!sess->challenge_valid)
                    return TEE_ERROR_BAD_STATE;
            sess->challenge_valid = false;   /* ONE USE. Clear
                                                it BEFORE doing
                                                the work.      */
            if (!verify_over(sess->challenge, cmd, sig))
                    return TEE_ERROR_SECURITY;
            return do_it();

/* The challenge is per-session state (chapter 13), so it dies
   with the session and cannot be replayed across one. Clearing
   it before the work - not after - means an error path cannot
   leave it usable.                                          */
```

How it shows up

Symptom	Cause
Attempt counter resettable by restoring a file	REE FS with no monotonic counter
Licence expiry bypassed by changing the date	`TEE_GetREETime` used as a security input
Old vulnerable firmware reinstallable	No NV counter check in the boot chain
`TEE_ERROR_TIME_NEEDS_RESET`	Persistent time was tampered with or lost — treat it as unusable, do not paper over it
RPMB writes start failing after long service	Counter or wear budget exhausted — you are incrementing too often
State unreadable after a power cut	Counter incremented but the write did not complete — the fail-closed design working
Same request accepted twice	No challenge, or the challenge not cleared after use
Rollback protection works on hardware, not on QEMU	Emulated RPMB is a file the normal world can restore
Cannot downgrade a bad release	NV counter bumped for a non-security change. This is permanent

Check yourself

- ✓ Name the three time sources and rank them by trustworthiness.
- ✓ Explain the four return values of `TEE_GetTAPersistentTime`.
- ✓ Show why an expiry check against `TEE_GetREETime` is not a check at all.
- ✓ Describe the rollback attack in five steps and say what cryptography does not prevent.
- ✓ Classify five kinds of data by whether rollback matters.
- ✓ Name five sources of monotonic counters and their limitations.
- ✓ Write a read/write pair that detects rollback, and justify the ordering.
- ✓ Explain the difference between failing closed and failing open here.
- ✓ Describe firmware anti-rollback and say when to bump the counter.
- ✓ Design a challenge-response that prevents request replay, and say when to clear the challenge.

Pseudo TAs and core drivers

A pseudo TA is a service compiled into OP-TEE itself, running at S-EL1 with the trusted OS's full privilege and none of its isolation. Sometimes that is the only way to do the job. Usually it is not, and the difference is worth being precise about before you write one.

Where a pseudo TA sits

```
S-EL0   +----------+  +----------+
        | user TA  |  | user TA  |   isolated from each
        |          |  |          |   other and from the core
        +----------+  +----------+   by the MMU
              |             |
              |  SVC        |
              v             v
S-EL1   +-----------------------------------------+
        |  OP-TEE CORE                            |
        |   scheduler, MMU, crypto, drivers       |
        |                                         |
        |   +-----------------------------------+ |
        |   |  PSEUDO TA                        | |
        |   |  same privilege as the core.      | |
        |   |  same address space as the core.  | |
        |   |  can call ANY core function.      | |
        |   |  a bug here is a bug in the       | |
        |   |  trusted OS.                       |  |
        |   +-----------------------------------+ |
        +-----------------------------------------+

A user TA that dereferences a wild pointer: that TA panics,
its session dies, the system continues.

A pseudo TA that dereferences a wild pointer: the trusted OS
panics, or worse, silently corrupts another TA's memory or
its own key material.

The privilege is the same as writing kernel code. Treat it
that way.
```

When it is actually right

Reason	Valid?
You need a core API not exposed to S-EL0 — direct hardware access, a core driver, internal state	**Yes.** This is the main reason
You must work before the normal world can load anything — early boot, before `tee-supplicant`	**Yes** — though an *early TA* may serve, and keeps S-EL0 isolation
You are implementing a service other TAs will call	**Sometimes.** A user TA can also be called by another TA
You need to service an interrupt in the secure world	**Yes** — as a core driver, not really as a TA
"It is faster"	**No.** You save one privilege transition, tens of nanoseconds, against a call that costs tens of microseconds
"It is simpler than packaging a .ta"	**No.** That is an hour of build setup against a permanent expansion of the trusted computing base

Reason	Valid?
"It avoids depending on tee-supplicant"	**Use an early TA instead** — same benefit, keeps isolation

Writing one

```
/* core/pta/my_service.c */

#include <kernel/pseudo_ta.h>
#include <kernel/user_access.h>
#include <mm/core_memprot.h>
#include <string.h>
#include <trace.h>

#define PTA_MY_SERVICE_UUID \
        { 0x7c1a9e30, 0x4d6b, 0x4f21, \
          { 0x9a, 0x3c, 0x11, 0x22, 0x33, 0x44, 0x55, 0x66 } }

#define TA_NAME  "my_service.pta"

#define PTA_CMD_READ_REG    0
#define PTA_CMD_WRITE_REG   1

static TEE_Result read_reg(uint32_t ptypes, TEE_Param params[4])
{
        uint32_t exp = TEE_PARAM_TYPES(TEE_PARAM_TYPE_VALUE_INPUT,
                                       TEE_PARAM_TYPE_VALUE_OUTPUT,
                                       TEE_PARAM_TYPE_NONE,
                                       TEE_PARAM_TYPE_NONE);
        vaddr_t base;
        uint32_t off;

        if (ptypes != exp)
                return TEE_ERROR_BAD_PARAMETERS;

        off = params[0].value.a;

        /* WHITELIST. A pseudo TA can read ANY address in the
           system. The client must never choose one. */

     TA_FLAG_CONCURRENT          allow concurrent invocations -
                                 you must then be thread safe
     PTA_DEFAULT_FLAGS = SINGLE_INSTANCE | MULTI_SESSION |
                         INSTANCE_KEEP_ALIVE                */
```

```
# core/pta/sub.mk
srcs-$(CFG_MY_SERVICE_PTA) += my_service.c

# core/pta/pta.mk  (or the platform's conf.mk)
CFG_MY_SERVICE_PTA ?= y

$ make CFG_MY_SERVICE_PTA=y
# It is now inside tee.elf. No .ta file, no signing, no
# tee-supplicant, and no way to update it without replacing
# OP-TEE.
```

TWO RULES THAT ARE NOT OPTIONAL IN A PSEUDO TA

Validate every address. A user TA that dereferences a client-supplied pointer faults harmlessly at S-EL0. A pseudo TA reads or writes whatever is there — another TA's key, the core's own state, a device register. Whitelist offsets against a known region; never accept an address.

Copy client data before using it. The double-fetch rule from chapter 7 applies with much worse consequences here. Use `copy_from_user` / `copy_to_user` when the caller is a user TA, and never act on shared memory in place.

The pseudo TAs that ship

PTA	Provides
`device.pta`	Enumerates TAs for the Linux TEE bus (chapter 10)
`system.pta`	Dynamic shared memory, TA-to-TA calls, entropy
`attestation.pta`	Measures a TA's binary and signs the measurement — remote attestation
`stats.pta`	The memory and TA statistics `xtest --stats` reads

PTA	Provides
`rtc.pta`, `scmi.pta`, `gprof.pta`	Real-time clock, SCMI, profiling
`secstor_ta_mgmt.pta`	Installing TAs into secure storage
`apply_patch.pta`	Live patching of the core

```
# Read these before writing your own - they are the reference
# for style and for how much validation is expected:
$ ls optee_os/core/pta/
attestation.c  benchmark.c  device.c  gprof.c  invoke_tests.c
rtc.c  scmi.c  secstor_ta_mgmt.c  stats.c  system.c ...

# attestation.c is the most instructive: it is short, it
# handles untrusted input carefully, and it does something a
# user TA genuinely cannot.
```

Early TAs: the middle option

```
/* An early TA is an ORDINARY user TA, at S-EL0, with full MMU
   isolation - but its binary is linked into tee.elf rather
   than loaded from the normal world.

   You get:
     + available before tee-supplicant, before Linux
     + no dependency on the normal-world filesystem
     + full S-EL0 isolation - a bug is contained
     + no separate signing/installation step
   You lose:
     - it cannot be updated without replacing OP-TEE
     - it occupies TEE_RAM permanently

   This is almost always the right answer when the reason you
   were reaching for a pseudo TA was "it must work early" or
   "I do not want to depend on the supplicant".            */

$ make CFG_EARLY_TA=y \
       EARLY_TA_PATHS="path/to/7f2e9c1a-....ta"

/* The TA is still signed, still verified, and still runs at
   S-EL0 - it is simply carried inside the OP-TEE image
   instead of fetched at runtime.                          */
```

TA-to-TA calls

```
/* A user TA can open a session to another TA. Often this is
   what you actually wanted when you considered a pseudo TA -
   a shared service, without giving it core privilege.      */

    TEE_TASessionHandle sess = TEE_HANDLE_NULL;
    TEE_UUID other = OTHER_TA_UUID;
    uint32_t origin;
    TEE_Param params[4] = {0};
    TEE_Result res;

    res = TEE_OpenTASession(&other, TEE_TIMEOUT_INFINITE,
                            0, params, &sess, &origin);
    if (res) return res;

    res = TEE_InvokeTACommand(sess, TEE_TIMEOUT_INFINITE,
                              CMD_DO_THING,
                              TEE_PARAM_TYPES(
                                  TEE_PARAM_TYPE_MEMREF_INPUT,
                                  TEE_PARAM_TYPE_NONE,
                                  TEE_PARAM_TYPE_NONE,
                                  TEE_PARAM_TYPE_NONE),
                              params, &origin);

    TEE_CloseTASession(sess);

/* The callee sees the caller's identity as
   TEE_LOGIN_TRUSTED_APP, with the caller's UUID - so it can
   authorise. Two S-EL0 TAs, isolated from each other, with an
   authenticated channel between them.

   CAUTION: the calling TA's thread is held for the duration
   (chapter 5), so a chain of TA-to-TA calls consumes one
   thread, not several - but a CYCLE deadlocks immediately.
   Keep the call graph acyclic and shallow.                */
```

How it shows up

Symptom	Cause
The whole TEE panics when a client misbehaves	A pseudo TA dereferencing a client-supplied address
One TA's data appears in another	A pseudo TA writing outside its intended region — no isolation to stop it
Pseudo TA works, cannot be updated in the field	By design: it is inside a signed OP-TEE image
Intermittent corruption under concurrency	`TA_FLAG_CONCURRENT` set without making the code thread safe
Normal-world client can reach an internal service	No caller check in `open_session`
TA-to-TA call hangs for ever	A cycle in the call graph, or the callee blocked
Service needed before `tee-supplicant`	Use an early TA rather than a pseudo TA
Security review rejects a pseudo TA	Usually correctly. Justify the privilege or move it to S-EL0

Check yourself

- ✓ State the privilege and isolation difference between a user TA and a pseudo TA.
- ✓ Give two valid reasons to write a pseudo TA and three invalid ones.

- ✓ Explain why "it is faster" does not justify one.
- ✓ Write a pseudo TA that exposes one register, with correct validation.
- ✓ Explain why address whitelisting is mandatory here and merely advisable in a user TA.
- ✓ Say how a pseudo TA restricts who may call it.
- ✓ Name four built-in pseudo TAs and what each provides.
- ✓ Describe an early TA and say which pseudo-TA use cases it replaces.
- ✓ Explain TA-to-TA calls, what identity the callee sees, and the deadlock hazard.
- ✓ Given a proposed pseudo TA, decide whether a user TA or an early TA would do instead.

Debugging OP-TEE and trusted applications

Debugging the secure world is harder than debugging Linux and easier than debugging firmware, and the tools are unfamiliar rather than absent. This chapter is the toolkit, ordered by how often you will need each thing, starting with the one that answers most questions.

Reading a panic

```
# A TA panic looks like this on the SECURE console. It is
# dense and it contains everything you need.

E/TC:0 0 tee_ta_verify_param:...  invalid memory access
E/TC:0 0 Status of TA 7f2e9c1a-3b4d-4e5f-8a9b-0c1d2e3f4a5b
E/TC:0 0  arch: aarch64  load address: 0x40016000
E/LD:  arch: aarch64
E/LD:  region  0: va 0x40016000 pa 0x0e56d000 size 0x002000 flags r-x
E/LD:  region  1: va 0x40018000 pa 0x0e56f000 size 0x001000 flags rw-
E/LD:  region  2: va 0x40019000 pa 0x0e570000 size 0x008000 flags rw- (stack)
E/TC:0 0 Core data-abort at address 0x0 (translation fault)
E/TC:0 0  esr 0x92000006  ttbr0 0x...  cidr 0x0
E/TC:0 0  cpu #0          cpsr 0x60000100
E/TC:0 0  x0 0000000000000000 x1 0000000040018210
E/TC:0 0  x2 0000000000000020 x3 0000000000000000
...
E/TC:0 0  elr 0x40016a3c
E/TC:0 0 Call stack:
E/TC:0 0  0x40016a3c
E/TC:0 0  0x40016b10
E/TC:0 0  0x400171d4

# THE PROCEDURE:
#
# 1. Note the LOAD ADDRESS: 0x40016000
# 2. Subtract it from each call-stack address:
#      0x40016a3c - 0x40016000 = 0xa3c
#      0x40016b10 - 0x40016000 = 0xb10
#      0x400171d4 - 0x40016000 = 0x11d4
# 3. Look those offsets up in the TA's ELF:

$ aarch64-linux-gnu-addr2line -f -p -e ta/my_ta.elf 0xa3c 0xb10 0x11d4
do_sign at /work/my_project/ta/my_ta.c:142
handle_command at /work/my_project/ta/my_ta.c:201
TA_InvokeCommandEntryPoint at /work/my_project/ta/my_ta.c:230

# 4. Decode the ESR: 0x92000006
#      EC = 0x24  data abort from a lower EL
#      DFSC = 0x06  translation fault, level 2
#      WnR = 1     it was a WRITE
#    So: a write to an unmapped address - and FAR says 0x0.
#    A NULL pointer write at my_ta.c:142.

# OP-TEE ships a script that does steps 1-3 for you:
$ optee_os/scripts/symbolize.py -d ta/ -d optee_os/out/.../core/ \
    < secure-console.log
# Pipe the whole console through it and every address becomes
# a file and line. Set this up once and never do the
# arithmetic again.
```

BUILD FOR SYMBOLISATION BEFORE YOU NEED IT

Two flags make panics readable: `CFG_UNWIND=y` for the call stack, and `CFG_CORE_ASLR=n` plus `CFG_TA_ASLR=n` so addresses are stable between runs. Keep the unstripped `.elf` next to every `.ta` you ship to a test device — without it, a panic log is a list of numbers.

Logging

```
# Levels, set at build time:
$ make CFG_TEE_CORE_LOG_LEVEL=3 CFG_TEE_TA_LOG_LEVEL=4
#   0 none  1 error  2 info  3 debug  4 flow

# In a TA:
    EMSG("failed: 0x%08x", res);    /* always              */
    IMSG("state now %u", n);        /* level 2             */
    DMSG("entering with %p", p);    /* level 3             */
    FMSG("tick");                   /* level 4             */
    DHEXDUMP(buf, len);             /* a hex dump          */

# Output carries the function and line automatically:
E/TA: do_sign:142 failed: 0xffff0006

# In the CORE, the same macros plus:
    MSG_RAW(...)      no prefix
    EMSG_RAW(...)
    panic("message"); /* takes the whole TEE down          */

# Per-TA level, without rebuilding everything - set it in the
# TA's own Makefile:
    CFG_TEE_TA_LOG_LEVEL ?= 4

# Level 4 on the core is extremely verbose and genuinely
# useful when you are lost:
F/TC:0 0 thread_alloc_and_run:...  thread 0
F/TC:0 0 tee_ta_open_session:...   uuid 7f2e9c1a-...
F/TC:0 0 ldelf_load_ta:...
F/TC:0 0 tee_ta_invoke_command:... cmd 0
# You can see exactly how far a call got before it failed.
```

GDB on the secure world

```
# QEMU's stub debugs every exception level (QEMU chapter 11).
# The secure world is not special.

$ cd ~/optee/build
$ make run-only GDBSERVER=y
# or add -s -S to the QEMU command line yourself

$ aarch64-linux-gnu-gdb
(gdb) target remote :1234

# Load symbols for every image, at its link address:
(gdb) add-symbol-file ~/optee/optee_os/out/arm-plat-vexpress/core/tee.elf \
        0x0e100000
(gdb) add-symbol-file ~/optee/trusted-firmware-a/build/qemu/release/bl31/bl31.elf
(gdb) add-symbol-file ~/optee/linux/vmlinux

# Break inside OP-TEE:
(gdb) break tee_ta_open_session
(gdb) break tee_entry_std
(gdb) break panic
(gdb) continue

# Which world are we in?
(gdb) monitor info registers | grep -E 'PSTATE|SCR'
# PSTATE ... EL1h  with SCR_EL3.NS == 0  ->  secure world

# A TA is loaded at a runtime address, so its symbols must be
# added AFTER it loads:
(gdb) break tee_ta_invoke_command
(gdb) continue
(gdb) p ctx->ts_ctx           # find the load address
(gdb) add-symbol-file ta/my_ta.elf 0x40016000
(gdb) break do_sign

# OP-TEE ships GDB helpers:
(gdb) source ~/optee/optee_os/scripts/gdb/optee.py
(gdb) optee_ta_list
(gdb) optee_mem_map
(gdb) optee_threads

# On real hardware you need a JTAG probe that can see the
# secure world - and many cannot, or are disabled by fuses in
# production. That asymmetry is why so much OP-TEE development
# happens on QEMU.
```

Function tracing inside a TA

```
# OP-TEE can instrument a TA's every function entry and exit,
# and dump the trace through tee-supplicant.

$ make CFG_TA_GPROF_SUPPORT=y CFG_FTRACE_SUPPORT=y \
       CFG_SYSCALL_FTRACE=y

# Build the TA with instrumentation:
#   in ta/Makefile:
    CFG_FTRACE_SUPPORT=y
#   or per-file:
    cflags-my_ta.c-y += -pg

$ tee-supplicant -d
# Run the client, then:
$ ls /tmp/ftrace-*.out
$ optee_os/scripts/ftrace_format.py /tmp/ftrace-7f2e9c1a-....out

  0.000 us | TA_InvokeCommandEntryPoint() {
  1.200 us |   do_sign() {
  0.400 us |     load_key() {
 12.100 us |       TEE_OpenPersistentObject();
             }   /* load_key: 13.900 us */
 45.300 us |     TEE_AsymmetricSignDigest();
             }   /* do_sign: 60.100 us */
             } /* TA_InvokeCommandEntryPoint: 61.500 us */

# This answers "where is the time going" definitively, and the
# answer is usually "the one call that does an RPC". Above,
# TEE_OpenPersistentObject costs 12 us of a 61 us call -
# cache it in the session context and the call halves.

# gprof-style profiling, for the same question aggregated:
$ make CFG_TA_GPROF_SUPPORT=y
$ ls /tmp/gmon-*.out
$ aarch64-linux-gnu-gprof ta/my_ta.elf /tmp/gmon-....out
```

Sanitizers

```
# OP-TEE can build itself and TAs with ASan and UBSan. On
# QEMU, where you have memory to spare, leave them on during
# development.

$ make CFG_CORE_SANITIZE_UNDEFINED=y \
       CFG_CORE_SANITIZE_KADDRESS=y \
       CFG_TA_SANITIZE_UNDEFINED=y

# A UBSan hit on the secure console:
E/TC:0 0 Undefined behavior at my_ta.c:88
E/TC:0 0   left shift of 1 by 31 places cannot be represented
           in type 'int'

# An ASan hit:
E/TC:0 0 KASAN: heap-buffer-overflow at 0x40018210
E/TC:0 0   write of size 4 at offset 68 of a 64-byte region

# These find, before shipping, exactly the class of bug that a
# security researcher would find after. The cost is memory and
# speed, both of which you have in development and neither of
# which matters in a test.

# Also worth running, and cheap:
$ xtest                       # the full GP conformance suite
$ xtest -t regression
$ xtest --stats               # memory high-water marks (ch. 13)
$ xtest -t benchmark
```

A procedure for "it does not work"

```
Work down. Each step is cheap and eliminates a layer.

1. Is there output on the SECURE console at all?
     no  -> the second serial port is not set up (ch. 4).
            Fix that before anything else.

2. What is the CLIENT's result and ORIGIN? (chapter 8)
     origin 1 (API)   -> your client's arguments
     origin 2 (COMMS) -> transport: /dev/tee0, the driver
     origin 3 (TEE)   -> OP-TEE core rejected it. The
                         secure console says why.
     origin 4 (TA)    -> your TA returned this deliberately

3. 0xFFFF0008 ITEM_NOT_FOUND?
     -> the .ta is not in /lib/optee_armtz, or the filename
        does not match the UUID, or tee-supplicant is not
        running.

4. 0xFFFF000F SECURITY?
     -> signed with the wrong key (chapter 14).

5. 0xFFFF3024 TARGET_DEAD?
     -> the TA panicked. Symbolize the log. Go to the top
        of this chapter.

6. 0xFFFF0006 BAD_PARAMETERS with origin 4?
     -> your paramTypes check is failing. Print what you
        got and what you expected:
          EMSG("ptypes 0x%08x expected 0x%08x", ptypes, exp);
        This one line resolves it in seconds and it is
        worth leaving in permanently.

7. It hangs?
     -> thread exhaustion or a supplicant deadlock (ch. 9).
        cat /proc/<client>/stack and
        cat /proc/<tee-supplicant>/stack

8. It works, then stops after a while?
     -> a leak. xtest --stats, and check handle cleanup on
        every error path (chapter 12).

9. Still lost?
     -> CFG_TEE_CORE_LOG_LEVEL=4 and read the flow trace.
        It shows exactly how far the call got.
```

How it shows up

Symptom	Cause
Panic log is just hex addresses	No `.elf` kept, or ASLR on. Rebuild with `CFG_TA_ASLR=n` and keep the ELF
Call stack is empty	`CFG_UNWIND=n`
`addr2line` gives nonsense	Forgot to subtract the load address, or used the `.ta` instead of the `.elf`
No output from `DMSG`	`CFG_TEE_TA_LOG_LEVEL` below 3
GDB breakpoint in a TA never hits	Symbols added before the TA was loaded, or at the wrong address
ftrace produces nothing	`tee-supplicant` not running, or the TA not built with `-pg`

Symptom	Cause
Sanitizer build runs out of memory	ASan needs shadow memory; raise `TA_DATA_SIZE` and `TZDRAM_SIZE`
Cannot attach a debugger on real hardware	Secure debug disabled by fuses. Expected in production
Bug disappears with logging enabled	A race — logging changed the timing. Look for shared state under `MULTI_SESSION`

Check yourself

- ✓ Given a panic log, recover the source file and line for every frame.
- ✓ Decode an ESR from a TA panic into fault type and direction.
- ✓ Name the two build flags that make panics readable.
- ✓ Give the four trace macros and the level each requires.
- ✓ Attach GDB to the secure world and break inside OP-TEE.
- ✓ Explain how to get symbols for a TA that is loaded at runtime.
- ✓ Use ftrace to find where a TA invocation spends its time.
- ✓ Name the sanitizer build flags and what each catches.
- ✓ Walk the nine-step procedure and say what each step eliminates.
- ✓ Explain why the return origin is the second thing to check, after the secure console.

Writing a TA that resists its own client

The client is the attacker. Not "might be" — the entire reason your TA exists is that the normal world may be compromised, so you must write every entry point assuming the caller is hostile, competent and patient. This chapter is the checklist, ordered by how often each mistake appears in real audits.

The mental shift

```
   ORDINARY LIBRARY                TRUSTED APPLICATION

   caller is your own code         caller is an attacker
   arguments are well-formed       arguments are chosen to break
                                     you
   a crash is a bug                a crash is a denial of
                                     service, and a controlled
                                     crash may be an exploit
   memory is stable                shared memory CHANGES WHILE
                                     YOU READ IT
   an error message helps          an error message may leak the
                                     secret
   timing does not matter          timing IS a channel

   Every parameter, every length, every index, every pointer.
   There is no trusted input.
```

1. Check parameter types. Always.

```
TEE_Result TA_InvokeCommandEntryPoint(void *sess, uint32_t cmd,
                                      uint32_t ptypes,
                                      TEE_Param params[4])
{
        const uint32_t exp =
                TEE_PARAM_TYPES(TEE_PARAM_TYPE_MEMREF_INPUT,
                                TEE_PARAM_TYPE_MEMREF_OUTPUT,
                                TEE_PARAM_TYPE_NONE,
                                TEE_PARAM_TYPE_NONE);

        if (ptypes != exp) {
                EMSG("ptypes 0x%08x expected 0x%08x", ptypes, exp);
                return TEE_ERROR_BAD_PARAMETERS;
        }
        ...
}

/* WITHOUT this, a client passes VALUE where you expect MEMREF.
   You then read params[0].memref.buffer - which is now an
   arbitrary 64-bit number the attacker chose - and
   dereference it with secure privilege.

   This is the number one OP-TEE TA vulnerability class. It is
   four lines. Check EVERY command, and check it in
   TA_OpenSessionEntryPoint too.                              */
```

2. Never read shared memory twice

```
/* WRONG - the classic double fetch. */

static TEE_Result bad(TEE_Param params[4])
{
        struct hdr *h = params[0].memref.buffer;

        if (h->len > MAX)                /* fetch 1: check    */
                return TEE_ERROR_BAD_PARAMETERS;

        /* the client's other thread changes h->len HERE */

        memcpy(dst, h->data, h->len);    /* fetch 2: use      */
        /* h->len is now 0xFFFFFFFF. Heap overflow, in the
           secure world, with attacker-controlled data.      */
}

/* RIGHT - copy once, then work only on the copy. */

static TEE_Result good(TEE_Param params[4])
{
        struct hdr local;
        uint8_t    buf[MAX];

        if (params[0].memref.size < sizeof local)
                return TEE_ERROR_BAD_PARAMETERS;

        /* ONE read of the shared region. */
        TEE_MemMove(&local, params[0].memref.buffer, sizeof local);

        /* Validate the COPY. It cannot change now. */
        if (local.len > MAX ||
            local.len > params[0].memref.size - sizeof local)
                return TEE_ERROR_BAD_PARAMETERS;

        TEE_MemMove(buf,
                    (uint8_t *)params[0].memref.buffer + sizeof local,
                    local.len);

        return process(buf, local.len);
}

/* The rule, stated once: SHARED MEMORY IS A NETWORK
   CONNECTION. You read from it once, into your own storage,
   and everything after that operates on your storage.     */
```

> **THIS IS THE BUG THAT GETS CVES**
>
> Search any TEE vendor's advisory list and the double fetch appears again and again, because the code looks correct — the check is right there, immediately above the use. The window is a few instructions wide and an attacker with another thread will hit it. There is no defence except never fetching twice.

3. Validate every length and index

```
/* Integer overflow in a bounds check is the second-commonest
   finding.                                                    */

    /* WRONG: offset + len can wrap */
    if (offset + len > buffer_size)
            return TEE_ERROR_BAD_PARAMETERS;
    /* offset = 0xFFFFFFF0, len = 0x20  ->  sum wraps to 0x10,
       check passes, and you read far outside the buffer.  */

    /* RIGHT: rearrange so nothing can overflow */
    if (offset > buffer_size || len > buffer_size - offset)
            return TEE_ERROR_BAD_PARAMETERS;

    /* Also wrong: */
    uint32_t total = count * sizeof(struct item);   /* wraps  */
    /* Right: */
    if (count > UINT32_MAX / sizeof(struct item))
            return TEE_ERROR_OVERFLOW;

    /* Signedness: */
    int idx = params[0].value.a;      /* a uint32_t from the
                                         client              */
    if (idx < n)                      /* -1 < n is TRUE       */
            table[idx] = ...;         /* writes before the
                                         table               */
    /* Use unsigned types for anything that indexes. */

    /* And check ranges explicitly, not implicitly: */
    if (params[0].value.a >= ARRAY_SIZE(g_slots))
            return TEE_ERROR_BAD_PARAMETERS;
```

4. Validate pointers with the API

```
    res = TEE_CheckMemoryAccessRights(
                TEE_MEMORY_ACCESS_READ |
                TEE_MEMORY_ACCESS_ANY_OWNER,
                params[0].memref.buffer,
                params[0].memref.size);
    if (res != TEE_SUCCESS)
            return res;

/* This asks OP-TEE whether that pointer, for that length, is
   really memory this session was given. It catches a client
   that registered a 4 KB buffer and then claimed 4 MB.

   It does NOT catch a double fetch - the memory is legitimate,
   it just changes. Both checks are needed.               */

/* When your TA is called BY ANOTHER TA (chapter 18), the
   buffer may be secure memory:
      TEE_MEMORY_ACCESS_SECURE      it must be secure
      TEE_MEMORY_ACCESS_NONSECURE   it must not be
   Being explicit about which you expect stops a confused
   deputy.                                                 */
```

5. Write output once, on success only

```
/* WRONG - leaks intermediate state on the error path. */
    memcpy(out, partial_result, n);      /* client can see this */
    if (verify_something() != OK)
            return TEE_ERROR_SECURITY;   /* too late            */

/* RIGHT */
    uint8_t local_out[MAX];

    res = compute(local_out, &n);
    if (res != TEE_SUCCESS)
            return res;                  /* client sees nothing */

    if (params[1].memref.size < n) {
            params[1].memref.size = n;   /* the ONE allowed
                                            early write         */
            return TEE_ERROR_SHORT_BUFFER;
    }
    TEE_MemMove(params[1].memref.buffer, local_out, n);
    params[1].memref.size = n;
    return TEE_SUCCESS;

/* For a crypto TA the intermediate state often IS the secret -
   a partially decrypted block, a key schedule, an unverified
   plaintext. Compute in private memory, publish at the end. */
```

6. Constant time where it matters

```
/* Comparison, of anything secret: */

    /* WRONG - returns as soon as bytes differ */
    if (TEE_MemCompare(mac, expected, 32) == 0) ...
    if (memcmp(pin, stored, 4) == 0) ...

    /* RIGHT */
    static bool ct_equal(const uint8_t *a, const uint8_t *b, size_t n)
    {
            uint8_t d = 0;
            for (size_t i = 0; i < n; i++)
                    d |= a[i] ^ b[i];
            return d == 0;
    }
    /* or, for MACs, the API does it: */
    TEE_MACCompareFinal(op, msg, len, mac, maclen);

/* Branching on secrets: */

    /* WRONG - the branch is observable */
    if (key[0] & 1)
            do_a();
    else
            do_b();

    /* Table lookups indexed by secrets are also observable,
       through the cache. This is how AES T-table
       implementations were broken. Use the hardware
       accelerator, or an implementation written to be
       constant time - do not write your own.              */

/* Error messages that distinguish cases: */

    /* WRONG - an oracle */
    if (!user_exists(u)) return TEE_ERROR_ITEM_NOT_FOUND;
    if (!pin_matches(p)) return TEE_ERROR_ACCESS_DENIED;

    /* RIGHT - one answer, one timing */
    bool ok = user_exists(u);
    ok &= pin_matches(p);          /* NOT &&: always evaluate */
    return ok ? TEE_SUCCESS : TEE_ERROR_ACCESS_DENIED;
```

7. Fail closed, and rate limit

```
    /* Default to refusal, not permission. */
    TEE_Result res = TEE_ERROR_ACCESS_DENIED;   /* not SUCCESS */
    ...
    if (everything_checked_out)
            res = TEE_SUCCESS;
    return res;

    /* A missing case in a switch must deny: */
    switch (cmd) {
    case CMD_A: return do_a(...);
    case CMD_B: return do_b(...);
    default:    return TEE_ERROR_NOT_SUPPORTED;   /* never
                                                     fall
                                                     through */
    }

    /* Anything guessable needs a counter, and the counter
       needs rollback protection (chapter 17): */
    if (state.failures >= MAX_FAILURES)
            return TEE_ERROR_ACCESS_DENIED;

    state.failures++;
    write_protected_state(&state);      /* BEFORE checking -
                                           so a power cut
                                           during the attempt
                                           counts against the
                                           attacker           */
    if (check_pin(pin)) {
            state.failures = 0;
            write_protected_state(&state);
            return TEE_SUCCESS;
    }
    return TEE_ERROR_ACCESS_DENIED;
```

8. Clean up on every path

```
static TEE_Result do_work(TEE_Param params[4])
{
        TEE_OperationHandle op  = TEE_HANDLE_NULL;
        TEE_ObjectHandle    key = TEE_HANDLE_NULL;
        uint8_t             secret[32] = {0};
        TEE_Result          res;

        res = TEE_AllocateOperation(&op, ...);
        if (res) goto out;

        res = TEE_AllocateTransientObject(&key, ...);
        if (res) goto out;

        res = actually_do_it(op, key, secret);
out:
        /* Wipe secrets BEFORE freeing - the heap is reused
           and OP-TEE does not zero on free.               */
        TEE_MemFill(secret, 0, sizeof secret);
        TEE_FreeOperation(op);          /* NULL-safe          */
        TEE_FreeTransientObject(key);   /* NULL-safe          */
        return res;
}

/* A leak here is not merely untidy: TA_DATA_SIZE is small
   (chapter 13), so a leak on an error path that an attacker
   can trigger repeatedly is a denial of service against the
   whole TA.                                                  */
```

The review checklist

#	Check	Look for
1	`paramTypes` checked in every entry point	A command with no `exp` comparison
2	No value read twice from shared memory	Any `params[i].memref.buffer` dereferenced more than once
3	Arithmetic cannot overflow	`a + b > limit`, `n * size`, signed indices
4	`TEE_CheckMemoryAccessRights` on client buffers	Missing before a large copy
5	Output written once, at the end	A write to `memref.buffer` before the final `return TEE_SUCCESS`
6	Constant-time comparison of secrets	`memcmp`, `TEE_MemCompare` on a MAC or PIN
7	Fails closed	A `switch` without `default`; a result variable initialised to success
8	Every handle freed, every secret wiped	An early `return` that skips cleanup
9	Rate limiting with rollback protection	A counter in REE FS (chapter 17)
10	No secrets in logs	`DHEXDUMP`, `%s` of key material
11	Session state is per session	A key in a global under `SINGLE_INSTANCE`
12	Thread safety under `MULTI_SESSION`	Any mutable global (chapter 13)
13	Attack surface is minimal	Commands that exist "for debugging"
14	No untrusted parsing	ASN.1, protobuf, JSON, X.509 inside the TA

> **ROW 14 DESERVES EMPHASIS**
> A parser for a complex, attacker-controlled format is the largest single source of memory-safety bugs in any codebase, and putting one inside the secure world concentrates the risk exactly where it hurts most. Parse in Linux; pass the TA a fixed-size, fully validated struct. If the TA genuinely must parse — a certificate, a TPM command — keep the parser small, total, and fuzzed.

Testing hostilely

```
/* Write a client whose job is to break your TA. Run it in CI. */

    /* wrong parameter types for every command */
    for (uint32_t pt = 0; pt < 0x10000; pt++) {
            op.paramTypes = pt;
            TEEC_InvokeCommand(&sess, cmd, &op, &origin);
            /* must never panic the TA */
    }

    /* boundary sizes */
    size_t sizes[] = {0, 1, MAX-1, MAX, MAX+1, SIZE_MAX};

    /* concurrent mutation - the double-fetch test */
    pthread_create(&t, NULL, mutate_shared_buffer_forever, shm);
    for (int i = 0; i < 100000; i++)
            TEEC_InvokeCommand(&sess, cmd, &op, &origin);

    /* every command in every order, including before the
       session is properly set up */

    /* resource exhaustion: open sessions until it fails, then
       check the TA still works after they close */

/* Fuzzing the parsing code natively is cheaper and finds more:
   compile the TA's pure logic for the host with
   -fsanitize=fuzzer,address and run libFuzzer against it. The
   GP API calls need stubbing, which is a good exercise in
   itself - it forces the security-relevant logic to be
   separable from the plumbing.                              */
```

How it shows up

Symptom	Cause
TA panics when a client sends odd arguments	Missing `paramTypes` check — and this is the mild version of that bug
Heap corruption only under concurrency	Double fetch
Read or write far outside a buffer	Integer overflow in a bounds check
Client observes partial results on failure	Output written before success
PIN recoverable in far fewer attempts than expected	Timing oracle, or distinguishable error codes
Attempt counter resettable	Rate limiting without rollback protection
TA stops working after repeated failed calls	A leak on an error path an attacker can trigger at will
Two clients interfere	Shared global state under `MULTI_SESSION`
Security review finds the whole design wrong	Untrusted parsing inside the TA

Symptom	Cause
Keys in a log from a shipped device	`DHEXDUMP` in a release build

Check yourself

- ✓ State the assumption you must make about every client.
- ✓ Write the `paramTypes` check and explain the attack it prevents.
- ✓ Explain the double fetch with a concrete example and give the rule that prevents it.
- ✓ Rewrite `offset + len > size` so it cannot overflow.
- ✓ Say what `TEE_CheckMemoryAccessRights` catches and what it does not.
- ✓ Explain why output must be written once, at the end.
- ✓ Write a constant-time comparison and say why `TEE_MemCompare` is unsuitable.
- ✓ Give two ways an error path can become an oracle.
- ✓ Explain why a leak on an error path is a security bug in a TA.
- ✓ Explain why untrusted parsing does not belong in the secure world.
- ✓ Design a hostile test client covering at least four of the checklist rows.

Project: a secure key store, client and TA

A complete, working pair: a trusted application that generates ECDSA keys which can never leave the secure world, and a command-line client that drives it. Everything from the previous twenty chapters appears here at once, and the result is a genuinely useful thing — a miniature Keymint.

What we are building

```
   ks create <name>        generate a P-256 keypair inside the
                           TEE. The private half never exists
                           outside it.
   ks pubkey <name>        print the public key
   ks sign   <name> <file> sign a file's SHA-256 digest
   ks verify <name> <file> <sig>
   ks list                 list stored key names
   ks delete <name>

   PROPERTIES WE ARE ENFORCING:

     * the private key is generated by TEE_GenerateKey and
       stored as a persistent OBJECT (chapter 15). It is never
       serialised into a buffer.
     * asking for the private attribute returns
       TEE_ERROR_ACCESS_DENIED - structurally, not by policy.
     * keys are scoped to the calling user (LOGIN_USER), so two
       Linux users cannot see each other's keys.
     * the client passes a NAME, never a pointer or an index
       into TA state.
     * every rule from chapter 20 is applied.

   Verification is done with OpenSSL on the host, to prove the
   signatures are real ECDSA and not something only this TA
   understands.
```

Project layout

```

BINARY = ks
all: $(BINARY)
$(BINARY): main.o
        $(CC) -o $@ $< $(LDADD)
clean:
        rm -f main.o $(BINARY)
```

```
$ export TA_DEV_KIT_DIR=~/optee/optee_os/out/arm-plat-vexpress/export-ta_arm64
$ export TEEC_EXPORT=~/optee/optee_client/out/export/usr
$ export CROSS_COMPILE=aarch64-linux-gnu-

$ make -C ta   CROSS_COMPILE=$CROSS_COMPILE
$ make -C host CROSS_COMPILE=$CROSS_COMPILE

# openssl for aarch64 is needed for the client's SHA-256. If
# your rootfs lacks it, either build it, or replace sha256_file
# with a small public-domain SHA-256 - the TA is unaffected.

$ cp ta/*.ta  ~/optee/out-br/target/lib/optee_armtz/
$ cp host/ks  ~/optee/out-br/target/usr/bin/
$ cd ~/optee/build && make buildroot run-only
```

Running it

```
# In the guest:
# ks create device-key
created 'device-key'

# Secure console shows:
#   I/TA: keystore TA loaded
#   I/TA: cmd_create:118 created key 'device-key'

# ks list
device-key

# ks pubkey device-key
04a1e5...c2  (130 hex chars: 04 || X || Y)

# echo "hello world" > /tmp/msg
# ks sign device-key /tmp/msg
3f8c1a...9e   (128 hex chars: r || s)

# ks verify device-key /tmp/msg 3f8c1a...9e
VALID

# Tamper with the file:
# echo "hello world!" > /tmp/msg
# ks verify device-key /tmp/msg 3f8c1a...9e
INVALID

# Survives a reboot - the key is in secure storage:
# reboot
# ks verify device-key /tmp/msg2 <sig>
VALID
```

Proving the signature is real

```
# The most satisfying part: verify with OpenSSL, on the host,
# with no OP-TEE involved at all. If this works, the TA is
# producing genuine ECDSA P-256 signatures.

# 1. Get the public key and turn it into a PEM.
$ PUB=$(ssh guest ks pubkey device-key)
$ echo $PUB | xxd -r -p > pub.raw          # 65 bytes: 04||X||Y

# Wrap it in the SubjectPublicKeyInfo DER prefix for
# prime256v1:
$ printf '3059301306072a8648ce3d020106082a8648ce3d030107034200' \
    | xxd -r -p > spki.der
$ cat spki.der pub.raw > pubkey.der
$ openssl ec -pubin -inform DER -in pubkey.der -out pubkey.pem
read EC key
writing EC key

$ openssl ec -pubin -in pubkey.pem -text -noout
Public-Key: (256 bit)
pub: 04:a1:e5:...
ASN1 OID: prime256v1
NIST CURVE: P-256

# 2. The TA emits raw r||s; OpenSSL wants DER. Convert.
$ SIG=$(ssh guest ks sign device-key /tmp/msg)
$ python3 - "$SIG" <<'EOF' > sig.der
import sys, binascii
raw = binascii.unhexlify(sys.argv[1])
r, s = raw[:32], raw[32:]
def der_int(b):
    b = b.lstrip(b'\x00') or b'\x00'
    if b[0] & 0x80:
        b = b'\x00' + b
    return b'\x02' + bytes([len(b)]) + b
body = der_int(r) + der_int(s)
sys.stdout.buffer.write(b'\x30' + bytes([len(body)]) + body)
EOF

# 3. Verify.
$ printf 'hello world\n' > msg
$ openssl dgst -sha256 -verify pubkey.pem -signature sig.der msg
Verified OK

# THAT is the point of the project. A key that was generated
# inside the secure world, that has never existed in normal-
# world memory, that survives reboots, and whose signatures any
# standard tool can verify.
```

> **RAW R||S VERSUS DER**
>
> GlobalPlatform's `TEE_AsymmetricSignDigest` returns the two ECDSA components concatenated and fixed-width. Almost every other ecosystem — OpenSSL, X.509, JWS with ES256 uses raw, but TLS and CMS use DER — expects an ASN.1 SEQUENCE of two INTEGERs. Converting is trivial and forgetting to is the commonest reason a TA's signatures "do not verify" when they are perfectly correct.

Extensions worth doing

Exercise	What it teaches
Return DER-encoded signatures from the TA	ASN.1 encoding inside a TA, and why you keep the encoder small
Add an attempt counter that locks a key after N failed verifies, stored in RPMB	Rollback protection (chapter 17)
Add `KS_CMD_WRAP`: export a key encrypted under another key	Key wrapping, and the policy questions it raises
Add RSA-2048 as an alternative key type	Handling more than one algorithm behind one interface
Make the TA `MULTI_SESSION` and stress it with concurrent clients	Everything in chapter 13, the hard way
Write the hostile client from chapter 20 against this TA	Whether your validation is real
Put a kernel driver in the middle — see chapter 25	Why the kernel would want a TA at all, and the ioctl ABI that follows
Bind a key to the device with `TEE_GetHUKDerivedKey`	Device binding (chapter 16)
Produce a self-signed X.509 certificate for the key	How device attestation actually ships

How it shows up

Symptom	Cause
`OpenSession: 0xFFFF0008`	`.ta` not installed, filename does not match the UUID, or `tee-supplicant` not running
`OpenSession: 0xFFFF0001` origin TA	The TA refused the login type — the client used `LOGIN_PUBLIC`
`cmd 0: 0xFFFF0006` origin TA	`paramTypes` mismatch; the TA's `EMSG` prints both values
`0xFFFF0003` on create	Key already exists — delete it first, by design
Signatures verify in the TA, fail in OpenSSL	Raw r‖s not converted to DER
Public key rejected by OpenSSL	Missing the `04` uncompressed-point prefix, or coordinates not left-padded to 32 bytes
Keys disappear after reflashing the image	Secure storage lives in `/data/tee`, which the rootfs image replaced
Two users see the same keys	Client used `LOGIN_PUBLIC`; storage is not scoped
Works on QEMU, keys unreadable on a second board	Correct — the HUK differs per device (chapter 15)

Check yourself

- ✓ Explain why the client sends a digest rather than the file.
- ✓ Say where the private key exists, from generation to use, and why it cannot be exported.
- ✓ Point to the `paramTypes` check, the single-fetch copy and the short-buffer protocol in the TA source.
- ✓ Explain why `copy_name` validates the copy rather than the shared buffer.
- ✓ Explain what the login-type check in `TA_OpenSessionEntryPoint` achieves.
- ✓ Explain why `TA_FLAG_MULTI_SESSION` was deliberately not set.
- ✓ Convert a raw r‖s signature to DER and verify it with OpenSSL.
- ✓ Say what happens to the keys if the normal world deletes `/data/tee`, and how you would defend against it.

- ✓ Extend the TA with one command and add the matching client subcommand.
- ✓ Run the hostile client from chapter 20 against this TA and fix anything it finds.

Project: a firmware TPM as a trusted application

A TPM is a small state machine with keys, counters and measurement registers, spoken to over a byte-stream protocol. That description does not require a chip — it requires isolation, and the secure world provides it. Microsoft's fTPM does exactly this, ships on real products, and is the most instructive TA in existence.

Why a TPM in software is a reasonable idea

	Discrete TPM (dTPM)	Firmware TPM (fTPM)
Where it runs	A separate chip on the SPI or LPC bus	A trusted application in the secure world
Bill of materials	A part, a footprint, routing	Nothing
Bus interception	**Possible** — the SPI bus is on the board and can be probed	Not applicable; there is no bus
Physical attack on the part	Hard — the chip is hardened, often certified	As hard as attacking the SoC, which is usually less hard
Shares fate with the CPU	No	**Yes** — an SoC compromise is a TPM compromise
Certification	Common Criteria, FIPS	Possible but harder
Updatable	Rarely	Yes, with the firmware
Performance	Slow bus, slow part	Fast — it is the application processor

The honest summary: an fTPM removes bus-probing attacks and costs nothing, at the price of sharing its fate with the SoC. For a phone or a laptop where the SoC is already the root of trust, that trade is clearly right — which is why Windows on ARM, most Android devices and AMD's fTPM all take it. For a system where the threat model includes an attacker with unlimited physical access and the CPU is not hardened, a discrete part still wins.

What a TPM actually is

```
Strip away the specification and a TPM 2.0 is four things:

1. PCRs - Platform Configuration Registers
     24 registers, each holding a hash. You cannot WRITE
     them; you can only EXTEND them:

         PCR[i] = SHA256( PCR[i] || new_measurement )

     One-way and order-dependent. Reset to zero only on
     reboot. So the value of PCR[4] after boot is a
     fingerprint of exactly which bootloader ran, in which
     order - and no software can fake a value it did not
     actually reach.

2. A KEY HIERARCHY
     Primary keys derived from persistent SEEDS:
       Endorsement Seed  -> the device's identity, set at
                            manufacture, never changes
       Storage Seed      -> the owner's key hierarchy
       Platform Seed     -> firmware's own hierarchy
     Child keys are created under a parent and stored
     OUTSIDE the TPM as encrypted blobs, loaded back on
     demand. That is how a TPM with 64 KB of storage
     manages thousands of keys.

3. NV STORAGE
     A few kilobytes of indexed, attribute-controlled
     space. Certificates, counters, policy data.
     Monotonic counters live here.

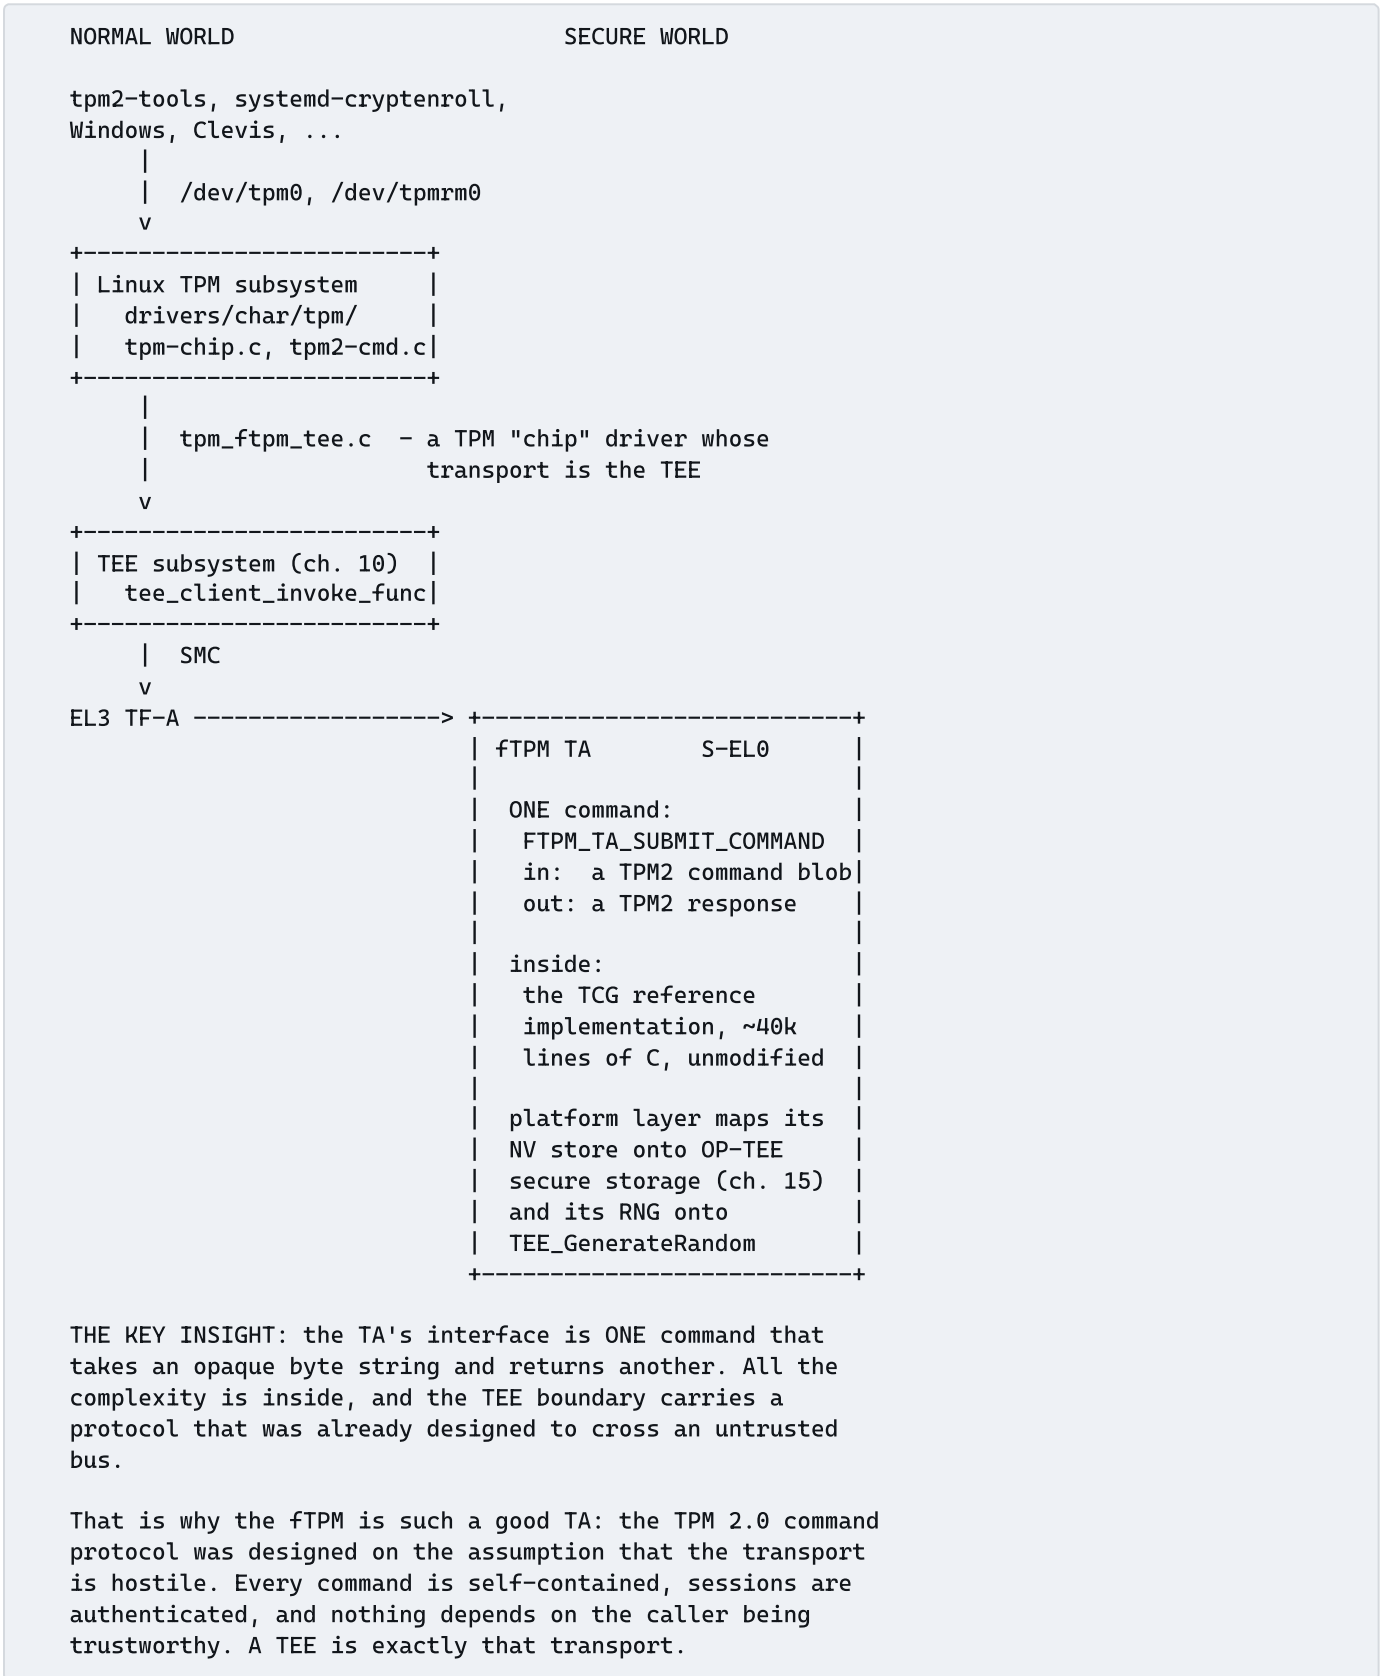
4. POLICY
     A session-based language for "this key may be used
     only if...". Conditions include PCR values, a
     password, a signature, a time, or a counter.
     This is what makes SEALING work.

SEALING, the flagship use, in one line:

  encrypt a secret so that it can only be decrypted when
  PCR[0..7] have exactly the values they had at seal time

which means: "decrypt only if the machine booted the same
software it did when I sealed this". That is BitLocker,
and it is the reason PCRs exist.
```

The fTPM stack



THE KEY INSIGHT: the TA's interface is ONE command that takes an opaque byte string and returns another. All the complexity is inside, and the TEE boundary carries a protocol that was already designed to cross an untrusted bus.

That is why the fTPM is such a good TA: the TPM 2.0 command protocol was designed on the assumption that the transport is hostile. Every command is self-contained, sessions are authenticated, and nothing depends on the caller being trustworthy. A TEE is exactly that transport.

THE DESIGN LESSON WORTH TAKING AWAY

A good TA interface is *narrow and self-authenticating*. The fTPM has one command and the payload carries its own authorisation. Compare a TA with forty commands, each with pointer parameters and implicit state — every one is an attack surface needing its own validation (chapter 20). If you can express your service as a protocol rather than an API, do it.

Getting the source

```
$ git clone https://github.com/microsoft/ms-tpm-20-ref.git
$ cd ms-tpm-20-ref

# Two things live here:
#   TPMCmd/           the TCG reference implementation. This
#                     is the actual TPM 2.0 specification,
#                     rendered as C, maintained by Microsoft.
#   Samples/ARM32-FirmwareTPM/optee_ta/
#                     the OP-TEE glue: entry points, the
#                     platform layer, the build.

