Embedded Learning Hub

A complete systems engineering curriculum

23 tracks · 490 chapters

Generated 2026-08-23

TRACK

Start here

How the curriculum is organised, what to read in what order, and how long it takes.

4 chapters

One concept per chapter.
Zero to systems engineer.

Twenty-three tracks, 490 chapters. Each chapter explains exactly one idea in depth — what it is, why it exists, how the hardware or software actually implements it, and how it fails. Read a track in order and you get a course; search a concept and you get a reference.

No prior kernel experience needed · Foundations included · ARMv8-A / AArch64 · Linux 6.x · Windows 11 WDK · Hands-on projects

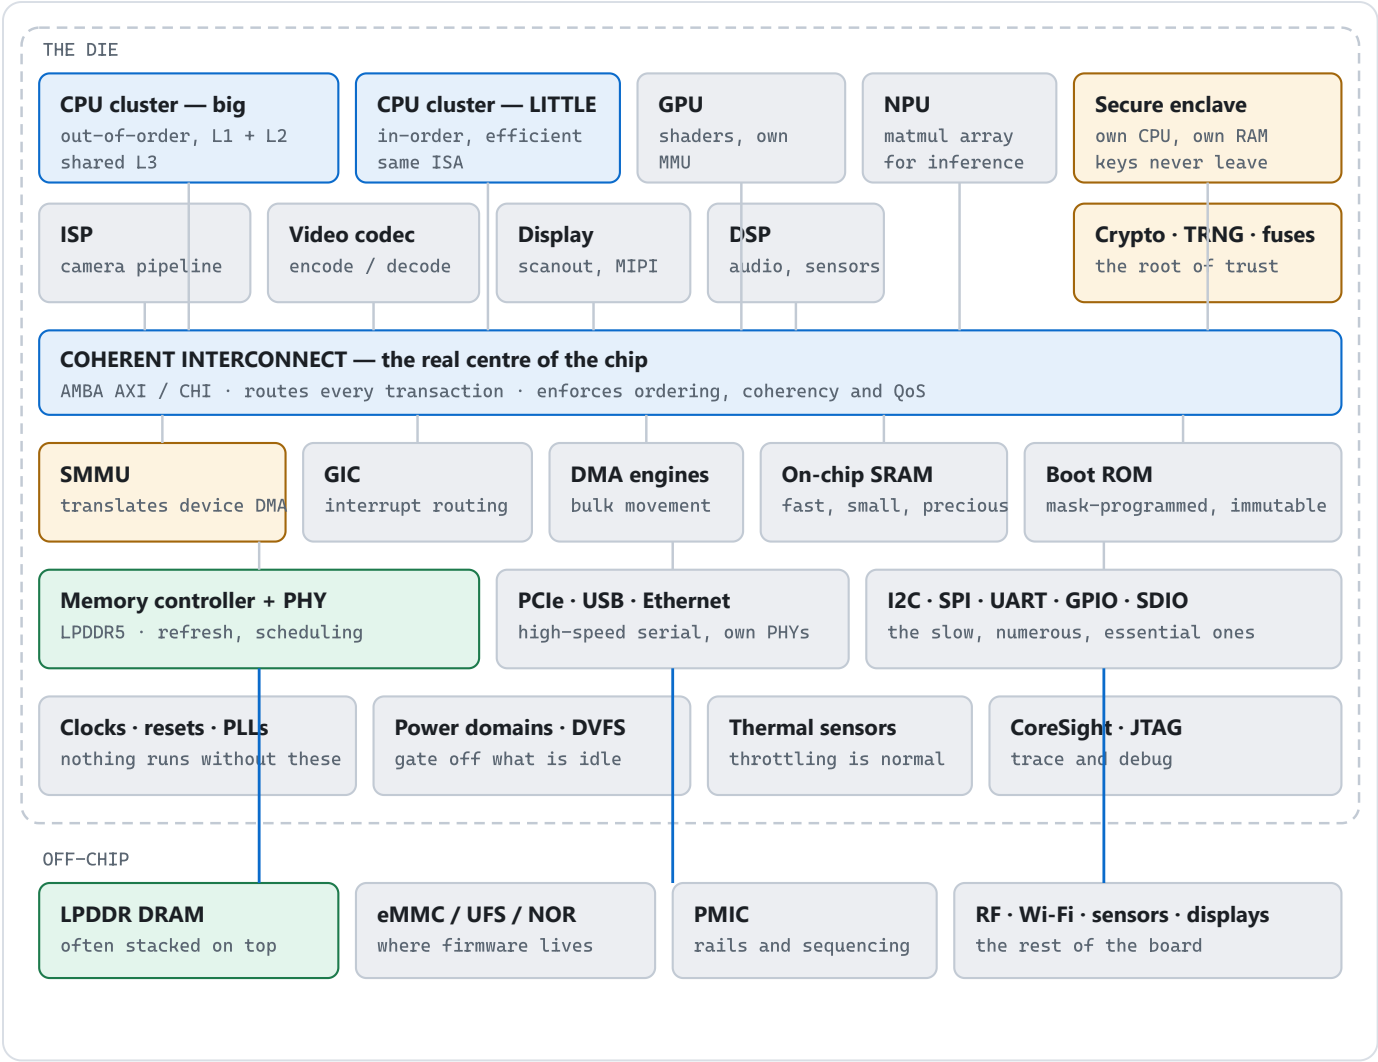
The twenty-two tracks

What a system-on-chip is

Nearly everything on this site runs on a **SoC** — a single piece of silicon holding not just processor cores but the memory controller, the graphics and AI engines, the camera pipeline, the interrupt controller, the security blocks and dozens of peripherals. A desktop PC spreads those across a motherboard. A phone, a car ECU, a router and a smart camera put them on one die, a few millimetres square.

That integration is not merely tidier. It is the reason the field looks the way it does:

Consequence of integration	What it forces on you
Wires on a die are thousands of times cheaper in power than wires on a board	Bandwidth that would be impossible off-chip, and thermal limits that arrive far sooner
Dozens of blocks share one memory system	Coherency, quality-of-service and contention become your problem, not the hardware's
Every block is a *bus master* that can read and write DRAM by itself	Memory protection must exist in the interconnect, not only in the CPU — this is why an SMMU exists
The chip is fixed at manufacture; bugs cost a mask set	Errata are worked around in firmware and drivers. A large part of systems work is compensating for silicon nobody can change
One vendor integrates blocks licensed from many others	Documentation is uneven, and the authoritative answer is often a register description rather than a manual



A representative ARM SoC. The exact blocks vary enormously; the shape — compute at the top, one coherent interconnect in the middle, memory and I/O below — does not.

THE INTERCONNECT IS THE CHIP

Beginners picture a SoC as "a CPU with peripherals attached". It is closer to a network with a CPU as one of its nodes. The GPU, the NPU, the ISP and every DMA engine issue their own memory transactions, compete for the same DRAM, and can corrupt anything they are allowed to reach. Once that clicks, the existence of the SMMU, of cache-coherency protocols, of QoS registers and of memory attributes stops feeling arbitrary.

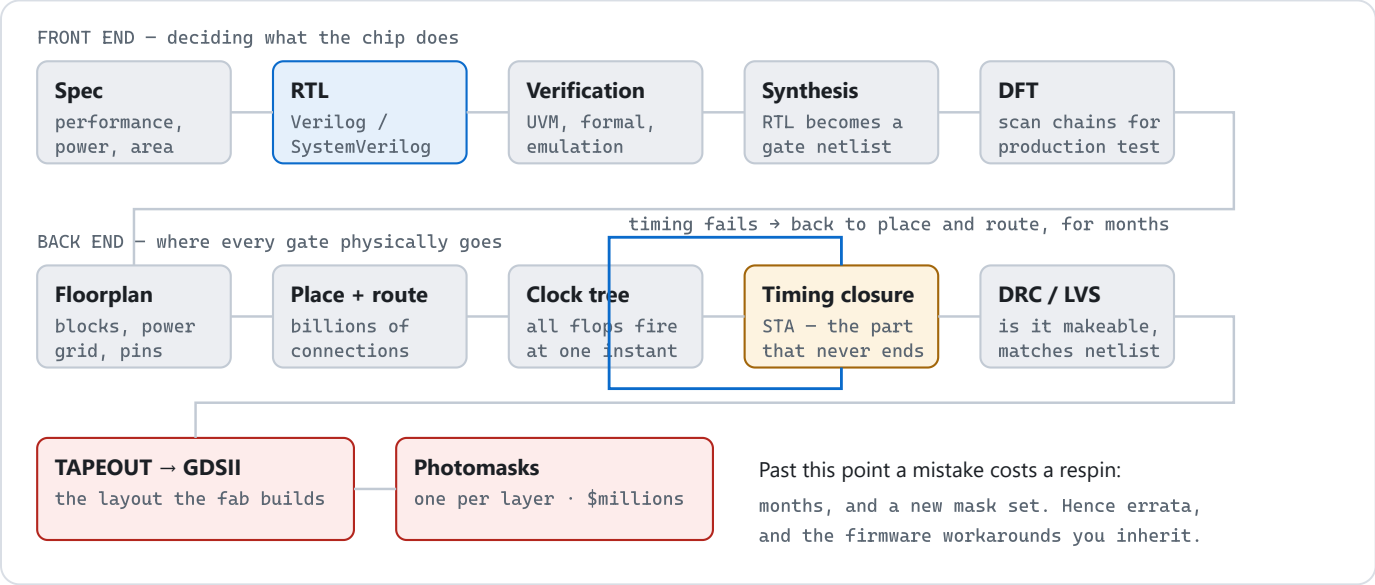
Which track covers which block

Block	Where it is taught
CPU cores, caches, pipelines, memory model	Computer architecture, then ARM architecture
Interconnect, AMBA, coherency, shareability	ARM — the AMBA and memory-model chapters
Memory controller, DRAM behaviour, DMA	Architecture and the driver tracks
GIC, timers, power states	ARM
SMMU, TrustZone, access-control firewalls	Isolation and security
Secure enclave, crypto engine, fuses, root of trust	Security, cryptography and OP-TEE
Boot ROM and the firmware chain	OP-TEE — the boot-flow chapters
Peripherals, and drivers for them	Linux or Windows kernel and drivers

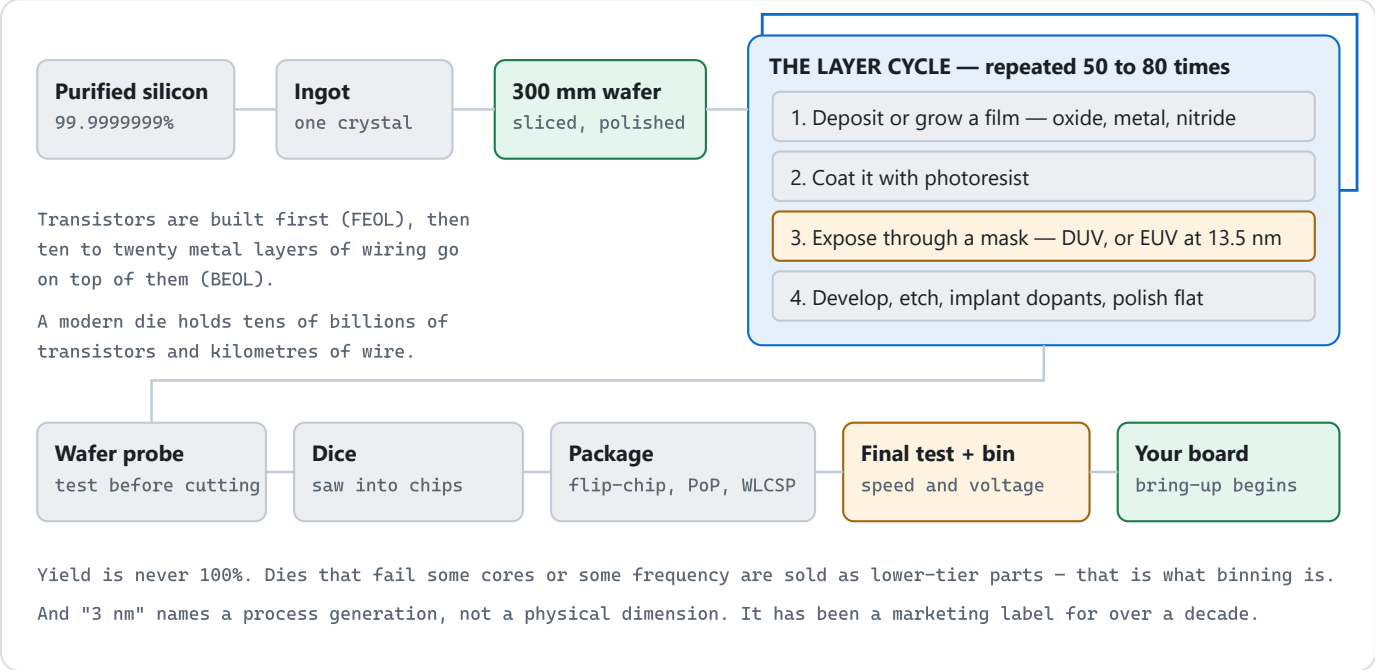
Block	Where it is taught
Running all of it before silicon exists	QEMU and virtualisation
NPU, quantisation, why inference is memory-bound	AI and large language models
CoreSight, JTAG, and finding out what went wrong	Debugging and reference

How a chip is made

Two long pipelines sit behind every SoC. The first turns an idea into a set of photographic masks; the second turns those masks into silicon. Together they take two to four years and hundreds of millions of dollars, which is why the errata document is thicker than you expect.



The design flow. Everything left of tapeout is software; everything right of it is a factory.



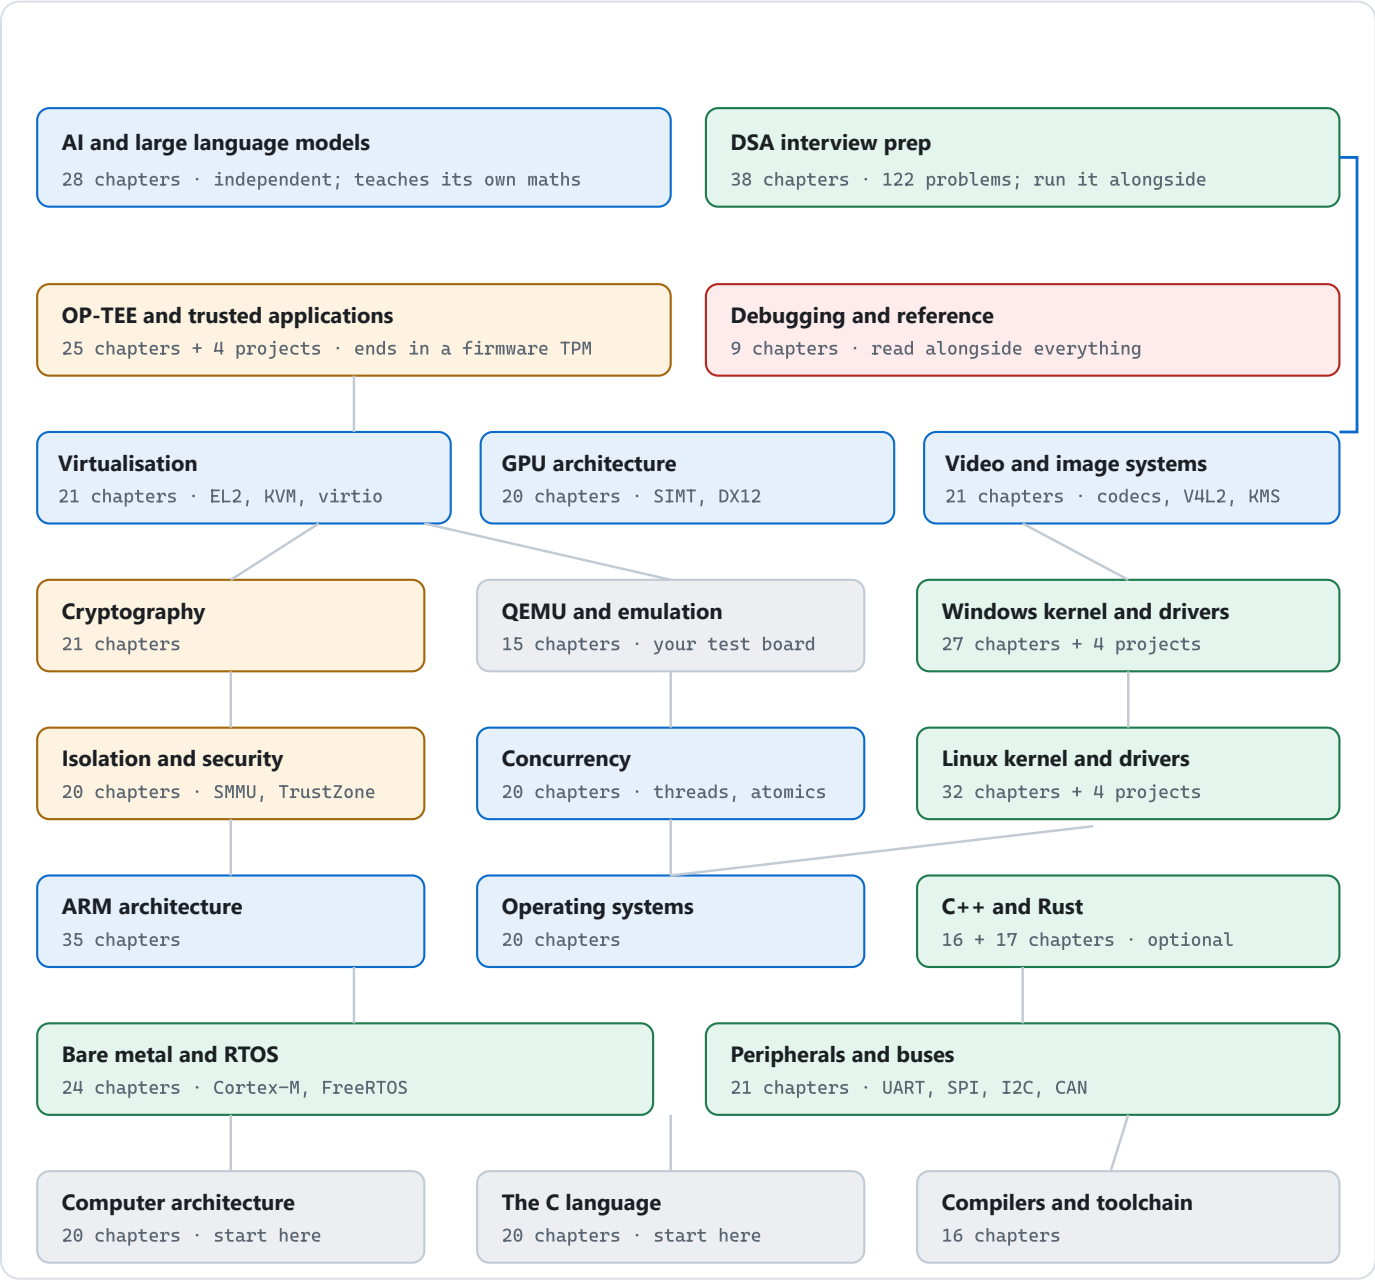
Fabrication. The cycle in the middle is the whole game: every layer of the chip is one pass through it, and a single dust particle in the wrong place kills the die.

WHY THIS MATTERS TO A DRIVER AUTHOR

Because silicon cannot be patched. When a block misbehaves — a DMA engine that ignores a coherency hint, a controller that needs a dummy read after a register write, an interrupt that fires spuriously at reset — the fix lands in firmware or in your driver, and it stays there for the life of the part. Reading an errata sheet and recognising your own bug in it is an ordinary Tuesday, and it makes far more sense once you know how little freedom the hardware team had after tapeout.

What order to read in

The tracks are not independent — later ones assume earlier ones. This is the dependency graph. Anything you read before its supports are in place will feel like memorisation instead of understanding.



Track dependencies. Two entry points (architecture and C); everything else stacks on them. The top two tracks are independent — start either at any time.

How each chapter is built

Every chapter follows the same shape, so you always know where to look for what you need:

Section	Answers
The problem	Why does this concept exist? What breaks without it?
The mechanism	How it actually works, drawn as a flow or diagram wherever possible
In practice	Real code, real register layouts, real command lines
How it fails	The bugs this concept causes, and their signatures
Check yourself	Questions you should be able to answer before moving on

> **CHAPTERS MARKED "DRAFTING"**
> The curriculum map is complete and fixed — every chapter listed is one that will exist, in that order. Chapters still being written are greyed out in the sidebar and marked *drafting* on their track page. Published chapters are finished, not stubs.

Where to start

1. **Read the prerequisites honestly.** If C pointers are shaky, the C track comes before everything else. There is no way around this.
2. **Follow the roadmap** for a week-by-week path with realistic time costs.
3. **Set up your workbench** — a cross-compiler, QEMU, and one Linux and/or Windows VM. Every project on this site runs without buying hardware.
4. **Then begin at computer architecture, chapter 01**, or jump to whichever track your job needs and backfill when you get stuck.

The learning roadmap

490 chapters is a lot of map. This page is the route through it: what to read in what order, how long each stage honestly takes, and the test that tells you a stage is finished.

The organising principle

Every track on this site answers one of four questions, and they must be answered in this order:

Question	Tracks	Why it comes when it does
What is the machine?	Computer architecture, ARM	Every abstraction above this is a lie told for convenience. You cannot debug a lie you do not know is one.
How do I express myself to it?	C, C++, Rust, Compilers	Languages are how you address the machine; the compiler is the translator whose assumptions you must share.
Who manages the machine?	Operating systems, Linux, Windows	An OS is a set of policies over the hardware. Learn the hardware, then the policy.
How do I keep it safe?	Isolation and security, Cryptography	Isolation is meaningless before you understand what is being isolated from what.
What sits above the kernel?	Virtualisation, OP-TEE, QEMU	A hypervisor and a trusted OS both use a privilege level the kernel cannot reach, so they come after you know what a kernel does. QEMU is the board you develop both on.

The AI track sits outside this ordering. It teaches its own mathematics and depends on the rest of the site only where performance meets hardware — memory bandwidth, quantisation, accelerators.

Eight phases

Phase 0 — Prerequisites (0–4 weeks)

Take the self-assessment. If you fail the C section, do the C track first and nothing else. Everything on this site is written in C or described in terms of it.

Exit test: you can write a function that packs three bitfields into a 32-bit word using shifts and masks, and explain why the compiler might reorder your two writes to a hardware register.

Phase 1 — The machine (4–7 weeks)

Computer architecture, all 20 chapters. This is the biggest single jump in the whole curriculum, and skipping it is why most self-taught engineers plateau.

Exit test: explain why a program that touches an array with stride 64 runs several times slower than one with stride 1, in terms of cache lines and prefetchers.

Phase 2 — The language, properly (4–6 weeks)

C in full, then the first half of compilers (chapters 01–06). Do these together: the compiler track explains why the C track's rules exist.

Exit test: given a small C function, predict its assembly, then check with `gcc -O2 -S` and explain every difference.

Phase 3 — The ARM architecture (5–8 weeks)

ARM, all 35 chapters. Long, but each chapter is one concept and they build tightly. Do not skip the memory-model chapters (20–22); they are where the hard bugs live.

Exit test: given a 48-bit virtual address and a set of table base registers, trace by hand which bits index which level of the page table, and say what happens at each possible failure point.

Phase 4 — Operating systems (4–6 weeks)

Operating systems for the vendor-neutral concepts, then pick Linux *or* Windows as your primary and skim the other. Both end in a complete driver you build.

Exit test: your driver deadlocks under load. Describe the tools and the order you would use them in, without opening a debugger first.

Phase 5 — Isolation and security (4–6 weeks)

Isolation and security, then cryptography. This is the part most engineers never reach, and it is what separates a driver writer from a platform engineer.

Exit test: a device DMAs to an address and faults. Name five distinct layers that could have produced that fault and the register you would read in each case.

Phase 6 — The two worlds and the machine underneath (5–8 weeks)

Two tracks that both start from the same place — an exception level above EL1 — and go in opposite directions. Virtualisation uses EL2 to run several kernels that each believe they are alone; OP-TEE uses the secure world to run one thing that the kernel cannot touch. Read QEMU alongside either: it is the board you develop both on, and it is short.

The virtualisation track needs phase 5's SMMU material for device passthrough. The OP-TEE track needs phase 5's TrustZone material and a working grasp of cryptography before its projects.

Exit test: write a trusted application and the client that drives it, then explain — with the register that enforces it — why the normal world cannot read the key it holds.

Phase 7 — Breadth and depth (ongoing)

- C++ or Rust, depending on where your industry is going. Rust if you want to be ahead of it.
- The second half of compilers — linking, loading, debug info.
- AI and LLMs, at any point; it is self-contained.
- Read real driver source. Bring up a real board. Send a patch upstream.

Realistic timeline

Phase	Chapters	Part-time (8 h/wk)	Full-time
0 · Prerequisites	0–20	0–4 weeks	0–1 week
1 · Computer architecture	20	6 weeks	2 weeks
2 · C + compiler basics	26	6 weeks	2 weeks
3 · ARM	35	8 weeks	3 weeks
4 · OS + one driver track	45–50	10 weeks	4 weeks

Phase	Chapters	Part-time (8 h/wk)	Full-time
5 · Security + crypto	41	8 weeks	3 weeks
6 · Virtualisation + OP-TEE + QEMU	60	8 weeks	3 weeks
To employable as a systems engineer		**~11 months**	**~17 weeks**

THESE NUMBERS ASSUME YOU ARE BUILDING, NOT ONLY READING

Reading a chapter takes fifteen minutes. Understanding it takes an hour of doing something with it — compiling the example, changing it until it breaks, and explaining the break. The timeline above assumes roughly one part reading to three parts hands-on. Halve the hands-on and you double the calendar time, because you will re-read everything.

Four ways people stall

COLLECTING BOARDS

A Raspberry Pi, a BeagleBone and three dev kits in a drawer is not progress. One board, broken and recovered ten times, teaches more than five untouched ones. Everything here runs in QEMU anyway.

READING THE ARM ARM COVER TO COVER

It is over 10,000 pages of reference material, not a textbook. Use it to answer a question you already have. That is what this site's ARM track is for: it gives you the questions.

SKIPPING THE MEMORY MODEL

Barriers, coherency and cache maintenance feel like optional detail right up until you have a bug that only reproduces on four cores under load. That bug costs a week. Those chapters cost a day.

WRITING DRIVERS WITHOUT READING DRIVERS

The kernel already contains a near-exact template for whatever you are writing. Professionals find it and adapt it. Search `drivers/` before you start typing.

Interview preparation runs alongside, not instead

The DSA interview prep track sits outside the seven phases deliberately. It is not a prerequisite for anything here, and nothing here is a prerequisite for it — it exists because getting the job and doing the job are measured differently, and the gap between them is real.

Start it when you have interviews booked, not before. Two to eight weeks is the usual window, and the track opens with a schedule for each. It shares the C track's assumptions about pointers and arrays and nothing else, so it can be read at any point.

The one genuine overlap is worth naming: the complexity reasoning in chapter 02 — amortised analysis, reading constraints backwards, knowing what an operation actually costs — is the same skill that tells you whether a driver's hot path is acceptable. That chapter earns its place regardless of whether you are interviewing.

Milestones worth naming

- ✓ **Junior:** you can write a working driver by adapting an existing one, and debug it with prints and a datasheet.
- ✓ **Intermediate:** you can read an unfamiliar subsystem and explain its locking, and you reach for the right tool before the debugger.
- ✓ **Senior:** you can look at an unfamiliar SoC's technical reference manual and, in an hour, identify its interconnect topology, DMA masters, isolation blocks and boot flow.
- ✓ **Beyond:** other people bring you the bugs nobody else could reproduce, and you have a method rather than a hunch.

Prerequisites & self-assessment

Be honest with this page. Starting the ARM track without solid C is the single most common way people waste three months. Everything here is teachable — but only in the right order.

The three hard requirements

1. C, at a working level

Not "I have written C". You need pointers to be boring. If any line below makes you pause, do the C track first.

```
int   a[5];
int  *p    = a;          /* what is the type of a here, and why?          */
int (*q)[5] = &a;        /* how does q differ from p?                     */
int  *r    = a + 2;      /* what address is this, in bytes?               */

char  s[] = "hi";        /* sizeof(s) is 3, not 2 — why?                  */
char *t   = "hi";        /* writing t[0] = 'H' is undefined — why?        */

struct f { uint8_t a; uint32_t b; };   /* sizeof is 8, not 5 — why?       */

void (*cb)(int) = handler;             /* declare an array of these       */

uint32_t v = 1u << 31;   /* now do 1 << 31 with a signed int. What breaks? */
```

You must be able to	Covered in
Read and write pointer declarations, including pointers to functions and to arrays	C 04, 05, 12
Predict struct size and layout from member order	C 07
Use `&`, `|`, `^`, `~`, `<<`, `>>` fluently and safely	C 08
Explain what `const`, `static` and `volatile` each mean in every position	C 09, 10
Say why signed overflow is undefined and unsigned overflow is not	C 15

2. Hexadecimal and binary fluency

You should read `0x4001_0080` and think "offset `0x80` inside the block at `0x4001_0000`" without pausing. Try these in your head:

Question	Answer
How many bytes is `0x1000`?	4096 — one page
`0xFFFF_FFFF` as an unsigned 32-bit value?	4,294,967,295 — about 4 G
Which bit does `0x0080` set?	Bit 7
`1 << 20` bytes is?	1 MiB
Mask for bits 11:4?	`0x0FF0`
Is `0x8000_0000` negative as a signed 32-bit value?	Yes — it is `INT32_MIN`

If those were slow, chapters CA 01 and CA 02 fix it in an afternoon.

3. A command line

You will live in a shell, even for Windows driver work. You need: navigating and searching a filesystem, pipes and redirection, `grep`, `find`, editing a file over SSH, and `git` at the level of clone, branch, diff, log, bisect.

Helpful but not required

Background	Where it helps	If you lack it
Any digital logic (gates, flip-flops)	Computer architecture 04–07	Those chapters teach it from zero
Basic electronics (voltage, current, pull-ups)	Board bring-up, signal debugging	Learn it when you first meet a scope
Assembly, any architecture	ARM track, compiler output	The ARM track teaches A64 from scratch
Linear algebra and calculus	AI track	AI chapters 02–11 teach exactly what is needed
Python	AI track experiments, build scripting	Pick it up alongside; it is not load-bearing elsewhere
A university OS course	Operating systems track	That track is written to replace one

> **WHAT YOU EXPLICITLY DO NOT NEED**
>
> A computer science degree. Prior kernel experience. Owning hardware. Knowing C++ or Rust. Familiarity with any specific SoC vendor. Every one of those is either taught here or genuinely optional.

The self-assessment

Score yourself honestly. Each question is answerable in two or three sentences.

Section A — C (must pass 5 of 6)

1. What is the difference between `char *p` and `char p[]` as a function parameter?
2. Why does `sizeof(struct {char a; int b;})` exceed the sum of its members?
3. What does `static` mean on a file-scope function, and on a local variable?
4. Give a concrete bug caused by omitting `volatile`.
5. What is wrong with `if (x = 5)`, and with `a[i++] = i;`?
6. How do you return two values from a C function? Give two different approaches and their trade-offs.

Section B — numbers and bits (must pass 3 of 4)

1. Convert `0b1011_0110` to hex and to decimal.
2. Write an expression that clears bits 5:3 of `reg` and sets them to the value `n`.
3. What is `-1` as an eight-bit two's-complement pattern, and why that pattern?
4. Why can `0.1 + 0.2 != 0.3` in floating point?

Section C — tools (must pass 3 of 4)

1. What does a linker do that a compiler does not?
2. What is in a `.o` file that is not in a `.c` file?
3. How would you find every use of a symbol across a 20-million-line source tree?
4. What does `git bisect` do, and when is it the right tool?

Result	Start at
Passed all three sections	Computer architecture 01 — or skim CA 01–03 and start at CA 04
Failed Section A	The C track, all of it, before anything else
Failed Section B only	CA 01–03, then continue normally
Failed Section C only	Continue, but read compiler chapters 01, 11, 12 early
Failed two or more sections	Spend a month on C and the shell. Come back. It will be a much better month than pushing on.

IF YOU ARE COMING FROM WEB OR APPLICATION DEVELOPMENT

Your instincts will fight you in three specific places, and it helps to name them in advance. **Memory is not free and not managed** — you allocate, you free, and you own the consequences. **There is no exception to catch** — a bad pointer is a crashed machine, not a stack trace. And **the abstraction is not the machine** — you will spend real time reasoning about caches, alignment and instruction ordering that a higher-level runtime hid from you. None of this is harder; it is just closer to the metal, and the feedback is less forgiving.

Setting up your workbench

Every exercise and project on this site runs without buying hardware. This page gets you a cross-compiler, an emulated ARM machine, a kernel-development host and a Windows driver target — in about an hour.

What you are building

```
YOUR MACHINE (any OS)
  │
  ├── a Linux environment            ← native, VM, or WSL2
  │     ├── native gcc + gdb          for C, C++, compiler exercises
  │     ├── aarch64 cross-compiler    for ARM assembly and bare metal
  │     ├── QEMU (system + user)      an emulated ARM64 machine
  │     └── kernel headers + build    for the Linux driver track
  │
  ├── a disposable Windows VM        ← only for the Windows track
  │     ├── test signing enabled
  │     └── kernel debugging to the host
  │
  └── optional: one real board       ← after you have done the emulated work
```

A Linux environment

Pick whichever is least friction for you. All three work for everything on this site except real hardware bring-up.

Option	Good	Watch out for
Native Linux	Fastest; USB and JTAG pass-through just work	Do not develop kernel modules on the machine you need working
A VM (VirtualBox, VMware, UTM, Hyper-V)	Snapshots. Break the kernel, roll back in seconds.	Give it 4+ cores and 8 GB if you will build kernels
WSL2 (Windows)	Zero-friction on a Windows host; excellent for C, C++, Rust, QEMU, compiler work	It runs Microsoft's kernel — you cannot `insmod` your own module without building a custom WSL kernel

```
Debian / Ubuntu — everything the site needs
```

```
# toolchain and basics
sudo apt update
sudo apt install -y build-essential git gdb make cmake pkg-config \
                    bison flex libssl-dev libelf-dev bc \
                    device-tree-compiler cscope universal-ctags

# ARM cross-compilers
sudo apt install -y gcc-aarch64-linux-gnu binutils-aarch64-linux-gnu \
                    gcc-arm-none-eabi          # bare metal / Cortex-M

# emulation
sudo apt install -y qemu-system-arm qemu-user-static

# kernel build (for the Linux driver track)
sudo apt install -y linux-headers-$(uname -r)

# nice to have
sudo apt install -y clang lld llvm valgrind strace ltrace linux-perf
```

Fedora equivalent

```
sudo dnf groupinstall -y "Development Tools"
sudo dnf install -y gcc-aarch64-linux-gnu binutils-aarch64-linux-gnu \
                    arm-none-eabi-gcc-cs qemu-system-aarch64 \
                    kernel-devel kernel-headers dtc cscope ctags \
                    openssl-devel elfutils-libelf-devel bc
```

Verify it

```
aarch64-linux-gnu-gcc --version
qemu-system-aarch64 --version
ls /lib/modules/$(uname -r)/build          # must exist for module builds

# a 30-second end-to-end check: compile for ARM64, run it under emulation
printf '#include <stdio.h>\nint main(void){printf("hello from %%s\\n","aarch64");}\n' > t.c
aarch64-linux-gnu-gcc -static t.c -o t
qemu-aarch64-static ./t
#   hello from aarch64
```

> **WHAT THE NAMING MEANS**
>
> A cross-compiler is `<arch>-<vendor>-<os>-<abi>-gcc`. `aarch64-linux-gnu-` targets 64-bit ARM running Linux with glibc. `aarch64-none-elf-` targets 64-bit ARM with *no OS* — bare metal. `arm-none-eabi-` is the 32-bit Cortex-M standard. Picking the wrong one produces link errors about missing `_start` or a libc that should not exist.

An emulated ARM64 machine

QEMU's `virt` machine is a synthetic ARM64 platform with a GIC, PCIe, an SMMU and virtio devices. It is where you will run kernels, examine exception levels, and single-step boot code.

```
# boot a kernel you built (Linux track, chapter 16)
qemu-system-aarch64 \
  -M virt -cpu cortex-a57 -smp 2 -m 1024 \
  -kernel arch/arm64/boot/Image \
  -initrd rootfs.cpio.gz \
  -append "console=ttyAMA0 earlycon" \
  -nographic

# add an emulated SMMU (security track)
  -M virt,iommu=smmuv3

# start at EL3 with firmware, rather than jumping straight to the kernel
  -M virt,secure=on,virtualization=on

# wait for a debugger before executing the first instruction
  -s -S
# then, in another terminal:
aarch64-linux-gnu-gdb vmlinux -ex 'target remote :1234' -ex 'hbreak start_kernel'
```

`-NOGRAPHIC` AND HOW TO GET OUT

`-nographic` puts the guest serial console on your terminal. To quit, press `Ctrl-A` then `x`. `Ctrl-C` goes to the guest, not to QEMU — this catches everyone once.

QEMU HAS A TRACK OF ITS OWN

The lines above are enough to get started. When you need to know what `-M virt` actually builds, how to wire a device onto a bus, why your guest has no network, or how to debug firmware and kernel together through one GDB session, the QEMU track covers it properly — including building a root filesystem, writing your own device model, and a ready-made command line for every track on this site.

Bare metal without an OS

For the ARM assembly chapters you want to run a handful of instructions with nothing underneath. This is the smallest possible setup.

`boot.S — prints a character and halts, on QEMU virt`

```
    .section .text
    .global _start
_start:
    ldr     x0, =0x09000000     // QEMU virt PL011 UART data register
    mov     w1, #'A'
    str     w1, [x0]            // memory-mapped I/O: one store = one character
1:  wfi                         // wait for interrupt = park the core
    b       1b
```

`link.ld and the build`

```
ENTRY(_start)
SECTIONS { . = 0x40000000; .text : { *(.text) } }
```

```
aarch64-none-elf-as boot.S -o boot.o        # or aarch64-linux-gnu-as
aarch64-none-elf-ld -T link.ld boot.o -o boot.elf
qemu-system-aarch64 -M virt -cpu cortex-a57 -nographic -kernel boot.elf
#   A

# inspect what you built
aarch64-none-elf-objdump -d boot.elf
aarch64-none-elf-readelf -S boot.elf
```

That is a complete embedded system: reset vector, memory-mapped I/O, and a parked core. Every chapter in the ARM track is an expansion of one of those three ideas.

Rust and C++ toolchains

```
# Rust, including a bare-metal ARM target (Rust track)
curl --proto '=https' --tlsv1.2 -sSf https://sh.rustup.rs | sh
rustup target add aarch64-unknown-none          # bare metal
rustup target add thumbv7em-none-eabihf         # Cortex-M4F
rustup component add rust-src llvm-tools
cargo install cargo-binutils probe-rs-tools

# C++: nothing extra, but you want a recent compiler for the modern chapters
g++ --version        # 13+ for good C++20/23 coverage
clang++ --version
```

A Windows driver target

Only needed for the Windows track. Two machines: a host with the tools, and a disposable VM that you will bug-check repeatedly.

1. **On the host:** Visual Studio 2022 with "Desktop development with C++", then the Windows SDK, then the WDK — *in that order*, matching versions. The WDK adds the driver project templates.
2. **Install WinDbg:** `winget install Microsoft.WinDbg`
3. **Create the test VM** (Hyper-V, VMware or VirtualBox) and **take a snapshot immediately**. You will restore it often.
4. **On the VM,** enable test signing and kernel debugging, then reboot.

```
on the TEST VM, elevated
```

```
bcdedit /set testsigning on
bcdedit /debug on
bcdedit /dbgsettings net hostip:192.168.1.10 port:50000 key:1.2.3.4
shutdown /r /t 0
```

```
on the HOST
```

```
windbg -k net:port=50000,key=1.2.3.4
.sympath srv*C:\symbols*https://msdl.microsoft.com/download/symbols;C:\myproject\x64\Debug
.reload /f
```

> **TEST SIGNING IS A DEVELOPMENT-ONLY SETTING**
> It puts a watermark on the desktop and weakens the machine's driver integrity guarantees. Enable it only on a disposable VM, never on a machine you rely on.

Navigating large source trees

The Linux kernel is over 20 million lines. Grep alone will not do. Set up one of these before you start the Linux track — it changes the experience completely.