$ ls Samples/ARM32-FirmwareTPM/optee_ta/
fTPM/          the TA itself
Makefile
README.md

$ ls Samples/ARM32-FirmwareTPM/optee_ta/fTPM/

   memcpy out. Forty thousand lines of TPM behind a twenty-line
   function.                                                  */
```

The platform layer: where the porting work is

```
/* The reference implementation calls out to a platform layer
   for everything the specification leaves to the
   implementer. Porting a TPM to a new environment IS writing
   this layer, and OP-TEE makes it short.                   */

/* --- NV STORAGE: the TPM's persistent state ------------- */
/* platform/NVMem.c                                         */

int _plat__NvCommit(void)
{
        /* The TPM's entire NV image is one blob, written back
           to OP-TEE secure storage (chapter 15).           */
        return NvFileCommit();   /* -> TEE_WriteObjectData   */
}

void _plat__NvMemoryRead(unsigned int startOffset,
                         unsigned int size, void *data)
{
        memcpy(data, &s_NV[startOffset], size);
}

/* The whole NV area is held in RAM and flushed on commit.
   Consequences:
     - a power cut between a state change and the commit loses
       that change. The TPM specification anticipates this and
       defines which operations must be committed
       synchronously.
     - the NV area is a few tens of kilobytes, so this is
       affordable.
     - REE FS gives no rollback protection. An fTPM that
       matters should be built with CFG_RPMB_FS=y, or its NV
       counters can be rewound (chapter 17). THIS IS THE
       SINGLE MOST IMPORTANT DEPLOYMENT DECISION HERE.     */

/* --- ENTROPY -------------------------------------------- */
int32_t _plat__GetEntropy(unsigned char *entropy, uint32_t amount)
{
        TEE_GenerateRandom(entropy, amount);
        return (int32_t)amount;
        /* Backed by the platform's TRNG where one exists.
           On QEMU it is not a real TRNG, which is one more
           reason the QEMU build is for development only. */
}

/* --- TIME ----------------------------------------------- */
uint64_t _plat__TimerRead(void)
{
        TEE_Time t;
        TEE_GetSystemTime(&t);      /* MONOTONIC, secure -
                                       not TEE_GetREETime.
                                       The TPM's clock must
                                       not be attacker-
                                       controlled (ch. 17). */
        return (uint64_t)t.seconds * 1000 + t.millis;
}

/* --- UNIQUE VALUES: where the seeds come from ----------- */
/* The Endorsement Primary Seed is the device's identity. It
   must be:
     - different on every device
```

```
     - stable for the life of the device
     - never derivable from outside the secure world

   Options, best first:
     1. TEE_GetHUKDerivedKey with a fixed label - derived from
        fuses, per-device, needs no storage (chapter 16).
     2. generated once with TEE_GenerateRandom and persisted
        to RPMB.
     3. provisioned at manufacture from an HSM, along with an
        EK certificate signed by your CA.

   Option 3 is what a product does, because an Endorsement Key
   is only useful for attestation if a relying party can chain
   it to a manufacturer they trust.

   The QEMU/development build uses a FIXED seed. Every
   "device" then has the same EK, which is fine for testing
   and completely useless for attestation.               */

/* --- PHYSICAL PRESENCE ---------------------------------- */
/* On a PC this is a person pressing a key during POST. In a
   TA there is nobody to ask, so the platform layer decides -
   usually by asserting presence for operations the platform
   owner is allowed to perform, and refusing otherwise.
   Getting this wrong lets the normal world clear the TPM.  */
```

Building it

```
$ cd ms-tpm-20-ref/Samples/ARM32-FirmwareTPM/optee_ta

$ export TA_DEV_KIT_DIR=~/optee/optee_os/out/arm-plat-vexpress/export-ta_arm64
$ export CROSS_COMPILE=aarch64-linux-gnu-
$ export TA_CPU=cortex-a53

$ make CFG_FTPM_USE_WOLF=y \
       CFG_TA_DEBUG=y \
       CFG_TEE_TA_LOG_LEVEL=3

#   CFG_FTPM_USE_WOLF=y   use wolfSSL for crypto. The
#                         alternative is OpenSSL, which is
#                         larger. Neither uses OP-TEE's own
#                         crypto API - the reference
#                         implementation brings its own, and
#                         that is a deliberate choice by the
#                         TCG so the TPM's crypto is
#                         auditable independently.

$ ls out/
bc50d971-d4c9-42c4-82cb-343fb7f37896.ta        # ~400 KB
bc50d971-d4c9-42c4-82cb-343fb7f37896.elf       # keep this for
                                               # panics (ch. 19)

# It is large. Check it fits:
#   TA_DATA_SIZE  must accommodate the NV image plus wolfSSL's
#                 working set
#   TA_RAM        must accommodate the whole mapped TA
# In fTPM/user_ta_header_defines.h:
#   #define TA_DATA_SIZE   (2 * 1024 * 1024)
# which is why TZDRAM_SIZE (chapter 6) needs to be generous.

$ cp out/*.ta ~/optee/out-br/target/lib/optee_armtz/
$ cd ~/optee/build && make buildroot run-only
```

> **SIZE IS THE FIRST THING THAT WILL BITE YOU**
> The fTPM is by far the largest TA most people will deploy: a 400 KB binary with a 2 MB heap. On QEMU with 48 MB of secure DRAM that is comfortable. On a real SoC with 4 MB of secure SRAM and a pager (chapter 5) it is a genuine engineering problem, and it is why the paged build exists. Budget the memory before you promise the feature.

A minimal TPM, if you want to understand rather than integrate

```
/* Building the real fTPM teaches you integration. Writing a
   tiny one teaches you what a TPM IS. This implements four
   commands in about 200 lines, and it is a genuinely useful
   exercise before chapter 23.                              */

/* Wire it to the single SUBMIT_COMMAND entry point exactly as
   the real fTPM does, and you have a TPM you can drive from
   Linux. It will not pass the TCG test suite, but it will
   extend and read PCRs, which is enough to understand what
   chapter 23 is doing.                                    */
```

How it shows up

Symptom	Cause
TA will not load, out of memory	`TA_DATA_SIZE` or `TZDRAM_SIZE` too small for a 2 MB heap
TPM state lost on every reboot	NV commit not reaching secure storage, or `tee-supplicant` not running when it tried
PCR values reset without a reboot	TA unloaded — needs `TA_FLAG_INSTANCE_KEEP_ALIVE`
Every device has the same EK	Fixed development seed. Correct for QEMU, fatal in a product
NV counters can be rewound	REE FS without RPMB (chapter 17)
Sealed data unsealable after a firmware update	Working as designed — the PCRs changed. This is the BitLocker recovery-key experience
Build fails on wolfSSL	Submodules not initialised in `ms-tpm-20-ref`
TPM commands time out	Response buffer smaller than `MAX_RESPONSE_SIZE`
Attestation rejected by a relying party	No EK certificate chaining to a trusted manufacturer

Check yourself

- ✓ Compare a discrete TPM and an fTPM, and say which threat each addresses that the other does not.
- ✓ Define a PCR and write the extend operation. Explain why it cannot be forged.
- ✓ Explain sealing in terms of PCRs, and say what happens after a firmware update.
- ✓ Explain why the fTPM TA has only one real command, and why that is good design.
- ✓ Name the four things the platform layer must provide and how OP-TEE supplies each.
- ✓ Say why the TPM's clock must come from `TEE_GetSystemTime`.
- ✓ Explain why the NV store should be in RPMB and what is lost if it is not.
- ✓ Give three ways to produce an Endorsement Seed and say which a product uses.
- ✓ Explain why the fTPM's size is an engineering constraint on a real SoC.
- ✓ Implement `PCR_Extend` and `PCR_Read` in a minimal TA and drive them from a client.

Project: driving the fTPM from Linux

The trusted application from the previous chapter is useless until something speaks to it. This chapter closes the loop: the kernel driver that presents a TA as `/dev/tpm0`, the userspace tools that then work unmodified, and three real exercises — extending PCRs, sealing a secret to boot state, and attesting to a remote party.

The driver that makes a TA look like a chip

```
The whole trick is that Linux's TPM subsystem already
abstracts the transport. A TPM driver's job is to move
bytes; where they go is its own business.

  tpm_tis.c      -> bytes over memory-mapped registers
  tpm_i2c_*.c    -> bytes over I2C
  tpm_vtpm_proxy -> bytes to a userspace process
  tpm_ftpm_tee.c -> bytes to a TRUSTED APPLICATION

All four register a struct tpm_chip and implement send()
and recv(). Everything above - the TPM 2.0 command layer,
/dev/tpm0, the resource manager, the integrity subsystem -
is shared and unmodified.

So tpm2-tools, systemd-cryptenroll, Clevis, IMA and
everything else work against an fTPM with no changes at
all. That is the payoff of a narrow, protocol-shaped TA
interface (chapter 22).
```

$ cat /sys/class/tpm/tpm0/tpm_version_major
2
```

> **USE `/DEV/TPMRM0`, NOT `/DEV/TPM0`**
>
> A TPM has room for only a few loaded objects and sessions at a time — three, typically. The resource manager virtualises that: it swaps objects in and out so several processes can use the TPM concurrently without colliding. `/dev/tpm0` is exclusive and unmanaged. Every tool should target `tpmrm0`; if two things fight over the TPM, this is why.

Exercise 1: PCRs and measurement

```
$ apt install tpm2-tools     # or: buildroot -> tpm2-tools
$ export TPM2TOOLS_TCTI=device:/dev/tpmrm0

# What are the PCRs now?
$ tpm2_pcrread sha256
sha256:
  0 : 0x0000000000000000000000000000000000000000000000000000000000000000
  1 : 0x0000...
  ...
# All zero, because on QEMU nothing measured the boot chain
# into them. On a real platform with measured boot, PCRs 0-7
# are populated by firmware before Linux starts.

# Extend one by hand and watch it change:
$ echo -n "hello" | sha256sum
2cf24dba5fb0a30e26e83b2ac5b9e29e1b161e5c1fa7425e73043362938b9824

$ tpm2_pcrextend 23:sha256=2cf24dba5fb0a30e26e83b2ac5b9e29e1b161e5c1fa7425e73043362938b9824
$ tpm2_pcrread sha256:23
  23: 0xF5A5FD42D16A20302798EF6ED309979B43003D2320D9F0E8EA9831A92759FB4B

# Verify the extend rule yourself - PCR_new = SHA256(0^32 || d)
$ python3 -c "
import hashlib, binascii
old = b'\x00'*32
d = binascii.unhexlify('2cf24dba5fb0a30e26e83b2ac5b9e29e1b161e5c1fa7425e73043362938b9824')
print(hashlib.sha256(old+d).hexdigest())
"
f5a5fd42d16a20302798ef6ed309979b43003d2320d9f0e8ea9831a92759fb4b
# Matches. The TA really is computing the extend correctly.

# Extend again with the SAME value - a different result,
# because extend is order- and history-dependent:
$ tpm2_pcrextend 23:sha256=2cf24dba...
$ tpm2_pcrread sha256:23
  23: 0x9B54...      # different again

# Only a reboot resets it:
$ tpm2_pcrreset 23         # allowed for PCR 16 and 23 only;
                           # 0-15 are reset-protected, which is
                           # what makes them trustworthy.

# Let the kernel measure files into PCR 10:
$ mount -t securityfs securityfs /sys/kernel/security
$ cat /sys/kernel/security/ima/ascii_runtime_measurements | head -3
10 8f4a... ima-ng sha256:e3b0... boot_aggregate
10 c1d2... ima-ng sha256:9f86... /init
$ tpm2_pcrread sha256:10
```

Exercise 2: sealing a secret to boot state

```
# This is BitLocker, in miniature: a secret that can only be
# recovered if the machine boots the same software.

# 1. Establish a known state.
$ tpm2_pcrreset 23
$ tpm2_pcrextend 23:sha256=$(echo -n "my-boot-state" | sha256sum | cut -d' ' -f1)
$ tpm2_pcrread sha256:23
  23: 0x4EF7...

# 2. Create a primary key in the owner hierarchy.
$ tpm2_createprimary -C o -g sha256 -G ecc -c primary.ctx

# 3. Build a policy: "only when PCR 23 has its current value".
$ tpm2_startauthsession -S session.ctx
$ tpm2_policypcr -S session.ctx -l sha256:23 -L policy.digest
$ tpm2_flushcontext session.ctx
$ xxd policy.digest

# 4. Seal a secret under that policy.
$ echo -n "the launch codes" > secret.txt
$ tpm2_create -C primary.ctx -i secret.txt \
      -u sealed.pub -r sealed.priv -L policy.digest \
      -a "fixedtpm|fixedparent"
$ tpm2_load -C primary.ctx -u sealed.pub -r sealed.priv -c sealed.ctx

#   fixedtpm    this object can never be duplicated to another
#               TPM. The secret is bound to THIS device.
#   fixedparent it cannot be rewrapped under a different parent.

# 5. Unseal - with the policy satisfied.
$ tpm2_startauthsession --policy-session -S session.ctx
$ tpm2_policypcr -S session.ctx -l sha256:23
$ tpm2_unseal -p session:session.ctx -c sealed.ctx
the launch codes
$ tpm2_flushcontext session.ctx

# 6. NOW CHANGE THE BOOT STATE and try again.
$ tpm2_pcrextend 23:sha256=$(echo -n "tampered" | sha256sum | cut -d' ' -f1)

$ tpm2_startauthsession --policy-session -S session.ctx
$ tpm2_policypcr -S session.ctx -l sha256:23
$ tpm2_unseal -p session:session.ctx -c sealed.ctx
ERROR: Esys_Unseal(0x99D) - tpm:session(1):a policy check failed
$ tpm2_flushcontext session.ctx

# The sealed blob is on the normal-world filesystem, readable
# by anyone. It is useless to them: the decryption key lives in
# the TPM and the TPM will not use it unless the PCRs match.
#
# And on this system the "TPM" is a trusted application. The
# whole guarantee rests on the secure world's isolation - which
# is exactly the claim chapter 1 started with.
```

SEALING TO PCRS IS A SUPPORT BURDEN

Every firmware update changes PCRs 0–7 and every sealed secret becomes unrecoverable. That is not a bug; it is the entire point. Real systems handle it by sealing to a policy signed by the vendor (`tpm2_policyauthorize`) so a new signed PCR set can be authorised after an update, and by always keeping a recovery path. Seal to raw PCR values only for experiments.

Exercise 3: attestation

```
# Prove to a remote party what this machine booted - without
# trusting anything the machine says about itself.

# --- On the device ---
# 1. An attestation key, restricted to signing TPM-internal
#    data. Restricted means it CANNOT sign arbitrary bytes,
#    so a quote cannot be forged by asking the TPM to sign a
#    fabricated one.
$ tpm2_createprimary -C e -g sha256 -G ecc -c ek.ctx
$ tpm2_create -C ek.ctx -G ecc -u ak.pub -r ak.priv \
      -a "fixedtpm|fixedparent|sensitivedataorigin|\
userwithauth|restricted|sign"
$ tpm2_load -C ek.ctx -u ak.pub -r ak.priv -c ak.ctx
$ tpm2_readpublic -c ak.ctx -o ak.pem -f pem

# 2. The verifier sends a random nonce. Freshness matters:
#    without it, a quote can be replayed (chapter 17).
$ NONCE=$(openssl rand -hex 20)

# 3. Quote: the TPM signs {PCR digest, nonce, clock, firmware
#    version} with the AK.
$ tpm2_quote -c ak.ctx -l sha256:0,1,2,3,4,5,6,7,10 \
      -q $NONCE -m quote.msg -s quote.sig -o pcrs.out -g sha256

# --- Send ak.pem, quote.msg, quote.sig, pcrs.out to the
#     verifier ---

# --- On the verifier ---
$ tpm2_checkquote -u ak.pem -m quote.msg -s quote.sig \
      -f pcrs.out -g sha256 -q $NONCE
pcrs:
  sha256:
    0 : 0x0000...
    10: 0x3F5A...
sig: signature is valid

# The verifier now knows:
#   - a genuine TPM produced this (if the AK chains to an EK
#     certificate from a manufacturer it trusts)
#   - these were the PCR values at quote time
#   - the quote is fresh (the nonce matches)
#
# It does NOT know the PCRs are "good" - that requires a
# reference set of expected values. Attestation proves WHAT
# ran; deciding whether that is acceptable is policy, and it
# is the hard part of every attestation system.

# THE MISSING PIECE ON QEMU: the EK has no certificate, and
# every emulated device shares a seed (chapter 22). So this
# proves the mechanism works, not that the device is genuine.
# A product provisions an EK certificate at manufacture.
```

What this is actually for

Use	Command
Unlock a disk if the boot chain is unchanged	`systemd-cryptenroll --tpm2-device=auto --tpm2-pcrs=0+2+7`

Use	Command
Same, on other distributions	`clevis luks bind -d /dev/sda2 tpm2 '{"pcr_ids":"7"}'`
SSH keys the machine cannot export	`tpm2-pkcs11`, then `ssh-keygen -D /usr/lib/libtpm2_pkcs11.so`
TLS client certificates bound to hardware	`tpm2-openssl` or `tpm2-tss-engine`
Runtime file integrity measurement	IMA, into PCR 10
Hardware entropy for the kernel	`CONFIG_HW_RANDOM_TPM`
Remote device health attestation	`tpm2_quote` plus a verifier
Anti-rollback for application state	TPM NV counters — `tpm2_nvdefine -a "nt=counter"`

```
# The one worth trying end to end, because it is a real
# workflow people actually deploy:

$ systemd-cryptenroll /dev/sda2 --tpm2-device=/dev/tpmrm0 \
      --tpm2-pcrs=7
$ reboot
# The disk unlocks with no password - unless PCR 7 changed,
# in which case it asks for the recovery passphrase.
#
# On this system, "the TPM" is a trusted application running
# beside Linux in the secure world. Nothing above it knows.
```

How it shows up

Symptom	Cause
No `/dev/tpm0`	`CONFIG_TCG_FTPM_TEE` off, TA not installed, or the TA lacks `TA_FLAG_DEVICE_ENUM`
Driver probes then fails	Session open failed — check the secure console; usually the TA is missing or unsigned
`tpm2_*` hangs or errors with a TCTI failure	Pointing at `/dev/tpm0` while something else holds it. Use `tpmrm0`
Permission denied	Not in the `tss` group
`out of memory for object contexts`	Too many loaded objects — use `tpmrm0`, or `tpm2_flushcontext -t`
PCRs all zero on a real board	Firmware is not doing measured boot; the fTPM is fine
PCRs reset without a reboot	The TA unloaded — needs `TA_FLAG_INSTANCE_KEEP_ALIVE`
Unseal fails after an update	PCRs changed. Correct behaviour; use a signed policy
TPM state lost across reboot	NV commit not persisting (chapter 22)
`tpm2_checkquote` fails	Nonce mismatch, wrong PCR selection, or the AK is not restricted
Attestation rejected by a real verifier	No EK certificate — expected on QEMU

Check yourself

- ✓ Explain how one driver makes a TA indistinguishable from a TPM chip, and why nothing above it changes.
- ✓ Point to the `send()` path and say how command and response share one buffer.
- ✓ Explain why `recv()` has nothing to do.

- ✓ Say what the resource manager does and why tools should use `/dev/tpmrm0`.
- ✓ Verify the PCR extend rule by hand against the TPM's output.
- ✓ Explain why PCRs 0–15 cannot be reset and what that buys.
- ✓ Seal a secret to a PCR value and demonstrate that changing the PCR prevents unsealing.
- ✓ Explain what `fixedtpm` and `fixedparent` guarantee.
- ✓ Explain why an attestation key must be *restricted*, and what the nonce prevents.
- ✓ State what a quote proves and what it does not.
- ✓ Enrol a disk with `systemd-cryptenroll` against the fTPM and explain what happens after a firmware update.

Porting OP-TEE to new hardware

Everything so far ran on QEMU, where the platform port already existed and the secure memory was imaginary. Bringing OP-TEE up on real silicon is a different kind of work: a few hundred lines of platform code, one console, one memory carve-out that must be enforced by hardware, and a long list of questions only the SoC's security manual can answer.

What a port actually is

```
OP-TEE is mostly platform-independent. A port is a
directory:

  core/arch/arm/plat-<yours>/
    conf.mk            what the platform has and wants
    main.c             console, early init, hardware setup
    platform_config.h  addresses and sizes
    sub.mk             which files to build
    kern.ld.S          only if your layout is unusual

Plus decisions made OUTSIDE OP-TEE, which are the hard part:

  TF-A            must load OP-TEE as BL32 and pass a
                  correct boot argument (chapter 2)
  TZASC / XPU     must actually FENCE the secure DRAM
                  (chapter 6) - firmware's job, not
                  OP-TEE's
  device tree     Linux must be told OP-TEE is there
  fuses / keys    the HUK, the TA signing key, secure boot

Rough effort on a well-supported SoC whose vendor already
ships TF-A:

  console up ................. half a day
  first TA runs .............. two days
  xtest passing .............. one to two weeks
  RPMB, HUK, secure boot .... weeks, and mostly paperwork

The middle number is small and the last one is not. Budget
accordingly: the port is easy, the PLATFORM SECURITY is
not.
```

THE QUESTION THAT DECIDES EVERYTHING

Can the hardware make a region of DRAM inaccessible to the non-secure world, and can that configuration be locked before non-secure code runs? If yes, a port is worth doing. If no — no TZASC, no XPU, no lockable firewall — then OP-TEE will run and provide *no isolation at all*, because normal-world Linux can read secure DRAM directly. Answer this before writing a line of code.

The information you need first

Question	Where the answer lives	Why it matters
Is there a TZASC/TZC-400, or a vendor XPU?	SoC security manual	Without it there is no secure memory (chapter 6)

Question	Where the answer lives	Why it matters
Which DRAM range can be made secure, at what granularity?	Memory map + TZC region docs	Sets `TZDRAM_BASE` / `SIZE` and their alignment
Is there secure on-chip SRAM, and how much?	Memory map	Decides whether you can run without a DRAM carve-out, and where `TEE_SHMEM` lives
Which UART can be made secure-only?	Peripheral firewall docs	The secure console. Sharing one with Linux works but interleaves badly
GICv2 or GICv3? Which interrupts are Group 0?	GIC integration section	OP-TEE's notification and its own timer
Is the CPU count and cluster topology known at build time?	TRM	`CFG_TEE_CORE_NB_CORE`
Does the vendor ship TF-A, and which version?	Vendor BSP	Determines the handover mechanism you must match
Is there an eMMC with RPMB, and is the RPMB key programmed?	Board schematic + manufacturing	Rollback protection (chapter 17)
Where does the HUK come from?	Security manual: fuses, key ladder, or crypto accelerator	All of secure storage depends on it
Is there a hardware TRNG?	Peripheral list	Otherwise entropy is a real problem

      BL33=u-boot.bin \
      ARM_TSP_RAM_LOCATION=dram \
      all fip

/* 2. The boot argument. TF-A passes OP-TEE a device tree
   pointer (or a legacy argument) in x0/x2 at entry. Getting
   this wrong gives you a hang with no output at all, which
   is the single most demoralising failure in this chapter.

   Debug it by putting a character out of the UART as the
   VERY FIRST instruction of OP-TEE's entry point:

       core/arch/arm/kernel/entry_a64.S, at _start:

           mov  x20, x0            // save the real arg first!
           ldr  x1, =0x1c090000    // UART DR
           mov  w2, #'0'
           str  w2, [x1]

   If '0' appears, TF-A reached you and the problem is later.
   If it does not, the problem is the load address, the
   entry point, or the TZASC fencing you off from your own
   code.                                                  */
```

The part that is not software

```
/* The carve-out must be enforced by HARDWARE, before any
   non-secure code runs, and the configuration must be
   LOCKED. This is TF-A's BL2/BL31 job.                    */

/* TZC-400 example, from a platform's BL2:                  */

void plat_acme_security_setup(void)
{
        tzc400_init(TZC400_BASE);
        tzc400_disable_filters();

        /* Region 0 is the background: everything not covered
           by another region. Make it NON-SECURE by default,
           so a region you forget to configure is at least not
           silently secure.                                  */
        tzc400_configure_region0(TZC_REGION_S_NS_RDWR, 0);

        /* Region 1: the OP-TEE carve-out. SECURE ONLY.
           No non-secure master - CPU or DMA - may touch it. */
        tzc400_configure_region(TZC_FILTERS_ALL, 1,
                TZDRAM_BASE,
                TZDRAM_BASE + TZDRAM_SIZE - 1,
                TZC_REGION_S_RDWR,      /* secure only       */
                0);                     /* no NSAID access   */

        tzc400_set_action(TZC_ACTION_ERR);  /* fault, do not
                                               silently drop */
        tzc400_enable_filters();

        /* And lock it, if the hardware supports locking.
           An unlocked TZASC can be reprogrammed by the
           normal world later, which defeats the whole
           exercise.                                         */
}

/* VERIFY IT. Do not assume. From Linux, as root:          */

$ devmem2 0x0e100000 w
/dev/mem opened.
Memory mapped at address 0xffff...
Bus error                       <-- CORRECT. The fence works.

# If instead you see:
Value at address 0x0E100000: 0x14000000
# then you are reading OP-TEE's own code from the normal
# world, and there is no isolation. Everything else in this
# track is theatre until this reads "Bus error".

# Also check DMA, which is the harder half: program a DMA
# engine to read the same address. The TZASC must block the
# device too, and on some SoCs devices are governed by a
# DIFFERENT firewall (an XPU) that you must configure
# separately.
```

> **THE TWO MISTAKES THAT VOID THE WHOLE PORT**
> First: configuring the TZASC but never locking it, so normal-world firmware can widen the window later. Second: fencing the CPU but not the DMA masters — the SMMU and the peripheral firewall are separate blocks with separate configuration, and a passthrough-capable DMA engine that is not covered can read secure DRAM on the guest's behalf. Test both paths explicitly; a passing `xtest` proves neither.

Telling Linux

```
/ {
        firmware {
                optee {
                        compatible = "linaro,optee-tz";
                        method = "smc";
                };
        };

        reserved-memory {
                #address-cells = <2>;
                #size-cells = <2>;
                ranges;

                /* The carve-out, so Linux never allocates
                   here. The TZASC would fault it anyway, but
                   a fault at a random later moment is far
                   worse than never touching it.           */
                optee@0e100000 {
                        reg = <0x0 0x0e100000 0x0 0x00f00000>;
                        no-map;
                };
        };
};

# Then in the guest:
$ dmesg | grep -i optee
optee: probing for conduit method.
optee: revision 4.1 (4a5b6c7d)
optee: dynamic shared memory is enabled
optee: initialized driver

$ ls -l /dev/tee*
crw------- 1 root root 234, 0 /dev/tee0
crw------- 1 root root 234, 16 /dev/teepriv0
```

Bring-up order that works

Step	Success looks like	If it fails
1. TF-A boots to BL33 *without* OP-TEE	U-Boot prompt	Not an OP-TEE problem yet
2. Add BL32, get one character out	Your debug character on the secure UART	Load address, entry point, or the carve-out is fencing OP-TEE from itself
3. OP-TEE banner	`OP-TEE version: 4.1`	Console clock or base address wrong
4. Secondary cores	`Secondary CPU 1 initializing`	PSCI or GIC per-CPU init

Step	Success looks like	If it fails
5. Linux probes the driver	`optee: initialized driver`	Device tree node, or the SMC conduit
6. `tee-supplicant` runs	No errors in its log	Missing `/data/tee`, or permissions
7. `optee_example_hello_world`	An incrementing value	TA not installed, or signature key mismatch
8. `xtest -l 0`	All pass	Read the secure console; failures are usually crypto or storage
9. `xtest` full	All pass	Now it is a real port
10. `devmem2` on the carve-out	**Bus error**	You have no isolation. Stop and fix the firewall
11. RPMB, HUK, secure boot, signing keys	Product-ready	Mostly manufacturing process

What separates a port from a product

```
/* A port that passes xtest is a development port. Shipping
   requires all of the following, and none of them is code you
   write in OP-TEE.                                          */

  1. A REAL HUK.
     The default is often zeros or a build-time constant. Then
     every device derives the same storage key and secure
     storage protects nothing (chapter 16). Wire
     tee_otp_get_hw_unique_key() to fuses or a key ladder,
     and prove two boards produce different values.

  2. A REAL TA SIGNING KEY.
     The default key ships in the source tree. Anyone can sign
     a TA for your device. Generate one, keep the private half
     in an HSM, and pass TA_SIGN_KEY= at build time
     (chapter 14).

  3. SECURE BOOT, enabled and fused.
     A verified boot chain that is not enforced by fuses is a
     boot chain an attacker replaces.

  4. RPMB, with the key programmed at manufacture.
     CFG_RPMB_WRITE_KEY=y is a development convenience that
     programs a one-time-writable key. Shipping it lets the
     first attacker claim the RPMB.

  5. LOGGING TURNED DOWN.
     CFG_TEE_CORE_LOG_LEVEL=1, CFG_TEE_TA_LOG_LEVEL=0. Debug
     output from the secure world is an information leak, and
     DMSG in a hot path is a timing side channel.

  6. CFG_CORE_ASLR=y, and no CFG_TEE_CORE_DEBUG.

  7. A DOCUMENTED THREAT MODEL.
     Which attacks is this defending against? Bus probing?
     A malicious app? A compromised kernel? Physical
     decapping? The answer decides whether the port is
     adequate, and it is the question an auditor asks first.
```

How it shows up

Symptom	Cause
Total silence after TF-A hands over	Wrong load address or entry point, or the TZASC is fencing OP-TEE out of its own memory
Garbage on the secure console	`CONSOLE_UART_CLK_IN_HZ` wrong
Interleaved secure and normal output	Both worlds driving one UART; firewall it or accept the mess in development only
Panic with a translation fault in a driver	Missing `register_phys_mem_pgdir()` for that MMIO range
Boots on one core, hangs on SMP	`CFG_TEE_CORE_NB_CORE` wrong, or per-CPU GIC init missing
Random corruption under load	`CACHELINE_LEN` wrong
Linux never probes the driver	Device tree `firmware/optee` node missing or `method` wrong
Everything works and `devmem2` reads the carve-out	No hardware fencing. The port provides zero isolation
Secure storage readable on another board	HUK is a constant
A TA signed by someone else loads	Default signing key still in use
Works on the EVK, fails on production silicon	Different fuse configuration, or a firewall the EVK left open

Check yourself

- ✓ Name the four files in a platform port and what each contributes.
- ✓ State the one hardware question that decides whether a port is worth doing.
- ✓ Explain what `register_phys_mem_pgdir()` does and the failure when it is missing.
- ✓ Explain why `register_ddr()` matters for TA parameter validation.
- ✓ Describe how TF-A loads OP-TEE and name the build variables involved.
- ✓ Give the first-character debug technique and say what each outcome tells you.
- ✓ Write the TZASC configuration for a secure carve-out and say why region 0 defaults to non-secure.
- ✓ Prove from Linux that the carve-out is genuinely fenced, and say what a successful read means.
- ✓ Explain why fencing the CPU is not sufficient, and what else must be configured.
- ✓ List the bring-up steps in order and give the success signal for each.
- ✓ Name five things that separate a working port from a shippable one.

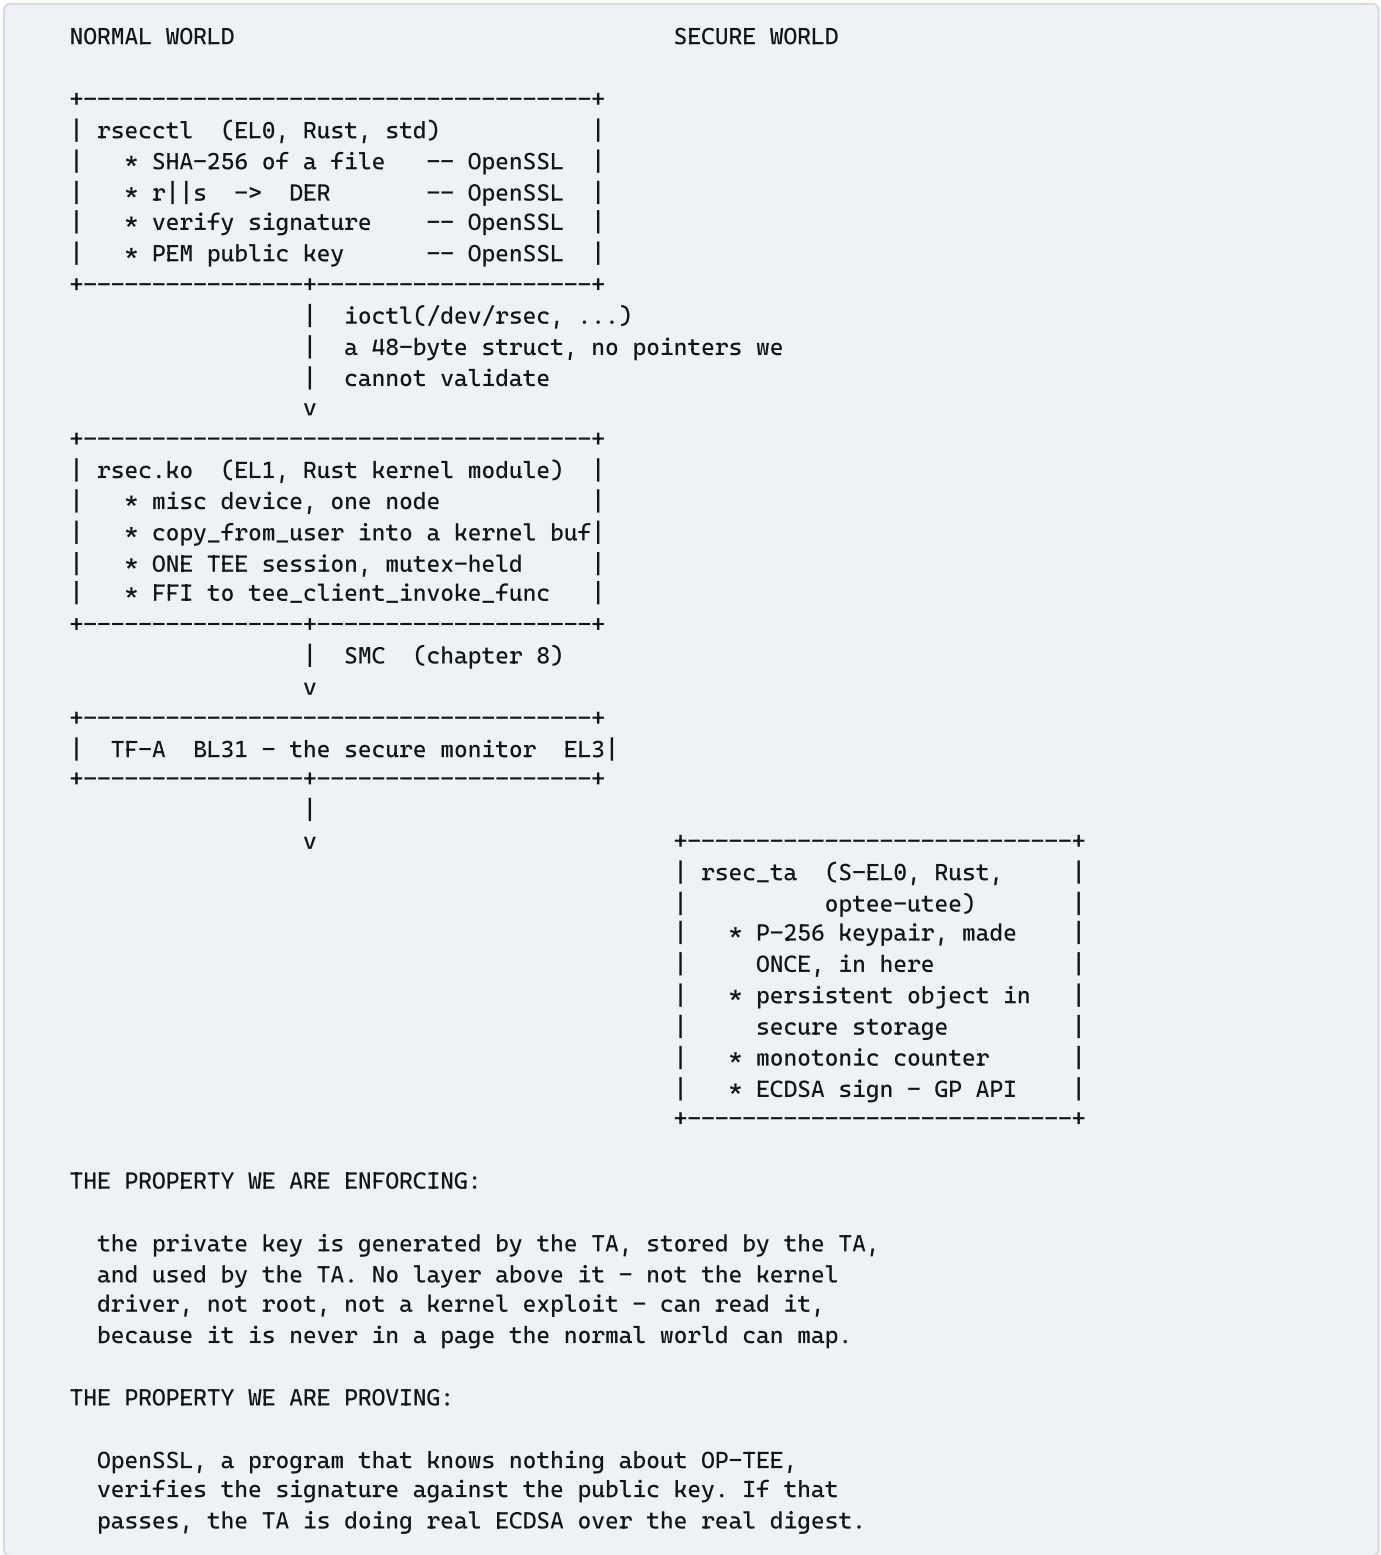
Project: a full-stack secure signing service in Rust

One request travels through four privilege domains — a user-mode driver, a kernel driver, the secure monitor, and a trusted application — and comes back with a signature made by a key that never existed in normal-world memory. Every line of it is Rust. OpenSSL, in the normal world, then verifies that signature, which is how you know the whole chain is real and not merely self-consistent.

WHERE THIS SITS

Harder than the key store, which talked to its TA directly from user space. Easier than the fTPM, which integrated forty thousand lines of someone else's C. The new idea here is the **kernel driver in the middle**, and the language is the other new idea.

What we are building



Why put a kernel driver in the middle at all?

The key store project called `libteec` straight from user space and worked perfectly. Adding a kernel layer is not free — it is a module to maintain, an ioctl ABI to freeze, and a new place for bugs. It earns its place for four reasons, and if none of them apply to your problem you should skip it.

Reason	What it buys
The kernel itself is a consumer	dm-crypt wants a key, IMA wants to extend a measurement, the RNG wants entropy. Kernel code cannot call `libteec` — it must use the in-kernel client API
Policy and serialisation	One TA session shared by every caller, with a mutex, instead of every process opening its own. OP-TEE has a fixed thread pool (chapter 5); uncontrolled session creation exhausts it
A standard interface	Present the service as a device, an `hwrng`, a `crypto_alg` or a TPM, and existing tools work unmodified — exactly what the fTPM driver does
The data is kernel-owned	A measurement taken from a device the kernel owns must not be laundered through user space on its way to the TEE, or the value proves nothing

> **THE COST, STATED HONESTLY**
>
> Every request now crosses user→kernel *and* normal→secure. On QEMU expect tens of microseconds per round trip; the extra syscall is noise next to the world switch. What the kernel layer really costs you is *an ABI you can never change*, which is why the ioctl design below gets a section to itself.

Where the cryptography lives

The brief says "cryptographic operations done with OpenSSL". That is right, and it belongs in the normal world — not inside the TA. This is worth being explicit about because it is a design decision, not a limitation I am working around.

```
OPENSSL, in rsecctl, normal world:

  SHA-256 over the file             bulk data. Megabytes.
                                    Hashing is not secret and
                                    moving megabytes through
                                    shared memory into a TA
                                    would be slow and pointless.

  raw r||s  ->  DER SEQUENCE        a format conversion.
                                    No secrets involved.

  ECDSA VERIFY                      uses the PUBLIC key. There
                                    is nothing to protect.

  SubjectPublicKeyInfo / PEM        packaging, for the rest of
                                    the world to consume.

THE TA, secure world, GP Internal API:

  key generation                    the private key must come
                                    into existence inside the
                                    boundary or the whole
                                    exercise is theatre.

  key storage                       secure storage, sealed to
                                    the HUK (chapter 15).

  ECDSA SIGN over a 32-byte digest  the only operation that
                                    touches the private key.

THE RULE, which generalises far beyond this project:

  put in the TEE exactly what must not leak, and nothing
  else. Every extra byte and every extra line inside the
  boundary is attack surface (chapter 20) and secure RAM
  you do not have (chapter 6).

And note what is NOT possible: linking OpenSSL into a TA.
A TA is S-EL0 with no OS, no sockets, no files, a few
hundred KB of heap and a libc subset. The fTPM manages it
with wolfSSL and a 2 MB heap (chapter 22) and that is a
serious undertaking. Use the GP crypto API inside; use
OpenSSL outside.
```

The ABI: the part you cannot change later

```
// crates/rsec-abi/src/lib.rs
//
// Shared by all three layers. The kernel module and the user
// program both depend on this crate, so a change that breaks
// one fails to compile the other. That is the entire point of
// putting it in a crate instead of writing the numbers twice.

#![cfg_attr(not(feature = "std"), no_std)]

```

> **FOUR ABI RULES, LEARNED THE HARD WAY BY EVERYONE**
>
> **1.** Pointers in ioctl structs are `u64`, never `usize` or a real pointer type — otherwise a 32-bit process on a 64-bit kernel sends a differently-sized struct and you need a whole `compat_ioctl` path. **2.** Every field is naturally aligned and the struct has no implicit padding, so there are no uninitialised bytes to leak back to user space. **3.** A version field is first, always, and the kernel rejects a mismatch. **4.** The size is baked into the ioctl number, so a struct that changes size produces `ENOTTY` rather than silent corruption.

The trusted application, in Rust

TAs in Rust are built with the Apache Teaclave TrustZone SDK, which wraps the GlobalPlatform Internal Core API in the `optee-utee` crate and emits an ordinary signed `.ta` file. The five entry points of chapter 12 become five attribute macros.

```
# ta/Cargo.toml
[package]
name    = "rsec-ta"
version = "0.1.0"
edition = "2021"

[dependencies]
optee-utee       = { git = "https://github.com/apache/incubator-teaclave-trustzone-sdk.git" }
optee-utee-sys   = { git = "https://github.com/apache/incubator-teaclave-trustzone-sdk.git" }
rsec-abi         = { path = "../crates/rsec-abi", default-features = false }

[build-dependencies]
optee-utee-build = { git = "https://github.com/apache/incubator-teaclave-trustzone-sdk.git" }

[profile.release]
panic = "abort"      # a TA has nowhere to unwind to
lto   = true
opt-level = "z"      # secure RAM is the scarce resource
```

```

> **`TA_FLAG_DEVICE_ENUM` IS NOT OPTIONAL HERE**
> Without it the TA is invisible to the Linux TEE bus, no device appears under `/sys/bus/tee/devices/`, and the kernel module's `probe` is never called — silently. The module loads, prints nothing, and creates no device node. This is the single most common way this project fails, and it fails in the one layer where there is no error message to read. See chapter 13.

```
// ta/build.rs
fn main() -> Result<(), Box<dyn std::error::Error>> {
    // Generates user_ta_header.rs from the constants above and
    // emits the linker script the TA dev kit needs.
    optee_utee_build::TaConfig::new_default_with_cargo_manifest()?
        .build()?;
    Ok(())
}
```

The kernel driver, in Rust

Rust for Linux gives you a misc device, a mutex and safe user-copy helpers. It does **not** give you the TEE client API — there is no `kernel::tee` module upstream. So the first thing this driver does is declare the C functions itself.

```
// rsec/src/tee_ffi.rs
//
// Hand-written bindings to drivers/tee's in-kernel client API.
// Everything here is EXPORT_SYMBOL_GPL, so a GPL module may call
// it. See include/linux/tee_drv.h for the authority.
//
// The types come from bindgen. For that to work you must add
//
//     #include <linux/tee_drv.h>
//
// to rust/bindings/bindings_helper.h in your kernel tree, or these
// `bindings::` paths will not resolve.

> **RUST-FOR-LINUX APIS MOVE**
> `MiscDevice`, `UserSlice` and the `pin_init` machinery have all changed shape between 6.8 and 6.13, and will change again. The *structure* above — one session, one mutex, copy in, validate, invoke, copy out with the lock dropped — is stable; the exact trait signatures are not. Check `rust/kernel/miscdevice.rs` in the tree you are building against and adjust. This is the current price of admission for Rust in the kernel, and it is worth saying out loud rather than discovering.

The user-mode driver, in Rust with OpenSSL

```
# host/Cargo.toml
[package]
name    = "rsecctl"
version = "0.1.0"
edition = "2021"

[dependencies]
libc     = "0.2"
openssl  = "0.10"
rsec-abi = { path = "../crates/rsec-abi", features = ["std"] }

# Cross-compiling openssl: either point at buildroot's copy
#   export OPENSSL_DIR=$HOME/optee/out-br/host/aarch64-buildroot-linux-gnu/sysroot/usr
#   export PKG_CONFIG_ALLOW_CROSS=1
# or build it from source into the binary:
#   openssl = { version = "0.10", features = ["vendored"] }
```

```
// host/src/lib.rs  -  the user-mode driver proper
//
// This is the layer that turns "an ioctl on a file descriptor"
// into an API a program would want to use. Keeping it separate
// from the CLI is what makes it a driver rather than a script.

```

Building all three

```
# 0. The OP-TEE QEMU tree, as in chapter 4.
$ mkdir -p ~/optee && cd ~/optee
$ repo init -u https://github.com/OP-TEE/manifest.git -m qemu_v8.xml
$ repo sync -j8
$ cd build && make toolchains -j4

# 1. Rust toolchain for both targets.
$ rustup target add aarch64-unknown-linux-gnu     # host binary
$ rustup toolchain install nightly                # the TA SDK wants it
$ rustup component add rust-src --toolchain nightly

# 2. The TA.
$ git clone https://github.com/apache/incubator-teaclave-trustzone-sdk.git
$ cd incubator-teaclave-trustzone-sdk
$ ./setup.sh
$ source environment          # sets OPTEE_DIR, TA_DEV_KIT_DIR, ...

$ cd ~/rsec/ta
$ make TARGET_TA=aarch64-unknown-linux-gnu
$ ls target/*/release/*.ta
7f2e5c10-9a41-4b8d-b3c6-1e0d5a72f491.ta

# 3. The kernel module. This is the fiddly one.
#    Rust modules need a kernel built with CONFIG_RUST=y, which the
#    OP-TEE manifest's kernel is usually NOT. Check first:
$ cd ~/optee/linux
$ make LLVM=1 ARCH=arm64 rustavailable
Rust is available!            # if not, it tells you exactly what is missing

$ ./scripts/config --enable RUST --enable SAMPLES_RUST
$ ./scripts/config --enable TEE  --enable OPTEE
$ make LLVM=1 ARCH=arm64 olddefconfig
$ make LLVM=1 ARCH=arm64 -j$(nproc) Image modules

#    Add linux/tee_drv.h to the bindings so `bindings::tee_context`
#    and friends exist on the Rust side:
$ grep -q tee_drv rust/bindings/bindings_helper.h || \
    sed -i '1i #include <linux/tee_drv.h>' rust/bindings/bindings_helper.h

#    Then build the module in-tree (out-of-tree Rust modules work but
#    are still rough):
$ cp -r ~/rsec/rsec drivers/misc/rsec
$ echo 'obj-m += rsec/' >> drivers/misc/Makefile
$ make LLVM=1 ARCH=arm64 M=drivers/misc/rsec modules

# 4. The user-mode driver.
$ cd ~/rsec/host
$ export OPENSSL_DIR=~/optee/out-br/host/aarch64-buildroot-linux-gnu/sysroot/usr
$ export PKG_CONFIG_ALLOW_CROSS=1
$ cargo build --release --target aarch64-unknown-linux-gnu

# 5. Stage everything into the image.
$ cp ~/rsec/ta/target/*/release/*.ta   ~/optee/out-br/target/lib/optee_armtz/
$ cp ~/optee/linux/drivers/misc/rsec/rsec.ko ~/optee/out-br/target/root/
$ cp ~/rsec/host/target/aarch64-unknown-linux-gnu/release/rsecctl \
     ~/optee/out-br/target/usr/bin/
$ cd ~/optee/build && make buildroot run-only
```

Running it on QEMU

```
# Three windows appear: the QEMU monitor, "Normal World" and
# "Secure World". In the monitor:
(qemu) c

# Normal world, log in as root:
# insmod rsec.ko
[  12.481203] rsec: initialising
[  12.494771] rsec: /dev/rsec ready

# Secure world console, at the same moment:
D/TC:? ldelf_init_with_ldelf:... loading TA 7f2e5c10-...
I/TA: [rsec-ta] loaded

# ls -l /dev/rsec
crw-------    1 root     root       10, 122 /dev/rsec

# First public key request generates the keypair:
# rsecctl pubkey
raw : 04a91f...c3
-----BEGIN PUBLIC KEY-----
MFkwEwYHKoZIzj0CAQYIKoZIzj0DAQcDQgAEqR8...
-----END PUBLIC KEY-----

# Secure world:
I/TA: [rsec-ta] generating a new P-256 keypair

# Sign something:
# echo "hello from the normal world" > /tmp/msg
# rsecctl sign /tmp/msg
4b7d2e...91

# Verify it, through OpenSSL:
# rsecctl verify /tmp/msg 4b7d2e...91
VALID

# Tamper and re-verify:
# echo "hello from the normal world!" > /tmp/msg
# rsecctl verify /tmp/msg 4b7d2e...91
INVALID

# The counter, which proves persistent storage works:
# rsecctl counter
0
# rsecctl counter inc
1
# rsecctl counter inc
2
# reboot, then:
# rsecctl counter
2                       # survived, because it is in secure storage
```

Proving it independently

```
# Everything above trusted our own code to verify our own code.
# Take the artefacts off the machine and check them with stock
# OpenSSL, which has never heard of OP-TEE.

# On the guest:
# rsecctl pubkey | sed -n '/BEGIN/,/END/p' > /tmp/pub.pem
# rsecctl der /tmp/msg > /tmp/sig.der

# Copy /tmp/pub.pem, /tmp/sig.der and /tmp/msg to the host, then:
$ openssl ec -pubin -in pub.pem -text -noout
Public-Key: (256 bit)
pub:
    04:a9:1f:...
ASN1 OID: prime256v1
NIST CURVE: P-256

$ openssl dgst -sha256 -verify pub.pem -signature sig.der msg
Verified OK

# THAT is the result the whole project exists to produce.
#
# A signature that verifies under a public key, over a digest of a
# file, where the corresponding private key was created inside the
# secure world, has never been present in any page the normal world
# could map, and cannot be extracted by root, by the kernel module,
# or by a kernel exploit.
#
# And the request travelled: Rust user program -> Rust kernel module
# -> SMC -> TF-A -> OP-TEE -> Rust trusted application, and back.
```

Checking the claim rather than assuming it

```
# The claim is "the private key is not reachable from the normal
# world". Test it, do not trust it.

# 1. It is not in the module's memory - the module never sees it.
#    Everything the driver copies is 32 or 64 bytes of digest or
#    signature. Grep the source for a private key: there is none.

# 2. Secure storage is opaque from the normal world.
# ls -l /data/tee/
-rw-------    1 root  root  128  0
# xxd /data/tee/0 | head -2
00000000: 8f3a 2c91 e5d7 ...     # AES-GCM ciphertext, keyed from
00000010: 1b44 90ff 7c22 ...     # the HUK (chapter 15)

# 3. The secure DRAM carve-out is fenced. On QEMU:
# devmem2 0x0e100000 w
Bus error                        # correct - see chapter 24

# 4. The TA is single-instance and keep-alive, so its heap - where
#    the loaded key object lives - is never handed back to the
#    normal world's allocator.
# cat /sys/kernel/debug/tee/... 2>/dev/null

# What this does NOT prove, and you should be clear about it:
#   * on QEMU the HUK is a fixed test value, so secure storage is
#     not device-bound (chapter 15). On real silicon it is.
#   * a compromised OP-TEE core, or a TA with a memory bug, still
#     reaches the key. The boundary is only as good as what runs
#     inside it (chapter 20).
#   * physical attacks are out of scope entirely.
```

If you cannot enable CONFIG_RUST

Rust kernel modules need a recent kernel, a matching `rustc`, `bindgen`, and patience. If the kernel you must ship on does not have it, the ABI in `rsec-abi` is language-neutral — a C module implementing the same three ioctls keeps the Rust TA and the Rust user-mode driver working unchanged.

```
/* rsec_shim.c - the same driver in C, if you need it.
   Abridged: the ioctl bodies mirror the Rust ones exactly.     */

static long rsec_ioctl(struct file *f, unsigned int cmd,
                       unsigned long arg)
{
        struct rsec_dev *d = f->private_data;
        int rc;

        switch (cmd) {
        case RSEC_IOC_SIGN: {
                struct rsec_sign req;
                u8 sig[64];

                if (copy_from_user(&req, (void __user *)arg,
                                   sizeof req))
                        return -EFAULT;
                if (req.version != RSEC_ABI_VERSION)
                        return -EINVAL;
                if (req.sig_len < 64)
                        return -ENOSPC;

                mutex_lock(&d->lock);
                memcpy(d->shm_va, req.digest, 32);
                rc = rsec_invoke(d, TA_CMD_SIGN, 32, 64);
                if (!rc)
                        memcpy(sig, d->shm_va + 64, 64);
                mutex_unlock(&d->lock);
                if (rc)
                        return rc;

                if (copy_to_user((void __user *)req.sig, sig, 64))
                        return -EFAULT;
                return 0;
        }
        ...
        default:
                return -ENOTTY;
        }
}

/* The point worth taking: because the ABI lives in a crate that
   generates the same numbers a C header would, swapping the middle
   layer's language changes nothing above or below it. That is what
   a frozen ABI is FOR.                                          */
```

Extensions worth doing

Exercise	What it teaches
Return DER from the TA instead of raw r‖s	ASN.1 inside a TA, and why you keep the encoder tiny
Register the driver as a Linux `hwrng` fed by `TEE_GenerateRandom`	Why the kernel wants a TEE at all — `/dev/hwrng` then works with no new user-space code
Add a `crypto_alg` registration so `dm-crypt` can use the key	The kernel-as-consumer case in full
Sign the counter value along with the digest	Replay resistance (chapter 17)
Emit a self-signed X.509 certificate with OpenSSL over the TA's key	How device attestation actually ships

Exercise	What it teaches
Add `compat_ioctl` and run a 32-bit ARM binary against it	Why the ABI uses `u64` for pointers
Hammer it with 64 concurrent `rsecctl sign` processes	The mutex, and OP-TEE's thread limit (chapter 5)
Run the hostile client from chapter 20 against the TA	Whether the validation is real
Remove the module while a signature is in flight	Reference counting, and why `Drop` order matters

How it shows up

Symptom	Cause
`insmod` succeeds, no `/dev/rsec`, no messages	TA missing `TA_FLAG_DEVICE_ENUM`, so no TEE device appeared and `probe` never ran
`rsec: no OP-TEE context yet, deferring` for ever	OP-TEE driver not loaded, or `CONFIG_OPTEE` off — check `dmesg | grep optee`
`open_session ret=0xFFFF0008`	`ITEM_NOT_FOUND`: the `.ta` is not in `/lib/optee_armtz`, or its filename does not match the UUID
`open_session` hangs	`tee-supplicant` not running; loading a TA needs it (chapter 9)
`ioctl: Inappropriate ioctl for device` (ENOTTY)	Struct size changed on one side only — the size is encoded in the ioctl number, which is the design working
`ioctl: Invalid argument` immediately	Version mismatch, or the TA's `paramTypes` disagree with what the module sent
Signature verifies in `rsecctl`, fails in `openssl dgst`	Raw r‖s not converted to DER
Public key rejected by OpenSSL	Missing the `0x04` prefix, or X/Y not left-padded to 32 bytes
Verification fails roughly 1 signature in 128	Exactly the left-padding bug — a coordinate with a leading zero byte
System stalls under concurrent load	Mutex held across `copy_to_user`, which can fault and sleep
Kernel oops on `rmmod`	`Drop` order — shared memory freed after the context, or a session still in use
TA panics, then every call returns `ETIME`	`TEE_ERROR_TARGET_DEAD`; the session must be torn down and reopened
Key changes after reflashing the rootfs	Secure storage lives in `/data/tee`, which the new image replaced (chapter 15)
Works on QEMU, key unreadable on a second board	Correct — the HUK differs per device

Check yourself

- ✓ Draw the request path through all four domains and name the mechanism that crosses each boundary.
- ✓ Give four reasons to put a kernel driver between user space and a TA, and one reason not to.
- ✓ Explain why OpenSSL does the hashing and verification while the TA does only the signing.
- ✓ Explain why a TA cannot realistically link OpenSSL.
- ✓ State the four ioctl ABI rules and the failure each one prevents.
- ✓ Explain why pointers in the ioctl structs are `u64`.
- ✓ Say what `TA_FLAG_DEVICE_ENUM` enables, and describe exactly how it fails without it.
- ✓ Point to the single-fetch copy, the `paramTypes` check and the fixed-size digest in the TA source.

- ✓ Explain the left-padding of X, Y, r and s, and the bug you get without it.
- ✓ Explain why the mutex is dropped before `copy_to_user`.
- ✓ Justify one shared TEE session rather than one per `open()`.
- ✓ Give the correct teardown order in `Drop` and say what breaks if you reverse it.
- ✓ Verify a TA-produced signature with stock `openssl dgst` and explain what that proves — and what it does not.

TRACK

Cryptography

From entropy to TLS to constant-time code — the cryptography a firmware and platform engineer is expected to know.

21 chapters

What cryptography guarantees

Four properties, and the precise threat model each defends. Most cryptographic failures in real systems come not from broken algorithms but from expecting a property the primitive never provided — so this chapter is about being exact.

The four goals

```
CONFIDENTIALITY   an adversary cannot learn the content
                  -> encryption

INTEGRITY         an adversary cannot modify the message
                  undetected
                  -> MACs, signatures

AUTHENTICITY      the message came from who it claims
                  -> MACs (shared key), signatures
                     (public key)

NON-REPUDIATION   the sender cannot later deny it
                  -> signatures ONLY, never MACs

AND THE ONES CRYPTOGRAPHY DOES NOT PROVIDE:
  availability      - a jammer, a flood, a cut cable
  traffic analysis  - who talked to whom, when, how much
  endpoint security - a compromised device signs whatever
                      it is told to
  correctness of the plaintext
  protection against a user who chooses to leak it

THE DISTINCTION THAT MATTERS MOST IN PRACTICE:

  A MAC proves the message came from someone holding the
  shared key. Since BOTH parties hold it, EITHER could
  have produced it - so a MAC cannot prove to a third
  party who sent it.

  A SIGNATURE proves it came from the holder of the
  private key, and only they hold it - so a third party
  can verify it, and the signer cannot deny it.

Choosing a MAC where non-repudiation was needed, or a
signature where a MAC would have been faster, is a design
error that no amount of correct implementation fixes.
```

Encryption alone is not enough

```
/* THE SINGLE MOST IMPORTANT RULE IN THIS TRACK:

     ENCRYPTION WITHOUT AUTHENTICATION IS BROKEN.

   Confidentiality does not imply integrity. An attacker who
   cannot READ your ciphertext can very often MODIFY it in
   ways that produce a predictable change in the plaintext.  */

/* --- THE BIT-FLIP ATTACK on a stream cipher --- */
        plaintext:   "TRANSFER 0100 TO ACCOUNT 12345"
        keystream:   k0 k1 k2 ...
        ciphertext:  p XOR k

/* The attacker does not know the key. But XOR is linear, so
   flipping bit i of the ciphertext flips bit i of the
   plaintext. They change "0100" to "9100" by XORing the
   right positions with a known delta - WITHOUT DECRYPTING
   ANYTHING.

   This applies to every stream cipher, and to CTR, OFB and
   CFB modes (chapter 05).

/* --- THE PADDING ORACLE on CBC --- */
/* If the receiver distinguishes "bad padding" from "bad
   MAC" - by an error message, a different response, or
   merely a TIMING DIFFERENCE - an attacker can decrypt the
   entire message by submitting modified ciphertexts and
   observing which are accepted. About 128 queries per byte.

   This broke TLS (Lucky 13), ASP.NET, XML encryption, and
   many devices. It is why the answer is not "fix the error
   messages" but "use authenticated encryption".

/* THE FIX, and it is the same in every case:

     USE AN AEAD (chapter 09): AES-GCM, ChaCha20-Poly1305,
     AES-CCM. They encrypt and authenticate together, in a
     construction that has been analysed as a whole.

   NEVER: encrypt then hope
   NEVER: encrypt-and-MAC or MAC-then-encrypt hand-rolled
   ALWAYS: an AEAD, or if you must compose, ENCRYPT-THEN-MAC
           over the ciphertext AND the IV AND the associated
           data.                                          */
```

> **THE RULE THAT PREVENTS MOST FAILURES**
>
> **Do not design cryptography. Do not implement primitives. Use a reviewed library, at the highest level of abstraction it offers.**
>
> Every chapter in this track explains how something works so you can reason about it, choose correctly, and read a security review. None of it is an invitation to write your own AES. The gap between "understanding the algorithm" and "implementing it without a side channel" is where the failures are (chapter 19).

Kerckhoffs's principle

```
/* THE SYSTEM MUST BE SECURE EVEN IF EVERYTHING ABOUT IT IS
   PUBLIC EXCEPT THE KEY.

   Stated in 1883, and still the property that separates
   cryptography from wishful thinking.

/* WHY: algorithms leak. They are reverse-engineered from
   firmware, extracted from silicon, leaked by employees,
   published by researchers. A system whose security depends
   on the algorithm staying secret has a single point of
   failure that cannot be rotated.

/* THE CASE STUDIES, all of them real:
     · A5/1 (GSM)         - reverse-engineered, then broken
     · CSS (DVD)          - reverse-engineered, 40-bit key
     · MIFARE Classic     - proprietary CRYPTO1, broken in
                            minutes
     · KeeLoq (car remotes) - broken once published
     · numerous vendor "encryption" schemes in IoT devices

   In every case the algorithm was weak, and secrecy delayed
   the discovery rather than preventing it.

/* THE CORRECT POSTURE:
     · use PUBLISHED, ANALYSED algorithms - AES, SHA-2,
       SHA-3, ChaCha20, Ed25519, ML-KEM
     · assume the attacker has your firmware and your
       schematics
     · put the secret in the KEY, and protect the key
       (chapter 18)
     · design so a compromised device does not compromise the
       fleet - per-device keys, not one key everywhere

/* AND THE COROLLARY that people miss: "we obfuscated it" is
   not a security control. It raises the cost of the first
   break and does nothing thereafter, because the result is
   published.                                              */
```

Threat models

```
/* A guarantee is meaningless without saying against WHOM.
   The standard adversary models, in increasing strength: */

   CIPHERTEXT-ONLY       sees ciphertexts
   KNOWN-PLAINTEXT       sees some plaintext/ciphertext pairs
   CHOSEN-PLAINTEXT      can get any plaintext encrypted
                         (CPA)
   CHOSEN-CIPHERTEXT     can also get chosen ciphertexts
                         DECRYPTED (CCA)
   ADAPTIVE CHOSEN-      can choose based on previous
   CIPHERTEXT (CCA2)     answers

/* MODERN SCHEMES TARGET CCA2, because that is what a network
   attacker actually has: they can send whatever they like to
   your server and observe the response.

   IND-CPA   "indistinguishable under chosen plaintext" - an
             attacker cannot tell which of two chosen
             plaintexts was encrypted. Requires
             RANDOMISATION: the same plaintext must not
             produce the same ciphertext, which is why every
             mode needs an IV or nonce.
   IND-CCA2  the same, with a decryption oracle available.
             AEADs provide this; unauthenticated modes do
             not.

/* AND THE PHYSICAL MODELS, which matter for embedded: */
   PASSIVE REMOTE        network observation only
   ACTIVE REMOTE         can inject and modify
   LOCAL SOFTWARE        code on the same machine - cache
                         timing (chapter 19)
   PHYSICAL, NON-        power and EM measurement
   INVASIVE
   PHYSICAL, INVASIVE    decapsulation, probing, laser fault
                         injection

/* THE EMBEDDED QUESTION: your threat model must state where
   on that scale you stop. "Resists a remote attacker" and
   "resists an attacker holding the device with an
   oscilloscope" are entirely different products
   (isolation chapter 16), and pretending otherwise is how
   security reviews go badly.                              */
```

Key sizes and security levels

Security level	Symmetric	RSA / DH	Elliptic curve	Hash
80 bits — **broken**	—	1024	160	SHA-1
112 bits — legacy only	3DES	2048	224	SHA-224
128 bits — the baseline	**AES-128**	3072	**256**	**SHA-256**
192 bits	AES-192	7680	384	SHA-384
256 bits	AES-256	15360	521	SHA-512

```
/* READ THE TABLE ROW-WISE: those entries are EQUIVALENT.
   AES-128, RSA-3072 and P-256 all give about 128 bits of
   security. Pairing AES-256 with RSA-2048 wastes the AES
   strength; the system is as strong as its weakest link.

/* WHAT "128 BITS" MEANS: roughly 2^128 operations to break.
   That is not merely large - it is beyond any conceivable
   physical computation. Counting to 2^128 at one operation
   per Planck time, using the entire energy output of the
   sun, does not finish.

/* SO KEY SEARCH IS NOT THE THREAT. Real breaks come from:
     · implementation bugs
     · side channels (chapter 19)
     · key management failures (chapter 18)
     · protocol errors
     · bad randomness (chapter 02)
     · using a broken primitive after it was broken

/* THE ASYMMETRIC SIZES ARE LARGER because the attacks are
   better than brute force: the number field sieve for
   RSA/DH factoring and discrete log, Pollard's rho for
   elliptic curves. ECC needs only 2n bits for n bits of
   security, which is why it dominates on embedded
   (chapter 14).

/* AND THE QUANTUM CAVEAT (chapter 20):
     Grover's algorithm halves symmetric security - AES-128
     becomes ~64 bits of quantum security, which is why
     AES-256 is recommended for long-term secrets.
     Shor's algorithm BREAKS RSA, DH and ECC entirely. The
     replacements are standardised (ML-KEM, ML-DSA) and
     deployment has begun.                                */
```

The primitives, and what each is for

Need	Use	Never
Encrypt a message	AES-GCM, ChaCha20-Poly1305, AES-CCM	ECB, unauthenticated CBC/CTR
Hash data	SHA-256, SHA-3, BLAKE2/3	MD5, SHA-1
Authenticate with a shared key	HMAC-SHA256, or the AEAD's tag	A hash of key‖message
Sign	Ed25519, ECDSA P-256, RSA-PSS	RSA PKCS#1 v1.5 for new designs
Key agreement	X25519, ECDH P-256	Unauthenticated DH
Derive keys from a key	HKDF	Truncating a hash
Hash a password	Argon2id, scrypt, bcrypt	Any plain hash, however salted
Random numbers	The OS CSPRNG, or a hardware TRNG	`rand()`, `time()`, a PRNG
Post-quantum KEM	ML-KEM (Kyber), hybrid with X25519	Anything unstandardised

```
/* THE LIBRARIES worth using, by environment:

   EMBEDDED / no OS
     mbedTLS          the standard for microcontrollers
     wolfSSL          small, certifiable, commercial
     TinyCrypt        minimal, NIST primitives only
     Monocypher       tiny, public domain, modern primitives
     RustCrypto       pure Rust, no_std, audited

   LINUX / POSIX
     libsodium        THE recommendation - a small, safe API
                      that is hard to misuse
     OpenSSL / BoringSSL   ubiquitous, large, easy to misuse
     the kernel crypto API   for in-kernel use

   HARDWARE
     the SoC's crypto accelerator, through the vendor driver
     a TPM or secure element, for key storage
     the TEE (isolation chapters 12-13)

/* PREFER THE HIGHEST-LEVEL API AVAILABLE:
     libsodium's crypto_secretbox()  rather than assembling
     AES-GCM from parts. The high-level API chose the nonce
     handling, the tag length and the composition for you,
     and those are exactly the choices that go wrong.     */
```

How it shows up

Symptom	Cause
Ciphertext modified undetectably	No authentication — use an AEAD
Plaintext recovered from error responses	A padding oracle — the same fix
Same plaintext gives the same ciphertext	No IV, reused IV, or ECB mode
Scheme broken once the firmware leaked	Security through obscurity — Kerckhoffs
One device compromised, whole fleet exposed	A shared key instead of per-device keys
AES-256 with RSA-1024	Mismatched security levels
A third party cannot verify a message's origin	A MAC was used where a signature was needed
Keys predictable across devices	Bad randomness at provisioning (ch. 02)
Passwords cracked from a stolen database	A plain hash instead of a password KDF
Key extracted with an oscilloscope	No side-channel countermeasures (ch. 19)
"We wrote our own so it is unique"	The most reliable predictor of a break

Check yourself

- ✓ Name the four goals and the primitive that provides each.
- ✓ Explain precisely why a MAC cannot give non-repudiation.
- ✓ List four things cryptography does not provide.
- ✓ Explain the bit-flip attack and why encryption alone is insufficient.
- ✓ Explain a padding oracle and why the fix is AEAD rather than better error messages.
- ✓ State Kerckhoffs's principle and give three systems that violated it.

- ✓ Name the adversary models and say which modern schemes target.
- ✓ Explain why every mode needs an IV or nonce.
- ✓ Read the equivalent-strength table and spot a mismatched pairing.
- ✓ Explain why key search is not the realistic threat.
- ✓ Choose the right primitive for nine common needs, and name what never to use.

Randomness and entropy

Every key, nonce, IV and salt depends on unpredictable numbers, and on an embedded device at first boot there is almost nothing unpredictable available. This is the most common single cause of real cryptographic failure in shipped products.

Three kinds of random

```
PRNG          deterministic from a seed. Fast, repeatable,
(non-crypto)  and PREDICTABLE. rand(), Mersenne Twister,
              xorshift, LCG.
              -> simulations, games, test data.
              -> NEVER for anything security-relevant.

CSPRNG        deterministic from a seed, but
              computationally infeasible to predict
              without it. ChaCha20-based, HMAC-DRBG,
              CTR-DRBG, AES-CTR.
              -> ALL cryptographic use.
              -> still needs a good seed.

TRNG          a physical entropy source: thermal noise, a
              ring oscillator's jitter, avalanche noise,
              radioactive decay.
              -> seeding the CSPRNG, and nothing else -
                 they are slow, and their raw output is
                 usually biased.

THE STANDARD ARCHITECTURE, and the one you should use:

     physical noise source (TRNG)
           |
     health tests, de-biasing (von Neumann, or a hash)
           |
     SEED (256 bits of real entropy)
           |
     CSPRNG  --> unlimited output, fast
           ^
           |
     periodic RESEEDING from the noise source

THE CSPRNG DOES THE WORK; the TRNG only ever provides the
seed. Reading a TRNG directly for every byte is slow and,
because raw output is biased, often worse.
```

How this fails in practice

```
/* --- 1. DEBIAN OpenSSL, 2006-2008 --- */
/* A developer removed a line that Valgrind complained about.
   It was the one mixing uninitialised memory into the pool.
   The seed collapsed to the process ID - 32,768 possible
   values. Every SSH and TLS key generated on Debian for two
   years was one of ~32,768 keys, enumerable in minutes.

/* --- 2. EMBEDDED DEVICES AT FIRST BOOT --- */
/* The 2012 "Mining Ps and Qs" study scanned the internet and
   found that 0.5% of TLS hosts and 1% of SSH hosts shared
   keys, or had keys sharing a prime factor - making them
   trivially factorable. The cause: routers and embedded
   devices generating keys at first boot, before any entropy
   existed.

   THE CONDITIONS THAT CAUSED IT, and every one of them is
   still common:
     · no hardware RNG
     · no persistent state from a previous boot
     · no user input
     · no network traffic yet
     · a real-time clock reading the same value on every
       device
     · the boot sequence identical every time

/* --- 3. THE PLAYSTATION 3 ECDSA KEY, 2010 --- */
/* Sony used the SAME nonce k for every signature. ECDSA
   leaks the private key immediately if k repeats
   (chapter 15). The master signing key was recovered from
   two signatures.

/* --- 4. ANDROID SecureRandom, 2013 --- */
/* An initialisation bug caused repeated nonces in Bitcoin
   wallet apps. The same ECDSA property applied. Funds were
   stolen.

/* THE PATTERN: in every case the ALGORITHM was fine. The
   randomness was not. That is where the failures are.   */
```

> **THE PROVISIONING RULE**
>
> An embedded device must **not** generate its long-term keys at first boot. Inject them during manufacturing, from a source with real entropy — an HSM on the production line — and burn the device-unique secret into fuses (isolation chapter 10). A device that generates its own identity before it has entropy is a device whose identity is predictable, and no amount of later reseeding fixes a key that has already been created.

Entropy sources

```
/* --- ON A HOSTED SYSTEM: use the OS. It is not optional to
       do better; it is impossible.                        */

    Linux    getrandom(buf, len, 0)     /* THE right call */
             /dev/urandom               /* the same pool  */
             /dev/random                /* identical since
                                           Linux 5.6 - the
                                           old blocking
                                           behaviour is
                                           gone           */
    Windows  BCryptGenRandom()
    macOS    getentropy(), SecRandomCopyBytes()
    POSIX    arc4random_buf()

/* getrandom() BLOCKS UNTIL THE POOL IS INITIALISED, which is
   exactly the behaviour you want at boot - and the reason
   some embedded systems hang at startup. The fix is to give
   the kernel entropy, not to stop blocking.

/* THE KERNEL'S SOURCES:
     interrupt timing jitter          the main one
     RDRAND / RNDR (ARMv8.5)          if available and
                                      trusted
     device-tree rng-seed             passed by the
                                      bootloader
     a stored seed file across reboots
     hardware RNG drivers (hwrng)

/* --- ON A MICROCONTROLLER --- */

    1. A HARDWARE TRNG, if the part has one. Most modern MCUs
       do: STM32 RNG, nRF RNG, ESP32 RNG, RP2040 ROSC.
       READ ITS DOCUMENTATION - some are only entropic when
       specific peripherals are active, and the ESP32's is
       only a true RNG when the radio is on.

    2. AN ADC ON A FLOATING INPUT, sampling the low bits. Some
       entropy, poorly characterised - use it only as one
       input among several, hashed.

    3. RING OSCILLATOR JITTER, if you have two independent
       oscillators. Sample one with the other.

    4. TIMING JITTER between an independent clock and the CPU.

    5. SRAM POWER-UP STATE. The uninitialised pattern is
       partly device-unique and partly random - useful as a
       PUF for device identity, weak as an entropy source.

/* AND ALWAYS: CONDITION THE OUTPUT. Never use a raw source
   directly: */
        uint8_t pool[64];
        collect_raw(pool, sizeof pool);   /* biased */
        sha256(pool, sizeof pool, seed);  /* 256 bits of
                                             conditioned
                                             output       */
        chacha20_seed(seed);              /* now use the
                                             CSPRNG       */
```

Using a CSPRNG

```
/* A ChaCha20-based CSPRNG - the modern standard construction,
   and what Linux, BSD and libsodium all use.             */

    struct Csprng {
        uint8_t key[32];
        uint64_t counter;
    };

    void csprng_seed(struct Csprng *r, const uint8_t seed[32])
    {
        memcpy(r->key, seed, 32);
        r->counter = 0;
    }

    void csprng_bytes(struct Csprng *r, uint8_t *out, size_t n)
    {
        uint8_t block[64];

        while (n) {
            chacha20_block(r->key, r->counter++, block);
            size_t take = n < 64 ? n : 64;
            memcpy(out, block, take);
            out += take; n -= take;
        }
        /* FAST KEY ERASURE: replace the key with fresh
           output, so a later compromise cannot recover
           earlier output. FORWARD SECRECY for the RNG.  */
        chacha20_block(r->key, r->counter++, block);
        memcpy(r->key, block, 32);
        secure_zero(block, sizeof block);
    }

/* THE FAST KEY ERASURE STEP is what makes this construction
   better than a plain counter mode: an attacker who reads
   the state cannot compute what you generated before.

/* THE OTHER STANDARD CONSTRUCTIONS (NIST SP 800-90A):
     HMAC-DRBG     conservative, easy to implement, slow
     CTR-DRBG      AES-CTR based; fast with an AES
                   accelerator
     Hash-DRBG
     (and Dual_EC_DRBG, which was withdrawn after evidence
      of a deliberate back door - a useful reminder that
      "standardised" is not the same as "trustworthy", and
      that public analysis is what matters)

/* RESEEDING: mix in fresh entropy periodically, and always
   after a fork, a restore from snapshot, or a VM clone -
   because all three duplicate the state, and a duplicated
   CSPRNG produces duplicated keys.                       */
```

Getting it right in code

```
/* --- ALWAYS CHECK THE RETURN VALUE --- */
    uint8_t key[32];
    if (getrandom(key, sizeof key, 0) != sizeof key)
            abort();            /* do NOT continue with a
                                   partly-filled buffer  */

/* A short read, a failed hardware RNG, or an uninitialised
   pool must be FATAL. Generating a key from a zero buffer is
   worse than not starting.

/* --- NEVER THESE --- */
    srand(time(NULL)); rand();          /* predictable */
    key = hash(serial_number);          /* not secret */
    key = hash(mac_address);            /* enumerable */
    key = hash(time());                 /* one second of
                                           entropy */
    for (i = 0; i < 32; i++)
            key[i] = adc_read() & 0xFF; /* biased, unconditioned */
    memcpy(key, uninitialised_buffer, 32);  /* UB, and not
                                               random */

/* --- NONCES AND IVs (chapter 05) --- */
/* THE REQUIREMENT DIFFERS BY MODE, and confusing them is a
   real bug:
     CBC     the IV must be UNPREDICTABLE (random)
     CTR/GCM the nonce must be UNIQUE, and need not be secret
             or random - a COUNTER is correct and often
             better, because a counter cannot collide
     A REPEATED GCM NONCE with the same key is catastrophic:
     it reveals the XOR of the plaintexts AND allows forgery
     of arbitrary messages.

/* SO FOR GCM, prefer a counter with persistent storage: */
    struct { uint32_t device_id; uint64_t counter; } nonce;
    nonce.counter = load_and_increment_persistent();
/* and if the counter can ever reset - a device that is
   reflashed, a state restore - rotate the key instead.

/* --- WIPE KEYS AFTER USE (compilers chapter 06) --- */
    explicit_bzero(key, sizeof key);        /* glibc, BSD */
    SecureZeroMemory(key, sizeof key);      /* Windows */
    sodium_memzero(key, sizeof key);
    /* plain memset is DELETED by the optimiser, because
       nothing reads the buffer afterwards */

/* --- AND FOR PASSWORDS, NEVER a plain hash (chapter 10) */
    argon2id(password, salt, ...);
```

Testing randomness

```
# --- STATISTICAL TEST SUITES ---
    dieharder -a -g 201 -f random.bin
    ent random.bin              # entropy, chi-square, mean
    NIST STS                    # SP 800-22
    PractRand                   # the most sensitive; catches
                                # what dieharder misses
    TestU01 BigCrush

# --- WHAT THEY CAN AND CANNOT TELL YOU ---
#   THEY DETECT: bias, short periods, correlations, stuck
#                bits, obviously broken sources
#   THEY DO NOT DETECT: a perfectly uniform but PREDICTABLE
#                sequence. AES-CTR with a key the attacker
#                knows passes every test.
#
#   SO: passing is necessary, not sufficient. It tells you
#   the source is not obviously broken; it says nothing about
#   whether it is secret.

# --- THE HEALTH TESTS THAT BELONG IN THE PRODUCT ---
    · REPETITION COUNT: fail if the same value repeats too
      often (SP 800-90B)
    · ADAPTIVE PROPORTION: fail if one value dominates a
      window
    · continuous self-test on every read from the hardware
      RNG
    · a startup test at boot, before generating anything
    · FAIL CLOSED: if the RNG fails its health test, refuse
      to operate. Do not fall back to a weaker source.

# --- ESTIMATING ENTROPY ---
#   min-entropy H∞ = -log2(max probability)
#   This is the conservative measure and the one that matters
#   for key generation - Shannon entropy overestimates when
#   the distribution is skewed.
#   A source producing 0 with probability 0.6 has 0.97 bits
#   of Shannon entropy and only 0.74 bits of min-entropy.
#   Collect enough raw bits that the CONDITIONED output has a
#   full 256 bits of min-entropy - typically several times
#   as many raw bits as you need.

# --- ON LINUX, CHECK THE POOL ---
    cat /proc/sys/kernel/random/entropy_avail
    dmesg | grep -i random
      random: crng init done      # this line is what you
                                  # need to see before
                                  # generating keys
```

The embedded checklist

Question	Right answer
Does the part have a TRNG?	Check the TRM, and check its *conditions* — some need a peripheral active
Where do long-term keys come from?	**Injected at manufacture**, not generated on device
Is there a device-unique secret in fuses?	There should be — it is the root of everything else
Is the RNG health-tested at boot?	Yes, and it must fail closed

Question	Right answer
Is a seed persisted across reboots?	Yes, in secure storage, and mixed with fresh entropy
Are GCM nonces counters or random?	Counters, persisted, with key rotation on reset
Are keys wiped after use?	With `explicit_bzero`, not `memset`
What happens if the RNG fails?	Refuse to operate — never a weaker fallback
Is every device's key different?	Yes — one compromise must not be fleet-wide
Has the source been characterised?	Min-entropy measured on real hardware, across temperature and voltage

How it shows up

Symptom	Cause
Two devices have the same key	Keys generated on device with no entropy
Keys share a prime factor	The same, during RSA generation
Boot hangs in `getrandom`	The pool is uninitialised — supply entropy, do not bypass it
Private key recovered from two signatures	A repeated ECDSA nonce
Ciphertexts reveal plaintext relationships	A repeated nonce in a stream cipher or CTR mode
GCM forgeries accepted	Nonce reuse — the authentication key is recoverable
Random values repeat after a VM clone	Duplicated CSPRNG state — reseed after cloning
Keys recoverable from a core dump	Not wiped, or wiped with `memset`
RNG passes dieharder but keys are guessable	Uniform but predictable — the tests cannot see it
Entropy quality varies with temperature	The source was characterised at one operating point

Check yourself

- ✓ Distinguish PRNG, CSPRNG and TRNG, and say what each is for.
- ✓ Draw the standard seed-and-expand architecture and explain why the TRNG only seeds.
- ✓ Describe two real failures and identify the common cause.
- ✓ List the conditions that make first-boot key generation predictable.
- ✓ State the provisioning rule and why later reseeding does not fix it.
- ✓ Name five entropy sources on a microcontroller and their weaknesses.
- ✓ Explain fast key erasure and what it protects.
- ✓ State the different requirements for a CBC IV and a GCM nonce.
- ✓ Explain why `memset` does not wipe a key.
- ✓ Say what statistical tests can and cannot detect.
- ✓ Explain min-entropy and why it is the conservative measure.
- ✓ Work the embedded checklist against a product you know.

The one-time pad and perfect secrecy

The only cipher that is provably unbreakable, why it is almost never usable, and what happens when the "one-time" part is violated. Understanding this fixes the intuition for every stream cipher that follows.

The construction

```
KEY: a truly random sequence, AS LONG AS THE MESSAGE,
     used exactly ONCE, known only to both parties.

ENCRYPT:  c = p XOR k
DECRYPT:  p = c XOR k

because  (p XOR k) XOR k = p

plaintext   0 1 1 0  1 0 0 1
key         1 1 0 1  0 1 1 0
ciphertext  1 0 1 1  1 1 1 1

THE CLAIM, proved by Shannon in 1949:

  For any ciphertext c and any candidate plaintext p' of
  the same length, there EXISTS a key k' = c XOR p' that
  produces it.

  Since every key is equally likely, every plaintext of
  that length is EQUALLY LIKELY given the ciphertext.

  The ciphertext therefore conveys ZERO information about
  the plaintext beyond its length.

PERFECT SECRECY: P(plaintext | ciphertext)
               = P(plaintext)

This holds against an adversary with UNLIMITED
computation — no future computer, no quantum algorithm,
no mathematical advance changes it. It is the only cipher
with that property.

AND THE COST OF IT: Shannon also proved that perfect
secrecy REQUIRES a key at least as long as the message.
That is not an artefact of this construction; it is a
lower bound. Which is why every practical cipher settles
for COMPUTATIONAL security instead.
```

Why it is unusable

```
/* THE FOUR REQUIREMENTS, and each one is a practical
   problem: */

   1. THE KEY MUST BE AS LONG AS THE MESSAGE.
      To send a gigabyte you need a gigabyte of key. But you
      must already have shared that key securely - and if you
      have a secure channel for a gigabyte of key, you could
      have sent the message on it.

   2. THE KEY MUST BE TRULY RANDOM.
      Not a PRNG (chapter 02). Real physical entropy, in the
      quantity above. Generating and storing that is itself a
      significant engineering problem.

   3. THE KEY MUST BE USED EXACTLY ONCE.
      See below - reuse is catastrophic, not merely
      weakening.

   4. THE KEY MUST BE DESTROYED AFTER USE.
      A stored key is a stored plaintext.

/* AND WHAT IT DOES NOT PROVIDE, which is the point people
   miss:

     NO INTEGRITY. XOR is linear (chapter 01), so flipping a
     ciphertext bit flips the plaintext bit. An attacker who
     knows the plaintext format can make arbitrary
     predictable changes without knowing the key at all.

     Perfect CONFIDENTIALITY, zero AUTHENTICITY. A one-time
     pad still needs a MAC.

/* WHERE IT IS ACTUALLY USED:
     · diplomatic and intelligence traffic, historically -
       the Moscow-Washington hotline used them
     · numbers stations broadcasting to agents with printed
       pads
     · quantum key distribution, where the physics provides
       the key material
   In every case the key distribution problem was solved by
   physical means - couriers, printed booklets, a fibre - and
   the volume was tiny.                                  */
```

> **THE LESSON THAT GENERALISES**
>
> Every stream cipher — RC4, ChaCha20, AES-CTR — is a one-time pad in which the long random key is replaced by a keystream generated from a short key. That substitution is what makes it practical, and it means every one of them inherits the one-time pad's properties: **keystream reuse is catastrophic**, and **there is no integrity**. Both facts follow directly from this chapter, and both are responsible for real breaks (chapter 06).

The two-time pad

```
/* Use the same key twice and perfect secrecy collapses
   completely. */

        c1 = p1 XOR k
        c2 = p2 XOR k

        c1 XOR c2 = (p1 XOR k) XOR (p2 XOR k)
                  = p1 XOR p2          /* THE KEY CANCELS */

/* The attacker now has the XOR of two plaintexts, with no
   key involved. That is enough:

     · if either plaintext is known, the other falls out
       immediately
     · if both are English text, CRIB DRAGGING recovers them:
       guess a common word at some offset, XOR it in, and see
       whether the result at that offset in the other message
       is plausible text. Iterate.
     · with several messages under the same keystream, it is
       nearly trivial - the statistical structure of natural
       language does the work
     · with structured data - a protocol with fixed headers -
       it is immediate

/* THE HISTORICAL CASE: the VENONA project. Soviet one-time
   pads were duplicated during wartime production pressure.
   US cryptanalysts exploited the reuse to read thousands of
   messages over four decades. The cipher was perfect; the
   procedure was not.

/* AND THE MODERN CASES, all the same mathematics:
     · WEP reused IVs after 2^24 packets, and often much
       sooner
     · MS-PPTP reused the RC4 keystream in both directions
     · TLS implementations that reused a GCM nonce
     · a device with a fixed IV compiled into the firmware -
       common in IoT

/* SO THE RULE, which applies to every stream cipher and
   every counter mode:

     NEVER REUSE A KEY-AND-NONCE PAIR. The nonce need not be
     secret or random, but it must be UNIQUE for the lifetime
     of the key (chapter 02).                              */
```

Computational security

```
/* Since perfect secrecy demands an impractical key, every
   real cipher settles for something weaker but sufficient. */

   PERFECT SECRECY
     an adversary with UNLIMITED computation learns nothing.
     Requires |key| >= |message|.

   COMPUTATIONAL SECURITY
     an adversary with BOUNDED computation - say 2^128
     operations - learns nothing useful.
     Allows a short key and an arbitrarily long message.

/* THE TRADE IS OVERWHELMINGLY WORTH IT: 2^128 operations is
   not merely impractical but physically impossible
   (chapter 01), and a 256-bit key encrypts a terabyte.

/* WHAT COMPUTATIONAL SECURITY RESTS ON:
     · that certain problems are hard - factoring, discrete
       log, or that AES behaves like a random permutation
     · NONE of these are PROVEN hard. They are believed hard
       because they have resisted concerted attack for
       decades.
     · P versus NP is unresolved; if P = NP, most of
       cryptography fails.

/* SO THE HONEST STATEMENT: modern cryptography is secure
   because nobody has found a way to break it, not because
   nobody can. That is a weaker claim than the one-time pad's
   and it is the best available for anything practical.

/* THE SEMANTIC SECURITY DEFINITION, which is the modern
   formalisation:

     An adversary chooses two plaintexts of equal length. One
     is encrypted at random. The adversary cannot do better
     than guessing which.

   This is IND-CPA (chapter 01), and it has a direct
   consequence: encryption MUST BE RANDOMISED. A
   deterministic cipher fails immediately, because the
   adversary encrypts one candidate themselves and compares.
   That is why every mode needs an IV or nonce, and why ECB
   (chapter 05) is broken.                                  */
```

Related "perfect" properties

```
/* Two other properties use the word, and neither is perfect
   secrecy. */

/* --- FORWARD SECRECY (sometimes "perfect forward
       secrecy") --- */
/* Compromising a long-term key does NOT reveal past session
   traffic, because each session used an EPHEMERAL key that
   was discarded.

     RSA key transport      NO forward secrecy - recover the
                            server's private key and every
                            recorded session decrypts
     ECDHE                  YES - the ephemeral keys are
                            discarded after the handshake

   THIS IS WHY TLS 1.3 REMOVED static RSA key exchange
   entirely (chapter 17). "Harvest now, decrypt later" is a
   real adversary model, and forward secrecy is the defence.

/* --- POST-COMPROMISE SECURITY (self-healing) --- */
/* After a compromise ENDS, security is RESTORED - because
   the parties ratchet to new keys. The Signal protocol's
   double ratchet provides it; TLS does not.

/* NEITHER IS PERFECT SECRECY. Both are computational
   properties about WHICH keys are exposed by a compromise,
   not about an unbounded adversary.

/* AND THE RELATED CONSTRUCTION worth knowing - SECRET
   SHARING, which does achieve information-theoretic
   security: */
        split a secret s into n shares
        any k shares reconstruct s
        any k-1 shares reveal NOTHING - information-
        theoretically

/* Shamir's scheme: pick a random degree-(k-1) polynomial
   with s as the constant term; the shares are points on it.
   k points determine the polynomial; k-1 leave every
   constant term equally likely - the same argument as the
   one-time pad.

   USED FOR: splitting a root key across several HSMs or
   people, so no one person can use it. Genuinely practical,
   unlike the one-time pad, because the secret is small.  */
```

How it shows up

Symptom	Cause
Two ciphertexts XOR to readable text	Keystream reuse — the two-time pad
Known plaintext reveals another message	The same
A fixed IV in the firmware	Every message uses the same keystream
Ciphertext modified undetectably	No integrity — XOR is linear (ch. 01)
Same plaintext gives same ciphertext	Deterministic encryption — fails IND-CPA

Symptom	Cause
Recorded traffic decrypted after a key leak	No forward secrecy — static key exchange
"We use a one-time pad" in a product	Almost certainly a stream cipher with a reused key
Nonce counter resets after a reflash	Reuse across the reset — rotate the key instead

Check yourself

- ✓ State the one-time pad construction and Shannon's perfect secrecy result.
- ✓ Explain why perfect secrecy requires a key as long as the message.
- ✓ List the four requirements and why each is impractical.
- ✓ Explain why the one-time pad provides no integrity.
- ✓ Derive the two-time pad attack and explain crib dragging.
- ✓ Name three modern systems broken by keystream reuse.
- ✓ State the nonce rule that follows, in the form that applies to AES-GCM.
- ✓ Contrast perfect with computational security and say what the latter rests on.
- ✓ Explain why semantic security requires randomised encryption.
- ✓ Distinguish forward secrecy and post-compromise security from perfect secrecy.
- ✓ Explain Shamir secret sharing and why it *is* information-theoretically secure.

Block ciphers and AES

A keyed permutation on fixed-size blocks — the workhorse primitive of symmetric cryptography. This chapter is how AES works, why its structure resists the known attacks, and what a hardware or software implementation actually costs.

What a block cipher is

```
E : {0,1}^k × {0,1}^n -> {0,1}^n

For each key K, E_K is a PERMUTATION of the n-bit blocks -
a bijection, so decryption exists and is unique.

THE SECURITY GOAL: E_K should be indistinguishable from a
RANDOM PERMUTATION chosen uniformly from all 2^n!
permutations, to an adversary who does not know K.

That is a strong requirement, and it is what the design
effort goes into. A block cipher is not "scrambling"; it
is an attempt to build something that behaves like a
randomly chosen lookup table of size 2^128, using a few
kilobytes of logic.

THE PARAMETERS THAT MATTER:

  BLOCK SIZE n     AES: 128 bits.
                   Too small is dangerous: with a 64-bit
                   block, a birthday collision appears
                   after ~2^32 blocks (32 GB), which is
                   the SWEET32 attack that killed 3DES
                   and Blowfish in TLS.
  KEY SIZE k       AES: 128, 192 or 256.

AND THE CRITICAL POINT: a block cipher encrypts ONE BLOCK.
Encrypting a message requires a MODE OF OPERATION
(chapter 05), and the mode is where most of the security
properties - and most of the mistakes - live.
```

Design principles

```
/* Shannon, 1949, and still the framework: */

   CONFUSION   the relationship between key and ciphertext
               must be complex.
               -> achieved by SUBSTITUTION (S-boxes),
                  which are non-linear.

   DIFFUSION   changing one plaintext bit must change about
               half the ciphertext bits.
               -> achieved by PERMUTATION and MIXING, which
                  spread local changes globally.

   A cipher applies both, alternately, for many ROUNDS. Each
   round is weak; the composition is not.

/* THE AVALANCHE CRITERION: flip one input bit, and each
   output bit should flip with probability 1/2. AES achieves
   full avalanche after two rounds - and then does eight more.

/* THE TWO STRUCTURES:

   SUBSTITUTION-PERMUTATION NETWORK (SPN) - AES
       every round transforms the WHOLE block:
           substitute -> permute -> mix -> add key
       decryption needs the INVERSE of each step.

   FEISTEL NETWORK - DES, Blowfish, Camellia
       split the block in half:
           L' = R
           R' = L XOR F(R, K)
       decryption is the SAME circuit with the round keys
       reversed - so F need not be invertible, which was
       valuable when gates were expensive.

/* THE ROUND COUNT is chosen with a SECURITY MARGIN: the best
   known attacks reach some number of rounds, and the cipher
   uses substantially more. AES-128 uses 10 rounds; the best
   published attack on reduced-round AES reaches 7. That
   margin is the design's insurance against future
   cryptanalysis.                                          */
```

AES

```
The state is a 4x4 matrix of BYTES - 128 bits - filled
COLUMN-WISE:

     b0  b4  b8  b12
     b1  b5  b9  b13
     b2  b6  b10 b14
     b3  b7  b11 b15

ROUNDS: 10 for AES-128, 12 for AES-192, 14 for AES-256.

ENCRYPTION:
     AddRoundKey(state, K0)
     for r = 1 .. Nr-1:
             SubBytes(state)
             ShiftRows(state)
             MixColumns(state)
             AddRoundKey(state, Kr)
     // the final round OMITS MixColumns
     SubBytes(state)
     ShiftRows(state)
     AddRoundKey(state, KNr)

THE FOUR OPERATIONS:

SubBytes     each byte replaced via a fixed 256-entry
             S-BOX. THE ONLY NON-LINEAR STEP, and
             therefore the whole source of confusion.
             Constructed as the multiplicative inverse in
             GF(2^8) followed by an affine map - chosen for
             provably good resistance to differential and
             linear cryptanalysis, not by trial and error.

ShiftRows    row 0 unchanged, row 1 left by 1, row 2 by 2,
             row 3 by 3. Spreads bytes ACROSS columns.

MixColumns   each column multiplied by a fixed matrix in
             GF(2^8). Every output byte of a column depends
             on all four inputs. Spreads WITHIN columns.
             ShiftRows and MixColumns together give full
             diffusion in two rounds.

AddRoundKey  XOR the round key. The only step involving
             the key.

THE KEY SCHEDULE expands the key into Nr+1 round keys,
using the S-box, a byte rotation and round constants -
deliberately non-linear so that recovering one round key
does not immediately give the others.

DECRYPTION uses InvSubBytes, InvShiftRows, InvMixColumns
with the round keys reversed - or, in the "equivalent
inverse cipher" form, the same structure with modified
keys, which is what implementations use.
```

WHY AES IS THE ANSWER

Selected in 2001 after a five-year open competition with fifteen candidates and worldwide public cryptanalysis. Twenty-five years later, the best attack on full AES-128 is a biclique attack costing about 2^{126} operations — a factor of four better than brute force, and entirely academic. Meanwhile every general-purpose CPU and most microcontrollers have hardware instructions for it. There is no reason to use anything else for block encryption, and choosing something else needs a specific justification.

Implementing it

```
/* --- 1. HARDWARE INSTRUCTIONS: always, if available --- */

    /* ARMv8 Cryptography Extension */
        aese  v0.16b, v1.16b        /* SubBytes + ShiftRows
                                       + AddRoundKey */
        aesmc v0.16b, v0.16b        /* MixColumns */
    /* two instructions per round; a full AES-128 block in
       about 10 cycles, and ~1 cycle/byte with pipelining
       across blocks.

    /* x86: AES-NI - aesenc, aesenclast, aeskeygenassist

    /* DETECT IT: */
        getauxval(AT_HWCAP) & HWCAP_AES         /* Linux ARM */
        __builtin_cpu_supports("aes")           /* x86 */
        ID_AA64ISAR0_EL1.AES                    /* bare metal */

/* HARDWARE AES IS ALSO CONSTANT TIME by construction - no
   table lookups, so no cache-timing side channel
   (chapter 19). That is at least as important as the speed.

/* --- 2. THE T-TABLE IMPLEMENTATION: fast, and UNSAFE --- */
    /* Precompute four 1 KB tables merging SubBytes,
       ShiftRows and MixColumns. One round becomes 16 table
       lookups and 16 XORs - very fast in software.       */
        s0 = T0[b0] ^ T1[b5] ^ T2[b10] ^ T3[b15] ^ rk[0];

/* AND IT LEAKS THE KEY. The table indices depend on the key,
   so an attacker sharing the cache observes which lines were
   touched and recovers the key - demonstrated repeatedly,
   including across VMs and from JavaScript. NEVER USE
   T-TABLES for anything an attacker can co-locate with.

/* --- 3. BITSLICED: constant time in software --- */
    /* Represent the state across registers so that one
       "bit" of each of N blocks lives in one register bit,
       and compute the S-box as a Boolean circuit - no
       lookups at all. Constant time by construction,
       and fast when processing several blocks in parallel
       (which CTR and GCM modes do).

    /* This is what a good software AES uses when the
       hardware instructions are absent: BearSSL's
       aes_ct64, or the RustCrypto soft backend.

/* --- 4. THE NAIVE S-BOX TABLE: small, and still leaky --- */
        state[i] = sbox[state[i]];
/* A single 256-byte table is four cache lines - fewer to
   distinguish, but still key-dependent. Acceptable ONLY on a
   microcontroller with no cache and no co-located attacker,
   and that assumption should be written down.

/* --- USING A LIBRARY, which is the actual advice --- */
    #include <mbedtls/aes.h>

    mbedtls_aes_context ctx;
    mbedtls_aes_init(&ctx);
    mbedtls_aes_setkey_enc(&ctx, key, 256);
    mbedtls_aes_crypt_ecb(&ctx, MBEDTLS_AES_ENCRYPT, in, out);
    mbedtls_aes_free(&ctx);
```

```
/* And note that raw ECB is exposed only because modes are
   built on it - you should be calling the AEAD interface
   (chapter 09), not this.                                */
```

The cryptanalysis

```
/* Understanding what these attacks look for explains why AES
   is shaped as it is. */

   DIFFERENTIAL CRYPTANALYSIS
     Track how a chosen INPUT DIFFERENCE propagates to an
     output difference. If some difference pair occurs with
     probability much higher than 2^-n, that bias reveals key
     bits.
     -> AES's S-box has a maximum differential probability of
        2^-6, which is the best achievable for an 8-bit
        S-box, and the wide-trail design bounds how few
        S-boxes an attack can involve.

   LINEAR CRYPTANALYSIS
     Find a linear approximation relating plaintext,
     ciphertext and key bits that holds slightly more often
     than half the time.
     -> AES's S-box has maximum linear bias 2^-3, again
        optimal.

   RELATED-KEY ATTACKS
     Exploit relationships between keys. AES-256's key
     schedule is weaker here than AES-128's - there is a
     related-key attack on full AES-256 at 2^99. It requires
     the attacker to obtain encryptions under keys with a
     chosen relationship, which a sane protocol never
     provides, so it is not a practical concern - but it is
     why "AES-256 is stronger than AES-128" is not
     unqualifiedly true.

   BICLIQUE ATTACK (2011)
     The best known attack on FULL AES: 2^126.1 for AES-128.
     A factor of four better than exhaustive search, and
     entirely theoretical.

   THE PRACTICAL BREAKS ARE ALL IMPLEMENTATION:
     cache timing on T-tables
     power analysis (DPA) on unprotected hardware
     fault injection (isolation chapter 16)
     nonce and IV misuse (chapter 05)
     key management failures (chapter 18)

/* WHICH IS THE THEME OF THIS WHOLE TRACK: the mathematics
   holds; the engineering is where things break.         */
```

The other block ciphers

Cipher	Block / Key	Status
AES	128 / 128-256	**The default.** Hardware everywhere
DES	64 / 56	**Broken** — 56-bit key, brute-forced since 1998
3DES	64 / 112	Deprecated — 64-bit block, SWEET32

Cipher	Block / Key	Status
Blowfish	64 / 32-448	Legacy — 64-bit block. `bcrypt` uses its key schedule
Twofish, Serpent	128 / 128-256	AES finalists, sound, unaccelerated
Camellia	128 / 128-256	Sound; standardised in Japan and in TLS
ARIA, SM4	128 / 128	National standards (Korea, China)
PRESENT, GIFT	64 / 80-128	Lightweight — tiny hardware, 64-bit block
ASCON	—	**NIST lightweight standard (2023)** — a permutation-based AEAD, not a block cipher
SPECK, SIMON	various	NSA-designed; rejected by ISO amid distrust

```
/* THE PRACTICAL SELECTION:

   Have AES hardware?                  -> AES-GCM
   No AES hardware, software only?     -> ChaCha20-Poly1305
                                          (chapter 06) - it
                                          is faster than
                                          software AES and
                                          constant time by
                                          design
   Extremely constrained hardware?     -> ASCON, the NIST
                                          lightweight
                                          standard
   Regulatory requirement for a
   national standard?                  -> whatever it
                                          mandates

   AND NEVER: DES, 3DES, RC4, or anything a vendor invented.
   The 64-bit block ciphers are excluded not because the
   ciphers are broken but because 64 bits is too small
   (SWEET32) - a reminder that block size is a security
   parameter, not just a performance one.                */
```

How it shows up

Symptom	Cause
Identical plaintext blocks give identical ciphertext	ECB mode — the cipher is working, the mode is wrong (ch. 05)
Key recovered by a co-located process	T-table cache timing — use hardware AES or bitsliced
Key recovered with an oscilloscope	Power analysis (ch. 19)
Collisions after ~32 GB	A 64-bit block cipher — SWEET32
AES much slower than expected	Hardware instructions not detected or not used
Encryption works, decryption gives garbage	Key schedule direction, or endianness of the block
Interoperability failure with another implementation	Byte order — AES fills the state column-wise from a byte string
"We use military-grade AES-256"	Says nothing about the mode, the nonce handling, or the key management

Check yourself

- ✓ Define a block cipher and state its security goal.
- ✓ Explain why block size is a security parameter and what SWEET32 exploits.
- ✓ Explain confusion and diffusion and which AES step provides each.

- ✓ Contrast an SPN with a Feistel network and say why Feistel was historically attractive.
- ✓ Name AES's four round operations and what each does.
- ✓ Say why the final round omits MixColumns.
- ✓ Explain what a security margin is and give AES's.
- ✓ Give four AES implementation strategies and their side-channel properties.
- ✓ Explain why T-tables leak and what to use instead.
- ✓ Describe differential and linear cryptanalysis and how AES resists them.
- ✓ Choose a cipher for four different constraints, and name what never to use.

Modes of operation

A block cipher encrypts 16 bytes. A mode turns it into something that encrypts a message — and the choice of mode determines almost every security property that matters. This is where most real encryption failures live.

ECB — never

```
ELECTRONIC CODEBOOK: encrypt each block independently.

     C_i = E_K(P_i)

THE FAILURE IS IMMEDIATE: identical plaintext blocks give
identical ciphertext blocks. The ciphertext preserves the
structure of the plaintext.

THE CANONICAL DEMONSTRATION is the "ECB penguin" - a
bitmap encrypted with ECB in which the image is still
plainly visible, because regions of uniform colour become
regions of uniform ciphertext.

WHAT THIS LEAKS IN PRACTICE:
  · repeated records in a database
  · structure in a protocol with fixed fields
  · whether two encrypted values are equal - which is
    enough to break a great many things
  · block boundaries and message structure

AND IT FAILS IND-CPA (chapter 03): encryption is
deterministic, so an adversary distinguishes two chosen
plaintexts trivially.

ECB IS ALSO MALLEABLE: an attacker can reorder, duplicate
or delete whole blocks, and the result decrypts.

THE ONLY LEGITIMATE USE: encrypting a single block of
random data - a key being wrapped, for instance - and even
there, use a proper key-wrap construction (RFC 3394)
instead.

IF YOU SEE ECB IN A CODEBASE, it is a finding.
```

CBC

```
/* CIPHER BLOCK CHAINING: XOR each plaintext block with the
   previous ciphertext block before encrypting.           */

        C_0 = E_K(P_0 XOR IV)
        C_i = E_K(P_i XOR C_{i-1})

        P_0 = D_K(C_0) XOR IV
        P_i = D_K(C_i) XOR C_{i-1}

/* PROPERTIES:
     + identical plaintext gives different ciphertext,
       provided the IV differs
     + a ciphertext error affects only two plaintext blocks
     - ENCRYPTION IS SEQUENTIAL - no parallelism
     + decryption IS parallelisable
     - requires PADDING to a block multiple
     - NO AUTHENTICATION

/* THE IV REQUIREMENT: it must be UNPREDICTABLE, not merely
   unique. A predictable IV enables a chosen-plaintext attack
   in which the adversary confirms a guessed plaintext block
   - which is exactly the BEAST attack on TLS 1.0, where the
   IV for each record was the previous record's last
   ciphertext block.

   SO: generate the IV with a CSPRNG (chapter 02), and
   transmit it in the clear alongside the ciphertext.

/* PADDING - PKCS#7, and it is where CBC goes wrong: */
        add N bytes each of value N, where 1 <= N <= 16
        a full block gets a WHOLE EXTRA BLOCK of padding

        "HELLO" -> 48 45 4C 4C 4F 0B 0B 0B 0B 0B 0B 0B 0B 0B 0B 0B

/* THE PADDING ORACLE (chapter 01): if the receiver
   distinguishes "bad padding" from "bad MAC" - through an
   error code, a response, or a TIMING DIFFERENCE - the
   attacker decrypts the whole message with about 128
   queries per byte. This broke TLS (Lucky 13), ASP.NET,
   Ruby on Rails, XML encryption and countless devices.

   THE FIX IS NOT constant-time padding checks - people
   tried, and Lucky 13 defeated them through timing anyway.
   THE FIX IS AEAD (chapter 09).

/* IF YOU MUST USE CBC: encrypt-then-MAC, with the MAC
   covering the IV and the ciphertext, and verify the MAC
   BEFORE attempting to decrypt or unpad. Then a forged
   message never reaches the padding check at all.       */
```

> **ENCRYPT-THEN-MAC, AND ONLY THAT ORDER**
>
> **Encrypt-then-MAC** — MAC over the ciphertext and IV. Provably secure, and a forgery is rejected before any decryption happens. **MAC-then-encrypt** (what TLS 1.0–1.2 did) requires decrypting before you can check, which is exactly what enables padding oracles. **Encrypt-and-MAC** (SSH) can leak plaintext information through the MAC. Use an AEAD and the question does not arise.

CTR

```
/* COUNTER MODE: turn the block cipher into a stream cipher
   by encrypting a counter and XORing the result.         */

        C_i = P_i XOR E_K(nonce ‖ counter_i)

/* PROPERTIES:
     + FULLY PARALLELISABLE, both directions
     + RANDOM ACCESS - decrypt block 1000 without the
       preceding blocks. Essential for disk and flash
       encryption.
     + NO PADDING - the keystream is truncated to the message
       length
     + only the ENCRYPT direction of the cipher is needed,
       which halves the code and table size on a
       microcontroller
     - NO AUTHENTICATION
     - CATASTROPHIC on nonce reuse

/* THE COUNTER BLOCK, typically:
        [ 96-bit nonce ][ 32-bit counter ]
   giving 2^32 blocks = 64 GB per nonce, which is the limit
   before the counter wraps into the next nonce's space.

/* THE NONCE REQUIREMENT: UNIQUE, not secret and not random.
   A counter is the correct choice, and better than random -
   because random nonces collide by the birthday bound
   (2^48 messages for a 96-bit nonce is uncomfortably close
   for a long-lived key), while a counter cannot collide
   until it wraps.

/* NONCE REUSE IS THE TWO-TIME PAD (chapter 03):
        C1 XOR C2 = P1 XOR P2
   and the key cancels. Everything in chapter 03 applies.