Tool	Setup	Strength
Elixir Bootlin	None — it is a website	Cross-referenced identifiers across every kernel version. Start here.
cscope	`make cscope` in the kernel tree	"Who calls this?" and "Where is this assigned?"
ctags	`make tags`	Jump to definition in vim/emacs
clangd	`make compile_commands.json` (kernel has a script)	Full IDE features in VS Code or any LSP editor
ripgrep	`cargo install ripgrep`	Fast enough that grepping the whole tree becomes a reflex

If you do want hardware

Buy *one* board, after you have completed at least one emulated project. A logic analyser is worth more than a second board.

Board	Best for
Raspberry Pi 4 / 5	Embedded Linux, device tree, real drivers, GPIO. The default first board.
BeagleBone Black	Excellent documentation and a clean mainline path
STM32 Nucleo / Discovery	Bare metal, Cortex-M TrustZone, on-board SWD debugger
NXP i.MX8 or ST STM32MP1 kit	A real secure world: TF-A, OP-TEE, and a resource-domain controller to study
Any 8-channel logic analyser	Seeing what your code actually does on the wire

Ready when

- ✓ `aarch64-linux-gnu-gcc` compiles a hello-world and `qemu-aarch64-static` runs it.
- ✓ The bare-metal `boot.S` above prints `A` under `qemu-system-aarch64`.
- ✓ `ls /lib/modules/$(uname -r)/build` shows a directory (Linux track only).
- ✓ WinDbg connects to your test VM and `.reload /f` succeeds (Windows track only).
- ✓ You can jump to the definition of `kmalloc` in a kernel tree in under five seconds.

TRACK

Computer architecture

How a computer works, from a single transistor-level abstraction up to a multi-core memory hierarchy. Everything else on this site assumes this track.

20 chapters

Binary, hex and number representation

A computer stores no numbers. It stores voltages, which we agree to read as bits, which we agree to group and interpret. Every bug in this chapter's territory comes from two pieces of code disagreeing about that interpretation.

The problem

A transistor is reliably good at one thing: being clearly on or clearly off. It is bad at holding "3.7 volts, meaning the digit 7". Noise, temperature and manufacturing variation smear analogue values; they barely touch a signal that only has to be distinguishably high or low.

So the machine gets two symbols. Everything else — integers, text, colours, machine instructions, your source code — is a convention layered on top of groups of those two symbols.

> **THE CENTRAL IDEA OF THIS WHOLE TRACK**
> A pattern of bits has **no inherent meaning**. `0100 0001` is 65, or the letter `A`, or a fragment of an ARM instruction, or a pixel's red channel. What it means is decided entirely by the code that reads it. "Type" in a programming language is nothing more than a compiler-enforced agreement about which interpretation applies.

Positional notation, generalised

Decimal is positional: each digit is worth its face value times a power of ten. Binary is the same system with base two, and hex with base sixteen.

```
Decimal 205
    2 × 10²  +  0 × 10¹  +  5 × 10⁰   =  200 + 0 + 5      = 205

Binary 1100 1101
    1×2⁷ 1×2⁶ 0×2⁵ 0×2⁴ 1×2³ 1×2² 0×2¹ 1×2⁰
    128 + 64 +  0 +  0 +  8 +  4 +  0 +  1              = 205

Hex 0xCD
    C × 16¹  +  D × 16⁰   =  12×16 + 13                 = 205

Same value. Three notations. The machine only ever has the middle one.
```

Why hexadecimal exists

Hex is not a third number system the machine understands — it is a shorthand for humans, chosen because **16 = 2^4**. One hex digit is exactly four bits, always, with no carrying between them. That makes the conversion mechanical rather than arithmetic:

```
  1100 1101 0011 1010
  ──┬─ ──┬─ ──┬─ ──┬──
    C    D    3    A     →  0xCD3A

Read four bits, write one hex digit. Never any arithmetic. This is why
every datasheet, debugger and hex dump uses hex and not decimal: you can
see the bits through it.
```

Hex	Binary	Dec	Hex	Binary	Dec
0	`0000`	0	8	`1000`	8
1	`0001`	1	9	`1001`	9
2	`0010`	2	A	`1010`	10
3	`0011`	3	B	`1011`	11
4	`0100`	4	C	`1100`	12
5	`0101`	5	D	`1101`	13
6	`0110`	6	E	`1110`	14
7	`0111`	7	F	`1111`	15

Memorise this table. Not because it is deep, but because fluency here is the difference between reading a register dump at a glance and translating it laboriously. It takes about twenty minutes to internalise and pays back for a career.

Widths and units

Name	Bits	Hex digits	Unsigned range	C type (typical)
Nibble	4	1	0 – 15	—
Byte	8	2	0 – 255	`uint8_t`
Halfword	16	4	0 – 65,535	`uint16_t`
Word	32	8	0 – 4,294,967,295	`uint32_t`
Doubleword	64	16	0 – ~1.8×10^{19}	`uint64_t`

> **"WORD" IS NOT A FIXED SIZE**
> In ARM documentation a word is 32 bits, always. In x86 documentation a word is 16 bits (for historical reasons) and 32 bits is a "dword". In C, `int` is whatever the platform chose. Never rely on the word "word" across ecosystems — say the bit count.

The powers you should know cold

Power	Value	Meaning in practice
2^{8}	256	One byte's worth of distinct values
2^{10}	1,024	1 KiB
2^{12}	4,096	**4 KiB — the standard page size**
2^{16}	65,536	A 16-bit address space; also the 64 KiB boundary DMA engines care about
2^{20}	1,048,576	1 MiB
2^{30}	~1.07×10^{9}	1 GiB
2^{32}	~4.29×10^{9}	4 GiB — the limit of a 32-bit address
2^{40}	~1.10×10^{12}	1 TiB; a common physical address width on ARM SoCs
2^{48}	~2.81×10^{14}	256 TiB — the default AArch64 virtual address size

KIB VS KB

KiB, MiB, GiB are powers of two (1024, 1048576, …). **KB, MB, GB** are strictly powers of ten (1000, 1000000, …). Memory is sold and addressed in powers of two; storage and network rates are usually quoted in powers of ten. This is why a "1 TB" disk shows as 931 GiB — nothing is missing, the units differ by 10%.

In practice: reading an address

Here is the skill this chapter is actually for. Given a peripheral base of `0x4001_0000` and a register at offset `0x0C`:

```
  0x4001_0000     base of the GPIO block
+ 0x0000_000C     offset of the DATA register
──────────────
  0x4001_000C     the address you load from

Now read a value out of it:  0x0000_00A5

  0x A       5
    1010   0101
    ||||   ||||
    ||||   |||└─ bit 0 = 1
    ||||   ||└── bit 1 = 0
    ||||   |└─── bit 2 = 1
    ||||   └──── bit 3 = 0
    |||└──────── bit 4 = 1
    ||└───────── bit 5 = 0
    |└────────── bit 6 = 1
    └─────────── bit 7 = 0

  "Pins 0, 2, 5 and 7 are high."   ← the whole point
```

Notice how much harder that would be if the register had been printed as decimal 165. Hex is chosen precisely so bit positions are visible.

Writing literals in C

```c
uint32_t a = 205;          /* decimal                                    */
uint32_t b = 0xCD;         /* hex — the default for anything hardware    */
uint32_t c = 0b11001101;   /* binary — C23; a GCC/Clang extension before */
uint32_t d = 0315;         /* OCTAL — a leading zero, almost never wanted */

/* digit separators, C23 and C++14, make long constants readable */
uint32_t page  = 0x0000'1000;
uint32_t mmio  = 0x4001'0080;
```

THE LEADING-ZERO TRAP

`int mode = 0755;` is octal (493 decimal) — which is what you want for a Unix file mode and almost never what you want anywhere else. `uint8_t id = 011;` is 9, not 11. A leading zero silently changes the base. This has caused real outages in configuration parsing and in IP address handling.

The same bits, different meanings

To make the opening claim concrete, take the 32-bit pattern `0x41424344` and ask four different questions of it:

Interpreted as	Value
Unsigned 32-bit integer	1,094,861,636
Signed 32-bit integer	1,094,861,636 (the top bit is 0, so identical)
Four ASCII characters	`"ABCD"`
IEEE 754 single-precision float	≈ 12.1414
An AArch64 instruction	a valid encoding — the CPU would execute it
Four bytes in memory, little-endian	`44 43 42 41` in increasing address order

Nothing in the bits distinguishes these. The distinction lives entirely in the instruction you use to read them and the type your compiler believes they have.

Byte order, briefly

A 32-bit value occupies four consecutive byte addresses. Which byte goes at the lowest address is the machine's **endianness**.

```
Storing 0x12345678 at address 0x1000

  Little-endian (ARM in practice, x86 always)
    0x1000: 78   ← least significant byte first
    0x1001: 56
    0x1002: 34
    0x1003: 12

  Big-endian ("network byte order", some legacy and some MIPS/PowerPC)
    0x1000: 12   ← most significant byte first
    0x1001: 34
    0x1002: 56
    0x1003: 78
```

It matters the moment bytes cross a boundary: a network packet, a file format, a message to a different processor on the same chip. Within one program on one machine you never notice it. This is covered in depth in chapter 08 and again in the C track.

How it fails

Symptom	Cause
A register value looks like nonsense until you print it as hex	Printing hardware state in decimal. Always `%#x` for registers.
A constant is off by a strange factor	Accidental octal from a leading zero
Values are byte-swapped over a link	Endianness mismatch; use explicit conversions, never a raw cast
A size calculation is out by 2.4%	Mixing GB and GiB
A field written to a register lands in the wrong bits	Counting bit positions from 1 instead of 0. **Bit 0 is the least significant bit.**

Check yourself

✓ Convert `0xB6` to binary and to decimal, in your head, in under ten seconds.

- ✓ Explain why hex rather than octal or decimal is used in every datasheet.
- ✓ Say what `0x1000` bytes is, and why that number appears everywhere.
- ✓ Give three different meanings the pattern `0x41424344` could have.
- ✓ Explain the difference between 1 MB and 1 MiB and where each is used.
- ✓ Say which bit `0x0040` sets, counting the way hardware does.

Signed integers and two's complement

Negative numbers do not exist in hardware. What exists is a representation clever enough that the adder does not need to know about them — and understanding why it works explains a whole family of security bugs.

The problem

You have eight bits. That is 256 distinct patterns. You want some of them to mean negative numbers. The naïve approach — steal the top bit as a sign flag — seems obvious:

```
Sign-and-magnitude (the obvious idea, and wrong)

  0000 0101  =  +5
  1000 0101  =  −5     top bit = sign, rest = magnitude

Two problems:
  1. 0000 0000 = +0  and  1000 0000 = −0.  Two zeros. Every comparison
     against zero needs a special case.
  2. Addition needs a subtractor.  5 + (−5) through a plain binary adder
     gives 1000 1010 = −10.  Wrong. The hardware must inspect the signs
     and choose between adding and subtracting.

That second point costs real gates, real area and real time.
```

The mechanism: two's complement

The trick is to choose a representation where **ordinary binary addition just works**, with no sign inspection at all. Represent $-n$ as the pattern that, added to n, produces zero after the carry out of the top bit is discarded.

```
Eight-bit two's complement: the number line wraps

  bit pattern   unsigned   signed
  0000 0000        0          0
  0000 0001        1         +1
  ...
  0111 1110      126       +126
  0111 1111      127       +127     ← largest positive
  1000 0000      128       −128     ← the wrap point
  1000 0001      129       −127
  ...
  1111 1110      254         −2
  1111 1111      255         −1     ← all ones is −1, always

The top bit still tells you the sign. But it is not a flag −
it carries a weight, and that weight is NEGATIVE:

  1111 1111  =  −128 + 64 + 32 + 16 + 8 + 4 + 2 + 1  =  −1
                 ┬┬
                 └└── the only negative weight in the whole number
```

> **THE ONE-SENTENCE DEFINITION**
>
> In an *n*-bit two's complement number, the most significant bit has weight -2^{n-1} and every other bit has its usual positive weight. That is the entire system; everything else follows.

Why addition needs no special case

```
   5 + (−5), eight bits

     0000 0101      ( +5 )
   + 1111 1011      ( −5 )
   ─────────────
   1 0000 0000
   ↑
   └── carry out of bit 7, discarded because the result is 8 bits

     result = 0000 0000 = 0   ✓

   7 + (−3)

     0000 0111      ( +7 )
   + 1111 1101      ( −3 )
   ─────────────
   1 0000 0100  →  0000 0100 = +4   ✓

The adder never looked at a sign. Subtraction is just addition of the
negation, so the CPU needs ONE arithmetic unit for both − which is why
every processor built since the 1960s uses this representation.
```

How to negate

Two equivalent recipes. Both give the same answer; use whichever is faster for you.

```
Method 1: invert all bits, then add one

    +5   =  0000 0101
  invert    1111 1010
  add 1     1111 1011  =  −5

Method 2: copy bits from the right up to and including the first 1,
          then invert everything above it

    +12  =  0000 1100
                  ┘└└  copy "100" unchanged
            1111 0100  =  −12
            └────┘ invert the rest

Sanity check: negating twice must return the original.
    −5  = 1111 1011 → invert 0000 0100 → +1 → 0000 0101 = +5  ✓
```

Ranges and the asymmetry

Width	Signed range	Unsigned range	C types
8	−128 … +127	0 … 255	`int8_t` / `uint8_t`
16	−32,768 … +32,767	0 … 65,535	`int16_t` / `uint16_t`
32	−2,147,483,648 … +2,147,483,647	0 … 4,294,967,295	`int32_t` / `uint32_t`

Width	Signed range	Unsigned range	C types
64	≈ -9.22×10^{18} … $+9.22\times10^{18}$	0 … ≈1.84×10^{19}	`int64_t` / `uint64_t`

> **THE ASYMMETRY THAT BREAKS CODE**
>
> There is one more negative number than positive. There are 128 negatives (−128…−1) and only 127 positives (1…127), because zero occupies a slot on the positive side.
>
> The consequence: `-INT_MIN` **is not representable.** `abs(INT_MIN)` returns `INT_MIN` — still negative. In C this is undefined behaviour, and on ARM the instruction simply produces `INT_MIN` back. Code of the form `if (abs(x) < limit)` can therefore be defeated by passing `INT_MIN`, which has been the root of real vulnerabilities.

Sign extension

When a narrow value is widened, the new high bits must be filled. Filling them with zero is correct for unsigned values and catastrophic for negative signed ones.

```
Widening 8-bit 0xFF (-1 signed, 255 unsigned) to 32 bits

  ZERO extension    0x000000FF  =  255      correct for uint8_t
  SIGN extension    0xFFFFFFFF  =   -1      correct for int8_t

The rule: replicate the top bit of the source into every new bit.

This is why ARM has separate instructions:
  LDRB   Wd, [Xn]     load byte, zero-extend  → unsigned
  LDRSB  Wd, [Xn]     load byte, sign-extend  → signed
  LDRSW  Xd, [Xn]     load 32-bit word, sign-extend to 64

Picking the wrong load instruction is a silent, data-dependent bug:
it only misbehaves when the value happens to have its top bit set.
```

```
/* the classic surprise */
char c = -1;                    /* char may be signed or unsigned!      */
int  i = c;                     /* -1 if signed char, 255 if unsigned   */

/* getchar() returns int, not char, precisely because of this */
int ch;
while ((ch = getchar()) != EOF)   /* EOF is -1; a char cannot hold it     */
        ...                       /*   distinctly from the byte 0xFF      */

/* always be explicit in systems code */
int8_t  signed_byte   = -1;       /* guaranteed signed   */
uint8_t unsigned_byte = 0xFF;     /* guaranteed unsigned */
```

Mixing signed and unsigned: the biggest trap in C

When C compares a signed and an unsigned value of the same rank, the signed operand is **converted to unsigned**. The negative number becomes enormous.

```
int      i = -1;
unsigned u =  1;

if (i < u)                    /* FALSE. i converts to 4294967295 */
        puts("as expected");
else
        puts("surprise");     /* this branch runs */
```

THE BUG THIS CAUSES, IN THE SHAPE IT ACTUALLY APPEARS

```
/* a length check that does not check */
int copy_in(void *dst, const void *src, int len)
{
        if (len > MAX_LEN)            /* len = -1 passes: -1 > 1024 is false */
                return -EINVAL;
        memcpy(dst, src, len);        /* memcpy takes size_t — UNSIGNED.     */
        return 0;                     /* -1 becomes SIZE_MAX. Heap destroyed. */
}
```

This exact pattern — a signed length validated against an upper bound, then passed to an unsigned API — is one of the most common serious vulnerabilities in C code. The fix is to use an unsigned type for the length *and* check both ends of the range.

```
/* the fixed version */
int copy_in(void *dst, const void *src, size_t len)
{
        if (len == 0 || len > MAX_LEN)
                return -EINVAL;
        memcpy(dst, src, len);
        return 0;
}
```

Overflow

```
Signed overflow, 8-bit:

    127 + 1  =  0111 1111 + 0000 0001  =  1000 0000  =  -128

The number line wraps from the largest positive straight to the most
negative. The carry INTO the top bit differs from the carry OUT of it —
that is exactly the hardware condition that sets the V (overflow) flag.

Unsigned overflow, 8-bit:

    255 + 1  =  1111 1111 + 0000 0001  = 1 0000 0000  →  0000 0000

Wraps to zero. Carry out of the top bit sets the C (carry) flag.
```

	Unsigned overflow	**Signed overflow**
Hardware behaviour	Wraps modulo 2^n, sets C	Wraps, sets V
C language status	**Defined** — wrapping is guaranteed	**Undefined behaviour**
What the optimiser may assume	Nothing special	That it never happens — see below

WHY SIGNED OVERFLOW BEING UB MATTERS IN PRACTICE

```
if (x + 1 < x)          /* trying to detect signed overflow */
        handle();       /* GCC deletes this branch entirely at -O2:  */
                        /* signed overflow "cannot happen", so x+1 < x */
                        /* is always false.                          */
```

The check compiles to nothing. Detect overflow with the builtins instead: `__builtin_add_overflow(a, b, &result)` returns true on overflow and is a single instruction on ARM (it reads the V flag). The kernel wraps these as `check_add_overflow()`.

The condition flags

Every arithmetic operation on ARM can set four flags, and their definitions come straight from this chapter:

Flag	Set when	Used for
N — negative	The result's top bit is 1	Signed comparisons
Z — zero	The result is all zero bits	Equality tests
C — carry	Carry out of the top bit (unsigned overflow)	Unsigned comparisons, multi-word arithmetic
V — overflow	Carry into the top bit ≠ carry out of it	Signed overflow detection

This is why ARM has two families of conditional branches: `B.HI` / `B.LO` (unsigned, test C and Z) versus `B.GT` / `B.LT` (signed, test N and V). The comparison instruction is identical; only the interpretation differs — the same theme as chapter 01.

How it fails

Symptom	Cause
A loop `for (unsigned i = n; i >= 0; i--)` never ends	An unsigned value is always ≥ 0; it wraps to `UINT_MAX`
A length check passes for a negative length	Signed/unsigned comparison conversion
A byte read as −1 instead of 255	`char` signedness is implementation-defined; use `uint8_t`
An overflow check is optimised away	Signed overflow is UB; use the compiler builtins
A value is correct on x86 and wrong on ARM	Plain `char` is signed on x86, unsigned on ARM
A timestamp difference goes hugely positive after wrap	Comparing absolute unsigned counters instead of differences; use `(int32_t)(a - b) > 0`

Check yourself

- ✓ Write −7 as an 8-bit pattern, both ways, and verify by adding it to +7.
- ✓ Explain why the top bit is not a flag but a negative weight.
- ✓ Say why there is one more negative value than positive, and name a bug it causes.
- ✓ Explain what `LDRB` does that `LDRSB` does not, and when choosing wrong is silent.
- ✓ Predict the output of `if (-1 < 1u)` and justify it from the conversion rules.
- ✓ State the difference between C and V, and which comparison instructions use each.

Floating point and IEEE 754

Floating point trades exactness for range. Understanding the trade precisely is what separates "why is my total off by a cent" from a correct design — and it is unavoidable knowledge for the AI track, where the entire performance story is about shrinking these formats.