/* AND CTR IS MALLEABLE, exactly like any stream cipher: flip
   a ciphertext bit, flip the plaintext bit. Which is why CTR
   alone is never correct, and why GCM = CTR + a MAC
   (chapter 09).                                          */
```

The rest

Mode	Parallel	Padding	Auth	Use
ECB	Yes	Yes	No	**Never**
CBC	Dec only	Yes	No	Legacy; only with encrypt-then-MAC
CTR	Yes	No	No	The basis of GCM; alone only inside a construction
CFB	Dec only	No	No	Legacy
OFB	No	No	No	Legacy
GCM	Yes	No	**Yes**	**The default** with AES hardware
CCM	Partly	No	**Yes**	Constrained devices; only needs encryption
OCB	Yes	No	Yes	Fast, formerly patent-encumbered
SIV / GCM-SIV	Yes	No	**Yes**	**Nonce-misuse resistant** — use where nonce uniqueness is not guaranteed
XTS	Yes	No	No	**Disk encryption** — the specific case below

Mode	Parallel	Padding	Auth	Use
KW / KWP	No	—	Yes	Key wrapping (RFC 3394)

```
/* --- XTS, and why disk encryption is different --- */
/* A disk sector must encrypt to exactly one sector - there
   is no room for an IV, a nonce or a tag. So XTS uses the
   SECTOR NUMBER as a tweak:                              */

        T = E_K2(sector) * α^j          /* in GF(2^128) */
        C_j = E_K1(P_j XOR T) XOR T

/* PROPERTIES: length-preserving, random access, and identical
   plaintext in DIFFERENT sectors encrypts differently.

   WHAT IT DOES NOT PROVIDE, and this is important:
     · NO AUTHENTICATION. An attacker with write access can
       modify sectors; the result decrypts to garbage, but
       predictable garbage in some cases.
     · NO FRESHNESS. An old sector can be replayed - the
       "watermarking" and rollback attacks on full-disk
       encryption.
     · identical plaintext in the SAME sector at different
       times gives identical ciphertext, so an observer sees
       when a sector did not change.

   XTS IS THE RIGHT ANSWER FOR DISKS anyway, because the
   alternatives require storing a tag per sector - which
   dm-integrity does, at a real cost. Know what you are not
   getting.

/* --- SIV and AES-GCM-SIV: nonce misuse resistance --- */
/* The tag is computed FIRST, over the plaintext, and used as
   the nonce for the encryption. So a repeated nonce with
   different plaintexts still produces different ciphertexts;
   the only leak is that identical (nonce, plaintext) pairs
   are visible as identical ciphertexts.

   USE IT when you cannot guarantee nonce uniqueness - a
   device that may be restored from backup, a stateless
   protocol, a system where the counter might reset
   (chapter 02). The cost is two passes over the plaintext,
   so it cannot stream.                                   */
```

Choosing

```
Do you need encryption?
     |
     +-- with authentication (you do)
     |     |
     |     +-- can you guarantee unique nonces?
     |     |     |
     |     |     +-- YES, and you have AES hardware
     |     |     |      -> AES-GCM
     |     |     +-- YES, no AES hardware
     |     |     |      -> ChaCha20-Poly1305
     |     |     +-- YES, very constrained device
     |     |     |      -> AES-CCM, or ASCON
     |     |     +-- NO / not sure
     |     |            -> AES-GCM-SIV
     |     |
     |     +-- and the API you should call is the AEAD
     |         one, not a mode plus a MAC you compose
     |         yourself (chapter 09)
     |
     +-- length-preserving, random access (a disk)
     |     -> AES-XTS, and understand what it omits
     |
     +-- wrapping a key
           -> AES-KW / KWP

WHAT NEVER TO CHOOSE:
  ECB, for anything
  CBC or CTR without a MAC
  a mode you assembled from primitives yourself
  a mode because it was in the example code you copied
```

Getting it right

```
/* --- THE MESSAGE FORMAT --- */
    [ nonce/IV ][ ciphertext ][ tag ]
/* The nonce is NOT secret and must be transmitted. The tag
   is typically 16 bytes. Put them in a fixed layout, and
   include the format version so it can change later.

/* --- NONCE MANAGEMENT, which is where products fail --- */
    /* GOOD: a persistent counter */
    struct Nonce { uint32_t device_id; uint64_t counter; };
    /* 96 bits total, unique per device, monotonic */

    /* AND WHAT HAPPENS WHEN IT COULD RESET:
         a device reflashed, a config restored, a clone
       -> ROTATE THE KEY. Do not hope. A repeated
          (key, nonce) pair with GCM does not merely leak the
          plaintexts - it leaks the AUTHENTICATION KEY, and
          the attacker can then forge arbitrary messages.  */

    /* ACCEPTABLE: random 96-bit nonces, if the number of
       messages per key stays well below 2^32 - the birthday
       bound gives a collision probability of about 2^-33 at
       that point.

    /* NEVER: a fixed nonce, a nonce derived from the
       plaintext, or a nonce that restarts at zero.

/* --- KEY AND MESSAGE LIMITS --- */
    AES-GCM     max 2^32 - 2 blocks (64 GB) per (key, nonce)
                and rekey well before 2^32 messages
    ChaCha20    2^32 blocks (256 GB) per nonce
    AES-XTS     one key per volume, sector number as tweak

/* --- USING A LIBRARY: the whole point --- */
    /* libsodium - the API to prefer */
    unsigned char nonce[crypto_aead_xchacha20poly1305_ietf_NPUBBYTES];
    randombytes_buf(nonce, sizeof nonce);
    crypto_aead_xchacha20poly1305_ietf_encrypt(
        ct, &ct_len, pt, pt_len,
        ad, ad_len, NULL, nonce, key);

/* XChaCha20 uses a 192-BIT nonce, which is large enough that
   random nonces are safe indefinitely - removing the entire
   nonce-management problem. Where it is available, it is the
   easiest correct choice.

    /* mbedTLS, on embedded */
    mbedtls_gcm_crypt_and_tag(&ctx, MBEDTLS_GCM_ENCRYPT,
                              len, iv, 12, ad, ad_len,
                              input, output, 16, tag);

/* AND ON DECRYPT, CHECK THE TAG FIRST AND IN CONSTANT TIME:
   */
    if (mbedtls_gcm_auth_decrypt(...) != 0) {
            /* DISCARD EVERYTHING. Do not use the plaintext,
               do not report which part failed, do not log
               the ciphertext. */
            return ERROR;
    }
```

How it shows up

Symptom	Cause
Structure visible in the ciphertext	ECB
Identical messages encrypt identically	ECB, a fixed IV, or a repeated nonce
Plaintext recovered from error responses	A padding oracle in CBC
Plaintext recovered from response timing	Lucky 13 — the same problem, through timing
Attacker confirms guessed plaintext	Predictable CBC IV — BEAST
Two ciphertexts XOR to plaintext	Nonce reuse in CTR or GCM
Forged messages accepted	GCM nonce reuse leaked the authentication key
Ciphertext modified undetectably	No authentication — the mode is unauthenticated
Disk sectors replayed successfully	XTS provides no freshness — expected
Decryption fails after 64 GB	CTR counter wrapped into the next nonce
Interop failure on the tag	Different tag lengths, or the AAD is not identical on both sides

Check yourself

- ✓ Explain why ECB fails, in three distinct ways.
- ✓ Write out CBC encryption and decryption and say why the IV must be unpredictable.
- ✓ Explain PKCS#7 padding and the padding oracle attack.
- ✓ State the three MAC composition orders and why only one is correct.
- ✓ Explain CTR mode and why a counter beats a random nonce.
- ✓ Explain why GCM nonce reuse is worse than CTR nonce reuse.
- ✓ Say what XTS provides and the three things it does not.
- ✓ Explain nonce-misuse resistance and when to use SIV.
- ✓ Choose a mode for five situations using the decision tree.
- ✓ Design a message format and a nonce scheme for a device that may be reflashed.
- ✓ State the message limits for AES-GCM and ChaCha20.

Stream ciphers

A pseudorandom keystream XORed with the plaintext — the one-time pad made practical. Fast, simple, constant-time by construction, and unforgiving of nonce reuse. ChaCha20 is the one to use.

The model

```
key, nonce ---> KEYSTREAM GENERATOR ---> k0 k1 k2 k3 ...
                                          |
plaintext  p0 p1 p2 p3 ...  ---------- XOR |
                                          v
ciphertext c0 c1 c2 c3 ...

ENCRYPTION AND DECRYPTION ARE THE SAME OPERATION - one
implementation serves both, which halves the code on a
constrained device.

PROPERTIES INHERITED FROM THE ONE-TIME PAD (chapter 03):
  + no padding - encrypt any length
  + no block alignment
  + can start encrypting before the length is known
  + a bit error in transit corrupts exactly one bit
  - NONCE REUSE IS CATASTROPHIC: c1 XOR c2 = p1 XOR p2
  - NO INTEGRITY: flipping a ciphertext bit flips the
    plaintext bit

AND THE TWO FAMILIES:

  SYNCHRONOUS       the keystream depends only on the key
                    and nonce, not on the data. ChaCha20,
                    RC4, AES-CTR.
  SELF-SYNCHRONISING the keystream depends on previous
                    ciphertext. CFB mode. Recovers from
                    insertions and deletions, at the cost
                    of error propagation. Rarely used.

NOTE THAT CTR MODE (chapter 05) IS A STREAM CIPHER built
from a block cipher. The distinction between "stream
cipher" and "block cipher in a streaming mode" is about
construction, not about the properties you get.
```

ChaCha20

```
/* Daniel Bernstein, 2008. A refinement of Salsa20, and the
   modern default for software encryption.                */

/* THE STATE: 16 words of 32 bits = 512 bits, 4x4 */

        c c c c          c = constants "expand 32-byte k"
        k k k k          k = the 256-bit key
        k k k k
        b n n n          b = 32-bit block counter
                         n = 96-bit nonce

/* THE QUARTER-ROUND, the entire nonlinear core: */
    #define QR(a, b, c, d)                    \
        a += b;  d ^= a;  d = rotl32(d, 16);   \
        c += d;  b ^= c;  b = rotl32(b, 12);   \
        a += b;  d ^= a;  d = rotl32(d,  8);   \
        c += d;  b ^= c;  b = rotl32(b,  7);

/* ADD, ROTATE, XOR - an "ARX" cipher. No S-boxes, no tables,
   NO DATA-DEPENDENT MEMORY ACCESS, and no data-dependent
   branches. CONSTANT TIME BY CONSTRUCTION, on every
   platform, with no special effort (chapter 19).

/* THE BLOCK FUNCTION: 20 rounds, alternating column and
   diagonal quarter-rounds, then add the original state. */

    void chacha20_block(const uint32_t in[16], uint32_t out[16])
    {
        uint32_t x[16];
        memcpy(x, in, sizeof x);

        for (int i = 0; i < 10; i++) {      /* 10 double
                                               rounds = 20  */
            /* column rounds */
            QR(x[0], x[4], x[ 8], x[12]);
            QR(x[1], x[5], x[ 9], x[13]);
            QR(x[2], x[6], x[10], x[14]);
            QR(x[3], x[7], x[11], x[15]);
            /* diagonal rounds */
            QR(x[0], x[5], x[10], x[15]);
            QR(x[1], x[6], x[11], x[12]);
            QR(x[2], x[7], x[ 8], x[13]);
            QR(x[3], x[4], x[ 9], x[14]);
        }

        for (int i = 0; i < 16; i++)
            out[i] = x[i] + in[i];      /* the feed-forward
                                           makes it
                                           non-invertible  */
    }

/* THE FINAL ADDITION MATTERS: without it the block function
   would be an invertible permutation and an attacker could
   run it backwards. Adding the input makes it one-way.

/* WHY IT IS THE DEFAULT NOW:
     · 3-4x faster than software AES on a CPU without AES-NI
     · constant time with no effort - which software AES
       requires bitslicing to achieve (chapter 04)
     · a 20-round design with a large margin; the best attack
```

```
       reaches 7 rounds
     · small: a few hundred bytes of code, 64 bytes of state
     · vectorises well - SSE, AVX2 and NEON implementations
       process several blocks at once
     · no patents, a public-domain reference implementation

/* XCHACHA20: extends the nonce to 192 bits by hashing the
   key and the first 128 nonce bits through the same
   permutation (HChaCha20) to derive a subkey. A 192-bit
   nonce is large enough that RANDOM nonces never collide -
   removing the nonce management problem entirely
   (chapter 05). Prefer XChaCha20-Poly1305 wherever it is
   available.                                              */
```

CHACHA20 OR AES?

Hardware AES available (any modern Arm application core, any x86): AES-GCM is faster — around 1 cycle/byte versus 3-4. **No hardware AES** (most microcontrollers, older cores): ChaCha20-Poly1305 wins on speed, code size and side-channel resistance simultaneously. TLS 1.3 negotiates between exactly these two for exactly this reason, and mobile clients without AES acceleration end up on ChaCha20.

RC4 — the cautionary tale

```
/* Designed 1987, leaked 1994, ubiquitous for two decades,
   comprehensively broken. Worth understanding because every
   one of its failures illustrates a general principle. */

    /* the key schedule */
    for (i = 0; i < 256; i++) S[i] = i;
    for (i = j = 0; i < 256; i++) {
        j = (j + S[i] + key[i % keylen]) & 0xFF;
        swap(S[i], S[j]);
    }
    /* the keystream */
    i = j = 0;
    while (n--) {
        i = (i + 1) & 0xFF;
        j = (j + S[i]) & 0xFF;
        swap(S[i], S[j]);
        *out++ = S[(S[i] + S[j]) & 0xFF];
    }

/* Beautifully small - which is why it spread. And:

   1. THE SECOND OUTPUT BYTE is 0 with probability 2/256
      instead of 1/256. There are biases throughout the first
      few thousand bytes.
      -> the RC4 NOMORE and Bar-Mitzvah attacks recovered
         plaintext from TLS and WPA-TKIP.

   2. THE KEY SCHEDULE IS WEAK. Related keys - a per-message
      IV concatenated with a fixed key - leak the key.
      -> THIS IS WEP. Concatenating a 24-bit IV with the
         shared key produced related keys, and WEP was broken
         to the point of key recovery in minutes.

   3. IT USES A KEY-DEPENDENT LOOKUP TABLE, so software
      implementations have a cache-timing side channel
      (chapter 19).

   PROHIBITED in TLS since RFC 7465. Removed from every
   modern library.

/* THE GENERAL LESSONS:
     · a cipher can be "unbroken" for years and then fall to
       accumulated statistical work
     · KEY SCHEDULES MATTER as much as the round function
     · concatenating an IV with a key is not a nonce
       mechanism - use a construction designed for it
     · small and elegant is not the same as secure         */
```

The others

Cipher	Status
ChaCha20	**The default.** TLS 1.3, WireGuard, SSH, the Linux CSPRNG
Salsa20	ChaCha20's predecessor. Sound; ChaCha has better diffusion
AES-CTR	A block cipher in stream mode — fine, inside an AEAD
RC4	**Broken.** Prohibited

Cipher	Status
A5/1, A5/2	**Broken.** GSM; A5/2 deliberately weakened
E0	**Weak.** Bluetooth classic
Trivium, Grain	eSTREAM hardware profile — tiny, sound, niche
Rabbit, HC-128, SOSEMANUK	eSTREAM software profile — sound, little-used
ASCON	**NIST lightweight standard (2023).** A sponge-based AEAD for constrained devices
ZUC, SNOW 3G	3GPP standards for LTE/5G air-interface encryption

```
/* THE PATTERN IN THE BROKEN ONES: A5/1, A5/2, E0 and CSS
   were all designed in secret, for constrained hardware, by
   committees under export-control pressure, and published
   only after deployment. Every one fell quickly once
   examined (chapter 01's Kerckhoffs point).

   THE eSTREAM PORTFOLIO (2008) and the NIST LIGHTWEIGHT
   COMPETITION (2019–2023) were run the opposite way - open
   submission, years of public cryptanalysis - and their
   outputs have held.                                    */
```

Using one correctly

```
/* --- THE ONLY CORRECT WAY: use the AEAD, not the raw
       cipher --- */

    /* libsodium, and this is the recommendation */
    #include <sodium.h>

    unsigned char nonce[crypto_aead_xchacha20poly1305_ietf_NPUBBYTES];
    randombytes_buf(nonce, sizeof nonce);   /* 192 bits -
                                               random is safe */

    crypto_aead_xchacha20poly1305_ietf_encrypt(
            ciphertext, &ct_len,
            plaintext, pt_len,
            aad, aad_len,
            NULL, nonce, key);

    /* decryption FAILS CLOSED if the tag does not verify */
    if (crypto_aead_xchacha20poly1305_ietf_decrypt(
            decrypted, &pt_len, NULL,
            ciphertext, ct_len, aad, aad_len,
            nonce, key) != 0) {
            /* FORGED OR CORRUPTED - discard everything */
            return -1;
    }

/* --- THE RAW CIPHER, only inside a construction you are
       building deliberately --- */
    crypto_stream_chacha20_ietf_xor(out, in, len, nonce, key);
/* No authentication. If you call this directly you are
   responsible for the MAC, and you should probably not be.

/* --- THE NONCE RULES, restated because they are what
       fails --- */
    ChaCha20 (IETF)   96-bit nonce, 32-bit counter
                      -> 256 GB max per (key, nonce)
                      -> random nonces collide at ~2^32
                         messages: USE A COUNTER
    XChaCha20         192-bit nonce
                      -> RANDOM NONCES ARE SAFE, always.
                         This is why it is preferable.

/* --- SEEKING WITHIN A STREAM, which stream ciphers make
       easy --- */
    crypto_stream_chacha20_ietf_xor_ic(out, in, len,
                                       nonce, block_index,
                                       key);
/* Set the counter to the block containing your offset and
   decrypt from there. Useful for a firmware image being
   decrypted in chunks, or a file being seeked - and one of
   the genuine advantages over CBC.

/* --- ON A MICROCONTROLLER --- */
    /* Monocypher: ~2 KB of code for the whole AEAD */
    crypto_aead_lock(ciphertext, mac, key, nonce,
                     aad, aad_len, plaintext, pt_len);

    if (crypto_aead_unlock(plaintext, mac, key, nonce,
                           aad, aad_len, ciphertext, ct_len))
            return ERROR;       /* non-zero = FORGED */
```

```
/* Monocypher is public domain, single-file, constant time,
   and implements exactly the modern primitives - ChaCha20,
   Poly1305, BLAKE2b, X25519, EdDSA, Argon2. For a
   microcontroller with no crypto accelerator it is often the
   right answer over mbedTLS, because it is a tenth the
   size.                                                  */
```

How it shows up

Symptom	Cause
Two ciphertexts XOR to readable text	Nonce reuse — the two-time pad (ch. 03)
Attacker flips bits in the plaintext	No authentication — use the AEAD
Key recovered from many WEP frames	RC4's key schedule with a concatenated IV
Plaintext recovered from many TLS sessions	RC4 keystream biases
Nonce counter resets after a reflash	Reuse across the reset — rotate the key
Random 96-bit nonces on a long-lived key	Birthday collision at ~2^{32} messages — use a counter or XChaCha20
Decryption fails after 256 GB	The 32-bit block counter wrapped
Key recovered by a co-located process	A table-based cipher — ChaCha20 has no tables
Interop failure between implementations	Original ChaCha20 (64-bit nonce) versus IETF (96-bit)
Decrypted plaintext used before the tag check	Never do this — verify first, then release

Check yourself

- ✓ Draw the stream cipher model and list the properties inherited from the one-time pad.
- ✓ Explain why encryption and decryption are the same operation.
- ✓ Describe ChaCha20's state and the quarter-round.
- ✓ Explain why an ARX design is constant time without effort.
- ✓ Say why the final addition in the block function matters.
- ✓ Give four reasons ChaCha20 is preferred where AES hardware is absent.
- ✓ Explain what XChaCha20 changes and why it removes a whole class of bug.
- ✓ Give three distinct reasons RC4 is broken, and the general lesson from each.
- ✓ Explain what WEP did wrong with its IV.
- ✓ Use an AEAD correctly, including the fail-closed decryption path.
- ✓ State the nonce and message limits for IETF ChaCha20 and XChaCha20.

Hash functions

A fixed-size fingerprint of arbitrary data, with three security properties that are routinely confused. Hashes underpin signatures, MACs, key derivation, secure boot and blockchains — and the property you need determines which is safe to use.

The three properties

```
H : {0,1}* -> {0,1}^n

PREIMAGE RESISTANCE
  given h, infeasible to find m with H(m) = h
  "one-way"
  cost to break: 2^n

SECOND PREIMAGE RESISTANCE
  given m1, infeasible to find m2 != m1 with
  H(m2) = H(m1)
  cost to break: 2^n

COLLISION RESISTANCE
  infeasible to find ANY m1 != m2 with H(m1) = H(m2)
  cost to break: 2^(n/2)     <-- THE BIRTHDAY BOUND

THE FACTOR OF TWO IS THE POINT. For SHA-256:
  preimage      2^256   - unreachable
  collision     2^128   - unreachable
For SHA-1 (160 bits):
  preimage      2^160   - still unreachable
  collision     2^80    - REACHED IN 2017 (SHAttered)

WHICH IS WHY SHA-1 IS BROKEN FOR SIGNATURES AND
CERTIFICATES but not yet for HMAC: signatures need
collision resistance (a forger picks BOTH messages), while
HMAC's security rests on the key and needs only much
weaker properties. The distinction matters when you are
deciding whether a legacy system must be changed
immediately.

AND THE BIRTHDAY PARADOX, since it is the whole reason:
among 23 people two share a birthday with probability
> 1/2, because there are 253 PAIRS. Collisions come from
pairs, so n/2 bits of work suffices - and any protocol
whose security depends on collisions needs twice the
output length you might expect.
```

What hashes are for

```
/* --- LEGITIMATE --- */
    integrity checking       compare H(file) with a known
                             value
    digital signatures       sign H(m), not m (chapter 15)
    MACs                     HMAC (chapter 08)
    key derivation           HKDF (chapter 10)
    commitment schemes       publish H(x), reveal x later
    Merkle trees             efficient verification of a
                             large set
    deduplication            content-addressed storage
    proof of work            find m with H(m) < target
    secure boot              measure each stage before
                             executing it
                             (isolation chapter 14)

/* --- NOT LEGITIMATE, and each is a real mistake --- */

    PASSWORD STORAGE with a plain hash
        Hashes are FAST - billions per second on a GPU. That
        is the wrong property here. Use Argon2id
        (chapter 10).

    A MAC AS H(key ‖ message)
        LENGTH EXTENSION (below) lets an attacker append data
        and produce a valid tag WITHOUT the key. Use HMAC.

    ENCRYPTION
        A hash is not reversible. "Hashing" data does not
        protect it if the input space is small - an attacker
        enumerates. H(email) is not anonymisation; H(phone
        number) is trivially reversible.

    RANDOM NUMBER GENERATION from a low-entropy input
        H(timestamp) has as much entropy as the timestamp
        (chapter 02).

    COMPARING SECRETS with memcmp
        Early-exit comparison leaks how many bytes matched
        (chapter 19). Use a constant-time compare.        */
```

How they are built

```
MERKLE-DAMGARD - MD5, SHA-1, SHA-2

  message -> pad -> split into blocks
  IV -> [f] -> [f] -> [f] -> ... -> output
         ^       ^       ^
         m0      m1      m2

  A compression function f applied iteratively to a
  chaining value. If f is collision resistant, so is the
  whole hash - which is the construction's theorem and the
  reason it was used.

  AND ITS FLAW: the output IS the final chaining value.
  So an attacker who knows H(m) can CONTINUE HASHING from
  that state:

     H(m ‖ padding ‖ extra)

  computed without knowing m - only its length. That is
  LENGTH EXTENSION, and it is why H(key ‖ message) is not
  a MAC.

SPONGE - SHA-3, ASCON, BLAKE3's tree mode

  a large state, split into RATE and CAPACITY:

    ABSORB:  XOR message blocks into the rate, permute
    SQUEEZE: read output from the rate, permute

    state  [ rate | capacity ]
              ^        ^
           message   never touched directly by
           goes in   the message or the output

  THE CAPACITY IS NEVER EXPOSED, so length extension is
  impossible. Output can be ANY LENGTH - which gives
  SHAKE128/256, the extendable-output functions used by
  the post-quantum schemes (chapter 20).

AND THE PRACTICAL CONSEQUENCE: SHA-3, BLAKE2 and BLAKE3
are all immune to length extension by construction, and
SHA-512/256 is immune because it truncates. SHA-256 is
not.
```

Which to use

Hash	Output	Status
MD5	128	**Broken** — collisions in seconds. Never
SHA-1	160	**Broken** for collisions (2017). Never for new use
SHA-256	256	**The default.** Hardware acceleration common
SHA-384 / SHA-512	384 / 512	Sound. **Faster than SHA-256 on 64-bit**
SHA-512/256	256	SHA-512 truncated — 256-bit output, no length extension, fast on 64-bit
SHA3-256 / SHAKE	256 / any	Sound, sponge-based. Slower in software, good in hardware
BLAKE2b / BLAKE2s	any ≤ 512	Faster than SHA-256, keyed mode built in

Hash	Output	Status
BLAKE3	any	Very fast, parallel, tree-structured
CRC32 / CRC16	32 / 16	**Not cryptographic.** Error detection only
SipHash	64 / 128	Keyed, for hash tables — resists collision-flooding DoS

```
/* CHOOSING:

   Interoperability required (TLS, signatures, standards)
        -> SHA-256, or SHA-384 where the standard says so

   64-bit CPU, performance matters
        -> SHA-512/256 or BLAKE2b - both faster than SHA-256
           because they work on 64-bit words

   Microcontroller with a SHA accelerator
        -> whatever it accelerates, usually SHA-256

   Microcontroller without one, code size matters
        -> BLAKE2s (~1 KB) or SHA-256 (~2 KB)

   Hashing very large amounts of data
        -> BLAKE3, which parallelises across cores and SIMD

   Need arbitrary-length output
        -> SHAKE128/256, or BLAKE2X, or BLAKE3

   Need a keyed hash
        -> BLAKE2's keyed mode, or HMAC (chapter 08)

   Hash table keys, attacker-controlled
        -> SipHash with a per-process random key

/* AND CRC IS NOT A HASH. It is linear, so an attacker can
   compute exactly what to change to preserve it. It detects
   accidental corruption, which is a completely different
   job. Using CRC32 for integrity against an adversary is a
   finding, and it appears in shipped firmware regularly. */
```

> **SHA-256 IS NOT ALWAYS THE FASTEST CHOICE**
>
> SHA-256 uses 32-bit operations; SHA-512 uses 64-bit ones and does fewer rounds per byte. On any 64-bit CPU without SHA hardware extensions, **SHA-512/256 is roughly 1.5x faster than SHA-256 and gives the same 256-bit output** — plus immunity to length extension. It is under-used simply because the name is unfamiliar.

Length extension, concretely

```
/* THE VULNERABLE CONSTRUCTION: */
        tag = SHA256(secret_key ‖ message)

/* THE ATTACK: the attacker knows `message` and `tag`, and
   the LENGTH of the key - not the key itself.

   1. SHA-256's output IS its internal state after the final
      block.
   2. Load that state into a fresh SHA-256 context.
   3. Continue hashing arbitrary `extra` data.
   4. The result is a valid tag for:

        secret_key ‖ message ‖ padding ‖ extra

   The attacker has forged a tag for a message they chose,
   without ever learning the key.

/* A REAL EXAMPLE, and this shape appears constantly: */
        /* the server checks: */
        tag == SHA256(key ‖ "user=alice&admin=false")

        /* the attacker produces a valid tag for: */
        "user=alice&admin=false" ‖ 0x80 00 ... len ‖
                                        "&admin=true"

   If the parser takes the LAST occurrence of a duplicated
   parameter - which many do - the attacker is now an
   administrator. This has broken Flickr's API, several
   payment gateways, and a long list of others.

/* THE FIXES, in order of preference:
     1. USE HMAC (chapter 08). It is designed for this and
        the nesting defeats the attack.
     2. Use a hash that is immune: SHA-3, BLAKE2/3,
        SHA-512/256.
     3. Use an AEAD, which authenticates as part of
        encryption (chapter 09).

   H(message ‖ key) is also weak - it reduces the forgery to
   finding a collision in H. HMAC exists precisely so that
   nobody has to reason about this.                       */
```

Using them

```
/* --- INCREMENTAL HASHING, which every API supports --- */
    #include <mbedtls/sha256.h>

    mbedtls_sha256_context ctx;
    uint8_t digest[32];

    mbedtls_sha256_init(&ctx);
    mbedtls_sha256_starts(&ctx, 0);         /* 0 = SHA-256 */
    while ((n = read_chunk(buf, sizeof buf)) > 0)
            mbedtls_sha256_update(&ctx, buf, n);
    mbedtls_sha256_finish(&ctx, digest);
    mbedtls_sha256_free(&ctx);

/* Streaming means you never need the whole message in
   memory - essential for verifying a firmware image larger
   than your RAM (isolation chapter 14).

/* --- COMPARING DIGESTS: constant time, always --- */
    /* WRONG: leaks how many bytes matched */
    if (memcmp(computed, expected, 32) == 0) accept();

    /* RIGHT: */
    static int ct_equal(const uint8_t *a, const uint8_t *b,
                        size_t n)
    {
            uint8_t diff = 0;
            for (size_t i = 0; i < n; i++)
                    diff |= a[i] ^ b[i];
            return diff == 0;
    }
/* Or the library's version: mbedtls_ct_memcmp,
   sodium_memcmp, CRYPTO_memcmp. This matters whenever the
   attacker can submit candidate digests and measure the
   response (chapter 19).

/* --- DOMAIN SEPARATION: hash a purpose, not just data --- */
    /* WRONG - the same hash used for two purposes: */
    key1 = SHA256(master ‖ "a");
    key2 = SHA256(master ‖ "ab");   /* and "a" ‖ "b" collides
                                       with "ab" ‖ "" */
    /* RIGHT - unambiguous encoding, or a proper KDF: */
    key1 = HKDF(master, info="encryption-key-v1");
    key2 = HKDF(master, info="mac-key-v1");
/* Concatenating variable-length fields into a hash input is
   a recipe for ambiguity. Include lengths, or use a KDF with
   an info string (chapter 10).

/* --- MERKLE TREES, for verifying a large image in
       pieces --- */
             root
            /    \
          h01     h23
         /  \    /  \
        h0  h1  h2  h3
        |   |   |   |
        b0  b1  b2  b3

/* Verify block 2 with h3, h01 and the root - three hashes
   instead of the whole image. Used by dm-verity
```

```
    (Linux chapter 14 / isolation chapter 14), by every
    package manager, and by BLAKE3's internal structure.  */
```

How it shows up

Symptom	Cause
Forged tag accepted for an appended message	Length extension on `H(key ‖ msg)` — use HMAC
Two different files with the same hash	MD5 or SHA-1 — a chosen-prefix collision
Passwords cracked at billions per second	A plain hash instead of a password KDF (ch. 10)
"Anonymised" identifiers reversed	Small input space — hashing is not anonymisation
Digest comparison leaks through timing	`memcmp` — use a constant-time compare
Integrity check passes on modified data	CRC used as if it were a hash
Two different inputs hash the same by construction	Ambiguous concatenation — add domain separation
Hash table performance collapses under load	Collision flooding — use SipHash with a random key
Certificate accepted that should not be	SHA-1 signature — collision attack
Hashing is the bottleneck	Try SHA-512/256, BLAKE2 or BLAKE3; check for hardware support

Check yourself

- ✓ State the three security properties and the cost of breaking each.
- ✓ Explain the birthday bound and why collision resistance is only n/2 bits.
- ✓ Explain why SHA-1 is broken for certificates but not for HMAC.
- ✓ List five legitimate uses and five misuses.
- ✓ Contrast Merkle–Damgård with the sponge construction.
- ✓ Explain length extension concretely and give three fixes.
- ✓ Say why `H(key ‖ msg)` and `H(msg ‖ key)` are both wrong.
- ✓ Choose a hash for six different situations.
- ✓ Explain why CRC is not a cryptographic hash.
- ✓ Write a constant-time digest comparison and say when it matters.
- ✓ Explain domain separation and the ambiguity it prevents.

Message authentication codes

A keyed tag proving a message came from someone holding the key and has not been modified. This is the integrity half of chapter 01 — and the one place where a hand-rolled construction is almost guaranteed to be broken.

The model

```
MAC : key × message -> tag

SENDER:    t = MAC(k, m);  send (m, t)
RECEIVER:  t' = MAC(k, m); accept iff t' == t
                                    (in CONSTANT TIME)

THE SECURITY GOAL: EXISTENTIAL UNFORGEABILITY under a
CHOSEN-MESSAGE ATTACK (EUF-CMA).

  An adversary who can obtain tags for any messages they
  choose still cannot produce a valid (m, t) pair for any
  message they have not seen.

WHAT A MAC PROVIDES:
  · INTEGRITY   - the message was not modified
  · AUTHENTICITY - it came from a holder of k

WHAT IT DOES NOT:
  · CONFIDENTIALITY - the message is in the clear
  · NON-REPUDIATION - BOTH parties hold k, so either could
    have produced the tag. A third party learns nothing
    about which. That needs a signature (chapter 15).
  · FRESHNESS - a valid (m, t) pair replays forever. Add a
    counter, a timestamp or a nonce, and authenticate it.

TAG LENGTH: 128 bits is standard. A truncated tag of t
bits gives an attacker a 2^-t chance per forgery attempt -
so 64 bits is acceptable only where the number of attempts
is rate-limited, and 32 bits is a bad idea in almost every
case.
```

HMAC

```
/* THE CONSTRUCTION, RFC 2104: */

    HMAC(K, m) = H( (K' XOR opad) ‖ H( (K' XOR ipad) ‖ m ) )

        K'    the key, padded to the hash's BLOCK SIZE
              (64 bytes for SHA-256), or H(K) if longer
        ipad  0x36 repeated
        opad  0x5C repeated

/* WHY THE NESTING: it defeats length extension (chapter 07).
   The inner hash's output is fed into an outer hash keyed
   differently, so an attacker who knows the tag cannot
   continue the computation - the outer hash's state is
   unknown.

/* WHY TWO DIFFERENT PADS: ipad and opad differ in every bit
   position of every byte pair, which makes the two derived
   keys effectively independent.

/* THE SECURITY PROOF is remarkable: HMAC is secure if the
   compression function is a pseudorandom function - a much
   weaker assumption than collision resistance. Which is why
   HMAC-SHA1 REMAINS SECURE despite SHA-1's collision breaks
   (chapter 07). It should still be replaced, but it is not
   urgent in the way an SHA-1 signature is.

/* IMPLEMENTATION: */
    #include <mbedtls/md.h>

    uint8_t tag[32];
    const mbedtls_md_info_t *info =
        mbedtls_md_info_from_type(MBEDTLS_MD_SHA256);

    mbedtls_md_hmac(info, key, key_len, msg, msg_len, tag);

    /* streaming, for a large message */
    mbedtls_md_context_t ctx;
    mbedtls_md_setup(&ctx, info, 1);        /* 1 = HMAC */
    mbedtls_md_hmac_starts(&ctx, key, key_len);
    while ((n = read(buf, sizeof buf)) > 0)
        mbedtls_md_hmac_update(&ctx, buf, n);
    mbedtls_md_hmac_finish(&ctx, tag);
    mbedtls_md_free(&ctx);

/* VERIFICATION, and this is where implementations fail: */
    /* WRONG - early exit leaks how many bytes matched */
    if (memcmp(tag, received, 32) == 0) accept();

    /* RIGHT */
    if (mbedtls_ct_memcmp(tag, received, 32) == 0) accept();
    /* or sodium_memcmp, CRYPTO_memcmp, or the loop from
       chapter 07                                          */

/* THE TIMING ATTACK IS REAL AND PRACTICAL: an attacker
   submits candidate tags and measures the response. Each
   additional matching byte takes measurably longer, so they
   recover the tag one byte at a time - 256 x 16 attempts
   instead of 2^128. This has broken real APIs, including
   over a network where the difference was nanoseconds -
```

```
   statistical averaging over many requests extracts it
   (chapter 19).                                          */
```

> **NEVER BUILD A MAC YOURSELF**
>
> `H(k ‖ m)` falls to length extension. `H(m ‖ k)` reduces to finding a hash collision. `H(k ‖ m ‖ k)` has weaknesses too. Encrypting a hash, XORing a key in, truncating cleverly — every ad-hoc construction has been tried and broken. HMAC exists precisely so nobody has to reason about this again, and it is one function call.

Poly1305 and universal hashing

```
/* A different construction entirely: a ONE-TIME MAC based on
   polynomial evaluation in a prime field. Much faster than
   HMAC, and the authenticator inside ChaCha20-Poly1305 and
   (in a related form) AES-GCM.                             */

    Poly1305(r, s, m):
        split m into 16-byte chunks c1..cn, each with a
        high bit set
        evaluate  ((c1*r^n + c2*r^(n-1) + ... + cn*r) mod
                   (2^130 - 5))  +  s   mod 2^128

/* r and s are derived from the key and the nonce, and r has
   some bits CLAMPED to make the arithmetic efficient.

/* THE CRITICAL PROPERTY - AND THE CRITICAL WARNING:

     POLY1305 IS A ONE-TIME MAC. The (r, s) pair must NEVER
     be reused for two messages.

   With two tags under the same key, the attacker gets two
   polynomial equations in the unknown r, and can SOLVE FOR
   THE AUTHENTICATION KEY. They can then forge arbitrary
   messages.

   This is exactly why GCM nonce reuse is worse than CTR
   nonce reuse (chapter 05): CTR reuse leaks plaintexts;
   GCM reuse additionally hands over the ability to forge.

/* SO IT IS ALWAYS USED WITH A NONCE-DERIVED KEY: */
    ChaCha20-Poly1305:
        (r, s) = first 32 bytes of ChaCha20(key, nonce,
                                            counter=0)
        ciphertext = ChaCha20(key, nonce, counter=1) XOR
                     plaintext
        tag = Poly1305(r, s, aad ‖ ciphertext ‖ lengths)

/* THE LENGTH FIELDS AT THE END MATTER. Without them, an
   attacker could move bytes between the AAD and the
   ciphertext while keeping the concatenation identical -
   producing a valid tag for a different (aad, ciphertext)
   split. Any construction concatenating variable-length
   fields into an authenticator needs unambiguous encoding.

/* GHASH, used by GCM, is the same idea over GF(2^128)
   instead of a prime field - faster in hardware (the
   PMULL/CLMUL instructions), and with the same one-time
   requirement.                                             */
```

CMAC and the block-cipher MACs

```
/* When you have an AES accelerator and no hash accelerator,
   a block-cipher MAC costs nothing extra.                 */

/* --- CBC-MAC: the naive version, and why it is broken --- */
       t = last block of CBC-encrypt(m) with IV = 0

/* SECURE ONLY for FIXED-LENGTH messages. With variable
   lengths:
        given  MAC(m1) = t1  and  MAC(m2) = t2
        then   MAC(m1 ‖ (m2[0] XOR t1) ‖ m2[1..]) = t2
   A forgery from two known tags, with no key.

/* --- CMAC (RFC 4493): CBC-MAC done correctly --- */
    Derive two subkeys K1, K2 from K.
    XOR the final block with K1 (if the message is a whole
    number of blocks) or pad and XOR with K2 (if not).
    That distinguishes padded from unpadded messages and
    closes the extension attack.

    /* mbedTLS */
    mbedtls_cipher_cmac(cipher_info, key, 128,
                        msg, msg_len, tag);

/* CMAC IS THE RIGHT CHOICE when:
     · you have AES hardware and no SHA hardware
     · you are already doing AES and want one primitive
     · a standard requires it (many do - it is NIST SP
       800-38B)

/* --- GMAC: GCM with no plaintext --- */
    AES-GCM with an empty plaintext and the data as AAD is a
    MAC. Very fast with PMULL/CLMUL. Inherits GCM's nonce
    requirement absolutely.

/* --- KMAC: the SHA-3 keyed mode --- */
    A sponge is naturally keyed - just absorb the key first.
    No HMAC-style nesting needed, because there is no length
    extension (chapter 07). Same for BLAKE2's keyed mode and
    BLAKE3's keyed_hash.                                    */
```

Choosing

MAC	Based on	Use when
HMAC-SHA256	Any hash	**The safe default.** Standard everywhere, no nonce needed
HMAC-SHA512	SHA-512	Faster on 64-bit CPUs
Poly1305	Polynomial	Inside ChaCha20-Poly1305. **Never standalone with a reused key**
GMAC / GHASH	GF(2^{128})	Inside GCM; fast with PMULL
CMAC	AES	AES hardware available, no hash hardware
KMAC	SHA-3	Where SHA-3 is already used
BLAKE2 keyed / BLAKE3	Their own	Fast software, no separate HMAC needed
SipHash	ARX	Short inputs, hash-table DoS resistance — *not* a general MAC
CBC-MAC	Any cipher	**Never** — use CMAC

```
/* THE DECISION, in practice:

   Encrypting anyway?           -> use an AEAD (chapter 09).
                                   The tag comes free and the
                                   composition is already
                                   correct.
   Authenticating only?         -> HMAC-SHA256
   AES hardware, no SHA?        -> CMAC
   Very constrained?            -> CMAC with the AES engine,
                                   or ASCON
   Already using BLAKE2/3?      -> its keyed mode

   AND ALMOST ALWAYS THE FIRST: if you find yourself choosing
   a MAC separately from a cipher, check whether you should
   be using an AEAD instead. Composing them by hand is where
   the mistakes are.                                        */
```

Using a MAC in a protocol

```
/* --- 1. AUTHENTICATE EVERYTHING THAT MATTERS --- */
    /* WRONG - the header is unprotected */
    tag = HMAC(k, payload);
    send(header, payload, tag);
    /* an attacker changes the header freely: the message
       type, the destination, the length */

    /* RIGHT */
    tag = HMAC(k, header ‖ payload);

/* --- 2. INCLUDE A COUNTER, OR REPLAY IS TRIVIAL --- */
    struct Message {
        uint32_t seq;           /* monotonic, per direction */
        uint8_t  type;
        uint16_t len;
        uint8_t  payload[];
    };
    tag = HMAC(k, seq ‖ type ‖ len ‖ payload);

    /* the receiver: */
    if (msg.seq <= last_seen_seq) reject();     /* REPLAY */
    if (!ct_equal(tag, computed, 16)) reject();
    last_seen_seq = msg.seq;

/* AND CHECK THE TAG BEFORE THE SEQUENCE, or an attacker can
   probe your sequence-number state with forged messages.
   Actually check BOTH, and reject on either - but never act
   on unauthenticated data.

/* --- 3. USE SEPARATE KEYS FOR EACH DIRECTION AND
       PURPOSE --- */
    k_c2s_enc = HKDF(master, "client-to-server encryption");
    k_c2s_mac = HKDF(master, "client-to-server mac");
    k_s2c_enc = HKDF(master, "server-to-client encryption");
    k_s2c_mac = HKDF(master, "server-to-client mac");

/* ONE KEY FOR BOTH DIRECTIONS allows REFLECTION: the
   attacker replays a client message back to the client, and
   it authenticates. Real protocols have fallen to this.
   Key derivation is cheap (chapter 10); use distinct keys.

/* --- 4. UNAMBIGUOUS ENCODING --- */
    /* WRONG: */
    tag = HMAC(k, user ‖ action);
    /* ("alice", "delete") and ("alic", "edelete") produce the
       same input */
    /* RIGHT: */
    tag = HMAC(k, len(user) ‖ user ‖ len(action) ‖ action);

/* --- 5. AND THE VERIFICATION DISCIPLINE --- */
    · constant-time comparison, always
    · compare the FULL tag, never a prefix
    · on failure: reject the whole message, log nothing
      attacker-controlled, and return an INDISTINGUISHABLE
      error - "authentication failed", never "bad sequence
      number" or "unknown message type"
    · rate-limit failures, so an attacker cannot make 2^32
      attempts                                              */
```

How it shows up

Symptom	Cause
Forged tag accepted for an extended message	Length extension on `H(k ‖ m)` — use HMAC
Tag recovered one byte at a time	Non-constant-time comparison
Forgery after two messages	Poly1305 or GHASH key reused — nonce reuse
Forgery from two known tags	Raw CBC-MAC with variable-length messages
Old messages replayed successfully	No sequence number or timestamp in the authenticated data
A client's own message accepted back	The same key in both directions — reflection
Header modified without detection	Only the payload was authenticated
Two different messages produce the same input	Ambiguous concatenation — add length prefixes
Attacker learns why a message was rejected	Distinguishable error responses
A third party cannot prove who sent a message	A MAC does not provide non-repudiation — by design

Check yourself

- ✓ State the MAC security goal and the three things a MAC does not provide.
- ✓ Write out the HMAC construction and explain why it is nested.
- ✓ Explain why HMAC-SHA1 remains secure while SHA-1 signatures are not.
- ✓ Explain the timing attack on tag comparison and why it works over a network.
- ✓ Explain why Poly1305 is a one-time MAC and what reuse hands to an attacker.
- ✓ Say why the length fields at the end of the Poly1305 input matter.
- ✓ Explain why raw CBC-MAC is broken and what CMAC changes.
- ✓ Choose a MAC for five situations, and say when the answer is really "use an AEAD".
- ✓ List the five protocol rules for using a MAC correctly.
- ✓ Explain reflection attacks and the key-separation fix.

Authenticated encryption

Confidentiality and integrity in one primitive, analysed as a whole. This is the answer to almost every "how do I encrypt this?" question, and using anything else needs a specific justification.

The interface

```
ENCRYPT(key, nonce, plaintext, associated_data)
     -> ciphertext, tag

DECRYPT(key, nonce, ciphertext, associated_data, tag)
     -> plaintext, or FAILURE

THE FOUR INPUTS:

  KEY               secret, 128 or 256 bits
  NONCE             not secret; MUST BE UNIQUE per key
  PLAINTEXT         encrypted AND authenticated
  ASSOCIATED DATA   authenticated but NOT encrypted

THE ASSOCIATED DATA IS THE UNDER-USED PART. It is for
anything that must be bound to the message but has to stay
readable:

  · a packet header the router must see
  · a message type or version field
  · a sequence number
  · the sender and recipient identifiers
  · the record layer header in TLS

Bind them, and an attacker cannot take a valid ciphertext
and replay it with a different header - which is a real
attack whenever the header carries routing or type
information.

THE FAILURE MODE IS THE POINT: decryption returns FAILURE,
not plaintext. There is no partial result, no "decrypt
then check", no window in which unauthenticated plaintext
exists. That is what makes an AEAD safe where a composed
construction is not (chapter 05's padding oracle).
```

AES-GCM

```
/* THE CONSTRUCTION: AES-CTR for confidentiality, GHASH for
   authentication, sharing one key.                          */

    H = AES_K(0^128)                    /* the GHASH key */
    J0 = nonce ‖ 0^31 ‖ 1               /* for a 96-bit
                                           nonce */
    ciphertext = AES-CTR_K(J0+1, plaintext)
    tag = GHASH_H(aad ‖ ciphertext ‖ lengths) XOR AES_K(J0)

/* GHASH is polynomial evaluation in GF(2^128) - the same
   universal-hashing idea as Poly1305 (chapter 08), and with
   the same one-time-key requirement.

/* WHY IT WON:
     · CTR mode is fully parallelisable
     · GHASH maps onto the PMULL (ARM) and PCLMULQDQ (x86)
       carry-less multiply instructions
     · with AES-NI or the ARM crypto extension, roughly
       1 cycle/byte
     · it is in every standard: TLS, IPsec, SSH, 802.11ac,
       NVMe, storage

/* THE NONCE RULE, and it is absolute:

     NEVER REUSE A (key, nonce) PAIR.

   Reuse does not merely leak the XOR of the plaintexts, as
   it would with plain CTR. It reveals H, THE
   AUTHENTICATION KEY - because two tags give two
   polynomial equations in H. The attacker can then FORGE
   ARBITRARY MESSAGES under that key.

   This is the single most damaging misuse in modern
   cryptography, and it has happened in shipped TLS stacks,
   VPNs and IoT devices.

/* THE LIMITS:
     96-bit nonce  the only size that avoids an extra GHASH
                   step; always use exactly 12 bytes
     2^32 - 2 blocks (about 64 GB) per (key, nonce)
     2^32 messages per key before the birthday bound on
       random nonces becomes uncomfortable - use a counter

/* TRUNCATED TAGS: GCM allows 96, 104, 112, 120 or 128 bits.
   USE 128. Short tags weaken the forgery bound far more than
   the arithmetic suggests, because a successful forgery with
   a short tag can leak information about H.              */
```

ChaCha20-Poly1305

```
/* RFC 8439. ChaCha20 for confidentiality (chapter 06),
   Poly1305 for authentication (chapter 08).              */

    one-time key (r, s) = ChaCha20(key, nonce, counter = 0)
                          [first 32 bytes]
    ciphertext          = ChaCha20(key, nonce, counter = 1)
                          XOR plaintext
    tag = Poly1305(r, s,
                   aad ‖ pad16 ‖ ciphertext ‖ pad16 ‖
                   len(aad) ‖ len(ciphertext))

/* THE PADDING AND LENGTH FIELDS make the encoding
   unambiguous - without them an attacker could shift bytes
   between the AAD and the ciphertext (chapter 08).

/* THE ONE-TIME KEY IS DERIVED FROM THE NONCE, which is what
   makes Poly1305's one-time requirement satisfiable.

/* WHY USE IT:
     · 3-4x faster than SOFTWARE AES-GCM
     · CONSTANT TIME with no effort - ARX, no tables
       (chapter 19)
     · small: a few kilobytes of code total
     · no timing variability, so no cache-attack surface

/* AND XCHACHA20-POLY1305, which is the version to prefer:
     192-bit nonce, derived via HChaCha20.
     RANDOM NONCES ARE SAFE INDEFINITELY - a 192-bit random
     nonce will not collide before the heat death of
     anything. That removes the entire nonce-management
     problem, which is where most AEAD misuse comes from.

/* THE PRACTICAL SPLIT: TLS 1.3 offers both AES-GCM and
   ChaCha20-Poly1305 and negotiates. A server with AES-NI
   picks GCM; a phone without AES acceleration picks
   ChaCha20. Both are correct choices for their hardware. */
```

THE DECISION, IN FOUR LINES

```
hardware AES available          -> AES-GCM (or AES-GCM-SIV)
software only                   -> XChaCha20-Poly1305
nonce uniqueness not guaranteed -> AES-GCM-SIV or XChaCha20
very constrained hardware       -> AES-CCM, or ASCON
```

And in all four cases: call the AEAD API, not a cipher plus a MAC you compose yourself.

The others

AEAD	Notes
AES-GCM	The standard. Fast with hardware. Absolutely nonce-critical
ChaCha20-Poly1305	Fast in software, constant time. 96-bit nonce
XChaCha20-Poly1305	192-bit nonce — random nonces are safe. **The easiest correct choice**

AEAD	Notes
AES-GCM-SIV	**Nonce-misuse resistant.** Two passes, so it cannot stream
AES-CCM	CTR + CBC-MAC. Only needs the encrypt direction — good on tiny hardware. 802.15.4, Zigbee, Bluetooth LE, WPA2
AES-OCB	One pass, very fast. Patents expired
AES-EAX	CTR + CMAC. Simple, streaming, no patents
ASCON	**NIST lightweight standard (2023).** Sponge-based, tiny hardware
AEGIS, MORUS	AES-round-based, extremely fast where AES-NI exists
Deoxys-II	CAESAR winner for misuse resistance

```
/* --- AES-CCM, worth understanding for embedded --- */
    CBC-MAC over the nonce, AAD and plaintext -> tag
    CTR mode to encrypt the plaintext AND the tag

/* IT NEEDS ONLY THE AES ENCRYPT DIRECTION, so the
   implementation is half the size - which matters when the
   whole crypto library must fit in 8 KB. And it is what
   every 802.15.4-derived protocol uses, so if you are doing
   Zigbee, Thread, Bluetooth LE or Matter, you are using CCM
   whether you chose it or not.

   THE COSTS: two passes over the data (so the length must be
   known in advance), not parallelisable, and it is
   MAC-then-encrypt in structure - which is provably fine
   here because it was analysed as a whole, but is a reminder
   that "use a standard construction" beats "apply a rule of
   thumb".

/* --- AES-GCM-SIV, and when to reach for it --- */
    tag = POLYVAL(auth_key, aad ‖ plaintext ‖ lengths)
    nonce_for_ctr = tag
    ciphertext = AES-CTR(enc_key, tag, plaintext)

/* The tag is computed FIRST, over the plaintext, and then
   used as the CTR nonce. So repeating a nonce with
   DIFFERENT plaintexts still gives different ciphertexts;
   the only leak is that identical (nonce, plaintext) pairs
   produce identical ciphertexts.

   USE IT WHEN NONCE UNIQUENESS CANNOT BE GUARANTEED:
     · a device that may be restored from a backup
     · a stateless server with no shared counter
     · firmware whose counter resets on reflash (chapter 02)
     · any design where "the counter is monotonic" is a hope
       rather than a mechanism

   THE COST: two passes, so no streaming, and the plaintext
   must be buffered.                                    */
```

Using one correctly

```
/* --- THE HIGH-LEVEL API, which is the recommendation --- */
    #include <sodium.h>

    /* KEY: from a KDF or the CSPRNG, never a password
       directly (chapter 10) */
    unsigned char key[crypto_aead_xchacha20poly1305_ietf_KEYBYTES];
    crypto_aead_xchacha20poly1305_ietf_keygen(key);

    unsigned char nonce[crypto_aead_xchacha20poly1305_ietf_NPUBBYTES];
    randombytes_buf(nonce, sizeof nonce);   /* 192 bits:
                                               random is safe */

    unsigned long long ct_len;
    crypto_aead_xchacha20poly1305_ietf_encrypt(
            ciphertext, &ct_len,
            plaintext, plaintext_len,
            header, header_len,             /* the AAD */
            NULL, nonce, key);

    /* transmit: nonce ‖ header ‖ ciphertext (tag included) */

    /* DECRYPT - and this is the whole error handling: */
    if (crypto_aead_xchacha20poly1305_ietf_decrypt(
            decrypted, &pt_len, NULL,
            ciphertext, ct_len,
            header, header_len,
            nonce, key) != 0) {
            /* FORGED, CORRUPTED, OR WRONG KEY.
               DISCARD EVERYTHING. Do not use any bytes of
               `decrypted`. Do not report which check failed.
               Do not log the ciphertext. */
            return -1;
    }

/* --- ON EMBEDDED, mbedTLS --- */
    mbedtls_gcm_context ctx;
    mbedtls_gcm_init(&ctx);
    mbedtls_gcm_setkey(&ctx, MBEDTLS_CIPHER_ID_AES, key, 256);

    mbedtls_gcm_crypt_and_tag(&ctx, MBEDTLS_GCM_ENCRYPT,
                              len, nonce, 12,
                              aad, aad_len,
                              input, output,
                              16, tag);      /* FULL 16-byte
                                                tag */

    /* and decryption, which checks the tag internally: */
    if (mbedtls_gcm_auth_decrypt(&ctx, len, nonce, 12,
                                 aad, aad_len, tag, 16,
                                 input, output) != 0)
            return ERROR;                   /* FAIL CLOSED */

    mbedtls_gcm_free(&ctx);

/* --- THE RULES, restated because each is a real failure --- */

  1. NEVER REUSE A (key, nonce) PAIR. Use a persistent
     counter, or a 192-bit random nonce.

  2. VERIFY BEFORE USING ANY PLAINTEXT. Not "decrypt then
```

```
   check" - a correct API does not give you the plaintext
   until the tag verified. If yours does, treat the buffer
   as untrusted until the check returns.

3. AUTHENTICATE THE HEADERS via the AAD. Anything that
   changes the meaning of the message must be bound to it.

4. USE THE FULL TAG LENGTH.

5. INCLUDE A SEQUENCE NUMBER, in the AAD, and reject
   replays (chapter 08). An AEAD gives no freshness.

6. ROTATE KEYS before the message or byte limits.

7. ON FAILURE, RETURN ONE INDISTINGUISHABLE ERROR, and
   rate-limit.                                          */
```

Where it still goes wrong

```
/* An AEAD removes most of the classic failures. These
   remain: */

   1. NONCE REUSE - by far the most common, and the most
      damaging. Sources: a hardcoded IV, a counter in
      volatile RAM, a device cloned from an image, a random
      nonce that is too short, a counter that resets.

   2. NOT AUTHENTICATING THE AAD YOU MEANT TO. Sending a
      header outside the AAD makes it forgeable.

   3. USING THE PLAINTEXT BEFORE VERIFICATION. Some
      streaming APIs release plaintext incrementally. If you
      act on it before the final tag check, you have
      re-created the padding-oracle situation.

   4. TREATING THE TAG AS OPTIONAL - truncating it, or
      skipping verification "for performance".

   5. NO REPLAY PROTECTION. A valid message replays forever.

   6. KEY REUSE ACROSS CONTEXTS - the same key for both
      directions, or for two protocols. Derive separate keys
      (chapter 10).

   7. EXCEEDING THE LIMITS - 64 GB per GCM nonce, and the
      message-count bounds.

   8. ENCRYPTING THE LENGTH AWAY BUT NOT THE PATTERN. An
      AEAD hides content, not size or timing. A protocol
      whose message lengths reveal the content - a keyboard
      remote, a voice codec - needs padding as well.

   9. AND THE ONE PEOPLE FORGET: AN AEAD DOES NOT
      AUTHENTICATE THE SENDER'S IDENTITY, only that they
      hold the key. If two parties share a key, either could
      have sent any message (chapter 01). For a real identity
      claim you need a signature or a properly authenticated
      key exchange (chapters 13 and 15).                */
```

How it shows up

Symptom	Cause
Forged messages accepted	GCM nonce reuse leaked the authentication key
Two ciphertexts XOR to plaintext	Nonce reuse
Header modified without detection	Not included in the AAD
Old messages replayed	No sequence number — AEADs give no freshness
Decryption fails after 64 GB	GCM block limit for one nonce
Interop failure on the tag	Different tag lengths, or AAD not byte-identical
Works one way, fails the other	Same key both directions, or nonce spaces overlapping
Plaintext acted on before verification	A streaming API used incorrectly
Attacker infers content from message sizes	An AEAD hides content, not length — pad
Nonce repeats after a factory reset	Counter in volatile storage — use GCM-SIV or XChaCha20

Check yourself

- ✓ State the AEAD interface and what associated data is for.
- ✓ Explain why the failure mode — no partial plaintext — is the security property.
- ✓ Describe AES-GCM's construction and why GCM nonce reuse is worse than CTR nonce reuse.
- ✓ State GCM's nonce size, tag size and message limits.
- ✓ Describe ChaCha20-Poly1305 and say why the length fields matter.
- ✓ Explain what XChaCha20 changes and why it removes a class of bug.
- ✓ Say when AES-CCM is the right choice and what it costs.
- ✓ Explain nonce-misuse resistance and four situations that call for it.
- ✓ Write a correct encrypt and a correct fail-closed decrypt.
- ✓ List the seven usage rules and the nine remaining failure modes.
- ✓ Explain what an AEAD does *not* authenticate.

Key derivation and password hashing

Turning one secret into many, and turning a low-entropy password into something that survives an offline attack. Two problems that look similar and need completely different tools.

Two different problems

```
PROBLEM 1: KEY DERIVATION (KDF)
  input:  a HIGH-ENTROPY secret
          - a Diffie-Hellman shared secret
          - a master key from a fuse or an OTP region
          - a random 256-bit key
  want:   several independent keys, each bound to a
          purpose
  cost:   SHOULD BE FAST. There is no offline guessing
          attack on 256 bits of entropy, so slowing down
          derivation buys nothing and costs you boot time.
  tool:   HKDF

PROBLEM 2: PASSWORD HASHING (PBKDF)
  input:  a LOW-ENTROPY secret
          - "hunter2", a 6-digit PIN, a passphrase
          - maybe 20-40 bits of real entropy
  want:   a key, and resistance to an attacker who has
          stolen the stored value and can guess offline
  cost:   MUST BE DELIBERATELY EXPENSIVE. That is the
          entire mechanism. If verification takes 100 ms
          on your hardware, an attacker's GPU farm gets
          far fewer guesses per second.
  tool:   Argon2id, scrypt, or PBKDF2

USING THE WRONG ONE:
  HKDF on a password   -> a GPU tries billions of guesses
                          per second; the password falls
                          in minutes
  Argon2 on a DH secret -> 100 ms and 64 MB of RAM wasted
                          per handshake, for no security
                          gain at all

AND THE WORST OPTION, still common in shipped firmware:
  SHA256(password) -> a rainbow table, or a GPU doing
  10^10 guesses/second. Not a password hash. Never.
```

HKDF

```
/* RFC 5869. Two steps, and the separation is deliberate. */

/* --- EXTRACT: concentrate whatever entropy exists into a
       uniform pseudorandom key --- */
    PRK = HMAC(salt, input_key_material)

    /* The salt is NOT secret and MAY be absent (a string of
       zeros). Its job is to make the extraction independent
       across contexts, not to hide anything.

       This step matters when the input is not uniform - a
       raw Diffie-Hellman output, for instance, is a group
       element with structure, not 256 uniform bits.       */

/* --- EXPAND: stretch the PRK into as much keying material
       as needed, each piece bound to a label --- */
    T(1) = HMAC(PRK, info ‖ 0x01)
    T(2) = HMAC(PRK, T(1) ‖ info ‖ 0x02)
    ...
    OKM  = first L bytes of T(1) ‖ T(2) ‖ ...

/* THE `info` PARAMETER IS THE IMPORTANT ONE and the one
   people leave empty. It is a CONTEXT STRING that makes each
   derived key independent. Compromise of one key tells you
   nothing about the others.                                 */

    #include <mbedtls/hkdf.h>

    uint8_t k_enc[32], k_mac[32], k_iv[12];
    const mbedtls_md_info_t *sha256 =
        mbedtls_md_info_from_type(MBEDTLS_MD_SHA256);

    mbedtls_hkdf(sha256,
                 salt, salt_len,
                 shared_secret, secret_len,
                 (const uint8_t *)"fw-update v1 encryption", 23,
                 k_enc, sizeof k_enc);

    mbedtls_hkdf(sha256, salt, salt_len,
                 shared_secret, secret_len,
                 (const uint8_t *)"fw-update v1 mac", 16,
                 k_mac, sizeof k_mac);

/* OR, MORE EFFICIENTLY, ONE EXTRACT AND SEVERAL EXPANDS: */
    uint8_t prk[32];
    mbedtls_hkdf_extract(sha256, salt, salt_len,
                         ikm, ikm_len, prk);

    mbedtls_hkdf_expand(sha256, prk, 32,
                        (const uint8_t *)"c2s enc", 7,
                        k_c2s_enc, 32);
    mbedtls_hkdf_expand(sha256, prk, 32,
                        (const uint8_t *)"s2c enc", 7,
                        k_s2c_enc, 32);
    /* ... and so on for each direction and purpose      */

/* GOOD CONTEXT STRINGS INCLUDE:
     · the protocol name and VERSION
     · the purpose ("encryption", "mac", "iv")
     · the DIRECTION ("client-to-server")
```

```
     · the session or device identifier, where it exists

   "myapp v2 device-4711 client-to-server encryption"

   INCLUDING THE VERSION MEANS a protocol upgrade derives
   entirely different keys, so a downgrade attack cannot
   reuse material across versions.                        */
```

ONE MASTER KEY, MANY DERIVED KEYS

A device with a single hardware root key should never use that key directly for anything. Derive: one key for firmware decryption, one for attestation, one for storage, one per peer session. Each has a distinct `info` string. Compromise of the storage key then tells an attacker nothing about the firmware key, and the root key never leaves the key-derivation step — which is exactly what a hardware key store enforces for you (chapter 18).

Password hashing

```
/* THE THREAT: your database or flash image is stolen. The
   attacker now guesses offline, as fast as their hardware
   allows. Your only defence is making each guess expensive.

/* --- ARGON2id: the current recommendation --- */
    Winner of the Password Hashing Competition, 2015.
    THREE cost parameters:

      m  MEMORY, in KiB    - the important one
      t  TIME (iterations)
      p  PARALLELISM (lanes)

    MEMORY-HARDNESS IS THE POINT. A GPU has thousands of
    cores but limited memory bandwidth and per-core memory.
    Requiring 64 MiB per guess reduces a GPU's advantage from
    ~1000x to single digits, and makes a dedicated ASIC
    expensive rather than trivial.

    THE THREE VARIANTS:
      Argon2d   data-dependent addressing - fastest, but
                side-channel exposed (chapter 19)
      Argon2i   data-independent - side-channel resistant,
                weaker against time-memory tradeoffs
      Argon2id  HYBRID: first pass independent, rest
                dependent. USE THIS ONE.

    /* libsodium */
    #include <sodium.h>

    char hashed[crypto_pwhash_STRBYTES];
    if (crypto_pwhash_str(
            hashed, password, password_len,
            crypto_pwhash_OPSLIMIT_MODERATE,   /* t */
            crypto_pwhash_MEMLIMIT_MODERATE)   /* 256 MiB */
        != 0)
            return OUT_OF_MEMORY;

    /* `hashed` is a self-describing string containing the
       algorithm, the parameters and the SALT. Store it as
       is. */

    /* verify - constant time internally */
    if (crypto_pwhash_str_verify(hashed, password,
                                 password_len) != 0)
            return AUTH_FAILED;

    /* AND: derive a KEY from a password */
    uint8_t key[32];
    crypto_pwhash(key, sizeof key, password, password_len,
                  salt,                    /* 16 random bytes,
                                              STORED */
                  opslimit, memlimit,
                  crypto_pwhash_ALG_ARGON2ID13);

/* --- SCRYPT: memory-hard, older, widely available --- */
    N  cost (a power of two; 2^15 = 32768 is reasonable)
    r  block size (8)
    p  parallelism (1)
    memory used ~= 128 * N * r bytes
```

```
/* --- PBKDF2: only when a standard requires it --- */
    HMAC repeated a large number of times. NOT memory-hard,
    so GPUs and ASICs get their full advantage. Still
    infinitely better than a bare hash.

    mbedtls_pkcs5_pbkdf2_hmac_ext(
            MBEDTLS_MD_SHA256,
            password, password_len,
            salt, 16,
            600000,              /* OWASP 2023 minimum for
                                    SHA-256 */
            32, key);

    USE IT WHEN: FIPS compliance demands it, a file format
    specifies it, or the device genuinely cannot spare the
    RAM for Argon2.                                       */
```

Choosing parameters

Setting	Argon2id	PBKDF2-SHA256
Server login	m=64 MiB, t=3, p=4	600 000 iterations
Disk encryption	m=1 GiB, t=4, p=4	—
Phone / tablet	m=64 MiB, t=3, p=2	210 000
Linux-class embedded (256 MB RAM)	m=32 MiB, t=4, p=1	310 000
MCU (256 KB RAM)	m=16 KiB, t=32 (weak)	100 000, or a rate limit instead

```
/* THE METHOD, not the table: MEASURE ON YOUR HARDWARE and
   pick the largest parameters that fit your latency budget.

     interactive login        ~100 ms  is the usual target
     disk unlock at boot      ~1 s     is acceptable
     a background operation   several seconds

/* AND FOR CONSTRAINED DEVICES, THE HONEST ANSWER: a 4-digit
   PIN has 13 bits of entropy. NO KDF SAVES IT. 10,000
   guesses is nothing, whatever the per-guess cost. The
   defence must be elsewhere:

     · A HARDWARE-BACKED ATTEMPT COUNTER that wipes the key
       after N failures - which is exactly what a secure
       element or TPM provides, and what phone secure
       enclaves do (chapter 18)
     · A DEVICE-UNIQUE SECRET mixed into the derivation, so
       the attacker must have the physical device:
           key = Argon2id(PIN ‖ device_secret, salt, ...)
       where device_secret comes from fuses or a PUF and
       never leaves the secure world (the isolation track)
     · RATE LIMITING with exponential backoff

   THE KDF BUYS TIME. IT DOES NOT CREATE ENTROPY.        */
```

Salts, peppers, and upgrades

```
/* --- SALT: unique per password, stored alongside it --- */
    · 16 random bytes, from the CSPRNG (chapter 02)
    · NOT SECRET
    · UNIQUE PER USER, generated fresh each time the
      password is set

    WHY: without a salt, identical passwords hash
    identically. An attacker sees which users share a
    password, and precomputes ONE table that breaks every
    account at once - the rainbow table. With per-user salts,
    each password must be attacked separately.

/* --- PEPPER: a site-wide secret, NOT in the database --- */
    stored_hash = Argon2id(password ‖ pepper, salt, ...)

    Keep the pepper in an HSM, a secure element, or an
    environment variable outside the database. A stolen
    DATABASE alone is then useless. It defends against
    exactly one thing - database-only compromise - and it is
    cheap, so it is usually worth having.

/* --- REHASHING ON LOGIN, the migration pattern --- */
    if (verify(stored, password) == OK) {
            if (needs_rehash(stored, current_params)) {
                    /* we have the plaintext password RIGHT
                       NOW and only right now */
                    new_hash = hash(password, current_params);
                    store(new_hash);
            }
            grant_access();
    }

    This is how you raise cost parameters over time, or
    migrate from PBKDF2 to Argon2id, without asking anyone to
    reset a password.

/* --- AND THE VERIFICATION DISCIPLINE --- */
    · compare in constant time (the library does this)
    · take the SAME TIME for an unknown username as a known
      one - otherwise you have a user-enumeration oracle.
      Hash a dummy value when the user does not exist.
    · never log the password, and never put it in an error
      message or a crash dump
    · zero the plaintext buffer as soon as it is consumed
      (chapter 19 - and note the compiler may remove a
      plain memset; use explicit_bzero or
      mbedtls_platform_zeroize)                          */
```

How it shows up

Symptom	Cause
Stolen database cracked in hours	A bare hash, or an unsalted one, instead of a password KDF
Identical hashes for different users	No salt, or a constant salt
Handshake takes 100 ms per connection	Argon2 used where HKDF belongs
Compromising one key exposes others	No `info` context separation in HKDF

Symptom	Cause
Login timing reveals valid usernames	No dummy hash on the unknown-user path
Argon2 fails on the device	Memory parameter exceeds available RAM
PIN brute-forced despite a strong KDF	Low entropy — needs a hardware attempt counter
Password recoverable from a core dump	Buffer not zeroed, or the memset optimised away
Cannot raise cost parameters	No rehash-on-login path
Downgrade attack reuses old session keys	Protocol version not in the KDF context string

Check yourself

- ✓ State the two problems and why one tool must be fast and the other slow.
- ✓ Explain HKDF's extract and expand steps and what each is for.
- ✓ Write a good `info` string and say what each component prevents.
- ✓ Explain why memory-hardness defeats GPUs, and pick between Argon2i, 2d and 2id.
- ✓ Choose parameters for a server, a phone and a 256 KB MCU, and justify the method.
- ✓ Explain why no KDF can save a 4-digit PIN, and name three things that can.
- ✓ Explain what a salt prevents and what a pepper adds.
- ✓ Describe rehash-on-login and why it is the only practical migration path.
- ✓ Explain the user-enumeration timing oracle and its fix.
- ✓ Say why a plain `memset` may not clear a password buffer.

Number theory for public-key cryptography

The minimum mathematics needed to understand what RSA, Diffie–Hellman and elliptic curves actually do — and, more importantly, what makes them hard to break and easy to implement wrongly.

Modular arithmetic

```
a mod n  is the remainder of a divided by n, always in
the range [0, n-1].

ARITHMETIC MODULO n WRAPS:
     (a + b) mod n
     (a * b) mod n
     (a ^ e) mod n

All of public-key cryptography lives inside one of these
wrapped worlds, because they are FINITE and because some
operations in them are EASY FORWARDS AND HARD BACKWARDS.

CONGRUENCE:  a ≡ b (mod n)  means n divides (a − b).

THE KEY STRUCTURES:

  Z_n        the integers 0..n-1 with + and *
  Z_n*       the elements of Z_n that have a MULTIPLICATIVE
             INVERSE — exactly those coprime to n

WHEN n IS PRIME p:
  every non-zero element is invertible, so Z_p is a FIELD.
  You can add, subtract, multiply AND DIVIDE. This is what
  makes prime moduli so useful.

WHEN n = p*q (RSA):
  the elements sharing a factor with n have no inverse —
  and finding one of them means factoring n, which is the
  hard problem RSA rests on.

THE PRACTICAL POINT FOR IMPLEMENTERS: these numbers are
2048 to 4096 bits wide. There is no CPU instruction for
them. Every operation is a loop over machine words, and
the TIMING of that loop is where the secrets leak
(chapter 19).
```

Euclid, inverses and the extended algorithm

```
/* --- GCD: the oldest algorithm still in daily use --- */
    gcd(a, b):
        while b != 0:
            a, b = b, a mod b
        return a

    gcd(252, 198) = gcd(198, 54) = gcd(54, 36)
                  = gcd(36, 18) = gcd(18, 0) = 18

/* --- EXTENDED EUCLID: also finds x, y with
       a*x + b*y = gcd(a, b)  --- */

    ext_gcd(a, b):
        if b == 0: return (a, 1, 0)
        (g, x, y) = ext_gcd(b, a mod b)
        return (g, y, x - (a / b) * y)

/* WHY THIS MATTERS: THE MODULAR INVERSE.

       a * a^-1 ≡ 1  (mod n)

   Set b = n. If gcd(a, n) = 1, then a*x + n*y = 1, so
   a*x ≡ 1 (mod n), and x is the inverse.

     inverse(a, n):
         (g, x, _) = ext_gcd(a, n)
         if g != 1: FAIL - no inverse exists
         return x mod n

/* USED FOR:
     · computing the RSA private exponent d from e
       (chapter 12)
     · converting projective to affine coordinates on an
       elliptic curve (chapter 14)
     · the s value in ECDSA signing (chapter 15)
     · Montgomery arithmetic setup

/* THE SIDE-CHANNEL WARNING: the loop above runs a
   DATA-DEPENDENT NUMBER OF ITERATIONS. Used on a secret, it
   leaks. Real libraries use a constant-time binary GCD, or
   Fermat's little theorem (a^(p-2) mod p) when the modulus
   is prime. Never write your own for secret inputs.      */
```

Fermat, Euler, and why exponents wrap

```
/* --- FERMAT'S LITTLE THEOREM --- */
    For prime p and a not divisible by p:

        a^(p-1) ≡ 1  (mod p)

    Consequences:
        a^p     ≡ a       (mod p)
        a^(p-2) ≡ a^-1    (mod p)   /* a constant-time
                                       inverse! */

/* --- EULER'S TOTIENT ϕ(n) --- */
    ϕ(n) = how many integers in [1, n] are coprime to n

        ϕ(p)     = p - 1              /* p prime */
        ϕ(p*q)   = (p-1)(q-1)         /* p, q distinct
                                         primes */
        ϕ(p^k)   = p^k - p^(k-1)

/* --- EULER'S THEOREM: the generalisation --- */
        a^ϕ(n) ≡ 1  (mod n)   when gcd(a, n) = 1

/* THIS IS EXACTLY WHY RSA WORKS.

   Choose e and d with  e*d ≡ 1 (mod ϕ(n)),
   so  e*d = 1 + k*ϕ(n)  for some k.

   Then:
        (m^e)^d = m^(e*d) = m^(1 + k*ϕ(n))
                = m * (m^ϕ(n))^k
                ≡ m * 1^k
                ≡ m   (mod n)

   Encryption and decryption are inverse operations because
   the exponents wrap modulo ϕ(n). That is the whole of RSA's
   correctness argument.

/* --- CARMICHAEL'S λ(n) --- */
    The SMALLEST exponent that works:
        λ(p*q) = lcm(p-1, q-1)
    It divides ϕ(n), so d computed mod λ(n) is smaller and
    decryption is faster. Modern RSA key generation uses λ.

/* --- THE CHINESE REMAINDER THEOREM --- */
    Knowing x mod p and x mod q, with p, q coprime, uniquely
    determines x mod (p*q).

    RSA-CRT makes private-key operations ~4x FASTER:
        m_p = c^(d mod p-1) mod p
        m_q = c^(d mod q-1) mod q
        m   = recombine(m_p, m_q)

    Two exponentiations on half-size numbers beat one on the
    full size, because modular exponentiation is roughly
    cubic in the bit length.

    AND THE FAMOUS DANGER: if a FAULT corrupts exactly one of
    m_p or m_q, the attacker computes
        gcd(m^e - c, n)
    and RECOVERS A PRIME FACTOR from a single faulty
    signature. This is the Bellcore attack. Real
```

```
   implementations VERIFY the signature before releasing it,
   which is why you sometimes see a public-key operation
   inside a signing routine.                              */
```

TWO HARD PROBLEMS HOLD UP EVERYTHING

```
FACTORING:  given n = p*q, find p and q.
            -> RSA (chapter 12)

DISCRETE LOG: given g and g^x mod p, find x.
            -> Diffie-Hellman (13), DSA, ElGamal
            and the same problem on an elliptic
            curve group -> ECC (14), ECDSA, Ed25519

Neither is PROVEN hard. Both have resisted centuries and
decades respectively of effort. Both FALL COMPLETELY to a
sufficiently large quantum computer (chapter 20).
```

Groups, generators and orders

```
/* A GROUP is a set with an operation that is:
     closed, associative, has an identity, and has inverses.

   For cryptography, always FINITE and usually ABELIAN
   (commutative).

/* --- THE MULTIPLICATIVE GROUP MOD p --- */
    Z_p* = {1, 2, ..., p-1} under multiplication mod p
    ORDER (size) = p - 1

    A GENERATOR g produces every element by repeated
    multiplication:
        g^1, g^2, ..., g^(p-1) = all of Z_p*
    Such a g is also called a PRIMITIVE ROOT.

    Example, p = 7:  3^1=3, 3^2=2, 3^3=6, 3^4=4, 3^5=5,
                     3^6=1
    3 generates all six non-zero elements, so 3 is a
    generator mod 7.

/* --- THE ORDER OF AN ELEMENT --- */
    The smallest k with g^k = 1. LAGRANGE'S THEOREM says it
    always divides the group order.

/* WHY THIS MATTERS IN PRACTICE:

   1. SAFE PRIMES. For Diffie-Hellman, choose p = 2q + 1
      with q also prime. Then the only subgroup orders are
      1, 2, q and 2q. An attacker cannot trap you in a small
      subgroup.

   2. SMALL-SUBGROUP CONFINEMENT ATTACKS. If p-1 has many
      small factors and you accept an arbitrary peer key, the
      attacker sends an element of small order. Your shared
      secret then lies in a tiny set, and they learn your
      private exponent modulo that small order. Repeat with
      several small factors, apply CRT, and they recover the
      key.

      THE DEFENCE: use a safe prime, VALIDATE the peer's
      public key (1 < y < p-1 and y^q ≡ 1), or use a curve
      designed so the check is unnecessary - X25519 clamps
      and has a cofactor of 8 (chapter 14).

   3. THE DISCRETE LOG PROBLEM. Given g, p and g^x mod p,
      find x. Best classical algorithms:
        · baby-step giant-step / Pollard rho: O(sqrt(order))
          -> so the SUBGROUP ORDER must be at least 2^256 for
             128-bit security
        · index calculus / number field sieve: SUBEXPONENTIAL
          in p, and this is why finite-field DH needs a
          3072-bit p for 128-bit security while an elliptic
          curve needs only 256 bits - index calculus does not
          apply to elliptic curve groups.              */
```

Generating primes

```
/* RSA and finite-field DH need large random primes.
   Deterministic primality proving is slow; probabilistic
   testing is what everyone uses.                          */

/* --- MILLER-RABIN --- */
    Write n - 1 = 2^s * d with d odd.
    Pick a random base a.
        compute a^d mod n
        if it is 1 or n-1: n MIGHT be prime
        else square up to s-1 times looking for n-1
        if never found: n is DEFINITELY COMPOSITE

    Each round has at most a 1/4 chance of being fooled, so
    k rounds give an error probability below 4^-k. For random
    candidates the true error rate is far lower; 40-64 rounds
    is standard, and FIPS 186-5 tabulates the requirement by
    key size.

/* --- THE GENERATION LOOP --- */
    do {
        p = random_odd_number(bits);
        p |= (1 << (bits-1));      /* force the top bit, so
                                      the modulus has the
                                      full length */
        p |= 1;                     /* force odd */
    } while (divisible_by_small_prime(p) ||
             !miller_rabin(p, rounds));

    /* the small-prime sieve first: trial division by the
       primes below ~2000 rejects ~90% of candidates for
       almost no cost, and Miller-Rabin is expensive */

/* --- WHAT GOES WRONG, and it has gone wrong at scale --- */

   1. A WEAK RNG. In 2012 researchers found that a
      meaningful fraction of TLS and SSH keys on the public
      internet shared a prime factor with another key -
      because embedded devices generated keys at first boot
      with almost no entropy (chapter 02). Computing
      gcd(n1, n2) over the whole set factored them all.
      THE FIX: never generate a key before the entropy pool
      is ready.

   2. THE PRIMES TOO CLOSE TOGETHER. If |p - q| is small,
      FERMAT FACTORISATION finds them immediately. Enforce a
      minimum difference.

   3. p-1 OR p+1 SMOOTH (having only small factors). Pollard
      p-1 and Williams p+1 then factor n cheaply. "Strong
      primes" avoid this; with random 1024-bit primes the
      probability is negligible, so modern standards no
      longer require the check.

   4. REUSED PRIMES ACROSS KEYS - same failure as (1), and
      the same gcd attack.

/* AND THE ADVICE: DO NOT IMPLEMENT KEY GENERATION. Use the
   library's, seeded from a real entropy source, and check
   that it is seeded before you call it.                   */
```

How it shows up

Symptom	Cause
Two devices' keys share a factor	Key generated before the entropy pool was seeded
A single faulty signature reveals a prime	RSA-CRT without verify-after-sign — the Bellcore attack
Private exponent recovered over many handshakes	Small-subgroup confinement — no key validation, unsafe prime
Modular inverse returns garbage	`gcd(a, n) ≠ 1`, so no inverse exists
Key operation timing correlates with the key	Data-dependent GCD or exponentiation loop
Modulus is shorter than requested	Top bit not forced during prime generation
n factored instantly	p and q too close — Fermat factorisation
Key generation takes minutes on an MCU	No small-prime sieve before Miller–Rabin
3072-bit DH needed where 256-bit ECC suffices	Index calculus applies to finite fields, not curves

Check yourself

- ✓ Explain why `Z_p` is a field and `Z_n` for composite `n` is not.
- ✓ Use extended Euclid to find a modular inverse, and say when none exists.
- ✓ Derive RSA correctness from Euler's theorem.
- ✓ Explain what CRT buys RSA and what fault attack it opens.
- ✓ Define a generator and the order of an element, and state Lagrange's theorem.
- ✓ Explain a small-subgroup confinement attack and three defences.
- ✓ Say why finite-field DH needs 3072 bits where a curve needs 256.
- ✓ Describe Miller–Rabin and why a small-prime sieve comes first.
- ✓ Explain the 2012 shared-factor result and what caused it.
- ✓ Name the two hard problems and which primitives rest on each.

RSA

The first practical public-key system, still everywhere in firmware signing and PKI, and the one whose textbook description is dangerously incomplete. The padding is not a detail — it is most of the security.

The core operation

```
KEY GENERATION
  1. pick two large random primes p, q  (1024 bits each
     for a 2048-bit key)
  2. n = p * q                    the MODULUS, public
  3. λ(n) = lcm(p-1, q-1)
  4. e = 65537                    the PUBLIC EXPONENT
  5. d = e^-1 mod λ(n)            the PRIVATE EXPONENT

  PUBLIC KEY  = (n, e)
  PRIVATE KEY = (n, d)  plus p, q and the CRT values
  AND p AND q MUST BE DESTROYED or protected exactly as
  hard as d - either one factors n instantly.

THE OPERATIONS
  "encrypt" / verify:   c = m^e mod n
  "decrypt" / sign:     m = c^d mod n

  They are inverses because e*d ≡ 1 (mod λ(n)) - the
  derivation is in chapter 11.

WHY e = 65537 = 2^16 + 1
  · only two set bits, so verification is 17 squarings and
    one multiply - very fast, which matters because
    verification happens on every boot
  · large enough to avoid the small-exponent attacks that
    killed e = 3
  · TINY e MAKES VERIFICATION FAST AND SIGNING SLOW, which
    is the right trade: a device verifies constantly and
    signs never.

THE ASYMMETRY IN COST
  verify (e=65537)    ~0.1 ms      2048-bit
  sign   (d, w/ CRT)  ~2 ms
  A 4096-bit key is roughly 6-8x slower to sign with, and
  ~3x slower to verify.
```

Why textbook RSA is broken

```
/* "Just compute m^e mod n" fails in at least five distinct
   ways. Every one of these has broken a real system.     */

/* 1. IT IS DETERMINISTIC.
      Same message -> same ciphertext. An attacker who
      suspects the plaintext just encrypts the guess and
      compares. For a small message space - a command byte,
      a PIN, a yes/no - this breaks it completely.        */

/* 2. SMALL MESSAGES DO NOT WRAP.
      With e = 3 and a short m, m^3 < n, so no modular
      reduction happens. The attacker takes an ORDINARY CUBE
      ROOT over the integers and recovers m. No key needed. */

/* 3. IT IS MULTIPLICATIVELY HOMOMORPHIC.
          E(m1) * E(m2) = (m1*m2)^e = E(m1 * m2)  mod n

      So an attacker can BLIND a ciphertext: send c * r^e to
      a decryption oracle, get back m * r, divide by r,
      recover m. This is a total break of any system that
      decrypts attacker-supplied ciphertexts.

      The same property lets an attacker forge signatures:
      given signatures on m1 and m2, they have one on
      m1 * m2.                                            */

/* 4. NO STRUCTURE MEANS NO INTEGRITY.
      Any n-bit value is a "valid" ciphertext, decrypting to
      garbage the receiver cannot distinguish from a real
      message. Padding provides the redundancy that makes
      forgery detectable.                                 */

/* 5. RELATED MESSAGES LEAK.
      Håstad's attack: the same m encrypted to three
      recipients with e = 3 is recoverable by CRT plus a cube
      root. Franklin-Reiter: two messages with a known linear
      relation are both recoverable.                      */

/* THE RULE THAT FOLLOWS:

     NEVER CALL A RAW MODEXP ON A MESSAGE.
     ALWAYS USE A PADDING SCHEME - OAEP or PSS.

   And when you see mbedtls_rsa_public()/mbedtls_rsa_private()
   in code, that is the RAW primitive. The functions you want
   are mbedtls_rsa_rsaes_oaep_encrypt() and
   mbedtls_rsa_rsassa_pss_sign().                      */
```

OAEP: encryption padding

```
/* PKCS#1 v2, RFC 8017. Optimal Asymmetric Encryption
   Padding.                                              */

    EM = 0x00 ‖ maskedSeed ‖ maskedDB

    DB         = lHash ‖ PS(zeros) ‖ 0x01 ‖ message
    seed       = random, hLen bytes
    dbMask     = MGF1(seed, k - hLen - 1)
    maskedDB   = DB XOR dbMask
    seedMask   = MGF1(maskedDB, hLen)
    maskedSeed = seed XOR seedMask

    then  c = EM^e mod n

/* WHAT EACH PART DOES:
     the RANDOM SEED makes encryption probabilistic, killing
       problem (1)
     the two-way MASKING is a Feistel structure: every
       ciphertext bit depends on every plaintext bit
     lHash and the 0x01 SEPARATOR give the redundancy that
       makes an invalid ciphertext detectable, killing (4)
     the FULL-WIDTH ENCODED MESSAGE means m is always close
       to n, killing (2)

/* CAPACITY: k - 2*hLen - 2 bytes.
     2048-bit key, SHA-256:  256 - 64 - 2 = 190 bytes.

   SO YOU CANNOT ENCRYPT A LARGE MESSAGE WITH RSA. Nobody
   does. The pattern is HYBRID ENCRYPTION:

       k_session = random 32 bytes
       c1 = RSA-OAEP(pubkey, k_session)
       c2 = AES-GCM(k_session, plaintext)     /* chapter 09 */
       send c1 ‖ c2

/* --- PKCS#1 v1.5 ENCRYPTION PADDING: DO NOT USE --- */
    EM = 0x00 ‖ 0x02 ‖ random_nonzero_padding ‖ 0x00 ‖ m

    BLEICHENBACHER'S ATTACK (1998): if the receiver reveals -
    by an error message, a timing difference, or a connection
    reset - whether the 0x00 0x02 prefix was correct, the
    attacker decrypts any ciphertext with about a million
    adaptive queries. It has been rediscovered repeatedly:
    ROBOT (2017) found it live in load balancers from several
    major vendors, nineteen years later.

    THE ONLY SAFE HANDLING is to make the failure path
    completely indistinguishable - which is so hard to get
    right that TLS 1.3 REMOVED RSA KEY TRANSPORT ENTIRELY.
    Use OAEP, or better, use ECDH (chapter 13).          */
```

PSS: signature padding

```
/* RSASSA-PSS, and this is the more important half for
   embedded work, because firmware verification is where RSA
   still lives.                                            */

    mHash  = H(message)
    salt   = random, sLen bytes
    M'     = 0x00 * 8 ‖ mHash ‖ salt
    H2     = H(M')
    DB     = PS(zeros) ‖ 0x01 ‖ salt
    EM     = maskedDB ‖ H2 ‖ 0xBC

    signature = EM^d mod n

/* THE RANDOM SALT makes signatures PROBABILISTIC: signing
   the same message twice gives different signatures. That
   is not a bug - it gives PSS a tight security proof that
   v1.5 does not have.

/* --- PKCS#1 v1.5 SIGNATURES: legacy but everywhere --- */
    EM = 0x00 ‖ 0x01 ‖ 0xFF...0xFF ‖ 0x00 ‖ DigestInfo ‖ H(m)

    Deterministic. NOT KNOWN TO BE BROKEN when implemented
    correctly, and mandated by so many existing formats and
    boot ROMs that it is not going away. USE IT WHEN A FORMAT
    REQUIRES IT; use PSS for anything new.

/* AND THE IMPLEMENTATION BUG THAT KEEPS RECURRING -
   BLEICHENBACHER'S SIGNATURE FORGERY, "BERserk":

   A LAZY VERIFIER parses the structure left to right,
   finds the hash, compares it, and IGNORES TRAILING BYTES.
   With e = 3, an attacker can construct a value whose cube
   root has the right prefix and arbitrary garbage after -
   and forge a signature WITH NO PRIVATE KEY.

   THE CORRECT VERIFICATION:
     · RECONSTRUCT the full expected EM from the hash
     · compare the ENTIRE block, byte for byte, in constant
       time
     · never parse-and-extract

   NSS, GnuTLS, Firefox, Chrome and several TLS libraries
   have all shipped this bug. If you are writing a boot ROM
   verifier, this is the bug to look for.               */
```

VERIFY A FIRMWARE SIGNATURE LIKE THIS

```
1. hash the image with SHA-256
2. RSA-verify with PSS (or v1.5 if the format demands)
3. compare the FULL reconstructed encoding
4. check the key against a hash burned in OTP
5. check the version against an anti-rollback counter
6. only then jump to the image
```

Steps 4 and 5 are not part of RSA and are just as important — see the secure boot chapter.

Key sizes and the alternatives

RSA size	Security	Equivalent ECC	Status
1024-bit	~80-bit	P-160	**Broken.** Factorable by a well-funded attacker
2048-bit	~112-bit	P-224	Acceptable to about 2030
3072-bit	~128-bit	P-256	The current recommendation
4096-bit	~140-bit	P-313	Common for long-lived roots
15360-bit	~256-bit	P-521	Impractical — use ECC

```
/* THE SIZE CURVE IS BRUTAL: doubling RSA security multiplies
   the key size by roughly five, because the number field
   sieve is subexponential. ECC scales linearly - 256 bits
   for 128-bit security (chapter 14).

/* SO WHY IS RSA STILL EVERYWHERE IN EMBEDDED?

     · BOOT ROMS ARE MASK-PROGRAMMED and were fixed years
       ago. If the ROM verifies RSA-2048 PKCS#1 v1.5, that
       is what your firmware is signed with, permanently.
     · VERIFICATION IS FAST with e = 65537 - actually faster
       than ECDSA verification, which matters at boot.
     · UNIVERSAL TOOLING support.

   WHERE ECC WINS:
     · signature size: 64 bytes vs 256-512
     · key size: 32 bytes vs 256-512, which matters when the
       public key lives in OTP fuses
     · SIGNING speed
     · key GENERATION: microseconds vs seconds

   AND FOR NEW DESIGNS: use Ed25519 or ECDSA P-256, and plan
   for a post-quantum signature (chapter 20) if the device
   will live past 2035.                                  */
```

Implementation hazards

```
/* --- 1. TIMING ATTACKS ON THE PRIVATE OPERATION --- */
    A naive square-and-multiply branches on each bit of d:

        for each bit of d:
            square
            if bit: multiply          /* <-- LEAKS d */

    Kocher (1996) recovered private keys this way. Brumley
    and Boneh (2003) did it REMOTELY over a network against
    OpenSSL.

    DEFENCES: a Montgomery ladder (constant operation
    sequence), and BLINDING:
        c' = c * r^e mod n
        m' = c'^d mod n
        m  = m' * r^-1 mod n
    The exponentiation now runs on a randomised value, so its
    timing carries no information about c. Every serious
    library blinds by default; check that yours has it
    enabled.

/* --- 2. THE CRT FAULT ATTACK --- */
    One corrupted half of a CRT signature reveals a prime via
    gcd(s^e - m, n) (chapter 11).

    DEFENCE: VERIFY EVERY SIGNATURE BEFORE RELEASING IT.
        sign(); if (verify() != OK) { wipe(); abort(); }
    Costs one cheap public operation. Non-negotiable on
    anything physically accessible.

/* --- 3. LEAKING THE PRIMES --- */
    p and q are as sensitive as d. Zero them, keep them out
    of swap and core dumps, and never log a key structure.

/* --- 4. SMALL PUBLIC EXPONENTS --- */
    e = 3 is legal and fast and has a long history of
    breaking things. Use 65537. If you must accept e = 3,
    padding must be flawless.

/* --- 5. NOT VALIDATING A RECEIVED PUBLIC KEY --- */
    Before using someone's RSA key:
        · n has the expected bit length
        · n is ODD (an even n is trivially factorable)
        · e is odd and 3 <= e < n
        · e is 65537 if your policy says so
    A hostile "public key" with a smooth n turns your
    encryption into a no-op.

/* --- 6. THE CODE PATTERN, mbedTLS --- */
    mbedtls_rsa_context rsa;
    mbedtls_rsa_init(&rsa);
    mbedtls_rsa_set_padding(&rsa, MBEDTLS_RSA_PKCS_V21,
                            MBEDTLS_MD_SHA256);  /* PSS/OAEP */

    ret = mbedtls_rsa_rsassa_pss_verify(
              &rsa, MBEDTLS_MD_SHA256, 32, hash, sig);
    if (ret != 0) {
            /* INVALID. No detail in the error path. */
            return -1;
    }
```

```
    mbedtls_rsa_free(&rsa);

/* NOTE THE ARGUMENT ORDER AND THE PADDING MODE. Calling
   pkcs1_v15_verify on a PSS signature returns an error;
   calling the RAW primitive returns success on garbage. */
```

How it shows up

Symptom	Cause
Same plaintext gives the same ciphertext	No padding, or v1.5 with a broken RNG
Short message recovered without a key	Small `e`, no padding — an integer cube root
Signature forged with no private key	Lazy v1.5 parsing with `e = 3` — BERserk
Ciphertext decrypted with ~10^6 queries	Bleichenbacher oracle in PKCS#1 v1.5 decryption
Private key extracted over the network	Unblinded exponentiation timing
A prime recovered from one signature	CRT fault, no verify-after-sign
"Message too long" at 200 bytes	OAEP capacity — use hybrid encryption
Verification succeeds on random data	The raw primitive called instead of a padded verify
Signing takes 400 ms	CRT not enabled, or a 4096-bit key on a slow core
Interop failure with a valid signature	PSS vs v1.5 mismatch, or a different salt length

Check yourself

- ✓ Write out key generation and say why `p` and `q` must be destroyed.
- ✓ Explain why `e = 65537` and what the cost asymmetry is good for.
- ✓ List five ways textbook RSA breaks, with a concrete attack for each.
- ✓ Explain what each component of OAEP defends against.
- ✓ Compute OAEP capacity for a 2048-bit key and explain hybrid encryption.
- ✓ Describe the Bleichenbacher oracle and why TLS 1.3 dropped RSA key transport.
- ✓ Explain BERserk and write the correct v1.5 verification procedure.
- ✓ Explain blinding and why it defeats timing attacks.
- ✓ Explain the CRT fault attack and the one-line defence.
- ✓ List the checks to run on a received public key.
- ✓ Say why RSA persists in embedded boot ROMs and where ECC wins.

Diffie–Hellman and key exchange

Two parties who have never met agree on a shared secret over a channel an attacker is reading. The most surprising result in cryptography, and the foundation of every modern secure channel.

The basic exchange

```
PUBLIC PARAMETERS: a large prime p, a generator g.
Both are known to everyone, including the attacker.

  ALICE                                  BOB
  a = random secret                      b = random secret
  A = g^a mod p        ---- A ---->
                       <---- B ----      B = g^b mod p

  s = B^a mod p                          s = A^b mod p
    = (g^b)^a                              = (g^a)^b
    = g^(a*b) mod p    ===== SAME =====    = g^(a*b) mod p

THE EAVESDROPPER SEES p, g, A and B.
To compute s they must find a from g^a - the DISCRETE
LOGARITHM PROBLEM (chapter 11). No efficient classical
algorithm is known.

THE SHARED SECRET IS NOT A KEY YET. g^(a*b) mod p is a
structured group element, not uniform bits. RUN IT THROUGH
A KDF:

    k_enc = HKDF(s, salt, "protocol v1 encryption")
    k_mac = HKDF(s, salt, "protocol v1 mac")

Using the raw DH output as an AES key is a real and common
bug (chapter 10).

WHAT THIS BUYS AND WHAT IT DOES NOT:
  · a shared secret over a public channel        YES
  · secrecy against a PASSIVE eavesdropper       YES
  · FORWARD SECRECY, if a and b are ephemeral    YES
  · protection against an ACTIVE attacker        NO
  · authentication of who you are talking to     NO
  · a usable symmetric key without a KDF         NO
```

The man in the middle

```
/* UNAUTHENTICATED DH IS COMPLETELY BROKEN AGAINST AN ACTIVE
   ATTACKER, and this is not a subtle failure.            */

    ALICE          MALLORY          BOB
      A  ------->   (drops A)
                     M1  ------->
                     <-------  B    (drops B)
      <-------  M2

    Alice and Mallory share s1 = g^(a*m1).
    Mallory and Bob   share s2 = g^(m2*b).
    Mallory decrypts everything from Alice, reads it, and
    re-encrypts it to Bob. NEITHER SIDE SEES ANYTHING WRONG.

/* THE FIX IS ALWAYS AUTHENTICATION - proving that the public
   value you received belongs to the party you intended to
   talk to. The options:

   1. SIGN THE EPHEMERAL PUBLIC VALUES with a long-term key
      whose certificate chains to a trusted root. This is
      TLS's ECDHE + certificate (chapters 16, 17).

   2. STATIC-EPHEMERAL DH: one side's key is long-term and
      already known (e.g. burned into the device at
      manufacture), the other's is ephemeral.

   3. A PASSWORD-AUTHENTICATED KEY EXCHANGE (PAKE) - SPAKE2,
      OPAQUE, or the CPace family. Both sides prove knowledge
      of a shared low-entropy secret WITHOUT it being
      brute-forceable offline. This is how a device pairs
      with a phone using a 6-digit code.

   4. OUT-OF-BAND VERIFICATION: derive a short fingerprint
      from the transcript and have humans compare it. The
      "safety number" in a messaging app, or the SSH host key
      fingerprint you were supposed to check.

   5. TOFU - trust on first use. Remember the peer's key and
      alarm if it ever changes. SSH's known_hosts. Weak on
      the first connection, strong afterwards.

/* FOR EMBEDDED DEVICES the usual answer is a
   FACTORY-PROVISIONED IDENTITY: a device key pair generated
   at manufacture, its private half in a secure element, and
   a certificate signed by the vendor CA. The device then
   authenticates every exchange with it (chapter 18).     */
```

FORWARD SECRECY

Use a *fresh, ephemeral* `a` and `b` for every session and destroy them afterwards. An attacker who records all the traffic today and steals the device's long-term key in five years still cannot decrypt those recordings — the ephemeral secrets are gone. This is the "E" in ECDHE, and it is the single most valuable property a protocol design can have. A protocol that encrypts a session key *to* a long-term key (RSA key transport, chapter 12) has no forward secrecy at all, which is why TLS 1.3 removed it.

ECDH and X25519

```
/* The same protocol, in an elliptic curve group instead of
   the integers mod p (chapter 14). Same maths, far smaller
   numbers.                                                  */

    private:  a random scalar d
    public:   the point  Q = d * G
    shared:   d_A * Q_B = d_A * d_B * G = d_B * Q_A

/* SIZES, and this is the whole reason ECC won:
     finite-field DH, 128-bit security:  3072-bit p
                                         -> 384-byte messages
     ECDH P-256, 128-bit security:       -> 32-64 bytes
     X25519:                             -> 32 bytes exactly

/* --- X25519: the one to use --- */

    crypto_generichash_update(&h, q, 32);
    crypto_generichash_update(&h, client_pk, 32);
    crypto_generichash_update(&h, server_pk, 32);
    crypto_generichash_final(&h, session_key, 32);

/* HASHING BOTH PUBLIC KEYS ALONGSIDE THE SHARED SECRET binds
   the key to the specific exchange. Without it, some
   protocols admit key-reuse and unknown-key-share attacks.

/* WHY X25519 IS THE DEFAULT RECOMMENDATION:
     · every 32-byte string is a valid public key - no point
       validation code to get wrong
     · the Montgomery ladder is naturally constant time
     · clamping removes the small-subgroup problem
     · fast: ~100 microseconds on a Cortex-M4
     · no patents, no NIST-curve provenance questions
     · one function, no parameter choices to get wrong
```

```
   USE P-256 INSTEAD ONLY WHEN a standard, a certificate
   profile, or a hardware accelerator requires it.       */
```

Where key exchange goes wrong

```
/* --- 1. NO AUTHENTICATION --- */
    Covered above. The most common failure in home-grown
    protocols, and it is total.

/* --- 2. NOT VALIDATING THE PEER'S PUBLIC VALUE --- */
    Finite-field DH: reject y <= 1, y >= p-1, and check
    y^q ≡ 1 mod p for the subgroup order q. Otherwise:
    small-subgroup confinement (chapter 11).

    ECDH on a NIST curve: verify the point is ON THE CURVE.
    An INVALID CURVE ATTACK sends a point on a different,
    weaker curve; the scalar multiplication still "works" and
    leaks the private key a few bits at a time. This broke
    several TLS libraries and a Bluetooth implementation.

    X25519: the output being all zeros means a small-order
    input. Check it, or use a library that does.

/* --- 3. REUSING EPHEMERAL KEYS --- */
    Caching a "temporary" key across sessions - usually done
    for performance on a slow MCU - DESTROYS FORWARD SECRECY
    and enables key-recovery attacks against unvalidated
    implementations. If you must cache, cache for seconds,
    not for the device's lifetime.

/* --- 4. USING THE RAW SHARED SECRET AS A KEY --- */
    Always through a KDF, always with a context string.

/* --- 5. NOT BINDING THE TRANSCRIPT --- */
    Authenticate the ENTIRE HANDSHAKE - every message, in
    order, including the negotiated parameters. Otherwise a
    DOWNGRADE ATTACK works: the attacker strips the strong
    ciphersuites from the client's offer and both sides
    happily negotiate the weak one, each believing the other
    only supported it. LOGJAM downgraded TLS to 512-bit
    export DH this way; FREAK did the same to export RSA.

/* --- 6. WEAK OR SHARED PARAMETERS --- */
    LOGJAM again: a huge fraction of the internet used the
    SAME 1024-bit DH group. Precomputation against one group
    - expensive but feasible for a state actor - then breaks
    every connection using it. Use named, modern groups
    (RFC 7919) or, better, use a curve.

/* --- 7. TIMING LEAKS IN THE SCALAR MULTIPLY --- */
    Chapter 19. Use a constant-time implementation; X25519's
    ladder is one by construction.

/* --- 8. NO REPLAY PROTECTION ON 0-RTT DATA --- */
    TLS 1.3's early data can be replayed by an attacker. Only
    send idempotent requests in it.                       */
```

Real handshake patterns

```
/* --- TLS 1.3, simplified (chapter 17) --- */
    ClientHello:  key_share = ephemeral X25519 or P-256 pk
    ServerHello:  key_share = server's ephemeral pk
      -> both derive the handshake secret immediately, so
         the REST OF THE HANDSHAKE IS ENCRYPTED
    Certificate + CertificateVerify: the server SIGNS the
      transcript, authenticating the exchange
    Finished (both sides): a MAC over the whole transcript,
      closing the downgrade hole
    One round trip. Forward secret. Authenticated.

/* --- NOISE PROTOCOL FRAMEWORK --- */
    A construction kit for DH handshakes with a formal naming
    scheme. Used by WireGuard, WhatsApp, Lightning.

      Noise_NN   neither party authenticated
      Noise_NK   the responder's static key is known to the
                 initiator     <-- typical for a device
                                   talking to a known server
      Noise_XX   both authenticate during the handshake
      Noise_IK   initiator knows the responder's static key
                 and sends its own immediately

    EACH PATTERN IS A SHORT SEQUENCE OF DH OPERATIONS, mixed
    into a running hash. WireGuard's whole handshake is about
    150 lines. FOR AN EMBEDDED PROTOCOL, PICKING A NOISE
    PATTERN IS ALMOST ALWAYS BETTER THAN DESIGNING ONE.

/* --- THE DEVICE PROVISIONING PATTERN --- */
    factory:  generate a device key pair inside the secure
              element; the private half NEVER LEAVES
              (chapter 18)
              vendor CA signs the public half -> device cert
    field:    device does ECDHE with the server
              device signs the transcript with its device key
              server validates the cert chain to the vendor
              root and checks the device is not revoked
              server signs its side; device validates against
              a root PINNED IN FIRMWARE

    NOTE THE PINNING. A device that trusts the general
    public CA list can be attacked by any compromised CA in
    the world. Pin your own root (chapter 16).          */
```

How it shows up

Symptom	Cause
Traffic silently readable by a proxy	Unauthenticated DH — man in the middle
Old recorded sessions decrypted after a key theft	No forward secrecy — static keys or RSA key transport
Private key recovered over many handshakes	Invalid-curve or small-subgroup attack — no peer key validation
Connection negotiates 512-bit DH	Downgrade — transcript not authenticated (Logjam/FREAK)
Many devices share a DH group and all fall together	A common, precomputable 1024-bit group
Shared secret works but the AEAD fails	Raw DH output used as a key without a KDF, or mismatched context strings

Symptom	Cause
Same session key on two connections	Cached "ephemeral" key
X25519 returns all zeros	Small-order peer point — reject
Repeated requests executed twice	0-RTT early data replay
Device trusts a hostile certificate	Public CA list instead of a pinned vendor root

Check yourself

- ✓ Walk through basic Diffie–Hellman and say what the eavesdropper must solve.
- ✓ Explain why the raw shared secret is not a key.
- ✓ Draw the man-in-the-middle attack and list five ways to authenticate the exchange.
- ✓ Define forward secrecy and explain why RSA key transport lacks it.
- ✓ Compare finite-field DH and X25519 sizes at 128-bit security.
- ✓ List five properties that make X25519 hard to misuse.
- ✓ Describe an invalid-curve attack and the validation that stops it.
- ✓ Explain transcript binding and how Logjam exploited its absence.
- ✓ Name the Noise patterns and pick one for a device talking to a known server.
- ✓ Describe the factory-provisioning pattern and why the root must be pinned.

Elliptic curve cryptography

The same discrete-logarithm idea in a group where the best known attacks are much worse, so the keys are eight to twelve times smaller. That size difference is what makes public-key cryptography practical on a microcontroller.

The group

```
A SHORT WEIERSTRASS CURVE over the field F_p:

     y^2 = x^3 + a*x + b   (mod p)

The GROUP ELEMENTS are the (x, y) pairs satisfying it,
plus a POINT AT INFINITY O that acts as the identity.

POINT ADDITION, geometrically:
  · draw the line through P and Q
  · it meets the curve at a third point
  · REFLECT it in the x-axis -> that is P + Q

           |        .-'
           |  P  .-'      the chord through P and Q
           |  x-'         hits the curve at -(P+Q);
           | / \  Q       reflecting gives P+Q
      -----+------x-------------
           |       \
           |        x  P+Q

POINT DOUBLING (P + P) uses the TANGENT at P instead.

SCALAR MULTIPLICATION is repeated addition:
     k * P = P + P + ... + P     (k times)
done by DOUBLE-AND-ADD in O(log k) operations.

THE ELLIPTIC CURVE DISCRETE LOGARITHM PROBLEM (ECDLP):
     given P and Q = k*P, find k.

THE BEST KNOWN ATTACK is Pollard's rho, at O(sqrt(n))
where n is the group order. INDEX CALCULUS - the
subexponential algorithm that forces finite-field DH and
RSA to use thousands of bits - DOES NOT APPLY to elliptic
curve groups.

HENCE:
     256-bit curve  ->  ~128-bit security
     3072-bit RSA   ->  ~128-bit security
     Same strength. Twelve times the key.
```

The arithmetic, in practice

```
/* THE AFFINE FORMULAS, for reference: */

    P + Q, with P != Q:
        s  = (y2 - y1) / (x2 - x1)   mod p
        x3 = s^2 - x1 - x2           mod p
        y3 = s*(x1 - x3) - y1        mod p

    P + P (doubling):
        s  = (3*x1^2 + a) / (2*y1)   mod p
        x3 = s^2 - 2*x1              mod p
        y3 = s*(x1 - x3) - y1        mod p

/* THE DIVISIONS ARE MODULAR INVERSES (chapter 11), and they
   are EXPENSIVE - roughly 100x a multiplication.

/* SO REAL IMPLEMENTATIONS USE PROJECTIVE COORDINATES:
   represent a point as (X, Y, Z) with x = X/Z, y = Y/Z (or
   Jacobian: x = X/Z^2, y = Y/Z^3). Addition and doubling
   then need NO INVERSIONS - one inversion at the very end
   converts back to affine. This is not an optimisation
   detail you can skip; it is the difference between a
   scalar multiply taking 1 ms and 100 ms.