The problem

Integers are exact but their range is fixed by their width. A 32-bit integer cannot hold the mass of an electron and the mass of the sun. Scientific notation solves this for humans:

```
   6.022 × 10²³        significand × base^exponent
   ─┬──   ─┬─┘
    │       └── move the point this many places
    └──────────── the significant digits

The insight: store the digits and the exponent separately. The point
"floats" to wherever the exponent puts it. Precision stays constant
(a fixed number of significant digits) while range becomes enormous.
```

IEEE 754 is that idea in binary, standardised in 1985 so every machine produces bit-identical results. Before it, the same program gave different answers on different hardware.

The format

```
Single precision (float, 32 bits)

  31  30      23 22                                    0
 ┌───┬──────────┬──────────────────────────────────────┐
 │ S │ exponent │            fraction                  │
 └───┴──────────┴──────────────────────────────────────┘
   1      8                     23 bits

Double precision (double, 64 bits)

  63  62         52 51                                  0
 ┌───┬─────────────┬──────────────────────────────────────┐
 │ S │  exponent   │            fraction                  │
 └───┴─────────────┴──────────────────────────────────────┘
   1       11                    52 bits

value = (−1)^S  ×  1.fraction  ×  2^(exponent − bias)

  bias = 127 for float, 1023 for double
```

The three parts

- **Sign (S)** — one bit, 0 for positive. Unlike integers, this *is* a plain flag, which is why floating point has both `+0.0` and `-0.0`.
- **Exponent** — stored with a *bias* rather than as two's complement, so that comparing two positive floats as if they were integers gives the right answer. A stored 130 with bias 127 means an actual exponent of +3.
- **Fraction (mantissa)** — the digits after an *implied* leading 1. Since any normalised binary number starts with 1, storing that bit would waste it. This "hidden bit" buys one extra bit of precision for free.

Worked example: encoding −6.25

```
1. Sign:  negative  →  S = 1

2. Convert the magnitude to binary
     6.25 = 110.01₂          (4 + 2 + 0.25)

3. Normalise: shift until there is exactly one 1 before the point
     110.01  =  1.1001 × 2²

4. Exponent: actual 2, stored = 2 + 127 = 129 = 1000 0001₂

5. Fraction: the bits after the leading 1, padded to 23 bits
     1001 0000 0000 0000 0000 000

6. Assemble
     1 | 1000 0001 | 100 1000 0000 0000 0000 0000
     = 0xC0C80000

Check it:  printf("%#x\n", *(uint32_t*)&(float){-6.25f});
```

Special values

Two exponent patterns are reserved, which is how the format encodes infinities, NaNs and very small numbers.

Exponent	Fraction	Means
All zeros	Zero	`±0.0` — the sign bit still applies
All zeros	Non-zero	**Subnormal**: no hidden bit, fills the gap around zero at reduced precision
1 … 254 (float)	Any	Normal number, as described above
All ones	Zero	`±Infinity`
All ones	Non-zero	**NaN** — Not a Number

```
1.0 / 0.0   →  +inf          /* not a trap by default: a value      */
-1.0 / 0.0  →  -inf
0.0 / 0.0   →  NaN
sqrt(-1.0)  →  NaN
inf - inf   →  NaN

/* NaN is not equal to anything, INCLUDING ITSELF */
NaN == NaN  →  false
NaN != NaN  →  true          /* the standard idiom for detecting it  */
isnan(x)                     /* the readable way                      */

/* which is why this is a real bug pattern */
if (x == x) { /* normally always true; false exactly when x is NaN */ }
```

> **NAN POISONS EVERYTHING DOWNSTREAM**
>
> Any arithmetic involving a NaN produces a NaN. A single bad sample in a signal-processing chain, or one uninitialised weight in a neural network, silently turns an entire output tensor into NaNs with no error raised anywhere. This is why "loss went to NaN" is the most common training failure in machine learning — see AI chapter 15.

Precision: what you actually get

Format	Bits (S/E/F)	Decimal digits	Max value	Typical use
`float` (FP32)	1 / 8 / 23	≈ 7	≈ 3.4×10^{38}	Graphics, DSP, default ML training
`double` (FP64)	1 / 11 / 52	≈ 16	≈ 1.8×10^{308}	Scientific computing, the C default
`_Float16` (FP16)	1 / 5 / 10	≈ 3	65,504	ML inference, graphics
`bfloat16`	1 / 8 / 7	≈ 2	≈ 3.4×10^{38}	**ML training** — FP32's range with half the bits
FP8 (E4M3 / E5M2)	1 / 4 / 3 or 1 / 5 / 2	≈ 1	448 / 57,344	Large-model inference

> **WHY BFLOAT16 BEAT FLOAT16 FOR MACHINE LEARNING**
>
> Both are 16 bits. FP16 spends 10 bits on precision and only 5 on exponent; bfloat16 spends 7 on precision and 8 on exponent — exactly FP32's exponent field. Training cares far more about *range* (gradients spanning many orders of magnitude, which underflow to zero in FP16) than about the third decimal place. bfloat16 also converts to and from FP32 by truncating or padding, with no arithmetic at all.

The thing that surprises everyone

Binary fractions can only represent sums of negative powers of two. `0.5`, `0.25` and `0.75` are exact. `0.1` is not — in binary it is a repeating fraction, exactly as 1/3 is in decimal.

```
0.1 in binary =  0.0001100110011001100110011...  (repeating "0011")

Stored as the nearest float:
    0.100000001490116119384765625

Stored as the nearest double:
    0.1000000000000000055511151231257827021181583404541015625

Therefore:
    0.1 + 0.2  ==  0.30000000000000004     not 0.3
    (0.1 + 0.2) == 0.3   →   FALSE
```

```c
/* NEVER compare floats for equality */
if (a == b)                                  /* wrong */

/* absolute tolerance — fine when the scale is known */
if (fabs(a - b) < 1e-9)

/* relative tolerance — correct in general */
if (fabs(a - b) <= 1e-9 * fmax(fabs(a), fabs(b)))

/* money: do not use floating point at all */
int64_t cents = 1999;                        /* store the smallest unit  */
```

Precision is not uniform

Because the exponent scales the whole value, the gap between representable numbers grows with magnitude. This is the most under-appreciated property of the format.

Around this value (float)	Gap to the next representable number
1.0	$\approx 1.2 \times 10^{-7}$
1,000	$\approx 6.1 \times 10^{-5}$
1,000,000	≈ 0.0625
16,777,216 (2^{24})	**2.0** — consecutive integers stop being representable
10^9	≈ 64

```
float x = 16777216.0f;      /* 2^24 */
x = x + 1.0f;               /* x is STILL 16777216.0f — the +1 vanishes */

/* the same effect in a loop: this never terminates */
for (float f = 0; f != 20000000.0f; f += 1.0f)
        ;                   /* increments stop having any effect        */
```

ABSORPTION AND CATASTROPHIC CANCELLATION

Absorption: adding a small number to a large one loses the small one entirely, as above. Summing a million small values into a running total therefore loses accuracy progressively — sum smallest first, or use Kahan summation.

Cancellation: subtracting two nearly equal numbers destroys the significant digits. `(1.0000001f - 1.0f)` keeps almost no meaningful precision, and any subsequent division amplifies the error. Rearranging the algebra to avoid the subtraction is the fix.

Floating point in hardware

An FPU is a large, power-hungry block. Whether one exists, and whether you may use it, is a real design decision:

Context	Situation
Cortex-A (application)	FPU and NEON always present; freely usable in user space
Cortex-M0/M3	No FPU. Floating point is emulated in software — hundreds of cycles per operation.
Cortex-M4F / M7	Single-precision FPU; double precision still emulated
Linux kernel	**Floating point is effectively forbidden.** FP registers are not saved on kernel entry, so using them corrupts user-space state. `kernel_fpu_begin()` exists but is heavyweight and reserved for special cases.
Interrupt handlers	Avoid. FP context save/restore adds latency to every interrupt.

```
# ARM ABI variants — a mismatch produces link errors or silent corruption
arm-none-eabi-gcc -mfloat-abi=soft      # no FPU; library calls, FP args in integer regs
arm-none-eabi-gcc -mfloat-abi=softfp    # uses the FPU, but passes FP args in integer regs
arm-none-eabi-gcc -mfloat-abi=hard      # uses the FPU and passes FP args in FP registers

# deterministic-behaviour flags worth knowing
-ffast-math          # allows reassociation; BREAKS IEEE semantics. Read before enabling.
-ffp-contract=off    # stop the compiler fusing a*b+c into one FMA (changes results)
```

FIXED POINT: THE USUAL EMBEDDED ANSWER

When there is no FPU, represent fractions as scaled integers. In Q16.16 format, a 32-bit integer holds 16 integer bits and 16 fraction bits — the value is simply the integer divided by 65,536. Addition is plain integer addition; multiplication needs a shift afterwards. It is exact, fast, and deterministic, which is why audio, motor control and DSP code often uses it even on chips that do have an FPU.

```
typedef int32_t q16;
#define Q16(x)      ((q16)((x) * 65536.0))
#define Q16_MUL(a,b) ((q16)(((int64_t)(a) * (b)) >> 16))
#define Q16_ADD(a,b) ((a) + (b))
```

How it fails

Symptom	Cause
A total is off by a fraction of a cent	Money in floating point. Use integer minor units.
`a == b` fails for values that print identically	Printing rounds; the stored values differ. Compare with a tolerance.
A loop never terminates	Float loop counter reaching the absorption limit
Everything becomes NaN after one bad input	NaN propagation; validate inputs and check with `isnan()`
Results differ between debug and release builds	`-ffast-math`, FMA contraction, or x87 excess precision
User-space maths breaks after loading a driver	Floating point used in kernel code without saving FP state
ML training loss becomes NaN or stops improving	FP16 overflow or gradient underflow; use bfloat16 or loss scaling
Sudden 100× slowdown near zero	Subnormal numbers taking a microcode path; enable flush-to-zero if acceptable

Check yourself

- ✓ Encode −6.25 as an IEEE 754 single and verify the hex.
- ✓ Explain the hidden bit and what it buys.
- ✓ Say why `0.1 + 0.2 != 0.3` without using the word "rounding" alone.
- ✓ Explain why the gap between representable floats grows with magnitude, and give a bug it causes.
- ✓ State why bfloat16 is preferred to float16 for training.
- ✓ Say why the Linux kernel forbids floating point in ordinary driver code.
- ✓ Describe Q16.16 and how to multiply two values in it.

Boolean algebra and logic gates

Everything a processor does is built from a handful of operations on single bits. This chapter is the bridge from "a transistor is a switch" to "a machine can add" — and it is also where the bit-manipulation idioms you will write every day come from.

The problem

You have bits. You need to compute with them. What is the smallest set of operations that lets you build *any* function of bits at all — arithmetic, comparison, memory addressing, instruction decoding?

The answer, from George Boole in 1847 and Claude Shannon in 1937, is remarkably small: AND, OR and NOT suffice. In fact a single gate type suffices, which is why chips are physically built from just one or two.

The gates

Gate	C operator	Truth table (A, B → Y)	Says
NOT	`~` / `!`	0→1, 1→0	Invert
AND	`&`	00→0, 01→0, 10→0, 11→1	Both
OR	`|`	00→0, 01→1, 10→1, 11→1	Either
XOR	`^`	00→0, 01→1, 10→1, 11→0	Different
NAND	`~(a & b)`	00→1, 01→1, 10→1, 11→0	Not both
NOR	`~(a | b)`	00→1, 01→0, 10→0, 11→0	Neither

NAND IS UNIVERSAL

Every one of the other gates can be built from NAND alone:

```
NOT a       = a NAND a
a AND b     = NOT(a NAND b)        = (a NAND b) NAND (a NAND b)
a OR  b     = (NOT a) NAND (NOT b) = (a NAND a) NAND (b NAND b)
```

This matters physically: in CMOS, NAND and NOR are the *natural* gates — they need four transistors — while AND and OR are built as NAND followed by an inverter and therefore cost more. Synthesis tools rewrite your logic into NANDs and NORs for exactly this reason.

Why XOR earns its own gate

XOR is "these bits differ". That single property makes it the workhorse of arithmetic, error detection and cryptography:

```
a ^ 0 == a          /* identity: XOR with zero changes nothing           */
a ^ a == 0          /* self-inverse: the basis of parity and of one-time pads */
a ^ b ^ b == a      /* apply twice and you are back — reversible encryption  */

/* toggle exactly the bits set in a mask, leaving others alone */
reg ^= (1u << 3);   /* flip bit 3 */

/* the sum bit of a binary adder IS xor — see chapter 05 */
/* parity of a word: */
int parity(uint32_t v) { return __builtin_parity(v); }
```

The algebra

These identities are not academic — they are the rewrites the compiler and the synthesis tool perform, and knowing them lets you simplify register manipulation by hand.

Law	AND form	OR form
Identity	`a & 1 = a`	`a | 0 = a`
Null	`a & 0 = 0`	`a | 1 = 1`
Idempotence	`a & a = a`	`a | a = a`
Complement	`a & ~a = 0`	`a | ~a = 1`
Commutative	`a & b = b & a`	`a | b = b | a`
Distributive	`a & (b | c) = (a & b) | (a & c)`	
Absorption	`a | (a & b) = a`	
Involution	`~~a = a`	

De Morgan's laws

```
   ~(a & b)  ==  (~a) | (~b)
   ~(a | b)  ==  (~a) & (~b)

"Not both"    is    "either not"
"Neither"     is    "not either"
```

These are how a NAND-only fabric implements OR, and how a compiler rewrites your conditionals. They also catch a very common logic bug:

```
/* "if the flag is not READY and not ERROR" */
if (!(f & READY) && !(f & ERROR))     /* correct                          */
if (!(f & (READY | ERROR)))            /* also correct — De Morgan          */
if (!(f & READY & ERROR))              /* WRONG: true unless BOTH are set   */
```

In practice: the five bit idioms

Every driver you write uses these. They follow directly from the identity and null laws above.

Goal	Idiom	Why it works
Set bits	`reg |= mask;`	`x | 1 = 1`, `x | 0 = x` — masked bits forced high, others untouched

Goal	Idiom	Why it works
Clear bits	`reg &= ~mask;`	`x & 0 = 0`, `x & 1 = x`
Toggle bits	`reg ^= mask;`	`x ^ 1 = ~x`, `x ^ 0 = x`
Test bits	`if (reg & mask)`	Non-zero exactly when at least one masked bit is set
Extract a field	`(reg >> shift) & ((1u << width) - 1)`	Shift down, then mask off everything above the field
Insert a field	`reg = (reg & ~(m << s)) | ((v & m) << s);`	Clear first, then OR in — never OR without clearing

`the field macros every embedded codebase reinvents`

```
#define BIT(n)              (1u << (n))
#define GENMASK(h, l)       (((1u << ((h) - (l) + 1)) - 1) << (l))
#define FIELD_GET(mask, v)  (((v) & (mask)) / ((mask) & -(mask)))
#define FIELD_PREP(mask, v) (((v) * ((mask) & -(mask))) & (mask))

/* mask & -mask isolates the lowest set bit, which equals 1 << shift -
   so dividing by it is the same as shifting down, with no separate
   shift constant to keep in sync. This is the Linux kernel's trick. */

#define CTRL_MODE   GENMASK(5, 3)    /* bits 5:3 → 0x38 */
#define CTRL_ENABLE BIT(0)

uint32_t r = readl(base + CTRL);
uint32_t mode = FIELD_GET(CTRL_MODE, r);           /* read the field   */
r &= ~CTRL_MODE;                                    /* clear it         */
r |= FIELD_PREP(CTRL_MODE, 3) | CTRL_ENABLE;        /* set mode=3, on   */
writel(r, base + CTRL);
```

READ-MODIFY-WRITE IS NOT ALWAYS SAFE

`reg |= BIT(3)` is three operations: load, OR, store. If the hardware also modifies that register — a status bit setting itself, or another core writing it — you will read a stale value and write it back, silently undoing the hardware's change. Write-1-to-clear registers must be written directly (`reg = BIT(3)`), never read-modify-written, or you clear every other pending bit as a side effect. This theme returns in chapter 15.

Bitwise versus logical

```
/* BITWISE: operates on every bit position independently */
uint8_t a = 0x0C, b = 0x0A;
a & b   ==  0x08          /* 00001100 & 00001010 = 00001000 */
a | b   ==  0x0E
a ^ b   ==  0x06
~a      ==  0xF3

/* LOGICAL: treats each operand as a single true/false, and SHORT-CIRCUITS */
a && b  ==  1             /* both non-zero → true */
a || b  ==  1
!a      ==  0

/* the difference that bites */
if (flags & FLAG_A)       /* correct: tests the bit               */
if (flags && FLAG_A)      /* WRONG: true whenever flags is non-zero */

/* short-circuiting is a feature, not a detail */
if (p != NULL && p->field)  /* safe: p->field only evaluated if p is valid */
if (p != NULL &  p->field)  /* CRASH: bitwise & evaluates both operands    */
```

Shifts

```
Left shift:  a << n     multiply by 2ⁿ, zeros in from the right
   0000 1011 << 2  =  0010 1100        (11 → 44)

Logical right shift:  zeros in from the left — for UNSIGNED
   1011 0000 >> 2  =  0010 1100        (176 → 44)

Arithmetic right shift: the SIGN BIT replicates — for SIGNED
   1011 0000 >> 2  =  1110 1100        (−80 → −20)

C picks which one by the operand's type. ARM has separate
instructions: LSR (logical) and ASR (arithmetic).
```

SHIFT UNDEFINED BEHAVIOUR

Three ways a shift is UB in C, all of which the optimiser is allowed to exploit:

- Shifting by an amount ≥ the operand's width. `x << 32` on a 32-bit `int` is *not* zero — on ARM the shift amount is masked to 5 bits, so it is a shift by 0.
- Shifting a negative value left.
- Shifting a value into or past the sign bit of a signed type: `1 << 31` is UB because `1` is `int`. Write `1u << 31`, and `1ull << 40` for anything above 31.

How it fails

Symptom	Cause
A condition is true whenever any flag is set	`&&` used where `&` was meant
Setting a field also corrupts a neighbouring one	OR-ing in a value without clearing the field first
Clearing one interrupt clears several	Read-modify-write applied to a W1C register

Symptom	Cause
A 64-bit mask is zero above bit 31	`1 << n` with an `int` literal; needs `1ull`
A right shift of a negative value gives a huge positive one	Value stored in an unsigned type; logical rather than arithmetic shift
A null check does not protect the dereference	`&` instead of `&&` — no short-circuit

Check yourself

- ✓ Build NOT, AND and OR from NAND gates alone.
- ✓ State both De Morgan laws and use one to simplify `!(a & b)`.
- ✓ Write the six bit idioms from memory.
- ✓ Explain why you must clear a field before OR-ing a new value in.
- ✓ Give a case where `&` and `&&` produce different behaviour, not just different values.
- ✓ Name three ways a shift expression can be undefined behaviour.

Combinational logic building blocks

Gates alone are not useful. Four standard arrangements of them — adder, multiplexer, decoder, comparator — appear in every processor ever built, and once you can see them you can read a block diagram of a datapath.

The problem

Combinational logic has no memory: the outputs are a pure function of the current inputs. Change an input, and after a propagation delay the output settles to the new answer. There is no state, no clock, nothing to remember.

That constraint is exactly what makes it composable. The question this chapter answers is: which arrangements of gates are worth building once and reusing everywhere?

The adder

Binary addition, one column at a time, is exactly the arithmetic you learned as a child — and it maps onto two gates.

```
HALF ADDER — adds two bits, produces sum and carry

   A  B │ Sum  Carry
   ─────┼────────────
   0  0 │  0     0
   0  1 │  1     0
   1  0 │  1     0
   1  1 │  0     1        ← 1+1 = 10₂

   Sum   = A XOR B        ← "they differ"
   Carry = A AND B        ← "both"

FULL ADDER — also accepts a carry in, so adders can be chained

   Sum   = A XOR B XOR Cin
   Cout  = (A AND B) OR (Cin AND (A XOR B))
```

```
RIPPLE-CARRY ADDER — chain n full adders

   A₃B₃      A₂B₂      A₁B₁      A₀B₀
    ||        ||        ||        ||
  ┌─▼─┐     ┌─▼─┐     ┌─▼─┐     ┌─▼─┐
  │ FA │◄──┤ FA │◄──┤ FA │◄──┤ FA │◄── Cin
  └─┬─┘     └─┬─┘     └─┬─┘     └─┬─┘
 Cout S₃     S₂        S₁        S₀

Simple, small — and SLOW. Bit 31's answer cannot settle until the carry
has rippled through all 31 stages below it. Delay grows linearly with
width, and this sits directly on the critical path of the whole CPU.
```

> **WHY THIS MATTERS TO SOFTWARE PEOPLE**
> The carry chain is one of the longest combinational paths in a processor, so it strongly influences the maximum clock frequency. Real designs use **carry-lookahead** or **carry-select** adders, which compute in parallel whether each stage will generate or propagate a carry, trading area for delay proportional to log n rather than n. This is the first example of a pattern you will meet constantly: *spend transistors to buy time*.