/* --- THE SCALAR MULTIPLY, AND ITS SIDE CHANNEL --- */

    /* NAIVE - LEAKS EVERY BIT OF THE SCALAR */
    R = O;
    for (i = top_bit; i >= 0; i--) {
            R = double(R);
            if (bit_i_of_k)                 /* <-- BRANCH */
                    R = add(R, P);          /* <-- TIMING */
    }
    /* An attacker measuring power or time sees the pattern
       of doublings and additions, and reads k directly. This
       is textbook SPA - simple power analysis - and it works
       on an oscilloscope in an afternoon (chapter 19). */

    /* THE MONTGOMERY LADDER - constant operation sequence */
    R0 = O; R1 = P;
    for (i = top_bit; i >= 0; i--) {
            b  = bit_i_of_k;
            /* CONSTANT-TIME CONDITIONAL SWAP - no branch */
            cswap(b, &R0, &R1);
            R1 = add(R0, R1);
            R0 = double(R0);
            cswap(b, &R0, &R1);
    }
    return R0;
    /* EVERY ITERATION DOES EXACTLY ONE ADD AND ONE DOUBLE,
       whatever the bit. The cswap is a masked exchange:
           mask = -(uint64_t)b;
           t = mask & (R0[j] ^ R1[j]);
           R0[j] ^= t;  R1[j] ^= t;
       No branch, no memory-access difference.            */

/* AND EVEN THAT IS NOT ENOUGH AGAINST DIFFERENTIAL POWER
   ANALYSIS. Add SCALAR BLINDING (use k + r*n for random r;
   it computes the same point since n*P = O) and PROJECTIVE
   COORDINATE RANDOMISATION.                              */
```

The curves that matter

Curve	Bits	Form	Notes
Curve25519 / X25519	255	Montgomery	Key exchange. **The default choice.** Every 32-byte string is a valid key
Ed25519	255	Twisted Edwards	Signatures. Same curve, different form. Deterministic
P-256 (secp256r1)	256	Weierstrass	NIST/FIPS. Ubiquitous in TLS certificates and hardware
P-384, P-521	384/521	Weierstrass	Higher security levels; required by some suites
secp256k1	256	Weierstrass	Bitcoin and Ethereum. Koblitz curve, efficient endomorphism
Curve448 / Ed448	448	Edwards	~224-bit security, for a conservative margin
Brainpool	256+	Weierstrass	Verifiably pseudorandom parameters. Used in EU eID

```
/* WHY THE CURVE FORM MATTERS:

   MONTGOMERY (Curve25519): By^2 = x^3 + Ax^2 + x
     · x-coordinate-only ladder, very fast and naturally
       constant time
     · no point validation needed for X25519
     · perfect for KEY EXCHANGE, awkward for signatures

   TWISTED EDWARDS (Ed25519): -x^2 + y^2 = 1 + d*x^2*y^2
     · a COMPLETE addition formula - ONE formula works for
       every pair of points, including P+P and P+O
     · no special cases means no exceptional-case branches,
       and no exceptional-case bugs
     · perfect for SIGNATURES

   SHORT WEIERSTRASS (P-256): the classical form
     · addition and doubling are DIFFERENT formulas, and
       P + (-P) = O is a special case
     · so implementations have branches, and those branches
       are where the bugs and leaks live
     · but it is what FIPS specifies and what most hardware
       accelerators implement

/* THE NIST-CURVE CONTROVERSY, briefly: the P-curve
   parameters were generated by hashing unexplained seed
   values. Nobody has demonstrated a weakness, but nobody can
   explain the seeds either. Curve25519 and Brainpool were
   both designed with FULLY EXPLAINED, "NOTHING UP MY SLEEVE"
   parameter derivation as an explicit goal.

   THE PRACTICAL POSITION: P-256 is fine and you will use it
   whenever a certificate or an accelerator demands it.
   Choose 25519 when you are free to.                    */
```

WHAT TO PICK

```
key exchange, free choice      -> X25519
signatures, free choice        -> Ed25519
TLS certificates, hardware,
  FIPS, or an existing PKI     -> P-256 (ECDSA/ECDH)
higher margin                  -> Ed448 or P-384
blockchain interop             -> secp256k1
```

Point encoding and validation

```
/* --- ENCODING, for Weierstrass curves (SEC1) --- */
    0x04 ‖ X ‖ Y        UNCOMPRESSED, 65 bytes for P-256
    0x02 ‖ X            COMPRESSED, y even     33 bytes
    0x03 ‖ X            COMPRESSED, y odd

    Compression works because y^2 = x^3 + ax + b has exactly
    two solutions for y; one bit says which. Recovering y
    costs a modular square root - a single exponentiation,
    typically ~1/50 of a scalar multiply. WORTH IT when the
    key lives in OTP fuses or travels over a constrained
    radio link.

/* --- X25519 AND Ed25519 --- */
    Always 32 bytes. X25519 sends the x-coordinate only.
    Ed25519 sends y with the sign of x in the top bit.
    No format byte, no options, no negotiation.

/* --- VALIDATION: MANDATORY FOR WEIERSTRASS CURVES --- */

    int validate_point(const ec_point *Q, const ec_group *g)
    {
        /* 1. NOT the point at infinity */
        if (is_infinity(Q)) return -1;

        /* 2. coordinates are in range [0, p-1] */
        if (cmp(Q->x, g->p) >= 0) return -1;
        if (cmp(Q->y, g->p) >= 0) return -1;

        /* 3. THE POINT IS ACTUALLY ON THE CURVE */
        if (!on_curve(Q, g)) return -1;

        /* 4. it is in the correct SUBGROUP:  n*Q == O
              (skippable when the cofactor is 1, as for the
              NIST prime curves) */
        if (!is_infinity(scalar_mul(g->n, Q))) return -1;

        return 0;
    }

/* SKIPPING STEP 3 IS THE INVALID CURVE ATTACK. The attacker
   sends a point that satisfies a DIFFERENT curve equation -
   one whose group has small order. Your scalar multiply
   ignores `b` entirely (look at the formulas above: b never
   appears), so it happily computes on the attacker's curve
   and the result reveals your private scalar modulo a small
   number. Repeat with several curves, apply CRT, and the
   full key falls in a few thousand queries.

   THIS HAS BROKEN: several TLS libraries, a Bluetooth
   pairing implementation (CVE-2018-5383, affecting
   essentially every major OS), and multiple hardware
   wallets.

/* AND THE TWIST ATTACK is the same idea against
   x-coordinate-only implementations. Curve25519 was designed
   to be TWIST-SECURE - the twist's order also has a large
   prime factor - so X25519 needs no validation at all. That
   is a deliberate design decision to remove a class of
```

```
   implementation bug, and it is why X25519 is the
   recommendation.                                          */
```

Using it

```
/* --- ECDH WITH P-256, mbedTLS --- */
    mbedtls_ecdh_context ctx;
    mbedtls_ecdh_init(&ctx);
    mbedtls_ecdh_setup(&ctx, MBEDTLS_ECP_DP_SECP256R1);

    /* our ephemeral key, and the public part to send */
    mbedtls_ecdh_make_public(&ctx, &olen, buf, sizeof buf,
                             mbedtls_ctr_drbg_random, &drbg);

    /* the peer's - THIS VALIDATES THE POINT internally,
       and returning non-zero here is a security event, not
       a parse error */
    if (mbedtls_ecdh_read_public(&ctx, peer, peer_len) != 0)
            return INVALID_PEER_KEY;

    uint8_t secret[32];
    mbedtls_ecdh_calc_secret(&ctx, &olen, secret,
                             sizeof secret,
                             mbedtls_ctr_drbg_random, &drbg);
    /* PASSING THE RNG HERE ENABLES BLINDING. Do not pass
       NULL to "save time" - that disables the countermeasure
       (chapter 19). */

    /* AND THEN, ALWAYS, A KDF (chapter 10): */
    mbedtls_hkdf(sha256, salt, salt_len, secret, olen,
                 (const uint8_t *)"myproto v1 session", 18,
                 session_key, 32);

    mbedtls_platform_zeroize(secret, sizeof secret);
    mbedtls_ecdh_free(&ctx);

/* --- X25519, libsodium: the whole thing --- */
    unsigned char my_sk[32], my_pk[32], shared[32];
    randombytes_buf(my_sk, 32);
    crypto_scalarmult_base(my_pk, my_sk);
    /* send my_pk ... receive their_pk ... */
    if (crypto_scalarmult(shared, my_sk, their_pk) != 0)
            return BAD_KEY;
    /* then hash, as in chapter 13 */

/* --- PERFORMANCE, Cortex-M4 at 100 MHz, rough --- */
    X25519 scalar multiply       ~ 4 M cycles   ( 40 ms)
    P-256 with a good library    ~ 8 M cycles   ( 80 ms)
    Ed25519 sign                 ~ 5 M cycles   ( 50 ms)
    Ed25519 verify               ~14 M cycles   (140 ms)
    RSA-2048 verify (e=65537)    ~ 3 M cycles   ( 30 ms)
    RSA-2048 sign with CRT       ~90 M cycles   (900 ms)

   THE SHAPE TO REMEMBER: RSA VERIFICATION IS THE FASTEST
   THING HERE, which is why boot ROMs use it. Everything
   else favours ECC by a wide margin, and key generation
   favours it by orders of magnitude.

   AND IF THE PART HAS A PKA/CRYPTOCELL ACCELERATOR, these
   numbers drop by 10-50x - check before you optimise
   software.                                                */
```

How it shows up

Symptom	Cause
Private key recovered in a few thousand handshakes	Invalid-curve attack — the on-curve check was skipped
Key read from a power trace	Branching double-and-add — use a Montgomery ladder
Key recovered despite constant-time code	DPA — needs scalar and coordinate blinding too
Scalar multiply takes 100 ms instead of 1 ms	Affine coordinates — a modular inversion per step
Peer key rejected as malformed	Compressed vs uncompressed encoding mismatch
ECDH result differs between the two sides	Different curve, or one side hashing the point and the other the x-coordinate
Works with X25519, fails with P-256	P-256 needs explicit point validation; X25519 does not
Blinding silently disabled	`NULL` RNG passed to the ECDH/ECDSA call
Certificate rejects the device key	Ed25519 where the PKI profile requires ECDSA P-256
Signature verification slower than RSA	Expected — RSA verify with `e=65537` is very cheap

Check yourself

- ✓ Describe the curve group, its operation and its identity element.
- ✓ State the ECDLP and explain why 256 bits matches RSA-3072.
- ✓ Explain why projective coordinates are used and what they avoid.
- ✓ Write the naive scalar multiply, say what it leaks, and write the ladder.
- ✓ Explain a constant-time conditional swap.
- ✓ Compare Montgomery, Edwards and Weierstrass forms and say what each is good for.
- ✓ Describe point compression and when it is worth the cost.
- ✓ Write the four point-validation checks and explain what skipping each allows.
- ✓ Explain the invalid-curve attack, including why `b` never appearing matters.
- ✓ Say what twist security is and why it removes a whole class of bug.
- ✓ Recall the rough cycle counts and explain why boot ROMs still use RSA.

Digital signatures

Anyone can verify; only the key holder can produce. This is what makes secure boot, firmware updates and certificates possible — and ECDSA is the primitive with the sharpest edge in all of applied cryptography.

Signatures versus MACs

```
SIGN(private_key, message)  -> signature
VERIFY(public_key, message, signature) -> true / false

                  MAC                  SIGNATURE
keys              one shared           key PAIR
who can verify    only key holders     ANYONE
who can produce   any key holder       only the private
                                       key holder
NON-REPUDIATION   NO                   YES
size              16-32 bytes          64-512 bytes
speed             microseconds         milliseconds
key distribution  hard (must be         easy (the public
                  secret)              key is public)

THE ASYMMETRY IS THE POINT. A device can ship with a
VENDOR PUBLIC KEY in read-only memory and verify every
firmware image the vendor ever signs - without the device
ever holding a secret that could be extracted to forge
one. That is impossible with a MAC.

THE SECURITY GOAL, same as for MACs:
  EUF-CMA - existential unforgeability under chosen
  message attack. Even after seeing signatures on
  messages of their choosing, an attacker cannot produce
  a valid signature on a NEW message.

AND SOMETIMES STRONGER: SUF-CMA, which additionally
forbids producing a DIFFERENT valid signature on an
ALREADY-SIGNED message. ECDSA is NOT SUF-CMA - see
malleability below - and that has caused real bugs.
```

ECDSA, and the nonce

```
/* SIGNING with private key d, on curve with generator G and
   order n:

    1. e = leftmost n bits of H(message)
    2. k = A RANDOM NONCE in [1, n-1]        <<< DANGER
    3. (x1, y1) = k * G
    4. r = x1 mod n           (if r == 0, restart)
    5. s = k^-1 * (e + r*d) mod n   (if s == 0, restart)
    signature = (r, s)

   VERIFYING with public key Q:
    1. check 1 <= r, s <= n-1
    2. e = leftmost n bits of H(message)
    3. u1 = e * s^-1 mod n,   u2 = r * s^-1 mod n
    4. (x1, y1) = u1*G + u2*Q
    5. valid iff  r == x1 mod n

/* ======================================================
   THE NONCE k MUST BE UNIQUE AND SECRET AND UNPREDICTABLE.
   ANY FAILURE RECOVERS THE PRIVATE KEY FROM SIGNATURES.
   ====================================================== */

/* --- REUSE: two signatures with the same k --- */
        s1 = k^-1 (e1 + r*d)
        s2 = k^-1 (e2 + r*d)      /* same r, because same k */

    subtract:  s1 - s2 = k^-1 (e1 - e2)
        =>  k = (e1 - e2) / (s1 - s2)   mod n
        =>  d = (s1*k - e1) / r         mod n

    FOUR LINES OF ARITHMETIC AND THE KEY IS YOURS. And note
    that reuse is DETECTABLE FROM THE OUTSIDE: identical r
    values in two signatures are a public giveaway.

    THIS HAPPENED TO:
      · SONY PLAYSTATION 3 (2010) - a FIXED k in the boot
        code. The console signing key was published. Full
        homebrew.
      · ANDROID BITCOIN WALLETS (2013) - SecureRandom
        returned repeated values after a fork(). Coins
        stolen automatically by bots scanning the blockchain
        for repeated r.
      · Numerous hardware wallets and IoT devices since.

/* --- BIAS: k not uniform --- */
    Even a FEW BITS of bias - k always having its top bit
    clear, or k computed as (random mod n) with a slight
    modulo skew - lets LATTICE ATTACKS recover d from a few
    hundred signatures. "Minerva" and "TPM-FAIL" (2019) both
    exploited a handful of leaked bits from timing.

/* --- PARTIAL LEAK: k's top bits visible via timing --- */
    Same lattice attack. This is why the scalar multiply must
    be constant time AND the nonce generation must not depend
    on k's length (chapter 19).

/* ======================================================
   THE FIX: RFC 6979 DETERMINISTIC ECDSA
   ====================================================== */
        k = HMAC_DRBG(private_key, H(message))
```

```
    The nonce is derived deterministically from the key and
    the message. NO RNG INVOLVED.
      · unique, because different messages give different k
      · secret, because it depends on d
      · unbiased, by construction
      · REPRODUCIBLE, so signatures are testable

    USE IT ALWAYS. It removes the entire category. mbedTLS:
    build with MBEDTLS_ECDSA_DETERMINISTIC and call
    mbedtls_ecdsa_sign_det_ext().

    (One caveat: determinism makes FAULT ATTACKS easier -
    sign the same message twice, glitch one, and compare. On
    a physically exposed device, add a small random component
    - "hedged" signing, as Ed25519ph and some newer specs
    do.)                                                  */
```

NEVER GENERATE AN ECDSA NONCE FROM A DEVICE RNG YOU HAVE NOT AUDITED

A hardware RNG that has not finished seeding, a PRNG duplicated across a fleet by a firmware image, or a counter that resets on reboot will all produce repeated `k`. And unlike most cryptographic failures, this one is *publicly detectable*: anyone collecting your signatures can grep for a repeated `r`. Use RFC 6979, or Ed25519.

Ed25519

```
/* EdDSA on the Edwards form of Curve25519 (chapter 14).
   Designed specifically to remove every foot-gun above. */

    KEY GENERATION:
        seed  = 32 random bytes
        h     = SHA-512(seed)
        a     = clamp(h[0..31])       /* the scalar */
        prefix= h[32..63]             /* for nonces */
        A     = a * B                 /* public key,
                                         32 bytes */

    SIGN(message):
        r = SHA-512(prefix ‖ message)  mod L   /* NO RNG */
        R = r * B
        k = SHA-512(R ‖ A ‖ message)   mod L
        S = (r + k*a)                  mod L
        signature = R ‖ S              /* 64 bytes */

    VERIFY:
        k = SHA-512(R ‖ A ‖ message) mod L
        check  S*B == R + k*A

/* WHAT IT FIXES, point by point:
     · THE NONCE IS DETERMINISTIC by construction - not an
       option you can forget to enable
     · COMPLETE ADDITION FORMULAS - no exceptional cases, so
       no branches
     · CONSTANT TIME by design
     · the PUBLIC KEY IS HASHED INTO k, preventing
       key-substitution attacks
     · COLLISION-RESILIENT: forging needs a SHA-512
       collision, not just a hash collision on the message
     · FIXED SIZES: 32-byte keys, 64-byte signatures, no
       DER parsing at all

/* THE CODE: */
    unsigned char pk[crypto_sign_PUBLICKEYBYTES];  /* 32 */
    unsigned char sk[crypto_sign_SECRETKEYBYTES];  /* 64 */
    crypto_sign_keypair(pk, sk);

    unsigned char sig[crypto_sign_BYTES];          /* 64 */
    crypto_sign_detached(sig, NULL, msg, msg_len, sk);

    if (crypto_sign_verify_detached(sig, msg, msg_len, pk)
        != 0)
            return INVALID;

/* THAT IS THE ENTIRE API. No curve parameter, no hash
   choice, no nonce, no encoding options, no padding mode.
   Compare with the ECDSA and RSA sections and the appeal is
   obvious.

/* THE ONE INTEROP WRINKLE: verification strictness varies
   between implementations - cofactored vs cofactorless
   equations, and whether non-canonical encodings are
   rejected. It matters for consensus systems where every
   node must agree; for a device verifying its own vendor's
   signatures it does not. RFC 8032 plus the ZIP-215 rules
   are the strict reference.                              */
```

Choosing

Scheme	Sig size	Pub key	Verdict
Ed25519	64 B	32 B	**The default.** Fast, safe, no parameters
Ed448	114 B	57 B	Higher margin
ECDSA P-256	64 B (72 DER)	33/65 B	Where FIPS, PKI or hardware demand it. **Use RFC 6979**
RSA-PSS 3072	384 B	384 B	Fast verification — boot ROMs
RSA v1.5 2048	256 B	256 B	Legacy formats only. Verify the *whole* block
ML-DSA-65 (Dilithium)	3309 B	1952 B	Post-quantum (ch. 20)
SLH-DSA (SPHINCS+)	7856 B+	32 B	Hash-based, very conservative, huge signatures
LMS / XMSS	~2 KB	32 B	**Stateful** hash-based. NIST-approved for firmware signing

The other ways signatures fail

```
/* --- 1. MALLEABILITY --- */
    ECDSA: if (r, s) is valid, so is (r, n - s). An attacker
    modifies a signature into a different valid one WITHOUT
    the key.

    Harmless if you only care about the message. FATAL if you
    use the signature as an identifier - Bitcoin's original
    transaction IDs included the signature, so an attacker
    could change a transaction's ID after broadcast. That was
    "transaction malleability", and it took a protocol change
    to fix.

    THE RULE: require the canonical low-s form, and NEVER
    treat a signature as a unique identifier for what it
    signs.

/* --- 2. NOT VERIFYING WHAT YOU THINK YOU VERIFIED --- */
    /* WRONG: */
    if (verify(pubkey, hash, sig) == OK)
            install(image);       /* is `hash` the hash of
                                     `image`? */
    /* The classic bug: hash computed over a header, or over
       a buffer that is later replaced. TIME-OF-CHECK TO
       TIME-OF-USE.

    /* RIGHT: hash the exact bytes you are about to use,
       immediately before using them, from memory the
       attacker cannot modify in between. */

/* --- 3. NOT CHECKING WHOSE KEY IT IS --- */
    A valid signature from the WRONG KEY is not an
    authorisation. The verification must be against a key
    that is:
      · pinned (a hash in OTP), or
      · chained to a pinned root (chapter 16)
    "It verified" means nothing without "and the key was
    trusted for this purpose".

/* --- 4. ALGORITHM CONFUSION --- */
    If the signature format carries its own algorithm
    identifier and you trust it, an attacker sets it to
    "none", or to a scheme where they hold a key. JWT's
    alg:none is the famous instance, and the same shape
    appears in firmware container formats.
    THE FIX: THE VERIFIER DECIDES THE ALGORITHM, not the
    message.

/* --- 5. SIGNING WHAT YOU DID NOT MEAN TO --- */
    A signing oracle - anything that will sign
    attacker-supplied bytes - can be tricked into signing
    something meaningful in another context. USE DOMAIN
    SEPARATION: sign H("myapp firmware v1" ‖ data), never
    raw data.

/* --- 6. NO ROLLBACK PROTECTION --- */
    An OLD, GENUINELY SIGNED image with a known
    vulnerability verifies perfectly. Signatures give
    authenticity, not freshness (the same gap as MACs,
    chapter 08). You need a MONOTONIC VERSION COUNTER in
    fuses or a replay-protected memory block
```

```
    (chapter 18).

/* --- 7. DER PARSING BUGS --- */
    ECDSA signatures in X.509 are DER-encoded ASN.1: nested
    length-prefixed structures, with rules about minimal
    encoding and leading zero bytes. This is a rich source
    of parser bugs and signature-forgery CVEs. Ed25519's
    fixed 64 bytes avoid it entirely - one more reason to
    prefer it.                                          */
```

The firmware signing pattern

```
/* THE SIGNING SIDE, in a facility you control: */
    private key lives in an HSM. It NEVER exists as a file.
    the build server calls the HSM to sign; access is
      logged, multi-party, and revocable
    a manifest is signed, not just the image:

      struct manifest {
          uint32_t magic;
          uint32_t format_version;
          uint32_t fw_version;        /* ANTI-ROLLBACK */
          uint32_t image_len;
          uint8_t  image_hash[32];    /* SHA-256 of the
                                         image */
          uint32_t device_class;      /* not the neighbour's
                                         product */
          uint64_t not_before;
      };
      signature = Ed25519(sk, "vendor-fw-v1" || manifest);

/* THE VERIFYING SIDE, on the device: */
    1. read the manifest
    2. check magic and format_version - REJECT UNKNOWN
    3. verify the signature over the WHOLE manifest, with a
       key whose HASH IS IN OTP (or a cert chained to it)
    4. check device_class matches THIS product
    5. check fw_version >= the fuse counter  -- ROLLBACK
    6. hash the image and compare to image_hash IN CONSTANT
       TIME
    7. only now: erase and write, or jump

/* NOTE THE ORDER. Every check that can reject happens
   BEFORE anything irreversible. And note that step 6 hashes
   the image AFTER it is in its final location, so an
   attacker with DMA access cannot swap it in between
   (the isolation track).                                */
```

How it shows up

Symptom	Cause
Private key published after a few signatures	Repeated ECDSA nonce — identical `r` values
Key recovered from a few hundred signatures	Biased nonce — a lattice attack
A signature altered but still valid	ECDSA malleability — require low `s`
Unsigned firmware installed	Algorithm confusion — the verifier trusted the message's alg field
Old vulnerable firmware reinstalled	No anti-rollback counter

Symptom	Cause
Verified image differs from the installed one	TOCTOU between hashing and use
A valid signature from an untrusted key accepted	No key pinning or chain check
Signature forged via a malformed encoding	DER parser bug
The neighbouring product's firmware installs	No device class in the signed manifest
Key extracted by glitching a repeated signature	Deterministic signing plus fault injection — hedge it

Check yourself

- ✓ Contrast MACs and signatures on five axes, and say why a device can ship a public key safely.
- ✓ Write out ECDSA signing and verification.
- ✓ Derive the private key from two signatures sharing a nonce.
- ✓ Explain nonce bias and why a few leaked bits suffice.
- ✓ Explain RFC 6979 and the one situation where pure determinism is a liability.
- ✓ List five design decisions in Ed25519 that remove a class of bug each.
- ✓ Explain malleability and the Bitcoin transaction-ID failure.
- ✓ Explain algorithm confusion and state the fix in one sentence.
- ✓ Explain why "the signature verified" is not an authorisation decision.
- ✓ Write the seven-step firmware verification order and justify the ordering.

Certificates and PKI

A signature proves a message came from a key. A certificate is the machinery that tells you *whose* key it is — and getting that binding wrong is how otherwise-correct cryptography ends up protecting nothing.

The binding problem

```
You verified a signature with public key Q. Excellent.
WHO OWNS Q?

Without an answer, an attacker just generates their own
key pair, signs whatever they like, and hands you their
public key. Everything verifies.

A CERTIFICATE is a signed statement:

     "The key Q belongs to <identity>,
      valid from <date> to <date>,
      and may be used for <purposes>."
                          -- signed, some issuer

THE RECURSION: how do you trust the ISSUER's key?
Answer: another certificate. Until you reach a
SELF-SIGNED ROOT that you trust because it was PUT THERE
OUT OF BAND - shipped in your OS, burned into your OTP
fuses, compiled into your firmware.

THE CHAIN:

  ROOT CA (self-signed, in your trust store)
     |  signs
     v
  INTERMEDIATE CA
     |  signs
     v
  END-ENTITY CERT  ("device-4711", or
                    "api.example.com")

INTERMEDIATES EXIST so the root's private key can stay
OFFLINE, in a safe, powered off. If an intermediate is
compromised, it is revoked and replaced. If the root is
compromised, every device that trusts it must be
physically updated - which for embedded hardware may mean
never.

THE TRUST MODEL IS THE WEAK PART: with the public web PKI
you are trusting ~150 organisations worldwide, ANY OF
WHICH can issue a certificate for ANY name. Several have
been compromised or have misissued. DigiNotar (2011) was
used to intercept Gmail for 300,000 Iranian users, and the
CA went bankrupt.
```

Inside an X.509 certificate

```
Certificate:
  Data:
    Version: 3 (0x2)
    Serial Number: 04:1a:...              /* unique per CA;
                                             must be random
                                             (see below) */

/* THE FIELDS THAT ACTUALLY MATTER FOR SECURITY:

   BASIC CONSTRAINTS / CA:FALSE
     Says this certificate may NOT sign other certificates.
     A verifier that ignores it lets ANY certificate holder
     become a CA and issue a cert for any name. This was a
     REAL BUG in Internet Explorer, in the iPhone, and in
     several embedded stacks. It is the single most important
     extension.

   KEY USAGE / EXTENDED KEY USAGE
     What the key may do. A certificate issued for code
     signing should not authenticate a TLS server.

   SUBJECT ALTERNATIVE NAME
     THE NAMES THE CERT IS VALID FOR. The Subject CN is
     LEGACY and modern verifiers ignore it. Wildcards match
     ONE label: *.example.com covers a.example.com but NOT
     a.b.example.com and NOT example.com itself.

   VALIDITY DATES
     Which means the device NEEDS A CORRECT CLOCK - see
     below, because on embedded hardware it usually does
     not have one.

   PATH LENGTH CONSTRAINT
```

```
     How many intermediates may appear below this CA.

/* AND A NOTE ON ENCODING: all of this is DER-encoded ASN.1 -
   nested tag-length-value structures. X.509 PARSERS ARE A
   HISTORIC SOURCE OF MEMORY-SAFETY BUGS, because the parser
   runs on ATTACKER-CONTROLLED INPUT BEFORE any signature has
   been checked. If you are choosing a TLS library for a
   device, the quality of its ASN.1 parser matters more than
   its cipher performance.                                  */
```

Verifying a chain, correctly

```
/* THE FULL PROCEDURE. Skipping any step has broken real
   software.                                              */

  FOR EACH certificate from the leaf up to a trusted root:

   1. SIGNATURE: verify it with the ISSUER's public key.

   2. VALIDITY DATES: now is within [notBefore, notAfter].

   3. ISSUER/SUBJECT CHAINING: this cert's Issuer matches
      the next cert's Subject, byte for byte.

   4. FOR EVERY NON-LEAF: BASIC CONSTRAINTS says CA:TRUE.
      <-- THE STEP PEOPLE SKIP

   5. FOR EVERY NON-LEAF: KEY USAGE includes keyCertSign.

   6. PATH LENGTH within the constraint.

   7. NAME CONSTRAINTS, if the CA has any, are satisfied.

   8. CRITICAL EXTENSIONS you do not understand -> REJECT.
      That is what "critical" means.

   9. REVOCATION: not on a CRL, or OCSP says good.

  AND THEN, SEPARATELY, ON THE LEAF:

  10. NAME MATCHING: the SAN contains the name YOU INTENDED
      to connect to - not the name in the certificate, and
      not the name the server told you.

  11. EXTENDED KEY USAGE matches your purpose.

  12. THE CHAIN ENDS AT A ROOT IN YOUR TRUST STORE.

/* THE FAMOUS FAILURES:
     · Apple's "goto fail" (2014): a duplicated goto
       statement skipped the signature check entirely.
     · GnuTLS (2014): a return-value confusion made invalid
       certificates verify.
     · Countless mobile apps: implementing a custom
       TrustManager that returns "valid" unconditionally, to
       make a self-signed test certificate work - and
       shipping it.
     · Basic-constraints omissions in at least four major
       stacks.

   THE PATTERN: THE FAILURE IS ALWAYS "ACCEPTS WHAT IT
   SHOULD REJECT", AND IT IS INVISIBLE IN TESTING, because
   the happy path still works perfectly.

/* SO: TEST YOUR VERIFIER WITH BAD CERTIFICATES.
     - expired
     - wrong name
     - self-signed
     - signed by a non-CA leaf
     - a valid chain to an untrusted root
     - a revoked certificate
     - a truncated / malformed DER blob
```

```
   If all seven are rejected, you have a verifier. If you
   only ever tested the good certificate, you have nothing.
   openssl s_server plus a small script generates all of
   these in a few minutes, and badssl.com hosts them
   publicly.                                              */
```

NEVER DISABLE CERTIFICATE VERIFICATION "TEMPORARILY"

`curl -k`, `verify=False`, `MBEDTLS_SSL_VERIFY_NONE`, a custom `TrustManager` that always returns success — every one of these has shipped to production in a real product. If a self-signed development certificate is inconvenient, add it to the device's trust store for development builds. Make the insecure path impossible to compile into a release build, not merely discouraged.

Revocation, and why it barely works

```
/* A certificate is valid until it expires. If the private
   key is stolen before then, you need to say so. All the
   mechanisms are unsatisfying.                          */

/* --- CRL: certificate revocation list --- */
    A signed list of revoked serial numbers, published by the
    CA.
    PROBLEMS: it grows without bound (megabytes); it is
    cached, so revocation is delayed by hours or days; and
    fetching it needs network access at exactly the moment a
    connection is being established.

/* --- OCSP: online status protocol --- */
    Ask the CA about one certificate.
    PROBLEMS: a PRIVACY LEAK (the CA learns every site you
    visit); a latency cost on every connection; and the fatal
    one - MOST CLIENTS SOFT-FAIL. If the OCSP responder is
    unreachable, they proceed anyway. An attacker who can
    intercept your traffic can also block OCSP, so revocation
    checking provides no security against the attacker it
    was designed to stop.

/* --- OCSP STAPLING --- */
    The SERVER fetches its own signed OCSP response and
    includes it in the handshake. Fixes the privacy and
    latency problems. Still soft-fails unless the
    certificate carries the "must-staple" extension.

/* --- SHORT-LIVED CERTIFICATES: the practical answer --- */
    Issue for 90 days, or 7, or 1. Revocation becomes
    expiry. This is why ACME/Let's Encrypt automation
    exists, and the industry is moving toward 47-day
    maximum lifetimes.

/* --- FOR EMBEDDED DEVICES, be realistic --- */
    A device may be offline, may have no clock, and may live
    for fifteen years. The web PKI's assumptions do not hold.
    WHAT WORKS INSTEAD:

      · YOUR OWN CA, not the public one. You control issuance
        and you can make the certificates last as long as the
        hardware.
      · PINNING: the device trusts EXACTLY ONE root, whose
        hash is in OTP. No public CA can attack it.
      · A REVOCATION LIST DELIVERED WITH FIRMWARE UPDATES,
        signed, with a monotonic version.
      · A DEVICE IDENTITY THAT CANNOT BE STOLEN: the private
        key generated inside a secure element and never
        exported (chapter 18).
      · AND FOR THE CLOCK PROBLEM: either accept that
        notBefore/notAfter cannot be checked and rely on
        pinning plus revocation, or seed the clock from a
        SIGNED time source before doing any validation.
        Do not let an attacker set your clock to 2035 and
        use an expired certificate.                      */
```

Device PKI in practice

```
/* --- THE HIERARCHY --- */
      Vendor Root CA          offline, in an HSM, in a safe.
        |                     30-year validity. Its PUBLIC
        |                     KEY HASH goes into every
        |                     device's OTP.
        +-- Manufacturing CA  signs device certificates on
        |                     the production line
        +-- Firmware CA       signs firmware manifests
        |                     (chapter 15)
        +-- Service CA        signs the cloud endpoints the
                              device connects to

    SEPARATE INTERMEDIATES PER PURPOSE. A compromise of the
    factory does not let an attacker sign firmware.

/* --- PROVISIONING, on the line --- */
    1. the secure element GENERATES ITS OWN key pair; the
       private half never exists outside it
    2. it emits a CSR (certificate signing request) - the
       public key plus a self-signature proving possession
    3. the factory HSM signs it, embedding a DEVICE SERIAL
       and a PRODUCT CLASS
    4. the certificate is written back to the device (it is
       public; it needs no protection)
    5. the (serial -> certificate) mapping goes into the
       vendor's inventory database

    THE PRIVATE KEY IS NEVER TRANSPORTED, NEVER BACKED UP,
    AND NEVER KNOWN TO ANYONE. A compromised factory database
    leaks nothing secret.

/* --- MUTUAL TLS IN THE FIELD --- */
    device -> cloud:  presents its device certificate,
                      proves possession via the handshake
                      signature
    cloud  -> device: presents a service certificate, which
                      the device validates against its
                      PINNED vendor root

    The cloud additionally checks the device serial against
    its inventory: is this device registered, activated, not
    reported stolen, and running a firmware version we still
    accept?

/* --- WHAT TO PUT IN OTP --- */
    NOT the root certificate - it is too big for fuses.
    THE SHA-256 HASH of the root public key. 32 bytes.
    The certificate itself lives in flash, and the boot code
    hashes it and compares before trusting it. That way the
    fuse cost is fixed and small, and the certificate can be
    re-encoded or re-formatted without burning new fuses.

/* --- AND PLAN FOR ROTATION --- */
    Fifteen-year devices outlive algorithms. Provision
    SEVERAL root key slots in OTP, with a fuse indicating
    which are active, so a root can be retired without
    bricking the fleet. This costs a few hundred fuse bits
    and it is the difference between a recoverable incident
    and a recall.                                          */
```

How it shows up

Symptom	Cause
Any leaf certificate can sign for any name	Basic constraints not checked
Connection succeeds to the wrong host	SAN not matched against the intended name
Self-signed certificates accepted in production	A development bypass left compiled in
A stolen key still works	Revocation soft-fail — the attacker blocks OCSP
All connections fail on a device after a reboot	No RTC — `notBefore` in the future
An expired certificate accepted	Clock set by the attacker, or dates not checked
Crash while parsing a certificate	ASN.1 parser bug — runs before any signature check
One compromised CA anywhere breaks the device	Public CA list instead of a pinned vendor root
A factory database leak compromises devices	Private keys generated outside the secure element
Cannot retire a root algorithm	Single root hash burned in OTP, no spare slots
`*.example.com` fails for `a.b.example.com`	Correct — a wildcard matches one label

Check yourself

- ✓ Explain what a certificate binds and why the chain must terminate out of band.
- ✓ Say why intermediates exist and what a root compromise costs an embedded fleet.
- ✓ Name the five certificate fields that carry real security meaning.
- ✓ List the twelve chain-verification steps and name a real failure for three of them.
- ✓ Explain what "critical extension" obliges a verifier to do.
- ✓ List the seven bad certificates every verifier must be tested against.
- ✓ Explain why OCSP soft-fail provides no security against a network attacker.
- ✓ Give four revocation strategies that actually work for offline devices.
- ✓ Describe factory provisioning and why the private key is never transported.
- ✓ Say what goes in OTP and why it is a hash rather than a certificate.
- ✓ Explain why multiple root slots matter for a fifteen-year product.

TLS

Every primitive so far, assembled into a working secure channel. TLS 1.3 is the reference design for how to combine them — and the thirty years of attacks on its predecessors are the reference list of how not to.

The two layers

```
HANDSHAKE PROTOCOL
  · negotiate the version and the cipher suite
  · exchange keys (ECDHE - chapter 13)
  · authenticate the peer (certificates - chapter 16)
  · derive the traffic keys (HKDF - chapter 10)
  · confirm the whole transcript matched

RECORD PROTOCOL
  · fragment the byte stream into records
  · protect each with an AEAD (chapter 09)
  · number them implicitly, so reordering, deletion and
    replay are all detected

TLS 1.3 HANDSHAKE, one round trip:

CLIENT                                  SERVER
  ClientHello
    + supported_versions
    + key_share (X25519 pubkey)
    + signature_algorithms
    + server_name (SNI)         ------>
                                          ServerHello
                                            + key_share
                        <=== both sides now derive the
                             handshake keys; EVERYTHING
                             BELOW IS ENCRYPTED ===>
                                          {EncryptedExtensions}
                                          {Certificate}
                                          {CertificateVerify}
                                          {Finished}
                                <------
  {Finished}                    ------>
  [Application Data]            <------>  [Application Data]

  {} = handshake-key encrypted   [] = traffic-key encrypted

WHAT EACH MESSAGE IS FOR:
  key_share            ephemeral DH, so FORWARD SECRECY is
                       not optional
  Certificate          the server's identity
  CertificateVerify    a SIGNATURE OVER THE TRANSCRIPT -
                       this is what binds the certificate
                       to this exchange, and stops the
                       man in the middle
  Finished             a MAC over the whole transcript,
                       from both sides - this is what kills
                       downgrade attacks
```

What TLS 1.3 removed

```
/* The most important design work in TLS 1.3 was DELETION.
   Each removal closed a family of attacks.               */

   REMOVED                        ATTACK IT ENABLED
   ------------------------------------------------------
   RSA key transport              no forward secrecy;
                                  Bleichenbacher/ROBOT
                                  (chapter 12)
   Static DH / static ECDH        no forward secrecy
   CBC mode ciphersuites          BEAST, Lucky13, padding
                                  oracles (chapter 05)
   RC4                            biased keystream (ch. 06)
   3DES                           SWEET32 birthday bound
   MD5, SHA-1 signatures          collisions (chapter 07)
   Compression                    CRIME, BREACH
   Renegotiation                  the 2009 renegotiation
                                  injection flaw
   Custom DH groups               Logjam (chapter 13)
   Export ciphersuites            FREAK, Logjam
   Non-AEAD ciphers               everything above

   WHAT REMAINS: FIVE cipher suites, all AEAD, all forward
   secret.
       TLS_AES_128_GCM_SHA256
       TLS_AES_256_GCM_SHA384
       TLS_CHACHA20_POLY1305_SHA256
       TLS_AES_128_CCM_SHA256          <-- for constrained
       TLS_AES_128_CCM_8_SHA256            devices

   THE LESSON GENERALISES: A PROTOCOL'S SECURITY IS BOUNDED
   BY ITS WEAKEST NEGOTIABLE OPTION. Every algorithm you keep
   "for compatibility" is an algorithm an attacker will try
   to force you into. Delete, do not deprecate.

/* AND ON THE KEY SCHEDULE: TLS 1.3 derives every key with
   HKDF, with a distinct label for each purpose:
       "c hs traffic", "s hs traffic",
       "c ap traffic", "s ap traffic",
       "exp master",   "res master"
   Textbook key separation (chapter 10), including separate
   keys per direction (chapter 08).                       */
```

The record layer

```
/* Each record is protected with the negotiated AEAD.     */

    struct {
        ContentType type;          /* always 23
                                      "application_data" on
                                      the wire in 1.3 - the
                                      real type is INSIDE
                                      the encrypted body */
        uint16 legacy_version;     /* always 0x0303 */
        uint16 length;
        opaque encrypted_record[length];
    } TLSCiphertext;

/* THE NONCE IS NOT TRANSMITTED. It is derived:
        nonce = static_iv XOR sequence_number
   The sequence number is implicit and increments per record.

   THIS IS AN ELEGANT PIECE OF DESIGN, and it does three
   things at once:
     · guarantees nonce uniqueness without state on the wire
       (chapter 09's cardinal rule, enforced structurally)
     · makes REPLAY impossible - a replayed record decrypts
       under the wrong nonce and fails the tag check
     · makes REORDERING and DELETION detectable for free

/* RECORD SIZE AND THE KEY UPDATE:
     max 2^14 bytes of plaintext per record.
     KeyUpdate messages rotate the traffic keys mid-session,
     so the AEAD limits (chapter 09) never bite on a
     long-lived connection.

/* PADDING: TLS 1.3 lets you append zero bytes inside the
   encrypted body to hide the true length. Nobody uses it,
   and TRAFFIC ANALYSIS remains a real leak - the size and
   timing of your records still describe what you are doing.
   For a device that sends distinguishable commands, pad to a
   fixed size.                                             */
```

> **0-RTT IS NOT FREE**
> TLS 1.3 lets a resuming client send application data in its first flight. That data has *no forward secrecy* against a compromise of the resumption secret, and it *can be replayed* by an attacker who captured it. Only send idempotent requests in early data, and only enable it if the latency actually matters to your product.

DTLS, and TLS on constrained devices

```
/* --- DTLS 1.3: TLS over UDP --- */
    Needed because TLS assumes a reliable ordered stream, and
    UDP gives neither.
      · explicit sequence numbers in the record header
      · a REPLAY WINDOW (a sliding bitmap) instead of a strict
        counter
      · retransmission and reassembly of handshake messages
      · a HELLORETRYREQUEST COOKIE, so the server does no work
        and holds no state until the client proves it can
        receive at its claimed address - AMPLIFICATION DDOS
        PROTECTION

    USED BY: CoAP over DTLS, WebRTC, QUIC's ancestor, and
    most constrained-device IoT stacks.

/* --- WHAT TLS COSTS ON AN MCU --- */
    mbedTLS, ECDHE-ECDSA-AES128-GCM, Cortex-M4:
      code                 ~60-100 KB flash
      RAM per connection   ~20-40 KB   <-- usually the
                                           binding constraint
      handshake            ~300-800 ms in software
      record throughput    a few hundred KB/s

    THE RAM IS THE PROBLEM. Two 16 KB record buffers plus the
    certificate chain plus the session state. On a part with
    64 KB of SRAM, one TLS connection may be all you get.

/* --- HOW TO MAKE IT FIT --- */
    · MBEDTLS_SSL_MAX_CONTENT_LEN 2048  - the single biggest
      saving. Requires the max_fragment_length extension and
      a server that honours it.
    · MBEDTLS_SSL_KEEP_PEER_CERTIFICATE off - free the chain
      after verification
    · compile out every cipher suite you do not use; the
      default config includes dozens
    · use RAW PUBLIC KEYS (RFC 7250) instead of certificates
      where both ends are yours - no ASN.1, no chain, 32
      bytes
    · or use PSK, below
    · SESSION RESUMPTION to avoid repeated handshakes - one
      handshake per boot instead of one per message

/* --- PSK MODE: when public-key crypto will not fit --- */
    TLS_PSK_WITH_AES_128_CCM_8, or 1.3's psk_ke:
      a symmetric key provisioned per device at manufacture.
      TINY: no certificates, no ECC, a few kilobytes total.

    THE TRADE-OFFS, and they are serious:
      · NO FORWARD SECRECY in pure PSK mode (use psk_dhe_ke
        if you can afford one ECDH)
      · the server must hold every device's key - a database
        breach is a fleet compromise
      · key rotation is hard
      · if the key is not per-device, ONE EXTRACTED DEVICE
        BREAKS EVERYTHING. This is the classic IoT failure:
        a single symmetric key in every unit of a product.

    USE PSK ONLY WITH PER-DEVICE KEYS, stored in a secure
    element (chapter 18), and prefer psk_dhe_ke.
```

```
/* --- THE CLIENT CODE, mbedTLS, with the checks that
       matter --- */
    mbedtls_ssl_config_defaults(&conf,
            MBEDTLS_SSL_IS_CLIENT,
            MBEDTLS_SSL_TRANSPORT_STREAM,
            MBEDTLS_SSL_PRESET_DEFAULT);

    /* 1. VERIFICATION IS MANDATORY, NOT OPTIONAL */
    mbedtls_ssl_conf_authmode(&conf,
            MBEDTLS_SSL_VERIFY_REQUIRED);

    /* 2. OUR PINNED ROOT ONLY - not a system CA bundle */
    mbedtls_ssl_conf_ca_chain(&conf, &vendor_root, NULL);

    /* 3. FLOOR THE VERSION */
    mbedtls_ssl_conf_min_tls_version(&conf,
            MBEDTLS_SSL_VERSION_TLS1_2);

    /* 4. THE HOSTNAME - sets SNI *AND* enables name
          verification. FORGETTING THIS MEANS ANY VALID
          CERTIFICATE FROM ANY SERVER IS ACCEPTED. */
    mbedtls_ssl_set_hostname(&ssl, "api.example.com");

    /* 5. our device certificate, for mutual TLS */
    mbedtls_ssl_conf_own_cert(&conf, &dev_cert, &dev_key);

    ret = mbedtls_ssl_handshake(&ssl);
    if (ret != 0) { /* FAIL CLOSED. No retry without TLS. */ }

    /* 6. AND CHECK THE RESULT EXPLICITLY */
    uint32_t flags = mbedtls_ssl_get_verify_result(&ssl);
    if (flags != 0) { abort_connection(); }

/* STEP 4 IS THE ONE THAT GETS OMITTED, and it silently
   disables hostname verification. It is the embedded
   equivalent of the mobile TrustManager bug from
   chapter 16.                                          */
```

The attack history, and what it teaches

Attack	Year	Mechanism	General lesson
Bleichenbacher	1998	PKCS#1 v1.5 decryption oracle	Error messages are an oracle
BEAST	2011	Predictable CBC IV	IVs must be unpredictable
CRIME	2012	Compression before encryption	Never compress secrets with attacker data
Lucky13	2013	MAC-then-encrypt timing	Encrypt-then-MAC; use an AEAD
Heartbleed	2014	Missing length check	Memory safety *is* crypto security
goto fail	2014	Duplicated statement skipped a check	Test the rejection paths
POODLE	2014	SSLv3 padding, reached by downgrade	Remove old versions entirely
FREAK / Logjam	2015	Downgrade to export grade	Delete weak options, don't deprecate
DROWN	2016	SSLv2 on a server sharing a key	Key reuse across protocols is fatal
SWEET32	2016	64-bit block birthday bound	Block size limits data per key
ROBOT	2017	Bleichenbacher, again	Removed attacks come back if the code stays
Raccoon	2020	DH timing side channel	Constant time, everywhere

```
/* WHAT THE LIST ACTUALLY SAYS:

   · ALMOST NONE OF THESE BROKE A CIPHER. AES is fine. RSA is
     fine. The failures are in COMPOSITION, NEGOTIATION,
     ERROR HANDLING, PARSING and IMPLEMENTATION.

   · Half of them are DOWNGRADE or LEGACY-OPTION attacks. The
     old code you kept for compatibility is the attack
     surface.

   · Several are TIMING. Constant-time code is not paranoia
     (chapter 19).

   · One is a plain buffer over-read. MEMORY SAFETY IS PART
     OF CRYPTOGRAPHY, which is a large part of why Rust is
     appearing in this space (see the Rust track).

   · AND THE META-LESSON: USE A MAINTAINED LIBRARY AND KEEP
     IT UPDATED. Every one of these was fixed centrally, and
     every device that never got an update is still
     vulnerable. YOUR UPDATE MECHANISM IS A SECURITY CONTROL
     (chapter 15).                                        */
```

How it shows up

Symptom	Cause
Any server's valid certificate is accepted	`set_hostname` not called — no name verification
Handshake fails with "unknown ca"	Root not in the trust store, or an incomplete chain from the server
Handshake fails only after a power cycle	No RTC — certificate dates fail
Out of memory during the handshake	16 KB record buffers — set `MAX_CONTENT_LEN`
Connection negotiates an old version	No minimum version floor
Requests executed twice	0-RTT early data replay
One extracted device decrypts the whole fleet	A shared PSK instead of per-device keys
Traffic content inferred without decryption	Record sizes and timing — pad
Connection drops after hours of traffic	AEAD limits reached, KeyUpdate not implemented
DTLS server used for amplification	Cookie exchange disabled
Everything works, and a proxy reads it all	Verification disabled somewhere in the build

Check yourself

- ✓ Draw the TLS 1.3 handshake and say what each message contributes.
- ✓ Explain what CertificateVerify and Finished each prevent.
- ✓ List six things TLS 1.3 removed and the attack each removal closed.
- ✓ Explain how the record nonce is derived and the three properties it gives at once.
- ✓ State the two costs of 0-RTT.
- ✓ Say what DTLS adds over TLS and why the cookie exchange exists.
- ✓ Name the dominant resource constraint for TLS on an MCU and four ways to reduce it.
- ✓ Give the trade-offs of PSK mode and the one rule that makes it survivable.

- ✓ Write the six client-side configuration steps, and say which omission is silent.
- ✓ Explain why almost no TLS attack broke a cipher, and what that implies for your own protocols.

Key management and secure storage

Cryptography converts the problem of protecting a lot of data into the problem of protecting a small key. That is a good trade only if you actually protect the key — and on a device an attacker can hold in their hand, that is the hardest part of the whole system.

The key lifecycle

```
GENERATE -> STORE -> USE -> ROTATE -> DESTROY
     |         |       |        |         |
good entropy   |   never in     |     verifiably
(chapter 02)   |   plaintext    |     unrecoverable
               |   outside the  |
          hardware-backed,      |
          never exported   before the limits
                           (chapter 09)

AT EVERY STAGE, ASK:
  · who can read this key?
  · what happens if the device is stolen and
    decapsulated?
  · what happens if the manufacturing database leaks?
  · what happens when this key must be replaced?
  · how do we know it was destroyed?

THE HIERARCHY, and the whole design follows from it:

  ROOT OF TRUST      in hardware fuses or a PUF.
                     NEVER READABLE BY SOFTWARE.
     |  KDF (chapter 10)
     +-- storage key         encrypts the filesystem
     +-- attestation key     proves device identity
     +-- firmware key        decrypts update images
     +-- per-session keys    ephemeral, from ECDHE

THE ROOT IS USED ONLY AS A KDF INPUT, and ideally only
inside a hardware block that will not reveal it. Every
working key is derived, so every working key is
REPLACEABLE by changing its context string - without
touching the root.
```

Where keys must never be

```
/* --- 1. HARDCODED IN FIRMWARE --- */
    static const uint8_t key[16] = { 0xde, 0xad, ... };

    Anyone with the firmware image has the key. And firmware
    images are on vendor download pages, extracted from SPI
    flash with a $20 clip, or dumped over an unprotected
    JTAG port. `strings` and `binwalk` find them in seconds;
    entropy analysis finds them even when obfuscated.

    AND THE MULTIPLIER: it is the SAME KEY IN EVERY UNIT. One
    extraction compromises the entire product line, past and
    future. This is the single most common serious flaw in
    shipped IoT devices.

/* --- 2. IN A REPOSITORY --- */
    Committed keys live in git history forever. Rotating
    after a leak means rotating on every device that ever
    received the old one. Automated scanners find published
    keys within minutes of a push.

/* --- 3. IN LOGS, TRACES OR CRASH DUMPS --- */
    printf("key=%s", key)  - and it goes to a UART pad
    somebody can solder to, or to a cloud crash reporter, or
    into a support bundle a customer emails you.

/* --- 4. IN SWAP, HIBERNATION IMAGES OR CORE DUMPS --- */
    On Linux: mlock() the buffer, disable core dumps for the
    process, and prefer the kernel keyring or a TEE
    (see the isolation track).

/* --- 5. LEFT IN MEMORY AFTER USE --- */
    void f(void) {
        uint8_t key[32];
        derive(key);
        use(key);
        memset(key, 0, 32);   /* <-- THE COMPILER MAY DELETE
                                 THIS. The buffer is dead
                                 afterwards, so the store
                                 is "unobservable" and
                                 dead-store elimination
                                 removes it. */
    }

    /* USE ONE OF: */
    explicit_bzero(key, sizeof key);           /* BSD, glibc */
    memset_s(key, sizeof key, 0, sizeof key);  /* C11 annex K */
    mbedtls_platform_zeroize(key, sizeof key);
    sodium_memzero(key, sizeof key);
    SecureZeroMemory(key, sizeof key);         /* Windows */

    /* AND REMEMBER THE COPIES: a value in a register, a
       stack spill, a DMA buffer, an unencrypted cache line.
       Zeroing is best-effort; keeping the key in hardware
       and never materialising it is the real answer.     */

/* --- 6. THE SAME KEY FOR TWO PURPOSES --- */
    Derive (chapter 10). Always.

/* --- 7. TRANSPORTED FROM THE FACTORY --- */
    If a key is generated outside the device and injected,
```

```
    then it existed somewhere else, and that somewhere is now
    part of your attack surface for the life of the product.
    GENERATE ON-DEVICE, INSIDE THE SECURE ELEMENT
    (chapter 16).                                          */
```

Hardware key storage

```
/* IN INCREASING ORDER OF ASSURANCE AND COST.             */

/* --- OTP FUSES / eFUSE --- */
    One-time programmable bits in the SoC. Blown at
    manufacture.
      + cannot be changed, so cannot be rolled back
      + readable by the boot ROM before software runs
      - LIMITED SPACE, often a few hundred bits
      - VISIBLE UNDER A MICROSCOPE if not protected;
        decapsulation and optical or e-beam probing recovers
        fuse state on older processes
      - and once burned, WRONG IS FOREVER

    USE FOR: root public key HASHES (chapter 16), device
    serials, anti-rollback counters, lifecycle state.
    PREFER NOT TO USE FOR: raw symmetric secrets, unless the
    fuse block is a "hidden" region readable only by the
    crypto engine.

/* --- A HIDDEN/HW-ONLY KEY REGION --- */
    Many SoCs have fuses wired DIRECTLY INTO THE AES ENGINE
    and readable by nothing else. Software says "encrypt with
    the hardware key"; software never sees the key. This is
    the minimum bar for a device-unique storage key, and it
    is often free on parts you already use - check the TRM.

/* --- PUF: physically unclonable function --- */
    Derives a key from manufacturing variation in SRAM
    start-up values or ring oscillators, with error
    correction and helper data.
      + NO KEY IS STORED AT ALL - it exists only while
        powered
      + resistant to at-rest extraction
      - needs careful error correction; helper data must not
        leak the key
      - ageing and temperature drift must be handled

/* --- SECURE ELEMENT / SE --- */
    A separate chip (ATECC608, SE050, OPTIGA) on I2C or SPI.
      + keys GENERATED INSIDE and never exported
      + tamper detection, active meshes, sensors
      + certified against physical attack (Common Criteria)
      + a monotonic counter and a real RNG
      - an EXTERNAL BUS, so bind it to the host: the bus
        traffic must be authenticated, or an attacker just
        replays "authentication succeeded"

/* --- TPM --- */
    Standardised (TCG). PCRs for measured boot, sealing
    (release a key only if the PCRs match an expected boot
    state), attestation, monotonic counters. Discrete or
    firmware.

/* --- A TEE --- */
    TrustZone and a trusted OS. Keys live in secure world
    memory that the normal world cannot address at all. Much
    more flexible than an SE, and much larger attack surface.
    The isolation track covers this in depth.

/* --- HSM --- */
```

```
    For the SERVER side: the CA and signing keys. FIPS 140-3
    Level 3+, tamper-responding, with multi-party
    authorisation. YOUR FIRMWARE SIGNING KEY BELONGS IN ONE,
    not on a build server (chapter 15).