Subtraction comes free

From chapter 02: a − b = a + (~b) + 1. Feed `b` through XOR gates controlled by a "subtract" signal, and tie that same signal to the carry-in:

```
   sub = 0  →  B passes through unchanged, Cin = 0  →  A + B
   sub = 1  →  B is inverted,              Cin = 1  →  A + ~B + 1  =  A − B

One adder, one control bit, both operations. This is the heart of the ALU
and the reason two's complement won.
```

The multiplexer

A mux is a hardware `if`: it selects one of several inputs to pass to its output.

```
2-to-1 multiplexer

        A ──┐
            ├──► Y        Y = (A AND ~S) OR (B AND S)
        B ──┘
            ▲
            S              S = 0 → Y = A
                           S = 1 → Y = B

4-to-1 needs 2 select bits; n-to-1 needs ⌈log₂ n⌉.
```

Muxes are everywhere in a CPU, and naming them is how you read a datapath diagram:

Where	What it selects
ALU input	A register value, or an immediate from the instruction
Register write-back	The ALU result, or data loaded from memory
Next program counter	PC+4, or a branch target, or an exception vector
Forwarding network	The register file, or a result still in flight in the pipeline (chapter 11)

> **MUX VERSUS BRANCH, IN SOFTWARE TERMS**
> A mux computes *both* inputs and then discards one. That is precisely what a branchless conditional does: ARM's `CSEL Xd, Xn, Xm, cond` is a 64-bit multiplexer exposed as an instruction. It is often faster than a branch because it cannot be mispredicted — and it is the standard mitigation for timing side channels in cryptographic code, because its execution time does not depend on the condition.

The decoder

A decoder turns an n-bit binary number into a one-hot signal: exactly one of 2^n outputs goes high.

```
2-to-4 decoder

   A₁ A₀ │ Y₃ Y₂ Y₁ Y₀
   ──────┼────────────
    0  0 │  0  0  0  1
    0  1 │  0  0  1  0
    1  0 │  0  1  0  0
    1  1 │  1  0  0  0

   Yₖ = 1 exactly when the input equals k.
```

Two uses dominate, and both are ideas you meet again in software:

- **Address decoding.** The top bits of an address select which device responds. This is literally how a memory map is implemented — the `0x4001_0000` in a datasheet is a pattern the decoder matches to raise one peripheral's chip-select. See chapter 17.
- **Instruction decoding.** The opcode field indexes a decoder that enables the correct functional units. A64's fixed 32-bit encoding exists to make this decoder small and fast (chapter 09).

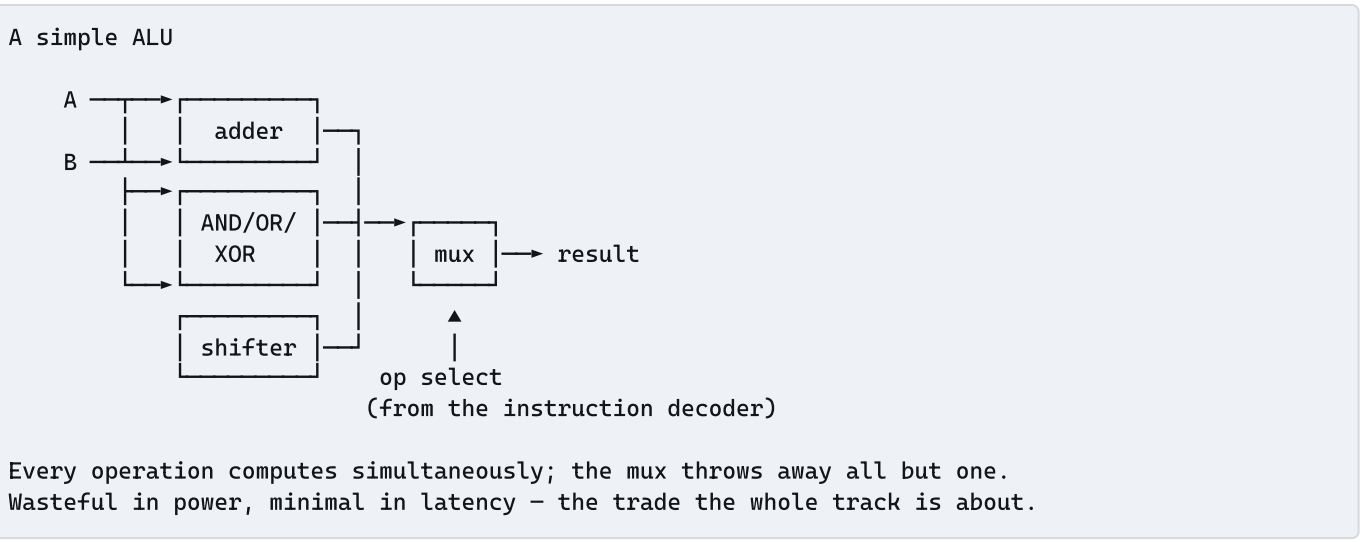
```
Address decoding on a small SoC

  address[31:28]  ──►  4-to-16 decoder  ──►  chip selects
      0x0            ──────────────────►  ROM
      0x2            ──────────────────►  SRAM
      0x4            ──────────────────►  peripheral bus
      0x8            ──────────────────►  DRAM controller

The "memory map" in the TRM is a description of this decoder's wiring.
```

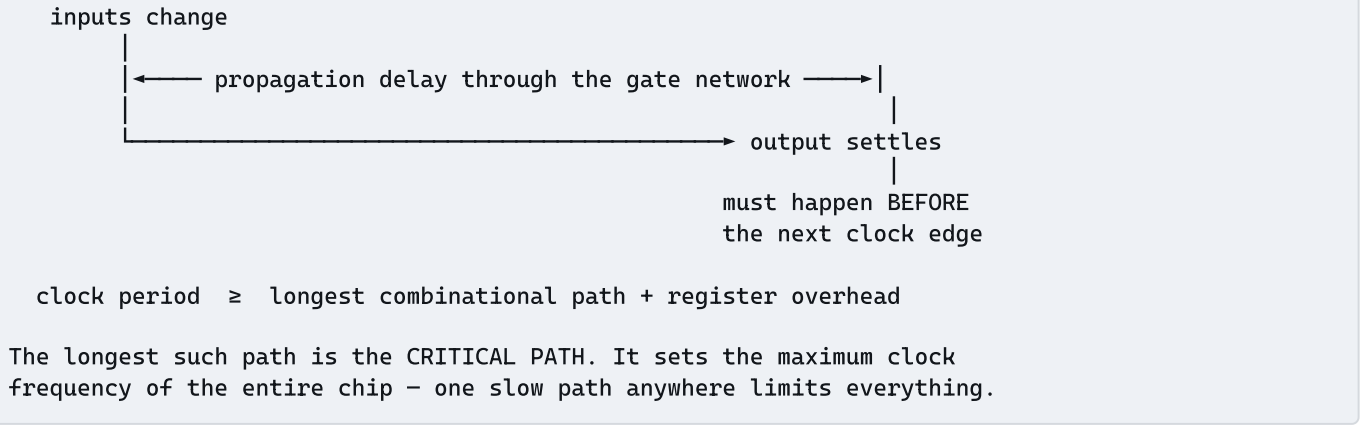
Comparators, shifters, and the ALU

Block	Built from	Note
Equality comparator	XNOR each bit pair, AND the results	"All bits match"
Magnitude comparator	A subtractor; inspect the flags	This is why `CMP` is just `SUBS` that discards its result
Barrel shifter	Layered muxes: shift by 1, 2, 4, 8, 16	Shifts any distance in one pass. ARM's is on the ALU input path, which is why `ADD X0, X1, X2, LSL #3` costs no extra cycle.
ALU	Adder + logic gates + shifter + output mux	The function-select bits come from the decoded opcode



Propagation delay: why any of this is a constraint

A gate does not switch instantly. Each contributes a few tens of picoseconds, and signals must settle before the result is captured.



> **THE CONNECTION TO PIPELINING**
> If the critical path is too long, you cannot clock faster. The fix is to cut the path in half with a register in the middle: each half now settles in half the time, so the clock can double, at the cost of taking two cycles end to end. That is pipelining, and it is the single most important idea in processor design. Chapter 06 supplies the register that makes it possible.

How it shows up in software

Observation	The combinational reason
`a * 8` compiles to a shift, folded into an addressing mode	The barrel shifter sits on the ALU input path and is free
`CSEL` beats a branch in a tight loop	A mux cannot be mispredicted
Division is 10–40× slower than multiplication	There is no cheap combinational divider; it is iterative
A comparison and a subtraction cost the same	They are the same hardware
Peripheral registers appear at "aligned, sparse" addresses	Address decoders match top bits only — full decoding costs gates
Constant-time crypto avoids data-dependent branches	Muxes take fixed time; branches do not

Check yourself

- ✓ Derive the half-adder's sum and carry equations from its truth table.
- ✓ Explain why a ripple-carry adder limits clock frequency, and what is done about it.
- ✓ Show how one adder performs both addition and subtraction.
- ✓ Name four places a multiplexer appears in a CPU datapath.
- ✓ Explain how a decoder implements a memory map.
- ✓ Define the critical path and say what it determines.
- ✓ Say why `CMP` and `SUBS` are the same instruction underneath.

Sequential logic, flip-flops and state machines

Combinational logic computes. To *remember* — and therefore to have registers, caches, program counters or anything resembling a computer — you need feedback. This chapter is where storage comes from.

The problem

Every block in chapter 05 forgets its inputs the instant they change. A machine built only from those blocks cannot hold a value, cannot count, cannot have a program counter — it can only react.

The missing ingredient is **feedback**: route an output back to an input, and the circuit can hold itself in a state.

From feedback to a latch

```
SR latch — two cross-coupled NOR gates

        S ──►┌──────┐
             │ NOR  ├──┬──► Q
        ┌───►└──────┘  │
        │              │
        │   ┌──────────┘
        │   │
        └───┼──┐
            │  │
        ┌──▼──▼┐
   R ──►│ NOR  ├────► ~Q
        └──────┘

   S  R │ Q      behaviour
   ────┼──────────────────────────
   0  0 │ hold   ← THE POINT: it remembers
   1  0 │  1     set
   0  1 │  0     reset
   1  1 │  ---   forbidden: both outputs 0, and the result on
               release depends on gate timing (a race)
```

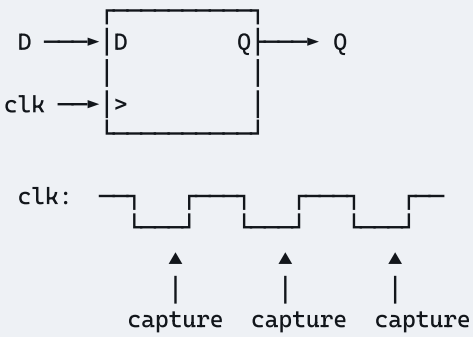
That "hold" row is the entire achievement. With `S = R = 0`, each gate's output feeds the other's input and the pair stays wherever it was. One bit is now stored — in nothing but the state of two gates driving each other.

Why latches are not enough

A plain latch is **level-sensitive**: while its enable is high, the output follows the input continuously. That transparency is dangerous — a signal can race through several latches in a single enable window, arriving somewhere it should not have reached until the next step.

Flip-flops: edge-triggered storage

```
D flip-flop — captures D only on the RISING EDGE of the clock
```



```
Between edges, the output is frozen no matter what D does.
The circuit is now SYNCHRONOUS: state changes only at known instants.
```

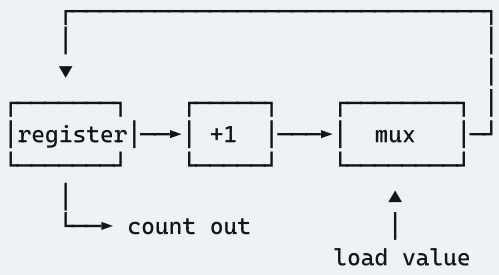
> **WHY EDGE-TRIGGERING MAKES DESIGN TRACTABLE**
>
> With edge-triggered storage, the whole machine advances in lockstep. Every combinational block gets one full clock period to settle, and the answer is sampled at a single, known instant. Reasoning reduces to a single question per path: *does this settle in time?* Without it, you would have to reason about overlapping propagation windows across the entire chip.

Registers

Put n flip-flops side by side, share the clock, and you have an n-bit register — the basic unit of storage in a processor.

Structure	Built from	In a CPU
Register	n flip-flops, common clock	`X0` – `X30`, `PC`, system registers
Register file	Registers + decoders + muxes for read/write ports	The 31 general-purpose registers, with 2 read ports and 1 write port
Shift register	Flip-flops chained output-to-input	Serial interfaces: UART, SPI, JTAG
Counter	Register + incrementer, fed back	Program counter, timers, cycle counters
Pipeline register	A register between two combinational stages	The thing that makes pipelining possible

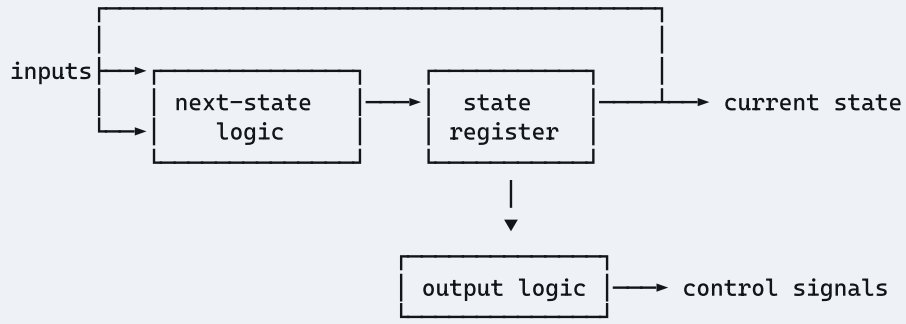
```
A counter — the simplest useful sequential circuit
```



```
This is a program counter. PC+4 each cycle, or a branch target when
the mux selects the load path.
```

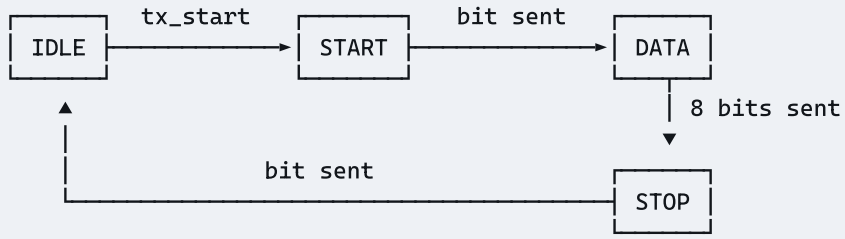
Finite state machines

Combine a register (holding "which state am I in") with combinational logic (deciding "given this state and these inputs, what next"), and you have the general model of every controller in a computer.



```
Moore machine:  outputs depend only on the state
Mealy machine:  outputs depend on state AND inputs (fewer states,
                but outputs can glitch mid-cycle)
```

A worked example: a UART transmitter



```
IDLE  : hold the line high, wait for tx_start
START : drive the line low for one bit period
DATA  : shift out 8 bits, LSB first, one per bit period
STOP  : drive high for one bit period, then return to IDLE

That is the whole transmitter. Every serial protocol you will meet is
a state machine of this shape.
```

THE SAME PATTERN IN SOFTWARE

You will write this structure constantly in drivers, and for the same reason: a device's behaviour is naturally a state machine, and modelling it as one makes illegal transitions impossible to express rather than merely unlikely.

```
enum state { IDLE, START, DATA, STOP };

static void tick(struct uart *u)
{
        switch (u->state) {
        case IDLE:  if (u->pending) { line(0); u->state = START; } break;
        case START: line(u->byte & 1); u->bit = 1; u->state = DATA;  break;
        case DATA:  line((u->byte >> u->bit) & 1);
                    if (++u->bit == 8) u->state = STOP;              break;
        case STOP:  line(1); u->state = IDLE;                        break;
        }
}
```

Windows' PnP state machine, Linux's device probe/remove lifecycle and USB's enumeration are all the same idea at a larger scale.

Reset: the state you start in

On power-up, every flip-flop holds an arbitrary value — whichever way it happened to settle. A design without reset starts in a random state and behaves unpredictably.

Kind	Behaviour	Trade-off
Asynchronous	Takes effect immediately, no clock needed	Works before the clock is running — but releasing it near a clock edge can cause metastability
Synchronous	Applied on a clock edge like any other input	Clean and timing-analysable — but useless if the clock is not yet running
Async assert, sync release	Both	The standard practice: assert immediately, release cleanly

This is why a datasheet lists a *reset value* for every register, why boot code must not assume a peripheral is in a known state unless it has reset it, and why "it works after a power cycle but not after a warm reset" is a recognisable class of bug — the two paths reset different things.

How it shows up in software

Observation	The sequential reason
A register reads back a value you never wrote	Reset value from the datasheet; the block was never programmed
A peripheral works after power cycle, fails after warm reset	Different reset domains; some state survives
You must hold a block in reset while configuring its clock	Flip-flops need a stable clock before they can capture reliably
A status bit is briefly wrong right after a write	Mealy-style output glitching, or a clock-domain crossing
A driver needs a delay after enabling a block	Internal state machine needs cycles to reach its ready state

Observation	The sequential reason
Reading a counter gives a torn value	A wide counter sampled across an edge; read high, low, then high again and retry if it changed

Check yourself

- ✓ Explain how two cross-coupled NOR gates store a bit.
- ✓ Say what is forbidden about `S = R = 1` and why.
- ✓ Give the difference between a level-sensitive latch and an edge-triggered flip-flop, and why designs use the latter.
- ✓ Draw a counter from a register and an adder.
- ✓ Draw the state diagram of a UART transmitter and name each state's job.
- ✓ Explain why every register has a documented reset value and what that means for driver code.

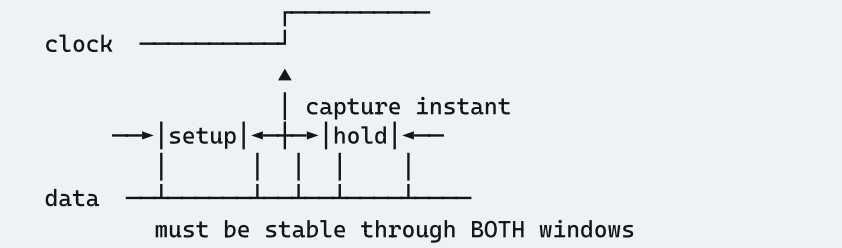
Clocks, timing and metastability

The clock is the heartbeat that makes a machine of gates behave predictably. This chapter explains what limits its speed, why crossing between two clocks is genuinely dangerous, and why so many driver bugs turn out to be "the block was not clocked".

The problem

From chapter 06, a flip-flop captures its input on a clock edge. But a real flip-flop is not instantaneous. It needs its input to be *stable for a while before* the edge and to *stay stable for a while after*. Violate either window and the captured value is not merely wrong — it may be neither 0 nor 1 for a time.

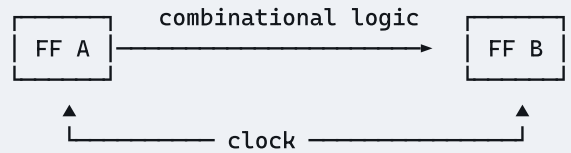
Setup and hold



```
  t_setup : input must be stable this long BEFORE the edge
  t_hold  : input must remain stable this long AFTER the edge

Violate either → the flip-flop may enter a METASTABLE state:
its output hovers between logic levels for an unbounded time
before resolving randomly to 0 or 1.
```

The maximum-frequency equation



```
  T_clock  ≥  t_clk→q  +  t_logic  +  t_setup  +  t_skew

    t_clk→q : delay from the edge to A's output being valid
    t_logic : propagation through the combinational cloud  ← the big one
    t_setup : B's setup requirement
    t_skew  : difference in clock arrival time between A and B

  f_max = 1 / T_clock

The path with the largest t_logic — the CRITICAL PATH — sets f_max
for the entire chip. One slow path anywhere limits everything.
```

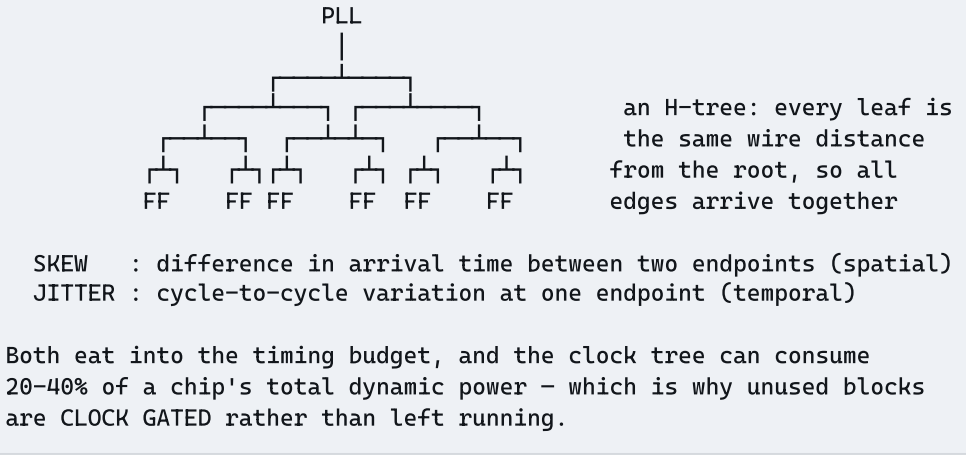
THE THREE WAYS TO GO FASTER

1. **Shorten the logic.** Better adders, fewer levels of gates.
2. **Cut the path in two with a register.** Each half now settles in half the time, so the clock can roughly double — at the cost of an extra cycle of latency. This is pipelining.
3. **Do more per cycle instead.** Wider issue, SIMD, more cores — chapter 19.

Frequency scaling stopped around 2005 because of power (chapter 20), which is why options 2 and 3 dominate every design since.

Clock distribution

A clock must reach millions of flip-flops at very nearly the same instant. It does not arrive by magic: it is driven through a large buffered tree that is among the most carefully engineered structures on the die.



```
  SKEW   : difference in arrival time between two endpoints (spatial)
  JITTER : cycle-to-cycle variation at one endpoint (temporal)

Both eat into the timing budget, and the clock tree can consume
20–40% of a chip's total dynamic power — which is why unused blocks
are CLOCK GATED rather than left running.
```

Where clocks come from

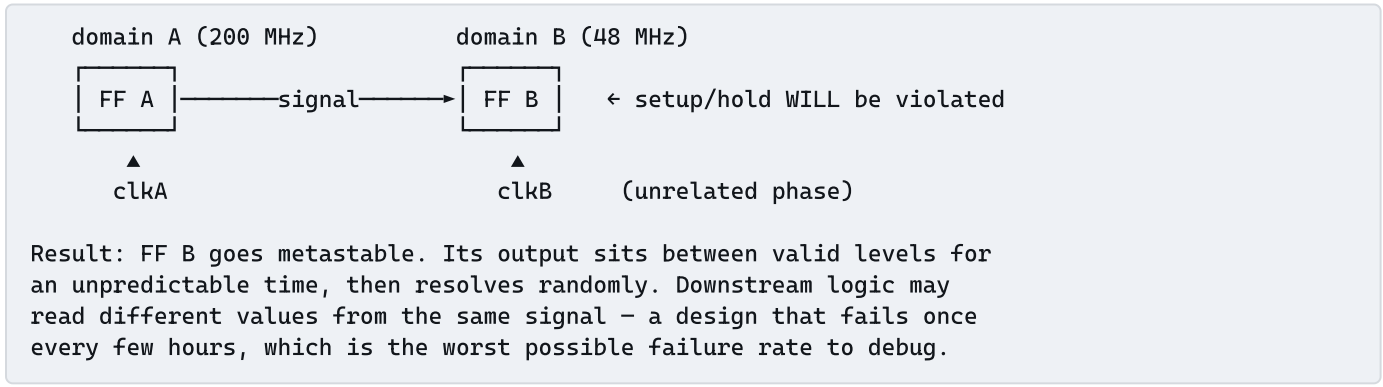
Source	Typical	Note
Crystal oscillator	12–50 MHz	The accurate reference everything derives from. Needs correct load capacitors — wrong ones give a subtly off frequency, which shows up as UART framing errors.
PLL	Multiplies to 1–3 GHz	Needs time to lock; boot code must wait for the lock bit before switching to it
Dividers	Per-peripheral	The clock tree software configures via the clock framework
RC oscillator	Low accuracy	Cheap, used for watchdogs and wake-up; too imprecise for serial links

THE NUMBER ONE BRING-UP BUG

A peripheral whose clock is not enabled reads back as all zeros, all ones, or aborts the access entirely — indistinguishable from a wrong address or a firewall denial. **Always verify the clock before debugging anything else.** On Linux, `cat /sys/kernel/debug/clk/clk_summary` shows every clock's rate and enable count. In a driver, this is what `clk_prepare_enable()` is for, and why it comes before the first register read in every `probe()` function.

Clock domain crossing

A real SoC has dozens of independent clocks: CPU, DDR, USB, audio, a slow always-on domain. When a signal passes from one to another, the receiving flip-flop's setup and hold windows are violated *eventually and unavoidably*, because the two clocks have no fixed phase relationship.



Result: FF B goes metastable. Its output sits between valid levels for an unpredictable time, then resolves randomly. Downstream logic may read different values from the same signal — a design that fails once every few hours, which is the worst possible failure rate to debug.

The standard fixes

Technique	For	How
Two-flop synchroniser	A single control bit	Chain two flip-flops in the destination domain. The first may go metastable; it is given a full clock period to resolve before the second samples it. Reduces failure probability to once in years.
Gray-coded counters	Multi-bit counters	Only one bit changes per increment, so a mid-transition sample yields either the old or the new value — never a nonsense combination
Asynchronous FIFO	Data streams	Dual-port memory with Gray-coded read/write pointers, each synchronised into the other domain
Handshake	Occasional transfers	Request/acknowledge, each synchronised — slow but simple and robust

WHY A SOFTWARE ENGINEER SHOULD CARE

Three reasons this is not just hardware trivia. First, it explains why some status registers must be read twice and compared, or why a datasheet says "this field is valid two cycles after the write" — you are seeing a synchroniser's latency. Second, the two-flop synchroniser is conceptually identical to a **memory barrier**: both are mechanisms for safely passing information between two things that do not share a timebase. Third, the "read a wide counter twice and retry if it changed" idiom in timer drivers exists precisely because the counter crosses a clock domain.

```
/* reading a 64-bit counter that updates in another clock domain */
do {
        hi1 = readl(base + CNT_HI);
        lo  = readl(base + CNT_LO);
        hi2 = readl(base + CNT_HI);
} while (hi1 != hi2);          /* retry if the low half wrapped mid-read */
```

Clock gating and dynamic scaling

Dynamic power is proportional to $C \cdot V^2 \cdot f$ — capacitance, voltage squared, frequency. Two consequences shape every modern SoC:

- **Clock gating.** Stop the clock to an idle block and its dynamic power goes to essentially zero. This is what a peripheral's "clock enable" bit does, and why disabling it makes the block's registers unreadable — there is no clock to capture the access.
- **DVFS** (dynamic voltage and frequency scaling). Lower frequency permits lower voltage, and because of the square term the energy saving is superlinear. This is what a CPU governor manipulates, and why a benchmark run at a low governor setting is not comparable to one at another.

```
Typical SoC clock hierarchy as software sees it

  crystal 24 MHz
       │
       ├─► PLL0 ──► 1.8 GHz ──► CPU cluster        [DVFS: 400 MHz – 1.8 GHz]
       │
       ├─► PLL1 ──► 800 MHz ──► DDR controller
       │
       └─► PLL2 ──► 480 MHz ──┬─► /4  → 120 MHz ──► AXI interconnect
                              ├─► /10 →  48 MHz ──► USB      [gateable]
                              └─► /30 →  16 MHz ──► APB ──┬─► UART  [gateable]
                                                          ├─► I2C   [gateable]
                                                          └─► SPI   [gateable]

Every "gateable" leaf is a clk_prepare_enable() call in some driver.
```

How it fails

Symptom	Cause
Peripheral registers read as 0 or 0xFFFFFFFF	Clock not enabled — check this first, every time
Access to a peripheral aborts	Clock or power domain off; the bus gets no response
UART output is garbage at every baud rate	Wrong crystal frequency assumed, or wrong load capacitors
System hangs immediately after switching to the PLL	Did not wait for the PLL lock bit
A failure once every few hours, never reproducible	Missing clock-domain synchroniser — classic metastability
A timer occasionally reads a wildly wrong value	Torn read across a counter's halves; use the retry loop
Works at low CPU frequency, fails at high	A timing path is marginal, or a delay loop was calibrated for one frequency
Benchmarks vary 3× run to run	DVFS and thermal throttling; pin the governor before measuring

Check yourself

- ✓ Define setup time and hold time, and say what happens when either is violated.
- ✓ Write the maximum-frequency equation and name its dominant term.
- ✓ Explain the difference between clock skew and clock jitter.
- ✓ Say why a two-flop synchroniser reduces, but never eliminates, metastability risk.
- ✓ Explain why Gray coding is used for pointers crossing clock domains.
- ✓ Give the first thing to check when a peripheral register reads as all zeros.
- ✓ Explain why lowering frequency saves more than proportional energy.

The stored-program computer

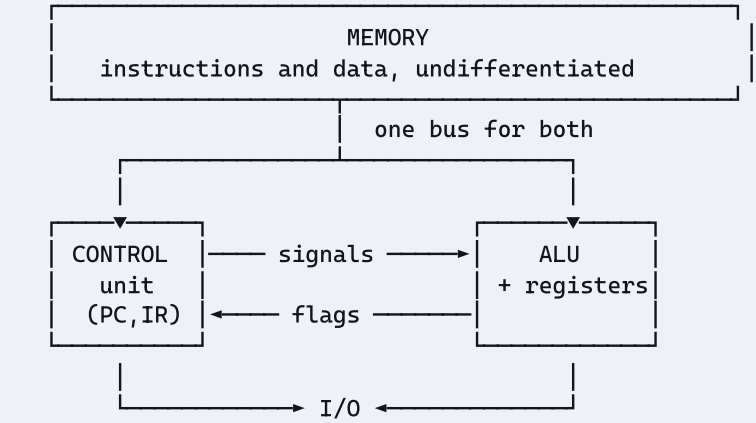
The idea that a program is just data in the same memory as everything else is what makes a computer general-purpose — and it is also the root of buffer overflows, JIT compilers, self-modifying boot code and the entire W^X security model.

The problem

Chapters 05 and 06 give you an ALU and registers. You could wire them into a machine that computes one fixed function — a calculator. To change what it does, you would rewire it. Early machines like ENIAC were literally reprogrammed by moving cables, which took days.

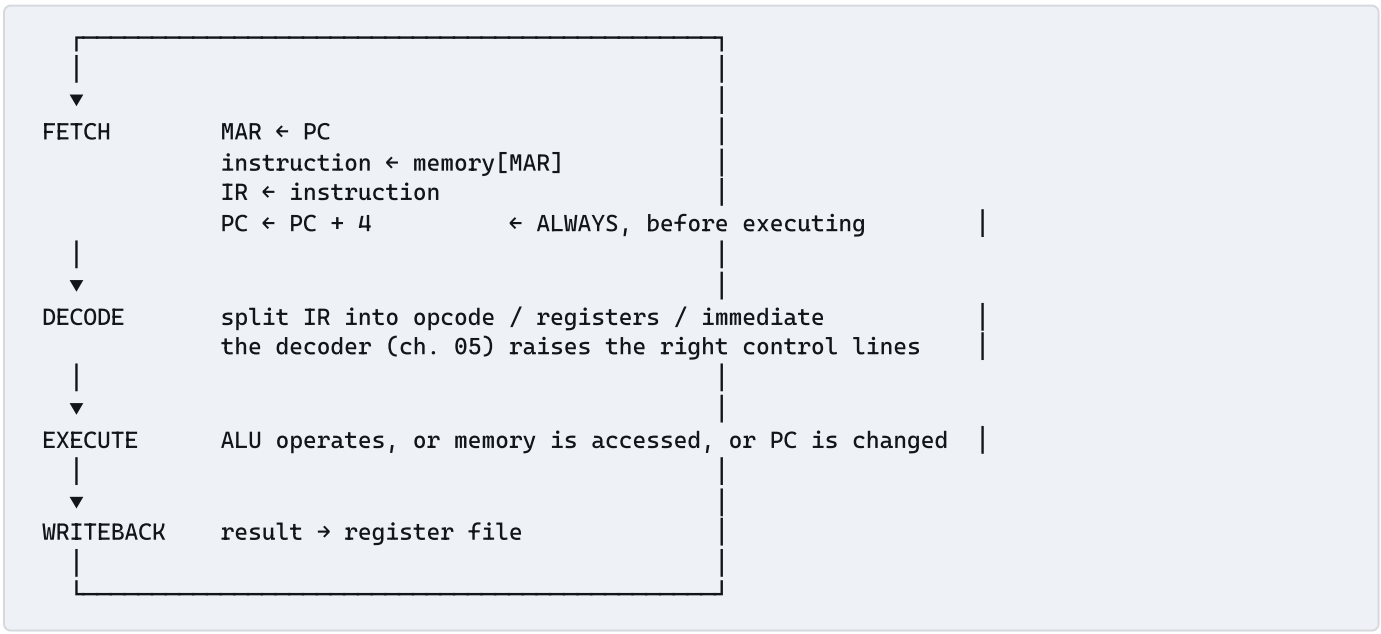
The stored-program insight, credited to the 1945 EDVAC report and usually named after von Neumann, is: **put the instructions in memory alongside the data**. Then changing the program is just changing memory contents, which the machine can do itself.

The von Neumann model



```
Five parts: memory, control unit, arithmetic unit, input, output.
Every processor since is a refinement of this drawing.
```

The fetch–decode–execute cycle



> **WHY PC IS INCREMENTED DURING FETCH, NOT AFTER EXECUTE**
> By the time a branch executes, the PC already points at the following instruction. A branch simply overwrites it. This is why a "relative branch" offset is measured from the instruction after the branch, and it is why `BL` (branch with link) can save the return address by copying the already-incremented PC into the link register — no separate addition needed. Every quirk of branch encoding traces back to this ordering.

Harvard and the modified Harvard architecture

Von Neumann's single memory port is a bottleneck: an instruction fetch and a data access compete for the same bus every cycle. The **Harvard** architecture gives instructions and data separate memories and separate buses, so both happen simultaneously.

	Von Neumann	Harvard	Modified Harvard
Memories	One, shared	Two, separate	One unified main memory, split L1 caches
Fetch + load in one cycle	No	Yes	Yes, when both hit in L1
Can code be written as data?	Yes, naturally	No, or only via special instructions	Yes, but requires explicit cache maintenance
Used by	The conceptual model	Small DSPs, some microcontrollers	**Every Cortex-A, and essentially every modern CPU**

```
Modified Harvard, as ARM actually implements it

          ┌──────────┐       ┌──────────┐
          │ L1 I-cache│       │ L1 D-cache│     separate: Harvard-like
          └──────┬───┘       └────┬─────┘
                 └──────┬─────────┘
                        ▼
                    ┌──────┐
                    │  L2  │                   unified: von Neumann-like
                    └──┬───┘
                       ▼
                    ┌──────┐
                    │ DRAM │
                    └──────┘

Best of both: parallel access at L1, one address space overall.
The COST appears the moment you write instructions as data.
```

THE CONSEQUENCE YOU WILL ACTUALLY HIT

Write instruction bytes into memory — a JIT compiler, a bootloader relocating code, a kernel patching an alternative instruction sequence, a debugger inserting a breakpoint — and those bytes sit in the **data** cache. The instruction cache and the prefetcher know nothing about them. Execute that address and you run stale instructions.

```
/* the mandatory sequence after writing code, on ARM */
dc      cvau, x0        /* clean D-cache to the point of unification  */
dsb     ish             /* wait for it to complete                    */
ic      ivau, x0        /* invalidate I-cache for that address        */
dsb     ish             /* wait                                       */
isb                     /* flush already-prefetched stale instructions*/
```

Covered in full in ARM chapter 18. Every self-modifying mechanism on the platform depends on getting this exactly right.

What the stored-program idea buys and costs

Because code is data…	You get
A program can load another program	Operating systems, loaders, dynamic linking
A program can generate code at runtime	JIT compilers, eBPF, GPU shader compilation
Code can be relocated after being loaded	Position-independent executables, ASLR, shared libraries
Code can be inspected and modified	Debuggers, breakpoints, hot patching, kernel live patching
Code can be transmitted	Firmware updates, containers, downloadable applications
Data can be executed	**Buffer overflow attacks, code injection, ROP**

W^X: taking the generality back

That last row is the problem. If an attacker can write bytes into a buffer and then redirect execution to it, the stored-program property is the vulnerability. The defence is to make memory **writable XOR executable**, never both, enforced by the MMU:

Region	Permissions	Enforced by
`.text` (code)	Read + Execute, not Write	Page table AP bits

Region	Permissions	Enforced by
`.rodata`	Read only	Page table AP bits
`.data`, `.bss`, heap, stack	Read + Write, **never Execute**	Page table UXN/PXN bits

Related hardware mitigations, all of which exist because of this chapter's central idea:

- **PXN / UXN** — privileged/unprivileged execute-never bits in ARM page descriptors.
- **PAN** — Privileged Access Never: the kernel cannot accidentally dereference a user pointer without explicitly enabling access.
- **BTI** — Branch Target Identification: an indirect branch may only land on a `BTI` instruction, which breaks jump-oriented programming.
- **Pointer authentication** — signs return addresses so a corrupted stack cannot redirect a return.

A JIT compiler must therefore map a page writable, emit code, then *remap it executable* — never holding both permissions at once. Apple platforms enforce this so strictly that they provide a dedicated API for the transition.

The memory wall

Von Neumann's single path to memory has a second consequence, and it has grown into the dominant performance constraint in computing.

```
Relative improvement since ~1980

  CPU speed     ████████████████████████████████  ~50,000×
  DRAM latency  ███                               ~10×

The gap is the "von Neumann bottleneck" or "memory wall".
A DRAM access costs 100–300 CPU cycles. The processor is not
compute-limited; it is waiting.

Everything in chapters 13–15 — caches, prefetching, the whole memory
hierarchy — exists to hide this one number.
```

> **WHY THIS MATTERS FOR AI WORKLOADS**
> Large language model inference is almost entirely memory-bandwidth-bound, not compute-bound: generating each token requires streaming the entire weight matrix through the arithmetic units, and every weight is used exactly once. This is why quantisation (making the weights smaller) speeds up inference far more than a faster multiplier would, and why accelerators are designed around memory bandwidth. See AI chapter 26.

How it shows up

Symptom	Cause
Freshly written code executes as garbage or crashes	Missing I-cache invalidate after writing instructions
A JIT works on x86 but faults on ARM	x86 keeps I-cache coherent in hardware; ARM does not
Segfault the moment a function pointer into a buffer is called	W^X: the page is not executable, which is working as intended

Symptom	Cause
A debugger breakpoint corrupts a nearby instruction	Breakpoints work by overwriting instructions — the stored-program idea in action
A performance profile shows most cycles stalled on loads	The memory wall; the fix is data layout, not faster arithmetic
Boot code hangs after relocating itself	Jumped to the new copy without cache maintenance

Check yourself

- ✓ State the stored-program idea in one sentence and name two things it makes possible.
- ✓ List the four phases of the instruction cycle and say when the PC is updated.
- ✓ Explain the difference between Harvard and modified Harvard, and which ARM uses.
- ✓ Give the exact reason writing instructions to memory requires cache maintenance.
- ✓ Explain W^X and name two ARM features that enforce it.
- ✓ Explain the memory wall and why it makes LLM inference bandwidth-bound.