/* THE PRINCIPLE THAT UNIFIES ALL OF THESE:

     THE BEST KEY STORAGE IS ONE WHERE THE KEY NEVER EXISTS
     IN CPU-ADDRESSABLE MEMORY. You hand data in, you get
     results out, and no software bug can leak what software
     never held.                                          */
```

THE LINUX EQUIVALENTS

```
keyctl / the kernel keyring   keys held in kernel memory,
                              not in your process
trusted keys                  sealed to a TPM or a TEE;
                              userspace sees only a blob
dm-crypt / LUKS2              volume key wrapped by an
                              Argon2id-derived key (ch. 10)
fscrypt                       per-directory file encryption
Op-TEE + a TA                 keys never leave secure world
```

See the Linux track for the driver-side mechanics.

Encrypting data at rest

```
/* --- THE KEY WRAPPING PATTERN, and use it everywhere --- */

    DEK   Data Encryption Key    encrypts the actual data
    KEK   Key Encryption Key     encrypts the DEK

    stored:  wrapped_DEK = AES-KW(KEK, DEK)
             ciphertext  = AES-GCM(DEK, data)

/* WHY THE INDIRECTION:
     · ROTATE THE KEK without re-encrypting terabytes -
       unwrap and rewrap one small blob
     · wrap the SAME DEK under SEVERAL KEKs: a user
       password, a recovery key, a corporate escrow key
     · the DEK can be random and full-strength even when the
       KEK comes from a weak password
     · CRYPTO-ERASE: destroy the wrapped DEK and the data is
       instantly unrecoverable, however many copies exist.
       This is how a "secure erase" completes in
       milliseconds on an SSD.

/* --- FULL-DISK ENCRYPTION AND THE SECTOR PROBLEM --- */
    A disk sector must be encrypted in place: same size in,
    same size out. THERE IS NO ROOM FOR A NONCE OR A TAG.

    So FDE uses XTS-AES: a tweakable block cipher where the
    SECTOR NUMBER is the tweak. Same plaintext in different
    sectors gives different ciphertext.

    AND THE HONEST LIMITATION: XTS PROVIDES NO INTEGRITY. An
    attacker who can write to the disk can flip ciphertext
    bits and corrupt the plaintext in a controlled,
    block-local way. FDE protects a LOST OR STOLEN device; it
    does not protect against an attacker who can modify the
    storage while you keep using it.

    IF YOU NEED INTEGRITY TOO: dm-verity for read-only
    volumes (a Merkle tree, chapter 07), dm-integrity plus
    dm-crypt for read-write, or a filesystem with built-in
    authentication.

/* --- FOR AN MCU WITH EXTERNAL FLASH --- */
    struct record {
        uint32_t version;      /* AAD - anti-rollback */
        uint8_t  nonce[12];    /* from a monotonic counter */
        uint8_t  ciphertext[N];
        uint8_t  tag[16];
    };

    key = KDF(hw_unique_key, "config storage v1");

    /* THE THREE THINGS TO GET RIGHT:
       1. THE NONCE COUNTER MUST SURVIVE RESET. In flash,
          not RAM. If it can ever restart, use
          AES-GCM-SIV or XChaCha20 (chapter 09).
       2. THE VERSION IS AUTHENTICATED, so an attacker
          cannot restore an old config blob - that is a
          rollback attack on your settings, and it is how
          "factory reset the password" attacks work.
       3. THE KEY IS DEVICE-UNIQUE, so a blob copied from
          one unit does not decrypt on another.
```

```
   /* AND ON WEAR LEVELLING: flash controllers move and copy
      blocks. An "overwritten" secret may still be present
      in a remapped block. Never rely on overwriting flash
      to destroy a secret - CRYPTO-ERASE instead: destroy
      the key and let the ciphertext rot.               */
```

Rotation, revocation and destruction

```
/* --- WHY ROTATE --- */
    · the AEAD usage limits (chapter 09)
    · to bound the damage from an undetected compromise
    · because someone left the company
    · because an algorithm aged out

/* --- HOW, WITHOUT AN OUTAGE --- */
    Every stored or transmitted object carries a KEY ID:

      struct blob {
          uint8_t  key_id;      /* which key encrypted this */
          uint8_t  nonce[12];
          ...
      };

    ROLLOUT:
      1. deploy the new key everywhere; keep accepting both
      2. switch WRITERS to the new key
      3. re-encrypt or let old data expire
      4. remove the old key

    A DESIGN WITH NO KEY ID CANNOT BE ROTATED WITHOUT A FLAG
    DAY. Add the field on day one; it costs one byte.

/* --- DESTRUCTION --- */
    · overwrite the RAM copy with an explicit zeroise
    · CRYPTO-ERASE anything on flash or disk
    · blow a fuse to disable a key slot, if the hardware
      supports it
    · and for an HSM, use its documented zeroise procedure -
      and get the certificate of destruction

/* --- LIFECYCLE STATES, which the SoC usually enforces --- */
      BLANK       -> nothing provisioned, debug wide open
      DEVELOPMENT -> keys provisioned, JTAG open, TEST KEYS
                     ONLY
      SECURED     -> production keys, DEBUG DISABLED,
                     secure boot enforced
      RMA         -> a controlled path back to debug, which
                     MUST ERASE ALL SECRETS FIRST
      DECOMMISSIONED -> keys destroyed

    THE TRANSITIONS ARE ONE-WAY AND FUSE-BACKED. THE RMA PATH
    IS THE DANGEROUS ONE: if a returned device can be put
    back into debug WITHOUT erasing its keys, an attacker
    with physical access has a key extraction procedure that
    the vendor documented for them. Verify that your SoC's
    RMA transition erases, and that it cannot be triggered
    without an authenticated command.

/* --- AND FINALLY, THE PART THAT IS NOT TECHNICAL --- */
    Write down, before the product ships:
      · every key in the system, and where it lives
      · who can access each one, and how that is enforced
      · the rotation procedure for each
      · what happens when each one is compromised
      · who is called, and in what order

    A COMPROMISE RESPONSE PLAN WRITTEN DURING AN INCIDENT IS
```

```
    NOT A PLAN. The devices are in the field; the options
    you have are the ones you designed in.              */
```

How it shows up

Symptom	Cause
Every unit of a product shares a key	Hardcoded in firmware — one extraction breaks the line
Key found by `strings` on the image	Key compiled in
Key recovered from a core dump	`memset` optimised away, or no `mlock`
Config blob copied between devices works	Storage key not device-unique
Old settings restored to bypass a lock	Version not authenticated — rollback on stored data
Secret still present after "erase"	Flash wear levelling — needed crypto-erase
Disk contents corrupted in a controlled way	XTS gives confidentiality, not integrity
Secure element bypassed entirely	Unauthenticated I2C bus — responses replayed
Cannot roll a key without a flag day	No key ID in the wire or storage format
Returned device yields production keys	RMA transition re-enables debug without erasing
Nonce repeats after a brownout	Counter kept in RAM instead of flash

Check yourself

- ✓ Draw the key hierarchy and explain why only derived keys are ever used.
- ✓ List seven places a key must never be, with the concrete attack for each.
- ✓ Explain why `memset` may not clear a key and name three portable alternatives.
- ✓ Compare fuses, PUFs, secure elements, TPMs, TEEs and HSMs on assurance and cost.
- ✓ State the principle that unifies all good key storage.
- ✓ Explain the DEK/KEK pattern and four things it enables.
- ✓ Explain why FDE uses XTS and what XTS does not provide.
- ✓ Write the three rules for encrypting a config blob on external flash.
- ✓ Explain crypto-erase and why flash wear levelling makes it necessary.
- ✓ Describe a zero-downtime key rotation and the one field it requires.
- ✓ List the lifecycle states and say why RMA is the dangerous transition.

Side channels and constant-time programming

The algorithm is secure. The implementation runs on real hardware that takes measurable time, draws measurable current and emits measurable radiation. Everything it does with a secret is potentially visible.

What leaks

```
THE CHANNELS, roughly by how easy they are to exploit:

TIMING             How long an operation takes.
                   Measurable REMOTELY, over a network,
                   by averaging many samples. No physical
                   access needed.

CACHE              Which memory lines were touched.
                   Measurable BY ANOTHER PROCESS on the
                   same machine - or another VM on the
                   same host.

BRANCH PREDICTOR   Which way a branch went. Same
                   cross-process reach as cache.

POWER (SPA/DPA)    Instantaneous current draw. Needs a
                   resistor in the power line and an
                   oscilloscope. ~$100 of equipment.

ELECTROMAGNETIC    Near-field emissions. Same information
                   as power, WITHOUT TOUCHING THE BOARD.

FAULT INJECTION    Not observation - INDUCED ERROR.
                   Voltage glitch, clock glitch, laser,
                   EM pulse. Makes the device compute
                   wrong, and wrong answers leak.

ACOUSTIC, THERMAL, PHOTONIC - real, demonstrated,
rarely the easiest route.

THE THREAT MODEL DECIDES WHICH MATTER:

  a server in a datacentre     -> timing, cache, branch
  a phone running your app     -> plus power, and
                                  untrusted co-resident
                                  code
  a device in a customer's
    hands                      -> ALL OF THEM. They own
                                  the hardware, they have
                                  unlimited time, and
                                  ChipWhisperer costs
                                  less than a phone.

AND THE RULE THAT FOLLOWS: IF THE ATTACKER CAN HOLD THE
DEVICE, ASSUME THEY CAN SEE POWER AND INJECT FAULTS.
Design for it, or accept that per-device keys will be
extracted.
```

The constant-time discipline

```
/* THE RULE, and it is short:

     NO BRANCH, NO MEMORY ADDRESS, AND NO VARIABLE-LATENCY
     INSTRUCTION MAY DEPEND ON SECRET DATA.

   Everything below follows from it.                      */

/* --- VIOLATION 1: BRANCHING ON A SECRET --- */
    if (secret_byte == 0x42) do_a(); else do_b();
    /* the branch predictor and the instruction timing both
       reveal which way it went */

/* --- VIOLATION 2: EARLY EXIT --- */
    for (i = 0; i < n; i++)
        if (a[i] != b[i]) return 0;    /* <-- leaks the
                                              match length */

    /* CONSTANT-TIME COMPARISON: */
    int ct_memcmp(const void *a, const void *b, size_t n)
    {
        const volatile uint8_t *pa = a, *pb = b;
        uint8_t diff = 0;
        for (size_t i = 0; i < n; i++)
                diff |= pa[i] ^ pb[i];   /* ALWAYS all n */
        return diff;                     /* 0 == equal */
    }
    /* the `volatile` stops the compiler proving it can
       stop early. Better still, call the library's:
       sodium_memcmp, CRYPTO_memcmp, mbedtls_ct_memcmp. */

/* --- VIOLATION 3: SECRET-DEPENDENT MEMORY ADDRESSES --- */
    value = table[secret_index];
    /* WHICH CACHE LINE was loaded is visible to any process
       sharing the cache. This is exactly the AES T-table
       attack (chapter 04), and it recovers a full AES key
       from another process in seconds. */

    /* CONSTANT-TIME TABLE LOOKUP - touch EVERY entry: */
    uint8_t ct_lookup(const uint8_t *tab, size_t n,
                      size_t secret_idx)
    {
        uint8_t r = 0;
        for (size_t i = 0; i < n; i++) {
                uint8_t m = ct_eq(i, secret_idx);  /* 0xFF or
                                                      0x00 */
                r |= tab[i] & m;
        }
        return r;
    }
    /* O(n) per lookup. For a 256-entry S-box this is
       expensive, which is why AES is BITSLICED instead -
       computing the S-box arithmetically with no table at
       all. */

/* --- VIOLATION 4: VARIABLE-LATENCY INSTRUCTIONS --- */
    Integer DIVIDE and MODULO take data-dependent time on
    many cores, including several Cortex-M and Cortex-A
    parts. So do some multiplies on small cores (the classic
    ARM7TDMI multiplier terminated early on small operands).
    AVOID div/mod ON SECRETS entirely; use masking and
```

```
    shifts.

/* --- THE PRIMITIVES YOU BUILD EVERYTHING FROM --- */

    /* mask: 0xFFFF... if b, else 0 */
    static inline uint32_t ct_mask(uint32_t b)
    {   return -(uint32_t)(b & 1); }

    /* select a or b without branching */
    static inline uint32_t ct_select(uint32_t cond,
                                     uint32_t a, uint32_t b)
    {   uint32_t m = ct_mask(cond);
        return (a & m) | (b & ~m); }

    /* equality -> 1 or 0, no branch */
    static inline uint32_t ct_eq(uint32_t x, uint32_t y)
    {   uint32_t d = x ^ y;
        return 1 ^ ((d | -d) >> 31); }

    /* greater-than, for bignum comparison */
    static inline uint32_t ct_gt(uint32_t x, uint32_t y)
    {   return (((y - x) ^ ((x ^ y) & ((x - y) ^ x)))
                >> 31) & 1; }

    /* conditional swap - the heart of a Montgomery ladder
       (chapter 14) */
    static void ct_cswap(uint32_t cond, uint32_t *a,
                         uint32_t *b, size_t n)
    {
        uint32_t m = ct_mask(cond);
        for (size_t i = 0; i < n; i++) {
                uint32_t t = m & (a[i] ^ b[i]);
                a[i] ^= t;  b[i] ^= t;
        }
    }
```

THE COMPILER IS NOT ON YOUR SIDE

A C compiler is permitted to turn your branchless `ct_select` back into a conditional branch if it decides that is faster, and modern optimisers do exactly that. The mitigations, in increasing order of reliability: use `volatile` on the inputs; use an inline-assembly barrier such as `asm volatile("" : "+r"(x))` to make the value opaque; use the library's tested primitives; or, for the innermost loops, write the assembly yourself. Then *verify* — see the tooling section below. This is not hypothetical: it has silently reintroduced timing leaks into libraries that had them fixed.

Power and fault attacks

```
/* --- SPA: SIMPLE POWER ANALYSIS --- */
    Read the secret from a SINGLE trace by looking at it.
    A square-and-multiply exponentiation shows square and
    multiply operations with visibly different current
    profiles - so the exponent bits are readable off the
    oscilloscope screen (chapters 12 and 14).
    DEFENCE: constant operation sequences. The ladder.

/* --- DPA: DIFFERENTIAL POWER ANALYSIS --- */
    Collect thousands of traces with known inputs.
    Hypothesise one byte of the key. Predict an intermediate
    value's Hamming weight. Correlate the prediction with the
    measured power at every time offset. The correct
    hypothesis shows a correlation spike.

    ONE KEY BYTE AT A TIME: 16 x 256 hypotheses for AES,
    instead of 2^128. A few thousand traces and an afternoon.
    CONSTANT-TIME CODE DOES NOT STOP THIS - the timing is
    identical, but the DATA VALUES still modulate the current.

    DEFENCES:
      MASKING     split every secret value into shares:
                  x = x1 XOR x2, with x1 random per
                  execution. Compute on the shares. The
                  measured power then correlates with random
                  values, not the secret. Costs 2-4x in
                  performance and is HARD TO GET RIGHT - the
                  shares must never recombine, including in a
                  register or a pipeline forwarding path.
      HIDING      random delays, dummy operations, shuffled
                  operation order. Raises the trace count,
                  does not eliminate the leak.
      HARDWARE    dual-rail logic, noise generators,
                  integrated voltage regulators. This is what
                  a certified secure element buys you
                  (chapter 18).

/* --- FAULT INJECTION --- */
    Voltage glitch, clock glitch, EM pulse, laser. Skip an
    instruction, corrupt a register, flip a bit.

    THE CLASSIC TARGET IS A SECURITY DECISION:
        if (signature_valid)     <-- glitch the compare
                jump_to_image();     or the branch

    AND THE CRYPTOGRAPHIC ONES:
      · RSA-CRT: one faulty half reveals a prime (ch. 11, 12)
      · Differential fault analysis on AES: one fault in
        round 9 recovers the key from a pair of correct and
        faulty ciphertexts
      · Glitching a deterministic signature to compare two
        outputs (chapter 15)

    DEFENCES:
      · VERIFY AFTER SIGN, always
      · DOUBLE-CHECK SECURITY DECISIONS with different code,
        separated in time, and use non-trivial constants:

            #define OK   0x5A3C96E1u
            #define FAIL 0xA5C36918u
```

```
            /* not 1 and 0 - a stuck-at fault produces 0 or
               all-ones far more easily than a specific
               32-bit value */

            uint32_t v1 = verify(sig);
            random_delay();
            uint32_t v2 = verify(sig);
            if (v1 != OK || v2 != OK || v1 != v2)
                    lockdown();

      · REDUNDANT LOOP COUNTERS, so a skipped iteration is
        detected
      · SENSORS: voltage, clock, temperature, light. Most
        secure MCUs have them; ENABLE THEM.
      · and a real INFINITE-LOOP-FREE failure path: on
        detection, wipe and halt.

/* THE HONEST ASSESSMENT: full fault resistance is
   specialist work. If your threat model includes a funded
   attacker with the device on a bench, PUT THE KEYS IN A
   CERTIFIED SECURE ELEMENT and let people whose whole job
   this is defend them.                                  */
```

Microarchitectural attacks

```
/* The cache and speculation attacks that reshaped CPU
   security from 2018 onward. Relevant to you if your device
   runs untrusted code - a browser, a container, a customer
   app - or if you are writing a driver or a hypervisor.  */

   FLUSH+RELOAD    flush a shared line, wait, time the
                   reload. Fast and precise; needs shared
                   memory (a shared library, page dedup).
   PRIME+PROBE     fill a cache set, wait, time it again.
                   No sharing needed.
   SPECTRE         mistrain the branch predictor so the CPU
                   speculatively reads out of bounds; the
                   access leaves a cache trace even though
                   the result is discarded.
   MELTDOWN        speculative reads across the
                   user/kernel boundary. Fixed in hardware
                   in current parts.
   ROWHAMMER       repeated DRAM row activation flips bits
                   in ADJACENT rows. Not a leak - a WRITE
                   primitive, from reads alone.

/* WHAT THIS MEANS FOR CRYPTOGRAPHIC CODE:
     · NO SECRET-DEPENDENT MEMORY ACCESS - the same rule as
       above, now with a second reason
     · no secret-dependent branches, because speculation
       executes both paths
     · AND THE HARD PART: an attacker on the same core can
       observe your code even if your code is perfect, via
       SMT/hyperthreading. Disable SMT for
       security-critical workloads, or pin them to a
       dedicated core.

/* ON ARM, THE RELEVANT MITIGATIONS: CSDB (consumption of
   speculative data barrier) and the SB instruction bound
   speculation explicitly; the DIT (Data Independent Timing)
   bit in PSTATE on Armv8.4+ guarantees data-independent
   timing for a defined instruction set - SET IT AROUND
   CRYPTOGRAPHIC CODE where the core supports it. See the
   ARM track for the barrier semantics.                 */
```

Verifying it

```
/* YOU CANNOT EYEBALL CONSTANT TIME. Measure and prove.   */

/* --- dudect: statistical timing test --- */
    Run the function with two input classes - one fixed, one
    random - many times. Apply Welch's t-test to the timing
    distributions. If |t| > 4.5, the timing depends on the
    data.
    Easy to integrate, catches real leaks, and NEEDS NO
    SOURCE ANALYSIS. Run it in CI.

/* --- ctgrind / MemSan-based checking --- */
    Mark the secret as UNINITIALISED memory for Valgrind:

        VALGRIND_MAKE_MEM_UNDEFINED(key, sizeof key);
        crypto_operation(key, ...);

    Valgrind already reports branches and memory addresses
    that depend on undefined data - which is EXACTLY the
    property you want to check. An elegant reuse, and it
    finds violations statically along the executed path.

/* --- ChipWhisperer --- */
    Open-source hardware plus software for power analysis and
    glitching. A few hundred dollars. IF YOU SHIP HARDWARE
    WITH KEYS IN IT, YOU SHOULD OWN ONE - because your
    attackers do, and finding your own DPA leak is much
    cheaper than reading about it.

/* --- OTHERS WORTH KNOWING --- */
    · binsec/rel, ct-verif: formal verification of
      constant-timeness
    · Compiler flags will not save you; there is no
      -fconstant-time
    · Cachegrind and perf counters for cache behaviour

/* --- AND THE PRACTICAL CHECKLIST --- */
    [ ] no branch on secret data
    [ ] no table index derived from secret data
    [ ] no div/mod on secret data
    [ ] all comparisons of secrets are constant-time
    [ ] blinding enabled on every asymmetric operation
    [ ] verify-after-sign on RSA-CRT
    [ ] security decisions double-checked, non-trivial
        constants
    [ ] secrets zeroised with an unremovable primitive
    [ ] dudect or ctgrind in CI
    [ ] and, if the threat model warrants it, the keys are
        not in the application processor at all         */
```

How it shows up

Symptom	Cause
MAC tag recovered byte by byte	Early-exit comparison
AES key recovered by a co-resident process	T-table lookups — cache timing
RSA key recovered over the network	Unblinded exponentiation timing

Symptom	Cause
ECDSA key from a few hundred signatures	Nonce bias from a leaky scalar multiply
Key read off an oscilloscope in one trace	SPA — branching square-and-multiply
Key recovered despite constant-time code	DPA — needs masking, not just timing equality
Signature check bypassed by a voltage pulse	Single unprotected branch on the security decision
A prime recovered from one signature	CRT fault, no verify-after-sign
A fixed leak reappears after a compiler upgrade	The optimiser reintroduced the branch
Timing varies only under load	SMT sibling contention — pin or disable SMT

Check yourself

- ✓ List the side channels and say which apply to a device in a customer's hands.
- ✓ State the constant-time rule in one sentence.
- ✓ Write constant-time equality, select, mask and conditional swap from memory.
- ✓ Explain why a constant-time table lookup is O(n) and what AES does instead.
- ✓ Name two instructions with data-dependent latency.
- ✓ Explain why the compiler can undo your branchless code, and three mitigations.
- ✓ Contrast SPA and DPA, and say why constant time does not stop DPA.
- ✓ Explain masking, and the subtlety that makes it hard to implement.
- ✓ Write a fault-resistant verification check and say why the constants are not 0 and 1.
- ✓ Explain Flush+Reload and why speculation makes secret-dependent branches worse.
- ✓ Describe dudect and ctgrind, and say what each catches that the other does not.

Post-quantum cryptography

A sufficiently large quantum computer breaks RSA and every elliptic curve completely. It does not exist yet. For a product that will still be in the field in 2040, that is not a reason to wait.

What quantum computers actually break

```
SHOR'S ALGORITHM (1994)
  Solves FACTORING and DISCRETE LOGARITHM in polynomial
  time.

  BROKEN COMPLETELY:
    RSA           any key size (chapter 12)
    Diffie-Hellman, finite field          (chapter 13)
    ECDH, ECDSA, Ed25519, all curves      (14, 15)

  "Use a bigger key" does not help. A 15360-bit RSA key
  falls to the same algorithm as a 1024-bit one; it just
  needs a slightly larger machine.

GROVER'S ALGORITHM (1996)
  Searches an unstructured space in O(sqrt(N)) instead of
  O(N).

  WEAKENED, NOT BROKEN:
    AES-128   -> effectively ~64-bit    -> UPGRADE
    AES-256   -> effectively ~128-bit   -> FINE
    SHA-256   -> ~128-bit preimage      -> FINE
    SHA-512, SHA-3                      -> FINE

  AND GROVER'S SPEEDUP IS HARD TO REALISE IN PRACTICE: it
  is inherently sequential, so it does not parallelise the
  way classical search does. The consensus is that
  doubling symmetric key sizes is sufficient and probably
  generous.

SO THE SUMMARY IS SIMPLE:

  SYMMETRIC CRYPTO SURVIVES. Use AES-256, SHA-384/512,
  and 256-bit MACs.

  ALL DEPLOYED PUBLIC-KEY CRYPTO DIES. It must be
  replaced.

WHEN? Nobody knows. Current machines have a few hundred
noisy qubits; breaking RSA-2048 is estimated to need
millions of physical qubits with error correction.
Estimates for a cryptographically relevant machine range
from "the 2030s" to "never". PLAN, DO NOT PANIC.
```

HARVEST NOW, DECRYPT LATER

An adversary can record encrypted traffic today and decrypt it once a quantum computer exists. So the relevant question is not "when will quantum computers arrive?" but "how long must this data stay secret?" If the answer is more than about ten years — medical records, state secrets, long-lived device identities — the migration is *already* late. Signatures are less urgent, since a signature only needs to resist forgery while it is still being verified. But a firmware root key burned into a 2026 device that ships until 2035 and runs until 2050 is exactly the case that needs planning now.

The NIST standards

Standard	Was called	Type	Based on
FIPS 203 — ML-KEM	Kyber	Key encapsulation	Module lattices (MLWE)
FIPS 204 — ML-DSA	Dilithium	Signature	Module lattices
FIPS 205 — SLH-DSA	SPHINCS+	Signature	Hash functions only
FIPS 206 — FN-DSA	Falcon	Signature	NTRU lattices
SP 800-208 — LMS / XMSS	—	**Stateful** signature	Hash functions only
HQC	—	Key encapsulation	Codes — a backup for ML-KEM

```
/* SIZES, AND THIS IS THE PART THAT HURTS EMBEDDED WORK
   (128-bit-class parameter sets)                          */

                    PUBLIC KEY   CIPHERTEXT/SIG   SECRET KEY
   X25519               32 B          32 B           32 B
   ML-KEM-768         1,184 B       1,088 B         2,400 B
                        ^37x          ^34x

   Ed25519              32 B          64 B           64 B
   ML-DSA-65          1,952 B       3,309 B         4,032 B
                        ^61x          ^52x
   FN-DSA-512           897 B         666 B         1,281 B
   SLH-DSA-128s          32 B       7,856 B           64 B
   LMS (h=20)            60 B      ~2,800 B          ~50 B

/* WHAT THAT MEANS IN PRACTICE:

   · A TLS HANDSHAKE grows by several kilobytes. Over a
     constrained radio link - LoRa, BLE, 802.15.4 with
     127-byte frames - that is a fragmentation and
     retransmission problem, not just a bandwidth one.
   · A FIRMWARE MANIFEST with an ML-DSA signature is 3 KB
     instead of 64 bytes. Fine.
   · A PUBLIC KEY IN OTP FUSES IS NOW IMPOSSIBLE at 1,952
     bytes. STORE A HASH (chapter 16) - which you should
     have been doing anyway.
   · RAM: ML-KEM-768 key generation needs a few kilobytes of
     working memory. Manageable on a Cortex-M4, painful on
     an M0+ with 16 KB.

/* SPEED IS ACTUALLY GOOD NEWS. Lattice operations are
   number-theoretic transforms and small-integer arithmetic -
   no big-number modular exponentiation. On a Cortex-M4,
   ML-KEM-768 encapsulation is roughly COMPARABLE TO OR
   FASTER THAN X25519, and dramatically faster than RSA. The
   cost is bandwidth and memory, not cycles.              */
```

Key encapsulation, and why the shape changed

```
/* PQ KEY EXCHANGE IS NOT DIFFIE-HELLMAN. There is no
   "raise the peer's value to my secret". The primitive is a
   KEM: KEY ENCAPSULATION MECHANISM.                      */

    KEYGEN()            -> (pk, sk)
    ENCAPS(pk)          -> (ciphertext, shared_secret)
    DECAPS(sk, ct)      -> shared_secret

/* THE FLOW:
     Alice generates (pk, sk), sends pk.
     Bob runs ENCAPS(pk), gets a random shared secret and a
       ciphertext. Sends the ciphertext.
     Alice runs DECAPS(sk, ct) and gets the same secret.

   ONE ROUND TRIP, same as DH, but ASYMMETRIC IN SHAPE - Bob
   chooses the secret rather than both contributing. That
   means SOME DH-BASED PROTOCOL PATTERNS DO NOT TRANSLATE
   DIRECTLY. Noise's DH-based patterns (chapter 13), for
   instance, needed a redesign; the PQNoise variants use KEMs
   explicitly.

/* --- HYBRID MODE: what everyone is actually deploying --- */

    shared_secret = KDF( X25519_output ‖ ML-KEM_output
                         ‖ transcript )

    THE POINT: THE RESULT IS SECURE IF *EITHER* PRIMITIVE IS
    SECURE.
      · if ML-KEM turns out to have a classical break - and
        it is a young algorithm; SIKE was broken in 2022 by a
        single laptop over a weekend, after reaching the
        final round - X25519 still protects you
      · if a quantum computer arrives, ML-KEM still protects
        you

    THIS IS THE RIGHT DEFAULT AND IT IS ALREADY DEPLOYED:
    X25519MLKEM768 is on by default in Chrome and Firefox,
    supported by OpenSSL 3.5+, and used by a large fraction
    of Cloudflare's traffic. If you are adding PQ to a
    product today, ADD IT AS A HYBRID.

/* --- THE CODE, liboqs --- */
    OQS_KEM *kem = OQS_KEM_new(OQS_KEM_alg_ml_kem_768);

    uint8_t pk[OQS_KEM_ml_kem_768_length_public_key];
    uint8_t sk[OQS_KEM_ml_kem_768_length_secret_key];
    OQS_KEM_keypair(kem, pk, sk);
    /* send pk (1184 bytes) */

    /* the peer: */
    uint8_t ct[OQS_KEM_ml_kem_768_length_ciphertext];
    uint8_t ss[OQS_KEM_ml_kem_768_length_shared_secret];
    OQS_KEM_encaps(kem, ct, ss, pk);
    /* send ct (1088 bytes) */

    /* back at the originator: */
    OQS_KEM_decaps(kem, ss, ct, sk);

    /* THEN HYBRID-COMBINE AND RUN IT THROUGH A KDF - never
       use a KEM output directly as a key (chapter 10): */
```

```
    hkdf(prk, x25519_ss ‖ ss, "myproto v2 hybrid", key, 32);

    OQS_KEM_free(kem);

/* NOTE: DECAPS NEVER FAILS. ML-KEM uses an implicit
   rejection construction - a malformed ciphertext produces a
   deterministic but WRONG shared secret rather than an
   error. That is deliberate: it removes a decryption oracle
   of exactly the Bleichenbacher shape (chapter 12). Your
   protocol finds out later, when the AEAD tag check fails.
   DO NOT ADD YOUR OWN "IS THIS CIPHERTEXT VALID" CHECK - you
   would be re-creating the oracle.                       */
```

Signatures, and the stateful option

```
/* --- ML-DSA (Dilithium): the general-purpose choice --- */
    Lattice-based, Fiat-Shamir with aborts. Fast, moderate
    sizes, no state. USE THIS unless you have a specific
    reason not to.

/* --- FN-DSA (Falcon): smaller, harder to implement --- */
    666-byte signatures - the smallest lattice option. But
    signing requires FLOATING-POINT GAUSSIAN SAMPLING, which
    is a side-channel minefield (chapter 19) and behaves
    differently across FPUs. VERIFICATION is easy and
    integer-only. A reasonable split: sign in the factory
    with a well-tested implementation, verify on-device.

/* --- SLH-DSA (SPHINCS+): the conservative choice --- */
    SECURITY RESTS ONLY ON HASH FUNCTIONS. No lattices, no
    new mathematical assumptions - if SHA-256 survives, this
    survives. Stateless.
    THE COST: 7-30 KB signatures and slow signing.
    USE FOR: a root of trust you cannot ever update. If your
    boot ROM's root key must be trustworthy for thirty years
    and you cannot patch it, the conservative assumption is
    worth the size.

/* --- LMS AND XMSS: STATEFUL, and read this carefully --- */
    Hash-based Merkle signature schemes. Small keys, moderate
    signatures, very conservative security.

    THE CATCH:

      EACH ONE-TIME KEY MAY BE USED EXACTLY ONCE.
      REUSING AN INDEX LEAKS THE PRIVATE KEY.

    So the signer must keep a COUNTER THAT NEVER GOES
    BACKWARDS - across crashes, backups, VM snapshots, and
    redundant signing servers. A restored backup is a key
    compromise. This is why NIST approved them ONLY for
    firmware signing (SP 800-208): a controlled,
    low-frequency, single-signer environment where the state
    can genuinely be managed.

    DO NOT USE THEM for anything with multiple signers or
    uncontrolled infrastructure.

/* --- THE PRACTICAL RECOMMENDATION TABLE ---
     TLS / session keys        hybrid X25519 + ML-KEM-768
     general signatures        ML-DSA-65 (hybrid with
                               Ed25519 during transition)
     firmware signing, updatable   ML-DSA-65 or LMS
     an unpatchable boot ROM root  SLH-DSA, or LMS with
                               rigorous state management
     symmetric everything      AES-256, SHA-384/512,
                               HMAC-SHA-384              */
```

Migrating a product

```
/* --- STEP 1: INVENTORY --- */
    Every place the product uses public-key cryptography:
      TLS to the cloud, firmware signature verification, the
      device identity certificate, secure boot, attestation,
      any licensing or pairing scheme, third-party SDKs.
    YOU CANNOT MIGRATE WHAT YOU HAVE NOT LISTED, and the
    third-party SDKs are the ones people forget.

/* --- STEP 2: CLASSIFY BY LIFETIME --- */
      confidentiality needed for > 10 years   -> URGENT,
                                                 harvest-now
      device identities lasting > 10 years    -> URGENT
      signatures verified only while current  -> can wait
      session data with short value           -> can wait

/* --- STEP 3: BUILD FOR CRYPTOGRAPHIC AGILITY --- */
    THIS IS THE HIGHEST-VALUE WORK, and it is useful even if
    quantum computers never arrive.

      · ALGORITHM IDENTIFIERS in every stored and transmitted
        format
      · KEY IDs, so keys can be rotated (chapter 18)
      · SIZE-AGNOSTIC BUFFERS AND FIELDS - a protocol with a
        fixed 64-byte signature field cannot ever carry a
        3 KB one. LENGTH-PREFIX EVERYTHING.
      · a NEGOTIATION mechanism, with a floor
      · no algorithm assumptions baked into wire formats or
        flash layouts
      · reserve space: OTP slots for multiple root key
        hashes, flash regions sized for larger manifests

/* --- STEP 4: DEPLOY HYBRIDS FIRST --- */
    Never a flag day. Support both, negotiate, measure, then
    deprecate.

/* --- AND THE HARDWARE QUESTION --- */
    Silicon designed today ships for years and lives for
    decades. If you are specifying an SoC now:
      · does the boot ROM support a PQ signature, or at
        least a second-stage loader that can?
      · is there enough OTP for larger key hashes and more
        slots?
      · enough RAM for lattice operations in the boot path?
      · a hash accelerator - SLH-DSA and LMS are almost
        entirely hashing
    A DEVICE WHOSE MASK-ROM ROOT OF TRUST IS RSA-2048 AND
    WHOSE ROM CANNOT BE UPDATED HAS A FIXED EXPIRY DATE.
    That is a business decision as much as a technical one,
    and it should be made deliberately rather than by
    default.                                              */
```

How it shows up

Symptom	Cause
Handshake fails over a constrained radio	Multi-kilobyte PQ messages exceed the frame or MTU budget
Cannot fit the public key in fuses	PQ keys are kilobytes — store a hash

Symptom	Cause
Out of memory during key generation	Lattice working buffers on a small MCU
A protocol cannot carry the new signature	Fixed-size signature field — no agility
Recorded traffic decryptable in 2040	Classical-only key exchange — harvest now, decrypt later
A new algorithm is broken and there is no fallback	PQ-only instead of hybrid
LMS private key compromised	State counter reused after a restore from backup
Falcon signatures leak the key	Floating-point Gaussian sampling side channel
A decryption oracle reappears	A custom "valid ciphertext?" check added around ML-KEM decaps
The product cannot be migrated at all	Unpatchable mask ROM with a classical root of trust

Check yourself

- ✓ Say precisely what Shor's and Grover's algorithms each do to which primitives.
- ✓ Explain harvest-now-decrypt-later and how it changes the urgency calculation.
- ✓ Name the four NIST standards and what each is for.
- ✓ Quote the size ratios versus X25519 and Ed25519, and name three practical consequences.
- ✓ Explain why PQ speed is not the problem but bandwidth and memory are.
- ✓ Define a KEM and say how its shape differs from Diffie–Hellman.
- ✓ Explain hybrid mode and give two independent reasons for it.
- ✓ Explain why ML-KEM decapsulation never fails, and why adding a check is dangerous.
- ✓ Say when SLH-DSA is worth its signature size.
- ✓ Explain the LMS/XMSS state requirement and why NIST restricted its use.
- ✓ List the four migration steps and the four hardware questions.

Cryptography in embedded systems

Everything in this track, applied to a device with 256 KB of RAM, no clock, a physically accessible attacker and a fifteen-year service life. The closing chapter: what to choose, what it costs, and what actually goes wrong in shipped products.

What makes embedded different

```
THE CONSTRAINTS

MEMORY        20–40 KB of RAM for one TLS session; a
              whole MCU may have 64 KB. RAM, not CPU, is
              usually what stops you.
FLASH         a TLS stack is 60–100 KB. On a 256 KB part
              that is a third of your budget.
POWER         a battery device may have a lifetime energy
              budget. Every handshake costs measurable
              charge.
NO CLOCK      no RTC, or one that resets. Certificate
              dates cannot be checked (chapter 16).
NO ENTROPY    at first boot, before any peripheral has
              produced noise (chapter 02).
NO UPDATES    or updates that many units never take.
BANDWIDTH     a 127-byte 802.15.4 frame; a LoRa payload
              measured in tens of bytes.
LIFETIME      15–20 years. Longer than the algorithms.

THE THREAT MODEL

THE ATTACKER OWNS THE HARDWARE. They can:
  · read the external flash with a $20 clip
  · probe the buses
  · glitch the power and clock (chapter 19)
  · decapsulate the die
  · buy a hundred units and destroy ninety-nine
  · and take as long as they like

AND THE ECONOMICS: BREAK ONE, BREAK ALL. If the key is the
same in every unit, one extraction is a product-wide
compromise, permanently, with no way to recall. This is
the single fact that should drive every design decision
in this chapter.

SO: PER-DEVICE KEYS, GENERATED ON-DEVICE, HELD IN
HARDWARE (chapter 18). Everything else is secondary.
```

Picking the algorithms

Need	Choose	Because
Encryption + integrity	AES-256-GCM with hardware; else ChaCha20-Poly1305	AEAD, one primitive, no composition mistakes (ch. 09)
Nonce uniqueness in doubt	AES-GCM-SIV or XChaCha20-Poly1305	Counters reset; misuse resistance is cheap insurance
Tiny AES-only hardware	AES-CCM	Encrypt direction only; what 802.15.4 uses anyway

Need	Choose	Because
Very constrained	ASCON	NIST lightweight standard; tiny in gates and code
Hashing	SHA-256 with hardware; else BLAKE2s	Accelerators are common; BLAKE2s is fast in software (ch. 07)
MAC	HMAC-SHA-256, or CMAC with AES hardware	ch. 08
Key exchange	X25519	32 bytes, constant time, no validation to get wrong (ch. 14)
Signatures (device)	Ed25519	No nonce to leak, no DER to parse (ch. 15)
Signatures (boot ROM)	Whatever the ROM implements	Not your decision — usually RSA-2048/3072 or ECDSA P-256
Password / PIN	Argon2id if RAM allows; else a hardware attempt counter	ch. 10 — and low entropy needs hardware, not maths
Key derivation	HKDF-SHA-256	Cheap, and it gives you key separation for free
Long-lived roots	Plan for ML-DSA or LMS	ch. 20

```
/* AND THE FIRST QUESTION, BEFORE ANY OF THAT:

     WHAT DOES THE SILICON ALREADY HAVE?

   Read the TRM's security chapter before choosing anything.
   Most modern MCUs have more than developers use:

     AES engine (often with GCM/CCM modes)
     SHA accelerator
     a true RNG
     a PKA / ECC accelerator
     a hardware-only key slot wired into the AES engine
     a unique device ID
     OTP fuses
     a tamper or glitch detector
     a monotonic counter

   USING THE ACCELERATOR IS 10-50x FASTER AND USUALLY MORE
   SIDE-CHANNEL RESISTANT than your software implementation.
   And the hardware key slot means the key never enters
   CPU-addressable memory at all - which is worth more than
   any amount of careful C.

   THE INTEGRATION POINT: mbedTLS ALT implementations
   (MBEDTLS_AES_ALT and friends), or the PSA Crypto API,
   which is the modern way - you ask for "an AES-GCM
   operation with key handle 3" and the implementation routes
   it to hardware or software as available. WRITE AGAINST
   PSA CRYPTO if your stack supports it; it makes the
   hardware/software choice a build-time concern instead of
   a code change.                                          */
```

What it costs

```
/* CORTEX-M4 AT 100 MHz, SOFTWARE, ROUGH ORDERS OF MAGNITUDE

   OPERATION                    TIME        FLASH
   AES-128-GCM, 1 KB            ~250 us     ~6 KB
     with hardware AES          ~10 us      ~1 KB
   ChaCha20-Poly1305, 1 KB      ~150 us     ~4 KB
   SHA-256, 1 KB                ~100 us     ~3 KB
     with hardware              ~5 us
   HMAC-SHA-256                 ~200 us     +1 KB
   X25519 scalar multiply       ~40 ms      ~8 KB
   Ed25519 sign                 ~50 ms      ~12 KB
   Ed25519 verify               ~140 ms
   ECDSA P-256 sign             ~80 ms      ~15 KB
   RSA-2048 verify (e=65537)    ~30 ms      ~10 KB
   RSA-2048 sign (CRT)          ~900 ms
   Argon2id, 16 MB              ~2 s        ~5 KB + 16 MB RAM
   ML-KEM-768 encapsulate       ~15 ms      ~15 KB

   A FULL TLS 1.3 HANDSHAKE, ECDHE + ECDSA, in software:
     ~400-800 ms and ~25 KB of RAM.
   With a PKA accelerator: ~50-100 ms.

/* THE ENERGY VIEW, which matters more on a battery:
     one handshake  ~ 50-200 mJ in software
     one AEAD record ~ negligible

   SO THE DESIGN RULE FOR BATTERY DEVICES:
     HANDSHAKE RARELY, ENCRYPT FREELY.
       · session resumption / PSK tickets, so one handshake
         per boot rather than per message
       · long-lived sessions rather than reconnecting
       · batch messages
       · and if the device wakes to send 20 bytes once an
         hour, a full TLS handshake each time may cost more
         energy than the radio. Consider a
         provisioned-symmetric design (chapter 17's PSK
         mode) with per-device keys, or OSCORE/EDHOC for
         CoAP - which were designed for exactly this
         profile.

/* AND THE SIZING SHORTCUT: if the part has hardware AES and
   SHA, symmetric crypto is essentially free and you should
   use it liberally. It is the PUBLIC-KEY operations that
   cost, so the design question is always "how often do we do
   asymmetric work?"                                        */
```

Four patterns worth copying

```
/* --- 1. SECURE BOOT --- */
    ROM (immutable)
      verify bootloader signature against a key hash in OTP
      check the anti-rollback counter
    BOOTLOADER
      verify the application signature
      check version, device class, image length
      measure into a TPM/PCR if present
    APPLICATION
      verify any signed data it loads

    EACH STAGE VERIFIES THE NEXT BEFORE TRANSFERRING
    CONTROL. The chain is only as strong as the ROM, which
    cannot be changed - so ROM bugs are permanent, and this
    is why boot ROM code is short and heavily reviewed.
    (Full treatment in the isolation track.)

/* --- 2. FIRMWARE UPDATE --- */
    a signed MANIFEST containing:
      format version, firmware version, device class,
      image hash, image length, timestamp
    encrypted image, if confidentiality matters
    verification BEFORE installation
    an anti-rollback counter in fuses
    A/B SLOTS AND A ROLLBACK-ON-FAILURE PATH

    THE ORDERING RULE: EVERY CHECK THAT CAN REJECT HAPPENS
    BEFORE ANYTHING IRREVERSIBLE. And hash the image in its
    final location, so DMA cannot swap it after the check
    (chapter 15).

/* --- 3. DEVICE IDENTITY --- */
    key pair generated INSIDE the secure element at
      manufacture; the private half never exists elsewhere
    a certificate signed by the vendor CA, containing the
      device serial and product class
    mutual TLS to the cloud, validated against a PINNED
      vendor root
    the cloud checks the serial against inventory:
      registered? activated? reported stolen? firmware
      version acceptable?
    (chapters 16 and 17)

/* --- 4. SECURE STORAGE --- */
    key = KDF(hardware_unique_key, "storage v1")
    each record: version ‖ nonce ‖ ciphertext ‖ tag
    version authenticated as AAD -> no rollback
    nonce from a counter IN FLASH, not RAM
    crypto-erase to destroy, never overwrite
    (chapter 18)                                          */
```

THE FIVE RULES, IF YOU REMEMBER NOTHING ELSE

1. PER-DEVICE KEYS, generated on-device, in hardware.
2. USE AN AEAD. Never compose a cipher and a MAC yourself.
3. NEVER REUSE A (key, nonce) PAIR.
4. USE A MAINTAINED LIBRARY, AND KEEP IT UPDATED.
   Your update mechanism is a security control.
5. VERIFY BEFORE YOU ACT. Signature, then version, then
   identity, then use — and only then anything
   irreversible.

The mistakes that ship

```
/* Ranked by how often they appear in real teardowns.     */

   1.  THE SAME KEY IN EVERY UNIT. Found by `strings`.
       One extraction, whole product line.

   2.  NO SECURE BOOT. Or secure boot present but disabled
       in production, because the fuse was never blown on
       the line. CHECK YOUR PRODUCTION UNITS, not your dev
       boards.

   3.  DEBUG PORTS OPEN. JTAG/SWD enabled in shipped
       hardware, or re-enabled by a lifecycle state that
       was never advanced.

   4.  CERTIFICATE VALIDATION DISABLED. The development
       bypass that shipped (chapter 16).

   5.  HOSTNAME VERIFICATION NOT ENABLED. A one-line
       omission that silently accepts any valid certificate
       (chapter 17).

   6.  WEAK ENTROPY AT FIRST BOOT. Keys generated before the
       RNG was seeded (chapter 02), producing duplicate or
       factorable keys across a fleet.

   7.  ROLLING YOUR OWN. A custom "encryption" scheme, an
       XOR obfuscation, a hand-built MAC. It is always
       broken, and it is always broken quickly.

   8.  ECB MODE. Because it was the default parameter
       (chapter 05).

   9.  NO ANTI-ROLLBACK. Old vulnerable firmware reinstalls
       with a perfectly valid signature.

   10. NO UPDATE MECHANISM AT ALL. Which converts every
       future vulnerability into a permanent one.

   11. NONCE COUNTERS IN RAM, resetting on every power
       cycle.

   12. UNAUTHENTICATED BUSES to a secure element - the SE
       is correct, and the attacker replays "OK" on the I2C
       lines.

   13. SECRETS IN LOGS on an accessible UART.

   14. NO PLAN FOR COMPROMISE. No key IDs, no rotation
       path, no revocation, no incident procedure.

/* NOTICE HOW FEW OF THESE ARE CRYPTOGRAPHIC. Almost every
   one is a PROVISIONING, CONFIGURATION, LIFECYCLE or
   PROCESS failure. That is the real lesson of this track:
   the algorithms are the easy part, and they are not where
   your product will fail.                                */
```

A pre-ship checklist

```
   KEYS
   [ ] every key is per-device
   [ ] device keys generated on-device, never exported
   [ ] no key material in the firmware image (verify with
       `strings` and an entropy scan on the RELEASE binary)
   [ ] all working keys derived from a root, with context
       strings
   [ ] key IDs in every stored and transmitted format
   [ ] a written rotation and compromise plan

   BOOT AND UPDATE
   [ ] secure boot enabled AND VERIFIED ON A PRODUCTION UNIT
   [ ] root key hash in OTP, with spare slots
   [ ] anti-rollback counter, and it is actually incremented
   [ ] update images signed; manifest includes version and
       device class
   [ ] verify-before-install, with A/B and recovery
   [ ] the update path itself has been tested from a
       corrupted state

   PROTOCOL
   [ ] AEAD everywhere; no hand-composed cipher+MAC
   [ ] nonce uniqueness guaranteed by a mechanism, not a hope
   [ ] certificate validation on, hostname verification on,
       root pinned
   [ ] minimum TLS version floored
   [ ] replay protection (sequence numbers) present
   [ ] tested against expired, wrong-name, self-signed and
       malformed certificates

   IMPLEMENTATION
   [ ] a maintained library, pinned version, CVE monitoring
       subscribed
   [ ] hardware accelerators used where present
   [ ] constant-time comparisons for all secrets
   [ ] secrets zeroised with a non-removable primitive
   [ ] dudect or ctgrind in CI if you wrote any primitive
       yourself

   LIFECYCLE
   [ ] debug ports disabled in the SECURED state
   [ ] the RMA path erases secrets before re-enabling debug
   [ ] no secrets on any log output
   [ ] production units audited, not just development
       boards

/* AND THE LAST ONE, WHICH IS NOT A CHECKBOX:

     HAVE SOMEONE ELSE TRY TO BREAK IT.

   An external review, or at minimum a colleague who did not
   write it, with a logic analyser, a flash clip and a
   ChipWhisperer. Every item above is something a reviewer
   finds in an afternoon and a designer misses for a year.
                                                          */
```

How it shows up

Symptom	Cause
A published exploit affects every unit ever made	Shared key, no update mechanism
Firmware dumped from SPI flash and read directly	No image encryption, no secure boot
Root shell over an unpopulated header	Debug port left enabled in production
Cloud traffic readable through a proxy	Certificate or hostname verification disabled
Duplicate device keys across a batch	RNG unseeded at first boot
Vulnerable firmware reinstalled deliberately	No anti-rollback counter
Handshake drains the battery	Full TLS handshake per wake-up — resume or use PSK
Out of RAM when the connection opens	16 KB TLS record buffers on a 64 KB part
Secure element bypassed	Unauthenticated bus between host and SE
Nothing can be fixed after disclosure	No update path, no key rotation, no revocation
It worked on the dev board	Fuses never blown on the production line

Check yourself

- ✓ List the eight embedded constraints and say which usually binds first.
- ✓ State the "break one, break all" economics and the design rule it forces.
- ✓ Choose algorithms for eight needs and justify each in one line.
- ✓ Say what to look for in a TRM before choosing anything, and why PSA Crypto helps.
- ✓ Recall the rough cost of a software TLS handshake in time, flash, RAM and energy.
- ✓ State the battery design rule and three ways to apply it.
- ✓ Describe the four standard patterns: secure boot, update, identity, storage.
- ✓ Recite the five rules.
- ✓ Name ten of the fourteen shipping mistakes, and say what most of them have in common.
- ✓ Walk the pre-ship checklist and name the item that is not a checkbox.

TRACK

Linux kernel & drivers

Kernel internals and driver development, ending in two complete drivers you build and break yourself.

32 chapters

The kernel source tree and how to navigate it

Forty million lines of C, and you will never read most of it. What you need is the skill of finding the twenty lines that matter in under a minute — which is a learnable, mechanical skill, and the first one to acquire.

Getting it

```
# The mainline tree, full history. ~4 GB, worth having.
git clone https://git.kernel.org/pub/scm/linux/kernel/git/torvalds/linux.git
cd linux

# Shallow, if you only want to read one version:
git clone --depth 1 --branch v6.12 \
    https://git.kernel.org/pub/scm/linux/kernel/git/torvalds/linux.git

# The trees you will care about in embedded work:
#   torvalds/linux          mainline - where everything lands
#   stable/linux-stable     the -stable branches, v6.12.y etc.
#   next/linux-next         everything queued for the NEXT merge
#                           window; check here before writing
#                           something that already exists
#   soc/soc                 the arm-soc tree
#   <vendor>/<board>        the BSP you actually ship, usually
#                           an old LTS plus 3,000 patches

# THE VERSION SCHEME:
#   6.12        a mainline release, roughly every 9-10 weeks
#   6.12.34     a stable update: fixes only, no features
#   6.12-rc3    a release candidate
#   LTS         one release a year, maintained ~2-6 years.
#               6.1, 6.6, 6.12... - this is what products ship.
```

The layout

```
linux/
  arch/          per-architecture code. arch/arm64/ is yours.
      arm64/boot/dts/       DEVICE TREES live here
      arm64/kernel/         entry.S, setup.c, the exception
                            vectors from ARM chapter 27
      arm64/mm/             page table code
      arm64/include/asm/    architecture headers

  block/         the block layer
  certs/         module signing keys
  crypto/        the crypto API

  Documentation/ genuinely good. Start here more often than
                 you think. Documentation/driver-api/,
                 Documentation/devicetree/bindings/ ...

  drivers/       ~70% of the tree. Where your code goes.
      base/      the DEVICE MODEL - bus, driver, device
      gpio/  i2c/  spi/  pci/  usb/  net/  mmc/  tty/
      char/      character devices
      dma/       DMA engine drivers
      iommu/     the SMMU drivers (isolation ch. 03-07)
      tee/       the OP-TEE driver (isolation ch. 12)
      clk/       the common clock framework
      regulator/ power supplies
      pinctrl/   pin muxing
      soc/       vendor SoC glue
      staging/   not yet good enough. Do not learn style here.

  fs/            filesystems. fs/proc/, fs/sysfs/, fs/ext4/ ...
  include/
      linux/     the headers you include. THE reference.
      uapi/      the USERSPACE ABI. Changing these breaks
                 programs; treat as immutable.
      asm-generic/
  init/          start_kernel() lives in init/main.c
  ipc/           SysV IPC
  kernel/        the core: sched/, locking/, irq/, time/,
                 rcu/, workqueue.c, module/, dma/
  lib/           data structures, string ops, sorting
  mm/            memory management: page_alloc.c, slub.c,
                 vmalloc.c, mmap.c
  net/           the network stack
  samples/       small worked examples. Underused.
  scripts/       build tooling, checkpatch.pl, coccinelle
  security/      LSMs: SELinux, AppArmor, IMA
  sound/         ALSA
  tools/         perf, bpf, selftests, and much else
  virt/          KVM
```

> **THREE DIRECTORIES CARRY MOST OF YOUR WORK**
>
> For embedded driver development it is `drivers/` for the code, `include/linux/` for the API you are calling, and `Documentation/` for why. `arch/arm64/boot/dts/` joins them the moment you touch hardware description. Everything else you visit occasionally.

Finding things — the actual skill

```
# SET UP ONE OF THESE ON DAY ONE. Grepping 40 million lines
# interactively does not scale.

# cscope + ctags, the classic:
make ARCH=arm64 cscope tags
#   vim -t symbol_name        jump to a definition
#   Ctrl-]                    follow
#   :cs find c func           who CALLS this?

# Or the modern option, and the better one:
#   clangd + compile_commands.json
make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- defconfig
make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- -j$(nproc)
./scripts/clang-tools/gen_compile_commands.py
# now any LSP editor gives you real go-to-definition,
# find-references, and call hierarchies - CONFIG-aware, which
# grep is not.

# Or the web: https://elixir.bootlin.com/linux/latest/source
# Cross-referenced, version-switchable, no setup. Use it when
# you are away from your build machine. It is excellent.

# git grep is fast enough for a lot:
git grep -n "devm_platform_ioremap_resource" -- drivers/ | head
git grep -n "EXPORT_SYMBOL_GPL(dma_alloc_attrs)"
git grep -W "static int spi_probe"        # -W = whole function

# Restrict by directory, always:
git grep -n "regmap_write" -- drivers/iio/
```

The five questions, and how to answer each

```
# 1. "WHAT DOES THIS FUNCTION DO?"
     git grep -n "^\(static \)\?[a-z_ *]*\bfunc_name\b *(" -- '*.c'
   The DEFINITION is what you want, not the 200 call sites.
   Then read the kernel-doc comment above it - most exported
   functions have one, and it is usually accurate.

# 2. "HOW DO I USE THIS API?"
     Find an EXISTING DRIVER that uses it, and copy its shape.
     git grep -l "devm_request_threaded_irq" -- drivers/ | head
   This is the single most effective kernel technique. The tree
   is its own best documentation, because every user compiles
   and most were reviewed.
     Prefer a RECENT, SIMPLE driver: check `git log --oneline -3`
   on the file. Old drivers use deprecated patterns.