Instruction set architecture: RISC vs CISC

The ISA is the contract between hardware and software — the only part of a processor that software can see, and the only part the manufacturer cannot change. This chapter explains what belongs in that contract, why the RISC/CISC argument happened, and why the answer today is stranger than either side predicted.

The problem: what must a processor promise?

A chip designer wants freedom. Caches, pipeline depth, how many instructions issue per cycle, whether execution is in order — all of that should be changeable between generations without breaking existing software.

A software author wants stability. A binary compiled in 2015 should still run in 2030.

The **instruction set architecture** is the negotiated boundary. It specifies exactly what software may rely on, and by omission grants the designer freedom over everything else.

> **ARCHITECTURE VERSUS MICROARCHITECTURE**
>
> **Architecture** is the specification: instructions, their encodings and effects, the register set, the memory model, the exception model. It is a document — for ARM, the Architecture Reference Manual.
>
> **Microarchitecture** is one implementation of that specification: Cortex-A78, Neoverse N2, Apple's M-series cores. Pipeline depth, cache sizes, branch predictor design, reorder buffer size.
>
> The distinction is the most practically useful one in this chapter. *Architectural* behaviour is portable across every implementation — if your code is architecturally correct it works everywhere. *Microarchitectural* behaviour is timing, and is chip-specific. When debugging, always ask which one you are fighting: architectural bugs reproduce anywhere, microarchitectural surprises (timing, cache effects, errata) do not.

What an ISA specifies

Element	Question it answers	AArch64's answer
Register set	How much named, fast storage is there?	31 general-purpose 64-bit registers, 32 vector registers, a zero register, separate stack pointers per privilege level
Instruction encoding	How are operations represented in memory?	Fixed 32 bits, always 4-byte aligned
Operations	What can be computed?	Arithmetic, logic, shifts, loads/stores, branches, atomics, system, SIMD
Addressing modes	How is an operand located in memory?	Base, base+offset, base+scaled index, pre/post-indexed, PC-relative
Data types	What sizes and formats are natively supported?	8/16/32/64-bit integers, IEEE 754 single/double/half, packed vectors
Memory model	What ordering do other observers see?	Weakly ordered, with explicit barriers and acquire/release accesses
Exception model	What happens on a fault or interrupt?	Four exception levels, a vector table, syndrome registers
Privilege model	Who may do what?	EL0–EL3, plus two security states

Everything *not* on that list — how many cycles an instruction takes, whether there is an L3 cache, how branches are predicted — is deliberately unspecified, and that omission is what lets a Cortex-A55 and a Cortex-X4 run identical binaries at wildly different speeds.

The CISC era and its logic

In the 1970s, memory was scarce and expensive, compilers were poor, and much code was written by hand in assembly. Those three facts pointed in one direction: make each instruction do as much as possible.

```
The CISC bet, stated plainly:

  - Programs are stored in expensive memory  →  make instructions DENSE
  - Humans write assembly                    →  make instructions EXPRESSIVE
  - Compilers are weak                       →  close the "semantic gap" in HARDWARE

Result: instructions that are almost statements in a high-level language.

  VAX-11 (the extreme case):
      MOVC3  len, src, dst      ; copy a string, one instruction
      POLYD  x, degree, table   ; evaluate a polynomial, one instruction
      INDEX  ...                ; bounds-checked array index with trap

  x86:
      REP MOVSB                 ; copy ECX bytes from ESI to EDI
      ADD  [ebx+ecx*4+8], eax   ; load, add, store — one instruction
                                ; and it can also set flags and fault mid-way
```

What went wrong with it

- **Variable-length encoding.** An x86 instruction is 1 to 15 bytes. You cannot know where instruction *n+1* begins until you have decoded instruction *n*. That makes decoding inherently serial — a severe problem once you want to decode four or eight instructions per cycle.
- **Microcode.** Complex instructions are not executed directly; they are interpreted by a small internal program. Microcode is slow, hard to pipeline, and a source of errata.
- **The 90/10 measurement.** Studies in the late 1970s found compilers used a small fraction of the available instructions. The exotic ones cost design effort, area and verification, and almost nobody emitted them.
- **Complex instructions can be slower than the equivalent sequence.** A famous finding: on some VAX models, `INDEX` was slower than the several simple instructions that did the same job — the hardware could not be optimised for every case.
- **Faults in the middle.** If `ADD [mem], eax` page-faults after the load but before the store, the machine must be able to restart or complete it precisely. This complicates the exception model enormously.

The RISC counter-argument

Berkeley RISC and Stanford MIPS, around 1980, inverted every assumption:

Principle	Reasoning
Fixed-length instructions	Decode becomes trivial and parallel; you can fetch and decode N instructions per cycle without knowing their contents
Load/store architecture	Only explicit loads and stores touch memory. Every other instruction is register-to-register, so only one class of instruction can fault on a data access.
Many registers	Keep values in registers rather than spilling to memory. RISC designs went from 8 to 32.

Principle	Reasoning
Simple addressing modes	One memory address computation per instruction, at most
No microcode	Instructions execute directly in hardware, one per cycle in the ideal case
Let the compiler do the work	Compilers had improved. Scheduling, register allocation and strength reduction move to software, where they can be improved without new silicon.

```
The same operation, both philosophies

CISC (x86-64):
    add    QWORD PTR [rbx+rcx*8+16], rax     ; one instruction
                                              ; internally: load, add, store

RISC (AArch64):
    add    x3, x1, x2, lsl #3    ; compute the address
    ldr    x4, [x3, #16]         ; LOAD
    add    x4, x4, x0            ; ADD  (registers only)
    str    x4, [x3, #16]         ; STORE

More instructions, more bytes. But each one is simple, fixed-width,
independently schedulable, and can fault in exactly one obvious place.
```

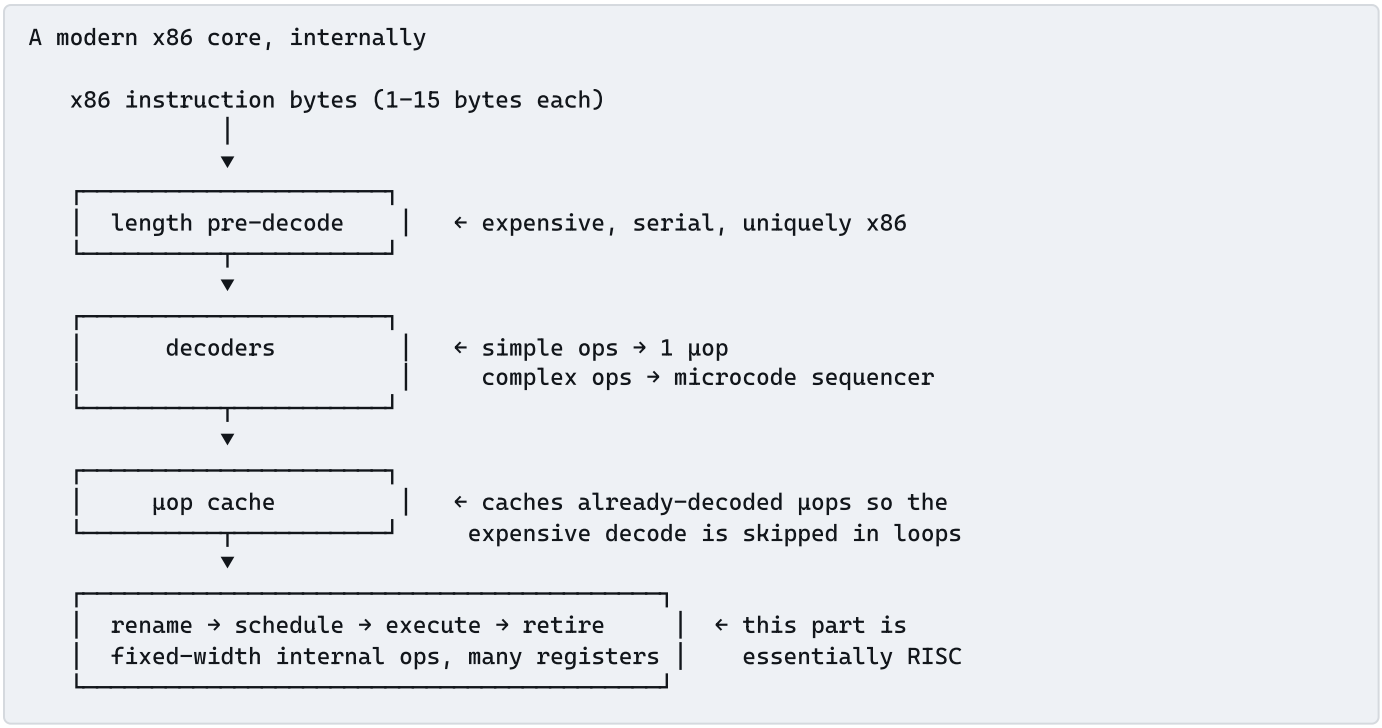
The cost RISC accepted

Code density. A fixed 32-bit encoding wastes bits on simple operations — `MOV X0, X1` uses the same four bytes as a complex shifted-add. Larger binaries mean more instruction-cache pressure, which is a real performance cost, not a cosmetic one.

ARM's answer to this was **Thumb** (1994) and later **Thumb-2**: a 16-bit encoding of the most common instructions, mixed freely with 32-bit ones, typically saving 30% of code size. Thumb is why ARM won the mobile market, where flash memory cost real money. Notably, AArch64 *removed* Thumb — by 2011 memory was cheap and decode simplicity mattered more.

Why the debate ended in a draw nobody predicted

Modern high-performance x86 processors decode their CISC instructions into internal RISC-like **micro-operations** and execute those on an out-of-order engine that would be entirely familiar to a RISC designer.



So RISC won *architecturally inside the chip*, while CISC survived *as an external interface* because of binary compatibility. Meanwhile ARM, nominally RISC, has accumulated crypto instructions, complex SIMD, atomic memory operations that execute near the memory controller, and load/store-pair instructions — none of which a 1980 RISC purist would have accepted.

> **WHERE THE DIFFERENCE STILL GENUINELY MATTERS**
>
> The lasting advantage is not instruction complexity, it is **decode**. Fixed 32-bit encoding means an ARM core can decode 8 instructions per cycle with 8 simple parallel decoders. An x86 core needs length pre-decode first, which is serial and power-hungry, and mitigates it with a µop cache — extra area and power that ARM simply does not spend. This is a large part of why ARM designs reach better performance per watt, and why Apple's cores could go so wide so cheaply.

Reading an instruction encoding

Fixed-width encoding is not just a design principle; it is something you will read directly when debugging without symbols. Here is an AArch64 instruction taken apart.

```
    ADD X0, X1, X2          encodes as 0x8B020020

 31 30 29 28    24 23 22 21 20   16 15    10 9    5 4    0
┌──┬──┬──┬─────────┬─────┬──┬───────┬────────┬──────┬──────┐
│sf│op│ S│ 0 1 0 1 │shift│ 0│   Rm  │  imm6  │  Rn  │  Rd  │
└──┴──┴──┴─────────┴─────┴──┴───────┴────────┴──────┴──────┘
  1  0  0   01011    00   0  00010   000000  00001  00000

  sf    = 1   → 64-bit operands (0 would mean 32-bit, Wn registers)
  op    = 0   → ADD (1 would be SUB)
  S     = 0   → do not set flags (1 gives ADDS)
  shift = 00  → LSL
  Rm    = 2   → X2
  imm6  = 0   → shift amount 0
  Rn    = 1   → X1
  Rd    = 0   → X0

Change sf to 0 and you have ADD W0, W1, W2 — same instruction, 32-bit.
Change S to 1 and it sets NZCV. Change op to 1 and it subtracts.

Every field is in a FIXED position. That is what makes the decoder
(chapter 05's decoder block) small and fast.
```

```
# see this for yourself
echo 'add x0, x1, x2' | aarch64-linux-gnu-as -o /tmp/t.o -
aarch64-linux-gnu-objdump -d /tmp/t.o
#   0:   8b020020        add     x0, x1, x2
```

Instruction classes every ISA has

Class	Purpose	AArch64 examples
Data processing	Compute on registers	`ADD`, `SUB`, `AND`, `ORR`, `EOR`, `MUL`, `UDIV`, `LSL`
Data movement	Load, store, register moves, constants	`LDR`, `STR`, `LDP`, `STP`, `MOV`, `MOVK`
Control flow	Change the PC	`B`, `BL`, `BR`, `RET`, `CBZ`, `TBNZ`, `B.EQ`
Comparison	Set flags or select without branching	`CMP`, `TST`, `CSEL`, `CSET`
Atomic / synchronisation	Multi-core correctness	`LDXR` / `STXR`, `CAS`, `LDADD`, `DMB`, `DSB`, `ISB`
System	Privilege, configuration, cache and TLB control	`MRS`, `MSR`, `SVC`, `ERET`, `TLBI`, `DC`, `WFI`
SIMD / vector	Data parallelism	NEON `ADD V0.4S,...`, SVE predicated operations

Notice that the last two classes are where a general-purpose ISA stops being general. System instructions are the entire subject of the ARM track's second half, and SIMD is the reason machine learning runs at all on a CPU.

Orthogonality and why compilers care

An ISA is **orthogonal** when any operation works with any register and any addressing mode, with no exceptions. Orthogonality makes a compiler's register allocator simple, because no register is special.

```
Non-orthogonal (8086, and it shaped a generation of compilers):
    - MUL always uses AX and DX implicitly
    - String instructions require SI, DI, CX
    - Only BX, SI, DI, BP may be used as base registers
    → the allocator must reason about which value must live where

Orthogonal (AArch64, nearly):
    - Any Xn can be any operand of almost any instruction
    - Exceptions are few and documented:
        · X30 is written by BL
        · X16/X17 may be clobbered by linker veneers
        · X18 is reserved on some platforms
        · SP must be 16-byte aligned at public interfaces
        · XZR reads as zero and discards writes
```

This is why the same compiler back end typically produces better code for ARM than for 32-bit x86: fewer constraints to satisfy, more registers to allocate into, less spilling to the stack.

How an ISA grows without breaking

An ISA must evolve — new workloads need new instructions — without invalidating existing binaries. The mechanisms are worth knowing because you will write the code that uses them.

1. **Reserve encoding space.** Undefined encodings are kept available and made to fault, so they can later be given meaning.
2. **Add optional extensions.** ARMv8.1 added LSE atomics; v8.3 added pointer authentication; v9 added SVE2. Each is optional at a given architecture level.
3. **Advertise features in ID registers.** `ID_AA64ISAR0_EL1` and friends report what this specific chip implements.
4. **Have software detect and adapt.** The OS reads the ID registers at boot and patches code paths accordingly.

```
/* Linux exposes CPU features to user space through HWCAP */
#include <sys/auxv.h>
#include <asm/hwcap.h>

unsigned long hw  = getauxval(AT_HWCAP);
unsigned long hw2 = getauxval(AT_HWCAP2);

if (hw & HWCAP_ATOMICS)   use_lse_atomics();    /* single-instruction atomics */
else                      use_ldxr_stxr();      /* the exclusive-monitor loop */

if (hw & HWCAP_ASIMD)     use_neon_kernel();
if (hw & HWCAP_SVE)       use_sve_kernel();
if (hw2 & HWCAP2_SVE2)    use_sve2_kernel();

/* the kernel does the same thing internally, but patches the code in
   place at boot with "alternatives" so there is no runtime branch:
   ALTERNATIVE("ldxr ...", "ldadd ...", ARM64_HAS_LSE_ATOMICS)          */
```

THE TRAP THIS CREATES

Code compiled with `-march=armv8.2-a+crypto` will execute an illegal-instruction fault on a chip lacking those extensions — usually as `SIGILL`, often long after startup, in a library you did not write. Distribution binaries therefore target a baseline and dispatch at runtime. When you see "Illegal instruction" on one machine and not another, this is almost always the reason.

How it shows up in practice

Symptom	ISA-level cause
`SIGILL` on one machine, fine on another	Built for an architecture extension the target does not implement
Disassembly is garbage after a certain point	Disassembling from a wrong offset. On ARM this self-corrects at the next 4-byte boundary; on x86 it may never resync — a direct consequence of variable-length encoding.
A constant needs four instructions to load	A 64-bit immediate does not fit in a 32-bit instruction; it is built with `MOVZ` + three `MOVK`s, or loaded from a literal pool
Code is much larger than the equivalent x86	Fixed-width encoding; consider `-Os`, and on 32-bit ARM, Thumb
A branch target "out of range" link error	Branch offsets are limited by the encoding (±128 MB for `B`); the linker inserts a veneer using `X16` / `X17`
Atomics are much faster after a kernel upgrade	The kernel began patching in LSE atomics after detecting the feature

Check yourself

- ✓ State the difference between architecture and microarchitecture, and give a bug type belonging to each.
- ✓ List six things an ISA specifies and two things it deliberately does not.
- ✓ Give the original reasoning behind CISC and explain which of its assumptions stopped being true.
- ✓ Explain why fixed-width encoding matters more for wide superscalar decode than for anything else.
- ✓ Decode `0x8B020020` field by field.
- ✓ Explain what a µop cache is compensating for.
- ✓ Describe how an ISA adds features without breaking old binaries, and the failure mode when software gets it wrong.

The datapath and the control unit

This is the chapter where a processor stops being a metaphor. Using only the blocks from chapters 05 and 06, we build a machine that actually executes instructions — and every later idea (pipelining, forwarding, speculation, exceptions) is a modification of this one drawing.

The problem

You have an ALU, a register file, muxes, decoders and memory. You have an instruction encoding from chapter 09. How do you wire them together so that fetching a 32-bit word from memory causes the right thing to happen?

The answer splits cleanly into two halves, and keeping them separate is the single most useful idea here:

DATAPATH AND CONTROL

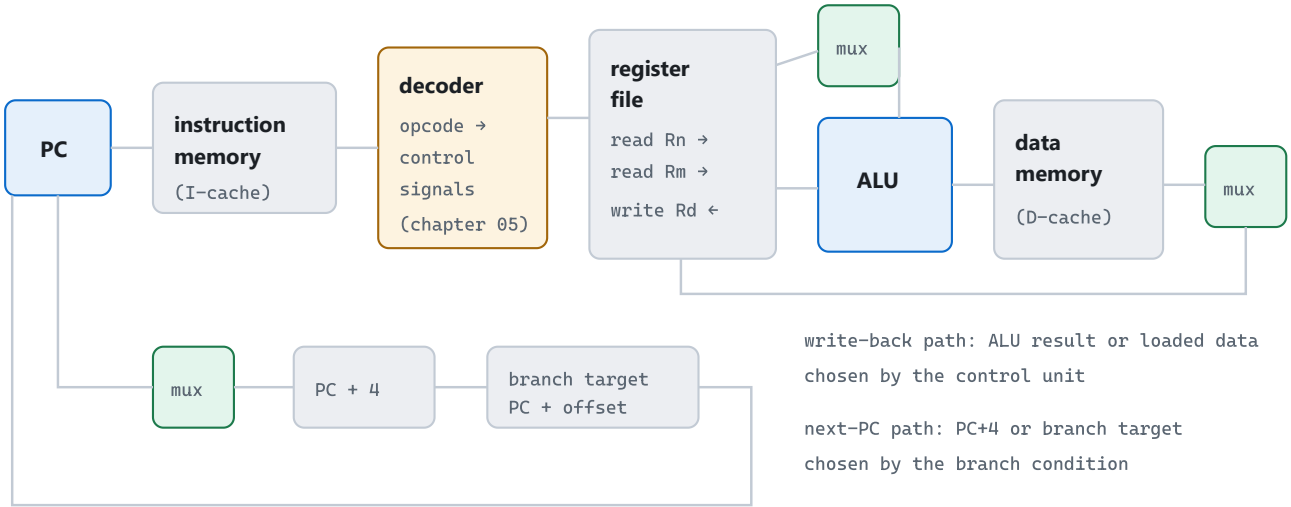
The **datapath** is where values flow: registers, ALU, memory ports, and the muxes that route between them. It is the plumbing, and it is the same for every instruction.

The **control unit** decides, for the current instruction, how every mux is set and which units are enabled. It is combinational logic driven by the opcode — the decoder from chapter 05.

The datapath makes everything *possible*; the control unit makes one thing *happen*.

A single-cycle datapath

Start with the simplest working design: every instruction completes in exactly one clock cycle.



A single-cycle datapath. Every wire exists for every instruction; the control unit decides which ones matter.