# 3. "WHY IS IT LIKE THIS?"
     git log -p --follow drivers/foo/bar.c
     git log -S "the_exact_string" -- drivers/foo/
     git blame drivers/foo/bar.c
   Kernel commit messages are unusually good. The one that
   introduced the odd-looking line usually explains the bug it
   fixed, with the reproducer.

# 4. "WHO CALLS THIS?"
     LSP find-references, or cscope, or:
     git grep -n "\bfunc_name\b" -- '*.c' '*.h'
   Watch for indirect calls through ops structures - grep finds
   `.probe = my_probe` but not the core code that invokes it.
   For those, search for the STRUCT MEMBER name instead:
     git grep -n "->probe(" -- drivers/base/

# 5. "IS THIS CODE EVEN COMPILED?"
     The most common wasted hour. Find the Makefile:
     cat drivers/foo/Makefile
       obj-$(CONFIG_FOO) += foo.o
     then check your .config:
     grep CONFIG_FOO .config
   And check the #ifdefs. Half the file may be behind
   CONFIG_PM or CONFIG_OF. Reading code that your build never
   compiles is a genuinely common failure mode - which is why
   an LSP with your real compile_commands.json beats grep.
```

> **READ A SUBSYSTEM IN THIS ORDER**
>
> 1. `Documentation/` for the subsystem — the design intent.
> 2. `include/linux/<subsys>.h` — the public API and the key structs. This is the contract.
> 3. The smallest, newest driver in that subsystem — the shape of a real user.
> 4. The core file — only now, and only the paths your driver touches.
>
> Going straight to the core file is the mistake everyone makes once. You will read 4,000 lines of generic machinery before learning what it is for.

Conventions that decode the code

You see	It means
`__init`	Used only at boot; freed afterwards. Calling it later is a bug.
`__exit`	Only in a module unload path; discarded if built in.
`__user`	A user-space pointer. **Never dereference** (ch. 08). Checked by `sparse`.
`__iomem`	An MMIO pointer. Use `readl` / `writel`, not `*p` (ch. 23).
`__percpu`, `__rcu`	Access only through the matching accessors.
`__must_check`	Ignoring the return value is a warning — and usually a bug.
`static`	File-local. Most driver functions are. If it is not static, ask why.
`EXPORT_SYMBOL_GPL`	Available to GPL modules only. The absence of an export is a deliberate boundary.
`devm_*`	Device-managed: freed automatically on unbind (ch. 26). Prefer these.
`__weak`	A default that an architecture or driver may override.
`likely()`, `unlikely()`	Branch hints. `unlikely` almost always marks an error path.
`ERR_PTR`, `IS_ERR`, `PTR_ERR`	An error code smuggled inside a pointer. Check with `IS_ERR`, never against `NULL`.
A trailing `_locked` or `__` prefix	The caller must already hold the relevant lock.

Kconfig: how code is selected

```
# drivers/foo/Kconfig
config FOO_DRIVER
        tristate "Foo device support"      # tristate: y/m/n
        depends on ARCH_MYSOC && OF        # only offered if...
        select REGMAP_MMIO                 # force this on
        default n
        help
          Say Y here if you have a Foo device.

# drivers/foo/Makefile
obj-$(CONFIG_FOO_DRIVER) += foo.o          # y -> built in
                                           # m -> a module
foo-objs := foo-core.o foo-hw.o            # multi-file module

# THE THREE STATES, and they matter:
#   y  compiled into vmlinux. Available at boot. No unload.
#   m  a .ko module. Loadable, unloadable, and therefore
#      exercisable - which makes development far faster.
#   n  not compiled at all.

# depends on   the option is HIDDEN unless the dependency is met
# select       forcibly enables another option - use sparingly,
#              it bypasses that option's own dependencies and is
#              a classic source of unbuildable configs

# FINDING WHY AN OPTION IS UNAVAILABLE:
make ARCH=arm64 menuconfig
#   press '/' and search for the symbol. It shows the full
#   dependency chain and what you must enable first. This one
#   keystroke answers 90% of "why can't I turn this on".
```

Where the real answers are

Resource	Use
elixir.bootlin.com	Cross-referenced source, any version. Best browser.
lore.kernel.org	Every mailing list, searchable. The design discussion behind any patch.
LWN.net	The best writing about kernel development anywhere. Read the merge-window summaries.
`Documentation/process/`	How to submit, how to report bugs, the coding style.
`scripts/get_maintainer.pl`	Who owns this file and which list to ask.
`git log`	Underrated. The answer to "why" is usually in a commit message.

```
# Who maintains the code you are about to change?
./scripts/get_maintainer.pl -f drivers/tee/optee/core.c

# What has changed in this file recently, and by whom?
git log --oneline -20 -- drivers/tee/optee/

# Has someone already proposed what I am about to write?
#   search lore.kernel.org, and check linux-next.
# This takes five minutes and occasionally saves a month.
```

How it shows up

Symptom	Cause
Your edits have no effect	The file is not compiled — check `CONFIG_` and the Makefile
Grep finds no callers of a function	Called indirectly through an ops struct — search the member name
The API you copied does not exist	Copied from a different kernel version; check against *your* tree
A Kconfig option cannot be enabled	An unmet `depends on` — use `/` in menuconfig
Enabling one option silently enables five	`select` chains
Code compiles in your editor, not in the build	Editor not using the real `compile_commands.json`; different `#ifdef`s active
Behaviour differs from the documentation	Your vendor BSP is old; read *its* source, not mainline
A pattern from `staging/` gets rejected in review	`staging/` is where non-conforming code waits — never a style reference

Check yourself

- ✓ Name what lives in `drivers/`, `include/linux/`, `include/uapi/`, `arch/arm64/` and `Documentation/`.
- ✓ Set up cscope/ctags or clangd against a configured tree, and jump to a definition.
- ✓ Answer all five questions for a function you have never seen.
- ✓ Explain why finding an existing user beats reading the core implementation first.
- ✓ Decode `__init`, `__user`, `__iomem`, `devm_` and `ERR_PTR` on sight.
- ✓ Read a Kconfig entry and say what it takes to enable it.
- ✓ Explain the difference between `y` and `m`, and why `m` is better during development.
- ✓ Use `get_maintainer.pl` and find the discussion behind a commit on lore.

Kernel versus user-space programming

You already know C. Kernel C is the same language with a different standard library, no safety net, and a set of rules that are not written in the compiler. This chapter is the list of everything that changes, so the first week costs you hours instead of days.

Everything that is different

	User space	Kernel
Standard library	libc: `printf`, `malloc`, `strcpy`	None. A kernel-specific subset: `pr_info`, `kmalloc`, `strscpy`
Floating point	Free	**Forbidden** without `kernel_fpu_begin()`; on ARM64 essentially never
Stack size	8 MB, grows	**16 KB total**, fixed, shared with interrupts
A bad pointer	SIGSEGV, one process dies	Oops or panic; the machine may go down
Memory leak	Freed at exit	Leaked until reboot
Preemption	Always	Depends on context and config; sometimes forbidden
Sleeping	Anywhere	Only in process context, never holding a spinlock
Concurrency	Threads you created	Every CPU, plus interrupts, plus timers — all at once
Debugging	gdb, valgrind, ASan	printk, ftrace, KASAN, and reading dumps
Errors	`errno`, exceptions	Negative return codes: `-ENOMEM`, `-EINVAL`
ABI stability	Stable for decades	**None internally**; the user-facing ABI is sacred
Compiler	Your choice of flags	`-ffreestanding`, no stdlib, kernel flags, strict warnings

The stack is 16 KB

```
/* THE most common beginner crash. On arm64, THREAD_SIZE is
   16 KB by default - and that is the whole kernel stack for
   the task, shared by every function on the call chain.     */

/* WRONG - 8 KB of stack in one line: */
static int my_ioctl(struct file *f, unsigned int cmd,
                    unsigned long arg)
{
        char buf[8192];                 /* half the stack */
        struct big_thing thing;         /* another 2 KB    */
        ...
}

/* RIGHT - allocate it: */
static int my_ioctl(struct file *f, unsigned int cmd,
                    unsigned long arg)
{
        char *buf;
        int ret;

        buf = kmalloc(8192, GFP_KERNEL);
        if (!buf)
                return -ENOMEM;
        ...
        kfree(buf);
        return ret;
}

/* THE RULE OF THUMB: keep any single frame under ~256 bytes,
   and never put an array larger than about 128 bytes on the
   stack. The compiler will warn above 1024 with
   -Wframe-larger-than, and the kernel sets that. DO NOT
   silence it.

   ALSO ON THE STACK, uninvited:
     · interrupt handlers, unless IRQ_STACKS is on
     · deep call chains through the block or network stack
     · recursion - which is why the kernel has almost none

   OVERFLOW SYMPTOM: not a clean error. You corrupt
   thread_info or the adjacent page and crash later,
   somewhere else, with a nonsensical backtrace. Enable
   CONFIG_VMAP_STACK (default on arm64) and overflow becomes a
   clean fault with a real trace instead.                   */
```

Context: the rule everything else follows

```
Kernel code runs in one of three contexts, and what you may do
depends entirely on which:

  PROCESS CONTEXT (also "task context")
     Entered via a syscall, or in a kernel thread.
     You have a `current` task. You may SLEEP.
     -> syscalls, ioctl, read/write, probe(), workqueues

  SOFTIRQ / TASKLET / BOTTOM-HALF CONTEXT
     Deferred interrupt work. No `current` you can rely on.
     MAY NOT SLEEP.
     -> network receive, some timers

  HARDIRQ CONTEXT (interrupt handler)
     Interrupts possibly disabled, must be FAST.
     MAY NOT SLEEP. May not call anything that might.
     -> your request_irq() top half

  AND A FOURTH STATE, orthogonal: ATOMIC.
     Holding a spinlock, or with preemption or interrupts
     disabled. MAY NOT SLEEP - even in process context.

  "MAY NOT SLEEP" MEANS you may not call:
       kmalloc(GFP_KERNEL)      -- may wait for reclaim
       mutex_lock()             -- may block
       copy_to_user()           -- may take a page fault
       msleep(), schedule()
       anything that says "might sleep" in its docs
       vmalloc(), most of the filesystem API

  and you MAY call:
       kmalloc(GFP_ATOMIC)      -- fails rather than waits
       spin_lock()
       readl()/writel()
       pr_info() (with care - it can be slow)

  HOW TO KNOW WHICH CONTEXT YOU ARE IN:
     read the caller. There is no runtime flag that answers it
     reliably - which is why the kernel gives you a checker:

       CONFIG_DEBUG_ATOMIC_SLEEP=y

     turns every illegal sleep into a loud
       "BUG: sleeping function called from invalid context"
     with a backtrace. TURN IT ON. It is the single most
     valuable debug option for a new kernel developer.
```

> **THE QUESTION TO ASK BEFORE EVERY CALL**
> "What context am I in, and can this function sleep?" Nearly every kernel bug a newcomer writes is an answer to that question they never asked. The kernel-doc for a function says *Context:* explicitly for many APIs; where it does not, the convention is that `GFP_KERNEL`, `mutex` and `_interruptible` in a name all imply sleeping.

The library you get instead

```
/* PRINTING */
        printf("x=%d\n", x);            /* NO */
        pr_info("x=%d\n", x);           /* yes */
        pr_err(), pr_warn(), pr_debug()
        dev_info(dev, "..."), dev_err(dev, "...")   /* BEST -
                       prefixes the device name automatically */

/* format specifiers differ - use the kernel's: */
        %pK    a pointer, hashed unless privileged
        %pa    a phys_addr_t / dma_addr_t
        %pOF   a device_node's full path
        %pe    an ERR_PTR, printed as "-ENOMEM"
        %*ph   a hex dump of n bytes
        size_t is %zu, not %lu

/* MEMORY */
        malloc(n)   ->  kmalloc(n, GFP_KERNEL)
        calloc      ->  kcalloc(n, size, GFP_KERNEL)
        realloc     ->  krealloc()
        free        ->  kfree()
        large       ->  vmalloc()  (virtually contiguous only)
        page-sized  ->  alloc_pages() / __get_free_pages()
        best        ->  devm_kzalloc(dev, n, GFP_KERNEL)
                        - freed automatically (chapter 26)

/* STRINGS - and the safe variants matter */
        strcpy      ->  strscpy(dst, src, sizeof(dst))
                        NOT strncpy, NOT strlcpy - strscpy
                        always NUL-terminates and returns
                        -E2BIG on truncation
        sprintf     ->  scnprintf(buf, size, ...)
                        returns what was ACTUALLY written,
                        unlike snprintf
        memcpy, memset, memcmp   -- these exist, use freely

/* ERRORS - negative errno, always */
        return -ENOMEM;
        return -EINVAL;
        return -EIO;
        return -EPROBE_DEFER;   /* kernel-specific: "try me
                                   again later" (chapter 17) */

/* POINTERS THAT ARE ERRORS */
        p = some_func();                /* returns ERR_PTR */
        if (IS_ERR(p))
                return PTR_ERR(p);
        /* NOT: if (!p) - a valid error pointer is non-NULL */

/* NO FLOATING POINT. None. The kernel does not save FP state
   on entry, so touching it corrupts user space's registers.
   Use fixed-point arithmetic:                                */
        /* instead of: temp_c = raw * 0.0625;              */
        temp_milli_c = (raw * 625) / 10;

/* DIVISION of 64-bit values on 32-bit builds needs helpers: */
        do_div(n64, d32);               /* modifies n64 */
        div_u64(n64, d32);
        div64_u64(n64, d64);
/* A plain `a / b` on two u64s can fail to link on 32-bit. */
```

Everything runs at once

```
/* In user space you know which threads you created. In the
   kernel, your code can be entered:

     · by every CPU simultaneously
     · re-entered by an interrupt on the same CPU
     · by a timer, a workqueue, or an RCU callback
     · by a different process through the same file descriptor
     · while your module is being unloaded

   ALL AT ONCE, from the first line you write.              */

/* WRONG - a shared counter with no protection: */
static int count;
static ssize_t my_write(...)
{
        count++;                /* read-modify-write RACE */
        ...
}

/* RIGHT - pick a mechanism (chapter 11): */
static atomic_t count = ATOMIC_INIT(0);
        atomic_inc(&count);

/* or, for anything more than a counter: */
static DEFINE_MUTEX(my_lock);           /* process context   */
static DEFINE_SPINLOCK(my_slock);       /* any context       */

/* AND THE SUBTLER ONE - your module can be unloaded while a
   callback is still queued: */
static void my_exit(void)
{
        cancel_delayed_work_sync(&work);  /* SYNC: wait for it */
        del_timer_sync(&timer);           /* SYNC */
        free_irq(irq, dev);
        /* only now is it safe for your code to disappear */
}
/* Get this wrong and you get "BUG: unable to handle page
   fault" inside freed module text - a crash with a
   backtrace pointing at addresses that no longer exist.  */
```

The compiler is not the one you know

```
# The kernel builds with, roughly:
    -ffreestanding          no assumptions about libc
    -fno-common
    -fno-strict-aliasing    the kernel type-puns deliberately
    -fno-delete-null-pointer-checks
    -fno-stack-protector    (or a kernel-specific one)
    -Wall -Wundef -Werror=implicit-function-declaration
    -Wframe-larger-than=1024 (or 2048)
    -std=gnu11
    no -O0 - the kernel REQUIRES optimisation to build
             correctly (inline assembly and __builtin
             constant folding depend on it)

# CONSEQUENCES:
#   · no libc headers. <stdio.h> does not exist. Use
#     <linux/kernel.h>, <linux/string.h>, <linux/types.h>.
#   · u8/u16/u32/u64 and s8..s64 instead of stdint types
#     (though stdint-style names exist via <linux/types.h>)
#   · __le32 / __be32 for explicit endianness, with
#     le32_to_cpu() etc. - and `sparse` checks you converted
#   · GNU extensions are used freely: statement expressions,
#     typeof, __attribute__, designated initialisers,
#     case ranges

# RUN SPARSE. It catches __user/__iomem/endian mistakes that
# the compiler cannot:
    make C=1 M=drivers/mydrv/          # check changed files
    make C=2 M=drivers/mydrv/          # check all files
```

Two kinds of ABI, opposite rules

	Internal kernel API	User-space ABI
Stability	**None.** Functions and structs change every release	**Absolute.** "We do not break user space"
Includes	`include/linux/`	`include/uapi/`, syscalls, ioctl numbers, sysfs paths, netlink messages, `/proc` formats
Consequence	Out-of-tree modules break on every upgrade — a reason to upstream	Design your ioctl interface once, carefully (ch. 21)

> **THE ASYMMETRY IS DELIBERATE**
>
> Internal churn is *allowed* precisely so that the kernel can be refactored to keep the external promise. That is why maintainers care so much about what your driver exposes to userspace and comparatively little about how it is structured internally: the first is forever, the second they can fix themselves.

Style, and why it is enforced

```
# Documentation/process/coding-style.rst. Non-negotiable in
# review, and mechanically checkable:

    ./scripts/checkpatch.pl --strict -f drivers/mydrv/mydrv.c

# The rules that trip people up:
#   tabs, 8 wide. Not spaces.
#   ~80 columns (100 tolerated, but aim for 80)
#   opening brace on the same line, EXCEPT for functions
#   no braces on single-statement bodies
#   typedef is discouraged - write `struct foo`
#   one declaration per line, no assignments in conditions
#   goto for error unwinding is CORRECT and idiomatic (ch. 26)
#   comments: /* ... */, not //, for multi-line

/* The idiomatic error path - learn to read and write this: */
static int my_probe(struct platform_device *pdev)
{
        struct my_dev *d;
        int ret;

        d = devm_kzalloc(&pdev->dev, sizeof(*d), GFP_KERNEL);
        if (!d)
                return -ENOMEM;

        d->base = devm_platform_ioremap_resource(pdev, 0);
        if (IS_ERR(d->base))
                return PTR_ERR(d->base);

        ret = my_setup(d);
        if (ret)
                return ret;            /* devm cleans up */

        platform_set_drvdata(pdev, d);
        return 0;
}
/* Note: `sizeof(*d)` not `sizeof(struct my_dev)` - so it stays
   correct if the type changes. This is house style and
   reviewers will ask for it.                                */
```

How it shows up

Symptom	Cause
Crash with a nonsensical backtrace	Stack overflow — check for large locals; enable `VMAP_STACK`
`BUG: sleeping function called from invalid context`	Slept while atomic — exactly what `DEBUG_ATOMIC_SLEEP` is for
`scheduling while atomic`	Same cause, caught elsewhere
Undefined reference to `__aeabi_uldivmod` or similar	64-bit division — use `div_u64()`
Undefined reference to `printf`, `malloc`	Used libc; there is no libc
Random user-space FP corruption	Floating point in kernel code
Crash inside freed module memory after `rmmod`	Timer, work or IRQ not cancelled synchronously
Works on one CPU, corrupts under load	Missing locking — it was always racy

Symptom	Cause
Checking a returned pointer against NULL still crashes	It was an `ERR_PTR`; use `IS_ERR`
Module loads on your kernel, not on the target's	No internal ABI stability — rebuild against the target's headers
Sparse warnings about `__user` or endianness	Real bugs. Fix them, don't cast them away

Check yourself

- ✓ List ten things that differ between kernel and user-space C.
- ✓ State the kernel stack size and rewrite a function with a large local buffer.
- ✓ Name the three contexts plus "atomic", and say what each forbids.
- ✓ Decide, for five given functions, whether they may sleep.
- ✓ Translate `printf`, `malloc`, `strcpy` and `sprintf` to their kernel equivalents, and say why `strscpy` beats the alternatives.
- ✓ Explain why floating point is forbidden and show a fixed-point replacement.
- ✓ Explain what `ERR_PTR` is for and check a result correctly.
- ✓ List four ways your code can be entered concurrently.
- ✓ Explain the opposite stability rules for internal and user-facing interfaces.
- ✓ Run `checkpatch.pl` and `sparse` on a file and fix what they report.

The ARM64 boot flow

From power-on to the first line of C. This is where the ARM architecture track and the Linux track meet: exception levels, the MMU, the device tree and secure firmware all appear in the first few hundred instructions, and knowing the sequence is what makes bring-up tractable.

The whole sequence

```
POWER ON
   |
   v
BOOT ROM (BL1)            EL3, MMU off, caches off
   |  verifies and loads BL2 (isolation ch. 14)
   v
BL2                       EL3 (or EL1S)
   |  initialises DRAM, loads BL31/BL32/BL33
   v
BL31 - TF-A runtime       EL3, stays resident forever
   |  installs the SMC handlers, PSCI, the vectors
   |  drops to...
   +--> BL32 - OP-TEE     S-EL1  (isolation ch. 12)
   |
   v
BL33 - U-Boot / UEFI      EL2 (usually) or EL1
   |  loads Image + DTB into DRAM
   |  may verify them (FIT signatures)
   v
KERNEL, at its entry point           EL2 or EL1
   |
   +-- head.S:  primary_entry
   |      preserve x0 = DTB physical address
   |      record the EL we were entered at
   |      if EL2: init_kernel_el -> either stay for KVM,
   |              or drop to EL1
   |      __create_page_tables    build the initial mapping
   |      __primary_switch        turn the MMU ON
   |      set up the stack, clear BSS
   v
start_kernel()            the first C function (chapter 04)
   |
   v
... subsystems, initcalls, drivers ...
   |
   v
init process, PID 1
```

The boot protocol

```
/* Documentation/arch/arm64/booting.rst - the CONTRACT between
   the bootloader and the kernel. Violate any of it and you get
   a silent hang with no output at all.                        */

   THE BOOTLOADER MUST:

   1. Load the kernel Image to a 2 MB-aligned address, anywhere
      in the first usable DRAM. The Image header declares where
      it wants to go and how big it is.

   2. Set:
        x0 = physical address of the DEVICE TREE BLOB
        x1 = 0    (reserved)
        x2 = 0
        x3 = 0

   3. Enter at the first byte of the Image, in:
        EL2 (preferred - enables KVM) or EL1 (non-secure)
        AArch64
        MMU OFF
        D-cache OFF          <-- and this one matters
        I-cache on or off
        interrupts (DAIF) masked

   4. Have CLEANED the kernel image and DTB TO THE POINT OF
      COHERENCY. With the MMU off, the kernel's accesses are
      Device/non-cacheable and will NOT snoop dirty lines the
      bootloader left in the cache (ARM chapters 18 and 19).
      This is the single most common cause of "loads, jumps,
      dies instantly".

   5. Ensure all secondary CPUs are either in a WFE holding
      pen, or - much better - parked and brought up via PSCI
      (isolation ch. 11).

   6. Provide a valid DTB, itself in memory the kernel can
      reach, with /memory and /chosen nodes.

/* THE IMAGE HEADER, first 64 bytes of arch/arm64/kernel/head.S: */

        code0           /* executable code, or an MZ magic for
                           EFI so the same file boots as a PE  */
        code1
        text_offset     /* where to load, relative to 2 MB     */
        image_size      /* total size including BSS - use this
                           to know how much room to leave      */
        flags           /* endianness, page size, placement    */
        res2..res4
        magic           /* "ARM\x64"                           */
        res5            /* PE header offset                    */

/* Read it with: */
        head -c 64 arch/arm64/boot/Image | xxd
```

"IT HANGS BEFORE ANY OUTPUT" — THE FOUR CAUSES

1. **Caches not cleaned** before jumping. The kernel reads stale memory.
2. **Entered at the wrong EL**, or in AArch32, or with the MMU on.
3. **A bad DTB** — wrong address in x0, corrupt magic, or a `/memory` node that does not describe real DRAM.
4. **The console is not where you think.** The kernel is running fine and printing to a UART you are not watching. Try `earlycon` before assuming a crash.

head.S, in order

```
/* arch/arm64/kernel/head.S. Read it once; it is only a few
   hundred lines and it demystifies the whole thing.        */

SYM_CODE_START(primary_entry)
        bl      record_mmu_state      /* were we entered with
                                         the MMU on? (EFI)    */
        bl      preserve_boot_args    /* stash x0..x3 - the
                                         DTB pointer!         */
        bl      create_idmap          /* an IDENTITY map: VA
                                         == PA, so we can keep
                                         executing across the
                                         MMU enable            */
        b       __primary_switch
SYM_CODE_END(primary_entry)

/* THE IDENTITY MAP TRICK - the central problem of MMU enable:

   Before:  PC = 0x40080000 (physical), MMU off
   After:   PC must be 0xffff800008080000 (virtual)

   You cannot change both at once. So:
     1. build a page table where VA 0x40080000 maps to
        PA 0x40080000 (the identity map), AND where the real
        kernel VA range maps to the same physical memory
     2. enable the MMU - the next instruction fetch at
        0x40080000 now translates through the identity map and
        finds the same code. Nothing appears to change.
     3. branch to the high virtual address
     4. tear down the identity map

   Same trick every OS uses, and the reason arm64 requires the
   kernel to be position-independent early on.             */

__primary_switch:

```

Which exception level, and why it matters

```
/* The kernel records the EL it was entered at, and behaves
   differently:                                              */

   Entered at EL2:
        · KVM is possible. The kernel installs a hypervisor
          stub at EL2 and runs itself at EL1.
        · With VHE (ARMv8.1, FEAT_VHE), the kernel runs
          DIRECTLY at EL2 with EL2 registers behaving like EL1
          ones - this is the normal case on modern hardware.
        · dmesg says:  "CPU: All CPU(s) started at EL2"

   Entered at EL1:
        · no KVM. Everything else works.
        · dmesg says:  "CPU: All CPU(s) started at EL1"
        · usually means the bootloader dropped to EL1 itself,
          or a hypervisor is already running above you

/* CHECK IT FIRST when virtualisation does not work: */
        dmesg | grep "CPU(s) started at"
        dmesg | grep -i kvm

/* A bootloader that drops to EL1 before entering Linux
   silently disables KVM forever. On U-Boot this is
   CONFIG_ARMV8_SWITCH_TO_EL1 - leave it off.               */
```

The device tree arrives

```
x0 at entry -> __fdt_pointer -> used in three phases:

  1. EARLY, before the MMU is fully set up:
       early_init_dt_scan()
         - /chosen  -> the kernel command line, initrd, stdout
         - /memory  -> how much DRAM, and where
         - reserved-memory -> carve-outs to keep out of the
           allocator (isolation ch. 18)
       These have to work with almost nothing available, so the
       early FDT code is a self-contained flat parser.

  2. UNFLATTENING, once memblock works:
       unflatten_device_tree() converts the flat blob into a
       tree of struct device_node objects with pointers.
       Now of_find_node_by_*() and friends work.

  3. DEVICE CREATION, much later, from an initcall:
       of_platform_populate() walks the tree and creates a
       struct platform_device for each node with a
       `compatible` - which is what your driver eventually
       binds to (chapter 17).

  So the DTB is consumed three times, in three different
  representations. Knowing which phase you are in explains why
  of_* APIs "do not work yet" in early code.
```

Getting output before the console exists

```
# The single most useful bring-up skill. A normal console is
# only registered once the serial DRIVER probes - hundreds of
# initcalls in. Everything before that is invisible by default.

# EARLYCON - a minimal, direct-MMIO UART writer, available
# almost immediately:

    earlycon                    # use /chosen/stdout-path from DT
    earlycon=pl011,0x9000000    # or name it explicitly
    earlycon=uart8250,mmio32,0xff000000
    earlycon=uart,mmio32,0x1c020000,115200n8

# combine with:
    keep_bootcon    # do not switch away when the real console
                    # registers - you see BOTH, and the handover
    ignore_loglevel # print everything regardless of loglevel
    debug           # raise the loglevel
    initcall_debug  # print every initcall and its result -
                    # invaluable for "it hangs during boot"

# A good bring-up command line:
    earlycon keep_bootcon ignore_loglevel initcall_debug \
      console=ttyAMA0,115200 root=/dev/mmcblk0p2 rw

# And in the device tree:
    chosen {
        stdout-path = "serial0:115200n8";
        bootargs = "earlycon console=ttyAMA0,115200";
    };

# IF EARLYCON PRODUCES NOTHING:
#   the address is wrong; the UART is not clocked; the pin mux
#   is not set; or the driver name does not match. Try writing
#   a character directly from the bootloader to confirm the
#   UART works at all before blaming the kernel.

# LAST RESORT: CONFIG_DEBUG_LL / earlyprintk with a hard-coded
# address, compiled in. Ugly, and it works when nothing else
# does.
```

> **`INITCALL_DEBUG` IS THE BOOT-HANG DEBUGGER**
>
> It prints every initcall before and after it runs, with the time it took. A hang shows as a `calling ...` line with no matching `initcall ... returned`. That names the exact function, which names the driver, in one boot. Pair it with `printk.time=1` and you also get a free boot-time profile.

Bringing up the other CPUs

```
/* Only CPU0 runs everything above. The rest are brought up
   much later, from smp_init(), using the method the device
   tree declares:                                          */

        cpus {
                cpu@0 {
                        device_type = "cpu";
                        compatible = "arm,cortex-a53";
                        reg = <0x0>;
                        enable-method = "psci";
                };
                cpu@1 { ... reg = <0x1>; enable-method = "psci"; };
        };

        psci {
                compatible = "arm,psci-1.0";
                method = "smc";          /* or "hvc" */
        };

/* PSCI path (isolation ch. 11):
        Linux issues SMC(CPU_ON, target_mpidr, entry_point)
        EL3 firmware powers the core and starts it at
        secondary_entry, which repeats the MMU setup and joins
        the scheduler.

   The older "spin-table" method has the bootloader park each
   secondary in a WFE loop watching a mailbox address. It works
   and it cannot power cores off - so PSCI is what you want.

/* SYMPTOM: only CPU0 online.
        cat /proc/cpuinfo          # one entry
        dmesg | grep -i psci
        dmesg | grep "CPU. failed to come online"
   Almost always: wrong `method` (smc vs hvc), missing PSCI
   node, wrong `reg` values (they must match MPIDR_EL1
   affinity), or firmware refusing CPU_ON. Check the TF-A
   console.                                                */
```

How the kernel learns about memory

```
        memory@80000000 {
                device_type = "memory";      /* REQUIRED */
                reg = <0x0 0x80000000 0x0 0x40000000>;  /* 1 GB */
        };

/* Consumed by early_init_dt_scan_memory() into MEMBLOCK - a
   simple early allocator that exists before the real page
   allocator (chapter 05).

   Then:
     reserved-memory nodes are removed from it
     the kernel image itself is reserved
     the initrd is reserved
     memblock hands the rest to the buddy allocator at
     mem_init()

   CHECK IT:
        dmesg | grep -i "Memory:"
          Memory: 892340K/1048576K available (...)
        cat /proc/iomem
        dmesg | grep -i memblock       (with memblock=debug)

   COMMON PROBLEMS:
     · device_type = "memory" omitted -> node ignored -> the
       kernel finds no RAM and hangs immediately
     · #address-cells/#size-cells mismatch -> the reg values
       are parsed wrong -> wildly wrong size, or an address of
       zero
     · memory described that does not physically exist -> a
       crash the first time the allocator hands out that range,
       long after boot
     · a secure carve-out NOT removed -> the kernel maps memory
       the TZASC denies -> an SError at an unpredictable moment
       (isolation ch. 18)                                  */
```

How it shows up

Symptom	Cause
Absolutely no output	Caches not cleaned; wrong EL; bad DTB pointer; or wrong console — try `earlycon` first
`earlycon` works, then output stops	Real console mismatch — add `keep_bootcon` to see the handover
Hangs after "Starting kernel..."	Load address, image alignment, or the DTB
Hangs at a specific driver	`initcall_debug` names it in one boot
"CPU(s) started at EL1", KVM unavailable	Bootloader dropped to EL1
Only CPU0 online	PSCI conduit or `enable-method` wrong; check TF-A
Kernel reports the wrong amount of RAM	`#address-cells` / `#size-cells` mismatch in the memory node
Immediate crash with no RAM found	`device_type = "memory"` missing
SError at a random later instruction	Mapped a carve-out the hardware denies — add `no-map`
Boots from one loader, not another	Boot protocol violated — check register state and cache maintenance

Symptom	Cause
Works cold, fails on warm reset	State left behind by the previous boot; firmware not reinitialising

Check yourself

- ✓ Draw the sequence from power-on to `start_kernel`, naming each stage.
- ✓ State the six requirements of the arm64 boot protocol.
- ✓ Explain why the caches must be cleaned before entering the kernel.
- ✓ Explain the identity-map trick and why the MMU cannot simply be switched on.
- ✓ Say what changes if the kernel is entered at EL1 instead of EL2, and how to check.
- ✓ Name the three phases in which the device tree is consumed.
- ✓ Build an `earlycon` command line for a board and say what to check if it is silent.
- ✓ Use `initcall_debug` to locate a boot hang.
- ✓ Explain how secondary CPUs start, and the three usual reasons they do not.
- ✓ Write a `/memory` node and list four ways it goes wrong.

`start_kernel` and initcalls

One function, about a hundred calls, and by the end the kernel is fully alive. Understanding its order is what lets you answer the two questions that dominate bring-up: *why is my driver probing too early*, and *where exactly did it hang*.

The order, and why it is that order

```
init/main.c :: start_kernel()

  set_task_stack_end_magic()   a canary on the init stack
  smp_setup_processor_id()     which CPU am I
  boot_cpu_init()              mark this CPU online
  page_address_init()
  setup_arch(&command_line)    <-- the big one, per-arch
     |  arch/arm64/kernel/setup.c
     |    setup_machine_fdt()     parse the DTB
     |    parse_early_param()     command line, early options
     |    arm64_memblock_init()   memory map, reserved regions
     |    paging_init()           REAL page tables
     |    bootmem_init()          zones, sparsemem, NUMA
     |    smp_init_cpus()         count CPUs from DT
     |    hyp_mode_check()        EL2 or EL1?
     v
  setup_boot_config()
  setup_command_line()
  setup_nr_cpu_ids()
  setup_per_cpu_areas()        per-CPU variables now usable
  boot_cpu_hotplug_init()

  build_all_zonelists()        the page allocator's structure
  page_alloc_init()
  parse_early_param() / parse_args()   the FULL command line
  jump_label_init()
  setup_log_buf()              printk's ring buffer resized
  vfs_caches_early_init()
  sort_main_extable()
  trap_init()
  mm_core_init()               <-- buddy allocator LIVE.
                                   alloc_pages() works now.
  poking_init()
  ftrace_init()
  early_irq_init()
  init_IRQ()                   the GIC driver runs here
                               (ARM ch. 23-24)
  tick_init()
  init_timers()
  hrtimers_init()
  softirq_init()
  timekeeping_init()
  time_init()                  the arch timer starts
                               (ARM ch. 32)
  local_irq_enable()           <-- INTERRUPTS ON. The system
                                   is now preemptible-ish and
                                   can actually respond.
  kmem_cache_init_late()       slab fully up: kmalloc works
  console_init()               <-- REAL consoles register.
                                   Everything before this was
                                   buffered, or earlycon.
  lockdep_init()
  ...
  rcu_init()
  ...
  fork_init()
  proc_caches_init()
  buffer_init()
  vfs_caches_init()
  pagecache_init()
  signals_init()
```

```
cgroup_init()
...
arch_call_rest_init()
      |
      v
   rest_init()
      kernel_thread(kernel_init)   -> becomes PID 1
      kernel_thread(kthreadd)      -> PID 2
      cpu_startup_entry(CPUHP_ONLINE)  -> CPU0 becomes the
                                          idle task, forever

THE INVARIANT that explains the whole ordering:
each step may only use facilities set up above it. That is
why memory comes before interrupts, interrupts before timers,
timers before scheduling, and drivers after all of it.
```

THREE LINES TO REMEMBER

- `mm_core_init()` — before this, no `kmalloc`. Early code uses memblock instead.
- `local_irq_enable()` — before this, nothing is asynchronous. No timers, no interrupts, no preemption.
- `console_init()` — before this, `printk` output goes into a ring buffer and is only flushed once a console exists. A crash before it, without `earlycon`, is silent.

Initcalls: how everything else runs

```
/* The kernel has thousands of subsystems and drivers to
   initialise. Rather than a giant list of calls, each one
   REGISTERS itself into a section of the binary, and the
   kernel walks those sections in order.                    */

static int __init my_init(void)
{
        pr_info("hello\n");
        return 0;               /* 0 = success. Non-zero is
                                   logged but boot continues. */
}
subsys_initcall(my_init);

/* The macro puts a POINTER to my_init into a section named
   .initcall4.init. The linker script gathers all such
   sections in order, and do_initcalls() walks them.        */

/* THE LEVELS, in execution order: */

  early_initcall          before most things; very restricted
  pure_initcall           0    no dependencies at all
  core_initcall           1    core subsystems
  postcore_initcall       2
  arch_initcall           3    architecture-specific
  subsys_initcall         4    BUSES register here
                               (platform, i2c, spi, pci)
  fs_initcall             5    filesystems
  rootfs_initcall         rootfs
  device_initcall         6    <-- MOST DRIVERS. module_init()
                                   becomes this when built in.
  late_initcall           7    things needing everything else

  and each has a _sync variant that waits for outstanding
  asynchronous work before the next level begins.

/* WHY THE LEVELS EXIST: a driver at device_initcall can rely
   on its bus existing, because buses registered at
   subsys_initcall. Ordering WITHIN a level is link order -
   i.e. Makefile order - which you must never depend on.

/* module_init() is level 6 when built in, and simply "when
   insmod runs" when built as a module. That difference is why
   a driver can work as a module and fail built-in, or the
   reverse.                                                 */

/* DO NOT solve ordering problems by changing your initcall
   level. That is the classic wrong fix - it works on your
   board and breaks on the next one. Use -EPROBE_DEFER
   instead (chapter 17).                                    */
```

Watching it happen

```
# initcall_debug on the command line:

    calling  gic_of_init+0x0/0x1a4 @ 1
    initcall gic_of_init+0x0/0x1a4 returned 0 after 1953 usecs
    calling  my_driver_init+0x0/0x28 @ 1
    initcall my_driver_init+0x0/0x28 returned -517 after 12 usecs
                                              ^^^^
                                              -EPROBE_DEFER

# READS AS:
#   "calling" with no matching "initcall ... returned"  -> IT
#     HUNG HERE. You just found your boot hang, by name.
#   returned -517  -> EPROBE_DEFER: a dependency was missing;
#     it will be retried later. Normal, not an error.
#   returned -19   -> ENODEV: no such device. Usually fine.
#   a huge "after N usecs" -> your boot-time regression.

# Sort the slow ones:
    dmesg | grep initcall | \
      sed 's/.*after \([0-9]*\) usecs/\1 &/' | sort -rn | head -20

# And the graphical version:
    systemd-analyze plot > boot.svg          # userspace
    cat /sys/kernel/debug/bootgraph          # with
                                             # CONFIG_BOOT_PRINTK

# printk timestamps, essential for any of this:
    printk.time=1        # or CONFIG_PRINTK_TIME=y
```

Handing over to user space

```
/* kernel_init() runs as PID 1, still in kernel mode: */

static int __ref kernel_init(void *unused)
{
        kernel_init_freeable();
             /* wait for async work
                do_basic_setup():
                   driver_init()          the device model
                   init_irq_proc()
                   do_ctors()
                   do_initcalls()      <-- ALL levels run here
                prepare_namespace()       mount the root fs */

        free_initmem();      /* __init code and data FREED.
                                "Freeing unused kernel memory:
                                 4096K" in dmesg. This is why
                                calling an __init function
                                later crashes.               */
        mark_readonly();

        /* Then try, in order: */
        if (execute_command) {          /* init= on cmdline */
                ret = run_init_process(execute_command);
                if (!ret) return 0;
                panic("Requested init %s failed (error %d).",
                      execute_command, ret);
        }

        if (!try_to_run_init_process("/sbin/init")  ||
            !try_to_run_init_process("/etc/init")   ||
            !try_to_run_init_process("/bin/init")   ||
            !try_to_run_init_process("/bin/sh"))
                return 0;

        panic("No working init found.  Try passing init= ...");
}

/* THE TWO FAMOUS PANICS:

   "Kernel panic - not syncing: VFS: Unable to mount root fs
    on unknown-block(0,0)"
        the ROOT FILESYSTEM was not found. Causes: wrong
        root=, the storage driver not built in (a module in an
        initramfs you did not supply), the filesystem type not
        compiled in, or the partition table not read.
        Look at the "Available partitions:" list the kernel
        prints just above - if it is empty, the storage driver
        never probed.

   "No working init found."
        the root filesystem MOUNTED but has no init. Wrong
        rootfs image, missing /sbin/init, a dynamically linked
        init with no libraries, or the wrong architecture
        binaries.
        Try init=/bin/sh to get a shell and look around.    */
```

> **`INIT=/BIN/SH` IS THE DEBUGGING TRAPDOOR**
> It skips the entire init system and drops you at a shell with the root filesystem mounted. From there you can check what is present, load modules by hand, and read `/proc`. If *that* works, the problem is in userspace, not the kernel — which halves the search space in one boot.

Kernel parameters

```
/* Two mechanisms, easily confused. */

/* 1. early_param - parsed in setup_arch(), very early, for
      things that must be known before memory is set up:   */

static int __init parse_my_option(char *p)
{
        my_value = memparse(p, &p);
        return 0;
}
early_param("my_option", parse_my_option);
        /* command line:  my_option=64M */

/* 2. module_param - a variable exposed as a parameter,
      settable at insmod time or via the command line:     */

static int buffer_size = 4096;
module_param(buffer_size, int, 0644);
MODULE_PARM_DESC(buffer_size, "Ring buffer size in bytes");

        /* as a module:   insmod mydrv.ko buffer_size=8192
           built in:      mydrv.buffer_size=8192
           at runtime:    /sys/module/mydrv/parameters/buffer_size
                          (because the mode is 0644)        */

/* The permission argument is the sysfs mode. Use 0444 for
   read-only visibility, 0644 to allow runtime changes - and
   only if changing it at runtime is actually safe, which for
   a buffer size it usually is not.                         */

/* SEEING what was passed: */
        cat /proc/cmdline
        cat /sys/module/mydrv/parameters/*
        dmesg | grep "Kernel command line"
```

The ordering problem, properly solved

```
/* THE SITUATION: your driver needs a clock, a regulator, a
   GPIO or a DMA channel that another driver provides - and
   that driver has not probed yet.

   THE WRONG FIXES:
     · changing your initcall level          (board-specific)
     · reordering the Makefile               (fragile, silent)
     · a retry loop with msleep()            (blocks boot)
     · initialising in module_init instead of probe (breaks
       hotplug and unbind)

   THE RIGHT FIX - return -EPROBE_DEFER: */

static int my_probe(struct platform_device *pdev)
{
        struct clk *clk;

        clk = devm_clk_get(&pdev->dev, "core");
        if (IS_ERR(clk))
                return dev_err_probe(&pdev->dev, PTR_ERR(clk),
                                     "failed to get core clock\n");
        ...
}

/* dev_err_probe() is the modern idiom: it logs at error level
   for real errors, at DEBUG level for -EPROBE_DEFER (so you
   are not spammed by the normal case), and returns the error.
   Use it for every resource acquisition in probe.

   The driver core keeps a DEFERRED PROBE LIST and retries
   everything on it whenever any new driver successfully
   probes. Eventually the dependency appears and you succeed -
   in any link order, on any board.                          */

/* WHEN IT NEVER RESOLVES: */
        cat /sys/kernel/debug/devices_deferred
   lists every device still waiting, and why. If your device is
   there at the end of boot, the provider driver is missing,
   not merely late - a missing CONFIG, or a DT node that does
   not match anything.                                       */
```

How it shows up

Symptom	Cause
Boot hangs at a named initcall	That function does not return — `initcall_debug` found it for you
Initcall returns `-517`	`-EPROBE_DEFER`. Normal; check `devices_deferred` if it never resolves
Driver works as a module, not built in	An ordering dependency masked by `insmod` timing — use deferred probe
Crash calling a function after boot	It was `__init` and the memory was freed
No output before a certain point	`console_init()` not reached — use `earlycon`
`Unable to mount root fs on unknown-block(0,0)`	Storage driver not built in, wrong `root=`, or missing filesystem support

Symptom	Cause
`No working init found`	Rootfs mounted but wrong contents — try `init=/bin/sh`
Parameter has no effect	Wrong prefix built-in vs module, or parsed too late
Boot is slow	Sort initcall durations; usually one driver with a long timeout
Works on one board, wrong order on another	Depending on link order — the bug deferred probe exists to remove

Check yourself

- ✓ Explain the invariant that determines `start_kernel`'s ordering.
- ✓ Say what becomes available at `mm_core_init`, `local_irq_enable` and `console_init`.
- ✓ Explain how initcalls are implemented, and name the levels in order.
- ✓ Say what `module_init` maps to when built in versus as a module.
- ✓ Read `initcall_debug` output and identify a hang and a deferral.
- ✓ Explain what `free_initmem` does and the bug it creates for `__init` functions.
- ✓ Diagnose both classic root-filesystem panics.
- ✓ Distinguish `early_param` from `module_param`.
- ✓ Explain why `-EPROBE_DEFER` is the correct fix for ordering, and use `dev_err_probe`.

Kernel memory allocators

Five allocators, layered on one another, each solving a problem the one below it cannot. Choosing wrongly costs you memory, performance, or — with DMA — a driver that silently corrupts data.

The stack of allocators

```
+-----------------------------------------------------------+
|  devm_kmalloc()     device-managed. Freed on unbind.      |
|                     USE THIS IN DRIVERS. (chapter 26)     |
+-----------------------------------------------------------+
|  kmalloc() / kmem_cache_alloc()          SLAB / SLUB      |
|     small objects, PHYSICALLY CONTIGUOUS                  |
|     8 bytes .. a few pages                                |
+-----------------------------------------------------------+
|  vmalloc()                                                |
|     large, VIRTUALLY contiguous only                      |
|     builds page tables; physically scattered              |
+-----------------------------------------------------------+
|  alloc_pages() / __get_free_pages()      BUDDY ALLOCATOR  |
|     power-of-two page runs, physically contiguous         |
|     the foundation everything above sits on               |
+-----------------------------------------------------------+
|  memblock                                                 |
|     boot only, before the buddy allocator exists          |
+-----------------------------------------------------------+
|  PHYSICAL MEMORY, from the device tree                    |
+-----------------------------------------------------------+

And, off to the side but important for drivers:

dma_alloc_coherent()   physically contiguous, DMA-mapped,
                       cache-coherent. (chapter 24)
CMA                    a reserved pool that can serve large
                       contiguous allocations at runtime
```

The buddy allocator

```
/* The foundation: allocates 2^order contiguous PAGES.       */

struct page *alloc_pages(gfp_t gfp, unsigned int order);
void         __free_pages(struct page *page, unsigned int order);

unsigned long __get_free_pages(gfp_t gfp, unsigned int order);
void          free_pages(unsigned long addr, unsigned int order);

        order 0  =  1 page   =  4 KB
        order 1  =  2 pages  =  8 KB
        order 2  =  4 pages  = 16 KB
        ...
        order 10 = 1024 pages = 4 MB    (MAX_ORDER limit,
                                         configurable)

/* HOW IT WORKS: free memory is kept in 11 lists, one per
   order. To satisfy an order-2 request with only order-4
   blocks free, it splits an order-4 into two order-3s, takes
   one, splits it into two order-2s, takes one. On free, if
   the adjacent "buddy" block is also free, they merge back.

   CONSEQUENCE - FRAGMENTATION. After hours of uptime, plenty
   of memory can be free while no high-order block exists.
   An order-0 allocation succeeds; an order-4 fails. This is
   why:

     · high-order allocations must ALWAYS be error-checked
     · a driver that needs 4 MB contiguous at runtime should
       use CMA, or allocate at probe time and keep it
     · "it works after reboot, fails after a week" is often
       exactly this

   SEE THE STATE:
        cat /proc/buddyinfo
   Node 0, zone   Normal   1432  882  341  102   43  12  3 0 0 0 0
                           ^order0                        ^order10
   Lots of low-order, nothing high-order = fragmented.   */
```

kmalloc and the slab allocator

```
void *kmalloc(size_t size, gfp_t flags);
void *kzalloc(size_t size, gfp_t flags);        /* zeroed */
void *kcalloc(size_t n, size_t size, gfp_t f);  /* n*size,
                                                   OVERFLOW-
                                                   CHECKED   */
void *krealloc(const void *p, size_t new, gfp_t f);
void  kfree(const void *p);
size_t ksize(const void *p);       /* what you ACTUALLY got */

/* kmalloc serves from a set of fixed-size caches:
        8, 16, 32, 64, 96, 128, 192, 256, 512, 1024,
        2048, 4096, 8192 ... up to KMALLOC_MAX_SIZE

   ROUNDING UP MATTERS: kmalloc(100) consumes 128 bytes.
   kmalloc(129) consumes 192. In a driver allocating one
   object per packet, choosing 128 over 129 is a 33% memory
   saving. Check with ksize().

   PROPERTIES:
     · PHYSICALLY CONTIGUOUS - so it is DMA-able (with the
       right GFP flags), and virt_to_phys() works on it
     · fast: per-CPU freelists, usually no locking
     · above ~2 pages it falls back to the page allocator, and
       becomes subject to fragmentation

   ALWAYS CHECK THE RETURN:
        p = kmalloc(n, GFP_KERNEL);
        if (!p)
                return -ENOMEM;
   Even GFP_KERNEL can fail. "Small allocations never fail" is
   almost true and entirely unsafe to rely on.             */

/* SIZE ARITHMETIC - use the checked helpers: */
        p = kmalloc(n * size, GFP_KERNEL);      /* CAN OVERFLOW */
        p = kmalloc_array(n, size, GFP_KERNEL); /* checked      */
        p = kcalloc(n, size, GFP_KERNEL);       /* checked+zero */
        p = kmalloc(struct_size(obj, items, n), GFP_KERNEL);
                        /* checked, for flexible array members */
```

Your own slab cache

```
/* When you allocate many objects of ONE type, a dedicated
   cache is tighter and faster than kmalloc's rounding.     */

static struct kmem_cache *my_cache;

static int __init my_init(void)
{
        my_cache = kmem_cache_create("my_request",
                                     sizeof(struct my_request),
                                     __alignof__(struct my_request),
                                     SLAB_HWCACHE_ALIGN, /* flags */
                                     NULL);              /* ctor */
        if (!my_cache)
                return -ENOMEM;
        return 0;
}

        obj = kmem_cache_alloc(my_cache, GFP_KERNEL);
        kmem_cache_free(my_cache, obj);

static void __exit my_exit(void)
{
        kmem_cache_destroy(my_cache);   /* WARNS loudly if
                                           objects are still
                                           allocated - which is
                                           a free leak detector */
}

/* USEFUL FLAGS:
     SLAB_HWCACHE_ALIGN   align to a cache line - avoids false
                          sharing between CPUs (CA ch. 15)
     SLAB_POISON          fill freed objects with a pattern
     SLAB_RED_ZONE        guard bytes around each object
     SLAB_ACCOUNT         charge to the memory cgroup

/* WHY BOTHER:
     · exact sizing: 100-byte objects cost 100 bytes, not 128
     · a NAMED line in /proc/slabinfo, so leaks are visible
       and attributable to your driver
     · kmem_cache_destroy() warning is a built-in leak test

   INSPECT:
        sudo cat /proc/slabinfo | grep my_request
        sudo slabtop -s c            # sorted by cache size  */
```

vmalloc

```
void *vmalloc(unsigned long size);
void *vzalloc(unsigned long size);
void  vfree(const void *addr);

/* Allocates SCATTERED physical pages and maps them into a
   contiguous VIRTUAL range by building page tables.

   USE IT FOR: large buffers where only the CPU touches the
   memory. Firmware images, big lookup tables, module text.

   DO NOT USE IT FOR:
     · DMA. The pages are not physically contiguous, and
       virt_to_phys() DOES NOT WORK on vmalloc addresses.
       This is a top-three driver bug: DMA "works" on a
       machine with little fragmentation, then corrupts
       random memory on a busy one.
     · anything in atomic context - vmalloc can sleep.
     · small allocations - the page-table overhead and TLB
       cost dominate.

   COMPARE:
                      kmalloc         vmalloc
     contiguous       physical+virt   virtual only
     max size         ~4 MB           very large
     speed            fast            slow (page tables, TLB)
     DMA-safe         yes             NO
     can sleep        depends on GFP  always
     virt_to_phys     works           BROKEN

   For a vmalloc buffer you must reach page by page:
        struct page *p = vmalloc_to_page(addr);           */
```

> **THE DMA RULE, STATED ONCE**
>
> Memory for DMA must be obtained from `dma_alloc_coherent()`, or from `kmalloc` / `alloc_pages` and then mapped with `dma_map_single()`. Never `vmalloc`. Never a stack buffer (it may not be DMA-able and its physical address is meaningless to a device). Never a module-static array without mapping it. Chapter 24 covers this properly, but the rule is worth learning before you need it.

Choosing

You need	Use
A small struct in a driver, freed on unbind	`devm_kzalloc()`
A small struct with a different lifetime	`kzalloc()` + explicit `kfree()`
Many objects of one type	`kmem_cache_create()`
An array	`kcalloc()` / `kmalloc_array()`
Whole pages	`alloc_pages()`
A large CPU-only buffer	`vmalloc()`
A DMA buffer, long-lived	`dma_alloc_coherent()`
A DMA buffer, streaming	`kmalloc()` + `dma_map_single()`

You need	Use
Many small DMA buffers	`dma_pool_create()`
Large contiguous at runtime	CMA, via `dma_alloc_coherent()`
In an interrupt handler	`kmalloc(..., GFP_ATOMIC)`, and check the result
Something that must not fail	Preallocate at probe time. There is no other answer.

CMA — contiguous memory at runtime

```
/* THE PROBLEM: a camera or video codec needs 32 MB physically
   contiguous, at runtime, after hours of uptime. The buddy
   allocator cannot deliver that - fragmentation guarantees it.

   THE SOLUTION: reserve a region at boot, but let MOVABLE
   pages (page cache, anonymous memory) use it meanwhile. When
   a contiguous allocation arrives, migrate them out.       */

        reserved-memory {
                #address-cells = <2>;
                #size-cells = <2>;
                ranges;

                cma_pool: linux,cma {
                        compatible = "shared-dma-pool";
                        reusable;          /* <-- makes it CMA */
                        size = <0x0 0x8000000>;   /* 128 MB */
                        alignment = <0x0 0x400000>;
                        linux,cma-default;
                };
        };

        my_codec: codec@1c000000 {
                compatible = "vendor,codec";
                reg = <0x0 0x1c000000 0x0 0x10000>;
                memory-region = <&cma_pool>;
        };

/* Then in the driver, dma_alloc_coherent() transparently comes
   from CMA:                                                  */
        of_reserved_mem_device_init(dev);
        buf = dma_alloc_coherent(dev, SZ_32M, &dma, GFP_KERNEL);

/* CAVEATS worth knowing before you rely on it:
     · migration can FAIL if a page is pinned - so CMA
       allocation can still fail, just much less often
     · migration takes time; a large allocation can stall for
       tens of milliseconds
     · `reusable` is what allows the memory to be borrowed. A
       carve-out without it is simply removed from the kernel's
       view entirely - which is what you want for a security
       boundary (isolation ch. 18), and not what you want for
       a codec buffer.

   MONITOR:
        cat /proc/meminfo | grep Cma
        CmaTotal:  131072 kB
        CmaFree:    98304 kB                               */
```

Finding leaks and overruns

```
# KASAN - the one that finds real bugs. Enable it in
# development and leave it on.
    CONFIG_KASAN=y
    CONFIG_KASAN_INLINE=y
# Catches: use-after-free, out-of-bounds read and write,
# double-free, use-after-scope. Reports with two backtraces -
# where it was allocated and where it was freed. ~2-3x slower
# and ~1/8 more memory, and worth every bit of it.

# KFENCE - a sampling version, cheap enough for production:
    CONFIG_KFENCE=y
    CONFIG_KFENCE_SAMPLE_INTERVAL=100
# Catches a small fraction of the same bugs at near-zero cost.