Walking three instructions through it

```
1.  ADD X0, X1, X2         register-to-register arithmetic

    PC → I-memory → instruction
    decode: opcode = ADD, Rn = 1, Rm = 2, Rd = 0
    register file: read X1 and X2
    ALU-src mux: select the REGISTER path (not the immediate)
    ALU: op = add
    mem-write: OFF, mem-read: OFF        ← data memory unused
    write-back mux: select the ALU RESULT
    register file: write X0
    next-PC mux: select PC + 4

2.  LDR X0, [X1, #16]      load

    decode: opcode = LDR, Rn = 1, Rd = 0, immediate = 16
    register file: read X1
    ALU-src mux: select the IMMEDIATE
    ALU: op = add           ← the ALU computes the ADDRESS, not a value
    data memory: read at that address
    write-back mux: select the MEMORY DATA
    register file: write X0
    next-PC mux: PC + 4

3.  CBZ X0, label          branch if zero

    decode: opcode = CBZ, Rn = 0, offset = label - PC
    register file: read X0
    ALU: compare against zero → sets the Z flag
    register write: OFF     ← nothing is written back
    next-PC mux: select the BRANCH TARGET if Z, else PC + 4
```

Notice that the ALU did three different jobs: arithmetic, address computation, and comparison. That reuse is deliberate and is why the ALU sits at the centre of the drawing.

The control unit

For this datapath, the control unit produces roughly eight signals. They are a direct function of the opcode — pure combinational logic, exactly the decoder of chapter 05.

Signal	Controls	`ADD`	`LDR`	`STR`	`CBZ`
`RegWrite`	Write the register file?	1	1	0	0
`ALUSrc`	Second ALU input: reg or immediate	reg	imm	imm	—
`ALUOp`	Which ALU function	add	add	add	sub
`MemRead`	Read data memory?	0	1	0	0
`MemWrite`	Write data memory?	0	0	1	0
`MemToReg`	Write back ALU result or memory data	ALU	mem	—	—
`Branch`	Allow the PC mux to take the target	0	0	0	1
`SetFlags`	Update NZCV	0	0	0	1

Reading that table row by row tells you what each instruction *is*, in hardware terms. A store is "a load with the memory direction reversed and no write-back". A compare is "a subtract that does not write its result". These are not analogies — they are literally the same wires with different control bits.

HARDWIRED VERSUS MICROCODED CONTROL

Hardwired: the control signals are produced by combinational logic directly from the opcode. Fast, small, inflexible. This is the RISC approach and how ARM implements the common instructions.

Microcoded: the opcode indexes a small ROM containing a *sequence* of control-signal sets, stepped through over several cycles by a microprogram counter. Slower, but it makes complex multi-step instructions possible and lets the manufacturer fix bugs by updating the microcode after shipping — which is exactly how Spectre and Meltdown mitigations were delivered on x86.

Modern chips use both: hardwired for the common cases, microcode for the complex or rare ones.

Why single-cycle is a bad design

It works, and it is easy to reason about. It is also slow, for a reason that follows directly from chapter 07.

```
The clock period must accommodate the LONGEST instruction path.

  ADD:  I-fetch  reg-read  ALU  reg-write
        250 ps + 150 ps + 200 ps + 100 ps            =  700 ps

  LDR:  I-fetch  reg-read  ALU  D-mem  reg-write
        250 ps + 150 ps + 200 ps + 250 ps + 100 ps   =  950 ps  ← longest

  clock period = 950 ps  →  f_max ≈ 1.05 GHz

Every ADD now takes 950 ps even though it needed only 700 —
250 ps of every arithmetic instruction is spent doing nothing.

Worse: each hardware unit is used for a small slice of the cycle
and sits idle for the rest. The memory port is busy for 250 of
950 ps. That is 74% waste on the most expensive resource.
```

The multi-cycle detour

One historical fix: break each instruction into several shorter cycles, and let different instructions take different numbers of cycles. `ADD` takes 4, `LDR` takes 5. The clock period drops to the longest single *step* rather than the longest instruction, and units can be reused across steps (one memory port serving both fetch and data access).

This improves clock frequency but not throughput — you are still finishing at most one instruction every 4–5 cycles. The real answer is to overlap instructions, which is chapter 11.

Inside the register file

Worth opening up, because its port count is a constraint that shapes ISAs.

```
A register file with 2 read ports and 1 write port

   read addr A (5 bits) ──► decoder ──┐
                                      ├──► mux tree ──► read data A
   read addr B (5 bits) ──► decoder ──┤
                                      └──► mux tree ──► read data B

   write addr  (5 bits) ──► decoder ──► enable one register's flip-flops
   write data           ──────────────► all registers' D inputs
   write enable         ──────────────► gates the decoder

Each additional port costs area roughly QUADRATICALLY (more wires
crossing more cells) and adds delay. This is why:

  · most instructions have at most 2 source and 1 destination register
  · LDP/STP (load/store PAIR) are special — they need extra ports,
    and are provided anyway because function prologues use them constantly
  · a wide out-of-order core needs many ports and the register file
    becomes one of the hottest, most area-expensive blocks on the die
```

> **AN ISA DESIGN DECISION YOU CAN NOW EXPLAIN**
> Why does AArch64 have no instruction with three source registers and two destinations? Because the register file ports would cost more than the instruction saves. When you see an ISA restriction, the usual explanation is a port count, a wire, or a decoder — not a lack of imagination.

Where exceptions enter the datapath

Every stage can fail, and the datapath must handle it. This is the hardware behind ARM chapter 28.

Stage	Possible failure	Datapath response
Fetch	Instruction address faults (unmapped, no-execute)	Squash the instruction; force the PC mux to the exception vector
Decode	Undefined encoding, or an instruction not permitted at this privilege	Same; record the reason in a syndrome register
Execute	Divide by zero, FP exception	Suppress the register write
Memory	Data address faults	Suppress write-back; latch the faulting address
Any time	Interrupt asserted	Complete instructions already past the point of no return, squash the rest, redirect the PC

The requirement that makes this hard is **precise exceptions**: from software's point of view, every instruction before the faulting one must have completed fully, and every instruction after it must have had no effect at all. Getting that guarantee out of a machine that runs instructions out of order and speculatively is one of the central difficulties of processor design — and the reason RISC's "only loads and stores touch memory" rule was such a good idea.

How this shows up in software

Observation	Datapath reason
`CMP` and `SUBS` have identical timing	Same wires; `CMP` just has `RegWrite = 0`
`LDR X0, [X1, X2, LSL #3]` costs no more than `LDR X0, [X1]`	The shifter and adder are already on the address path

Observation	Datapath reason
A load's result is not usable by the very next instruction without a stall	The memory stage is late in the datapath — the load-use hazard of chapter 11
Integer division takes 10–40× a multiply	No single-cycle divider exists; it iterates and does not fit the one-pass datapath
A faulting instruction reports the address that faulted, precisely	The datapath latches it and suppresses write-back
Microcode updates can change CPU behaviour after manufacture	Microcoded control paths are patchable; hardwired ones are not

Check yourself

- ✓ State the difference between datapath and control, and say which one changes per instruction.
- ✓ Trace `LDR X0, [X1, #16]` through the datapath naming every mux setting.
- ✓ Explain why the ALU is used for three unrelated purposes.
- ✓ Give the control-signal differences between `ADD` and `CMP`.
- ✓ Explain why single-cycle design wastes time, using the clock-period argument.
- ✓ Say why register-file port count constrains instruction set design.
- ✓ Define a precise exception and say why it is hard to provide.

Pipelining and hazards

Pipelining is the single most important idea in processor design, and the source of almost every counter-intuitive performance result you will ever measure. It also explains why the ARM memory model is weak, why branches are expensive, and why `ISB` exists.

The problem

Chapter 10 ended with an uncomfortable fact: in a single-cycle machine, every functional unit is idle most of the time. The memory port is busy for 250 ps out of a 950 ps cycle; the ALU for 200. You have paid for hardware that spends three quarters of its life waiting.

The insight is the same as an assembly line. You do not build one car at a time from start to finish. You divide the work into stations and keep a car at every station.

The mechanism

Insert registers (chapter 06) between the datapath stages. Each stage now works on a *different instruction* in the same cycle.

```
Classic 5-stage pipeline

  IF  — instruction fetch
  ID  — instruction decode and register read
  EX  — execute in the ALU
  MEM — data memory access
  WB  — write back to the register file

Sequential (no pipeline):

  cycle:  1   2   3   4   5   6   7   8   9  10  11  12  13  14  15
  i1:    IF  ID  EX MEM  WB
  i2:                        IF  ID  EX MEM  WB
  i3:                                        IF  ID  EX MEM  WB
                             ↑ 5 cycles per instruction

Pipelined:

  cycle:  1   2   3   4   5   6   7   8   9
  i1:    IF  ID  EX MEM  WB
  i2:        IF  ID  EX MEM  WB
  i3:            IF  ID  EX MEM  WB
  i4:                IF  ID  EX MEM  WB
  i5:                    IF  ID  EX MEM  WB
                          ↑
                    at this point FIVE instructions are in flight,
                    and one COMPLETES every cycle
```

LATENCY VERSUS THROUGHPUT

Pipelining does **not** make any individual instruction faster. Each still takes 5 stages — in fact slightly longer, because of the register overhead at each boundary. What changes is **throughput**: instructions complete at one per cycle instead of one per five.

This distinction is worth internalising because it recurs everywhere in systems work. A DMA engine does not reduce the latency of a transfer; it removes the CPU from it. An asynchronous I/O API does not make the disk faster. Confusing the two leads to optimisations that measure worse than the thing they replaced.

Why the clock also gets faster

```
Single cycle:   period = 250 + 150 + 200 + 250 + 100 = 950 ps  →  1.05 GHz

Pipelined:      period = longest SINGLE stage + register overhead
                       = 250 (IF or MEM) + 20                  →  3.7 GHz

Speedup ≈ 3.5× from frequency, plus the throughput gain.

Combined, an ideal 5-stage pipeline approaches 5× the single-cycle
machine — which is why every processor built since about 1985 is pipelined.
```

Pipeline depth in real designs

Core	Stages	Character
Cortex-M0	3	Fetch, decode, execute. Tiny, low power, very predictable timing.
Cortex-A53	8	In-order, efficiency-focused
Cortex-A78 / X-series	13–15	Out-of-order, deep front end
Pentium 4 (historical)	20–31	Chased clock frequency; mispredicts cost 30+ cycles. A cautionary tale.

Deeper is not simply better. Each extra stage shortens the clock period but increases the penalty when the pipeline must be flushed. The Pentium 4 pushed this to 31 stages, discovered the mispredict penalty was crippling, and the industry settled back to 10–15.

Hazards: when the assembly line breaks

The pipeline assumes instructions are independent. They are not. A **hazard** is any situation where the next instruction cannot execute in the next cycle.

Structural hazards

Two instructions need the same hardware in the same cycle. In the 5-stage pipeline above, IF needs memory and MEM needs memory — simultaneously.

```
  cycle:      4
  i1:        MEM   ← needs the memory port
  i4:        IF    ← also needs the memory port

Solution: separate instruction and data caches — the modified Harvard
architecture of chapter 08. This is not an optimisation; it is a
structural necessity for a pipeline.
```

Data hazards

An instruction needs a result that is still in flight.

```
    ADD X1, X2, X3      ; X1 is produced...
    SUB X4, X1, X5      ; ...and needed immediately

  cycle:    1    2    3    4    5    6
  ADD:     IF   ID   EX  MEM   WB
                           ↑ X1 written here
  SUB:          IF   ID   EX  MEM   WB
                     ↑ X1 read here — TWO CYCLES TOO EARLY

Naive fix: stall SUB for two cycles. Correct, but slow — and this
dependency pattern is extremely common in real code.
```

Forwarding (bypassing)

The result exists at the end of EX. It just has not reached the register file yet. So add wires that route it directly from the pipeline register to the ALU input — through a mux (chapter 05), naturally.

```
    ADD X1, X2, X3
    SUB X4, X1, X5

  cycle:    1    2    3    4    5
  ADD:     IF   ID   EX  MEM   WB
                     │
                     └─────── forward ──────┐
                                            ▼
  SUB:          IF   ID   EX  MEM   WB
                          ↑ uses the forwarded value — no stall

The forwarding network is a set of muxes on the ALU inputs, selecting
between the register file and results still in the pipeline. It is one
of the messiest parts of a real design and it eliminates most data
hazards entirely.
```

The load-use hazard: the one forwarding cannot fix

```
    LDR X1, [X2]        ; X1 comes from MEMORY
    ADD X3, X1, X4      ; needed in EX, one stage EARLIER

  cycle:    1    2    3    4    5
  LDR:     IF   ID   EX  MEM   WB
                          │ data available only at the END of MEM
                          └─┐
                            ▼ but ADD needs it at the START of EX
  ADD:          IF   ID  [stall]  EX   MEM   WB

You cannot forward backwards in time. One cycle of stall is unavoidable.
```

WHAT THIS MEANS FOR THE CODE YOU WRITE

The compiler schedules instructions to fill load-use gaps with unrelated work. That is why `-O2` output looks "shuffled" compared to your source: loads are hoisted early and their uses pushed later. It is also why a tight dependent pointer chase — `p = p->next` repeated — is much slower per instruction than it looks: every iteration is a load-use hazard, and on a cache miss it is hundreds of cycles rather than one.

```
/* dependent: each load must complete before the next can start */
while (p) { sum += p->val; p = p->next; }        /* latency-bound  */

/* independent: many loads in flight at once */
for (i = 0; i < n; i++) sum += a[i];             /* bandwidth-bound */

/* the second can be 10x faster for the same amount of data —
   this is why array-of-structs versus linked list matters so much */
```

Control hazards

The worst kind. When a branch is fetched, the processor does not yet know where to fetch next — the condition is not evaluated until EX.

```
    CBZ X0, target
    ADD ...             ; should these execute?
    SUB ...             ; nobody knows yet

  cycle:    1    2    3    4
  CBZ:     IF   ID   EX  ← the outcome is known only HERE
  ADD:          IF   ID  ← already fetched
  SUB:               IF  ← already fetched

If the branch is taken, both must be discarded — the pipeline is
FLUSHED and refilled from the target.

  Penalty ≈ number of stages between fetch and branch resolution.
    5-stage in-order   :  2–3 cycles
    15-stage out-of-order: 15–20 cycles
```

Branches are roughly one instruction in five. A 15-cycle penalty on 20% of instructions would triple execution time — completely unacceptable. The response is **branch prediction**, which is significant enough to have its own chapter (chapter 12).

Approach	How it works	Where used
Stall	Freeze until the outcome is known	Simple microcontrollers
Branch delay slot	The instruction after a branch *always* executes; the compiler fills the slot	MIPS, SPARC. An ISA-visible hack — never adopted by ARM, and now regretted by its users because it locks the pipeline depth into the architecture.
Predict and speculate	Guess, execute speculatively, flush if wrong	Everything modern
Predication	Execute both paths, discard one — a mux instead of a branch	ARM's `CSEL`, `CSET`; ARMv7's fully predicated instructions

Where the pipeline becomes software-visible

Pipelining is supposed to be invisible. Three places where it is not, and all three matter to systems programmers.

1. System register writes need ISB

Instructions already in the pipeline were fetched and decoded under the *old* configuration. If you enable the MMU, change `VBAR`, or alter `SCTLR`, instructions already in flight do not see the change.

```
    msr     sctlr_el1, x0       // enable the MMU
    isb                         // MANDATORY: flush the pipeline so that
                                // everything after this is re-fetched under
                                // the new configuration
    ldr     x1, [x2]            // this now goes through the MMU
```

`ISB` is a context-synchronising instruction: it discards everything prefetched and restarts the front end. Omitting it produces behaviour that varies by core and by build — the classic "works in the emulator, fails on silicon" bug.

2. Self-modifying code needs the full maintenance sequence

Instructions may already have been fetched into the pipeline and the instruction cache before you rewrote them in memory. Chapter 08 covered the cache half; `ISB` handles the pipeline half.

3. The weak memory model is a consequence of pipelining

Because instructions overlap and complete out of order, the order in which their memory effects become visible to other cores is not the program order. This is not a defect; it is the direct, unavoidable consequence of the assembly line. Recovering ordering when you need it is what barriers are for.

Quantifying it

```
   CPI = cycles per instruction

   Ideal pipeline:        CPI = 1.0
   Real:                  CPI = 1.0 + stalls per instruction

   CPI = 1
       + (branch frequency × mispredict rate × mispredict penalty)
       + (load frequency × load-use stall rate × 1)
       + (memory frequency × cache miss rate × miss penalty)      ← usually dominant
       + structural and other stalls

   Worked example:
       branches 20%, mispredict 5%, penalty 15   → 0.20 × 0.05 × 15 = 0.15
       loads 25%, load-use 30%, penalty 1        → 0.25 × 0.30 × 1  = 0.075
       memory ops 35%, L1 miss 2%, penalty 200   → 0.35 × 0.02 × 200 = 1.40

       CPI = 1 + 0.15 + 0.075 + 1.40 = 2.63

   Note which term dominates. Cache behaviour outweighs everything
   else combined — which is why chapters 13–15 exist, and why data
   layout beats instruction-level tuning almost every time.
```

```
# measure your own CPI and stall breakdown
perf stat -e cycles,instructions,branch-misses,cache-misses,stalled-cycles-frontend ./program

#  1,234,567,890  cycles
#    469,000,000  instructions      #  0.38 insn per cycle   ← CPI = 2.63
#      2,100,000  branch-misses
#      8,400,000  cache-misses
```

Beyond one instruction per cycle

If one per cycle is good, why not more? A **superscalar** processor widens every stage to handle several instructions at once.

```
  2-wide superscalar

  cycle:   1        2        3        4        5
  i1,i2:  IF/IF   ID/ID   EX/EX  MEM/MEM  WB/WB
  i3,i4:          IF/IF   ID/ID   EX/EX  MEM/MEM
                             ↑
                        two instructions complete per cycle
                        CPI = 0.5, or IPC = 2

Requirements this creates:
  · fetch 8+ bytes per cycle           → wide I-cache port
  · decode N instructions in parallel  → FIXED-WIDTH ENCODING helps enormously
  · more register file ports            → area cost (chapter 10)
  · dependency checking between the instructions issued together
  · multiple ALUs, multiple load/store units
```

Add **out-of-order execution** — buffer instructions, execute any whose operands are ready, retire them in program order to preserve precise exceptions — and you have the modern high-performance core. The reorder buffer is what keeps the *appearance* of sequential execution while the reality is anything but.

> **THE CONNECTION TO SECURITY**
> Speculative and out-of-order execution mean the processor performs work that is later discarded. The architectural state is correctly rolled back — but the *microarchitectural* state (cache contents, predictor history) is not. Spectre and Meltdown exploit exactly that gap: make the processor speculatively touch data it should not, then infer what it touched by timing the cache. This is a direct consequence of this chapter's optimisation, and it is why the distinction between architecture and microarchitecture from chapter 09 is not academic.

How it shows up in software

Observation	Pipeline reason
A branchy loop is far slower than a branchless one	Mispredict flushes; `CSEL` avoids them entirely
Traversing a linked list is much slower than an array with the same data	Dependent loads: every step is a load-use hazard plus a likely cache miss
`-O2` output has your statements reordered	The scheduler is filling hazard slots
A sorted array processes faster than an unsorted one	The branch in the loop becomes predictable — the famous Stack Overflow question
Enabling the MMU hangs on real silicon but works in QEMU	Missing `ISB`; the emulator does not model the pipeline
Two cores observe stores in different orders	Weak memory model, which is pipelining made visible
Timing varies with data values in crypto code	Data-dependent branches leaking through the predictor

Check yourself

✓ Explain why pipelining improves throughput but not latency.

- ✓ Name the five classic stages and one hazard associated with each boundary.
- ✓ Explain forwarding, and give the one hazard it cannot eliminate.
- ✓ Say why deeper pipelines are not automatically better.
- ✓ Explain why separate I- and D-caches are structurally required, not merely a speed choice.
- ✓ Write the CPI equation and say which term usually dominates.
- ✓ Explain exactly why `ISB` is required after enabling the MMU.
- ✓ Describe how pipelining makes Spectre-class attacks possible.

Branch prediction and speculation

A modern processor guesses. It guesses which way branches go, executes hundreds of instructions past the guess, and throws the work away when wrong. This is why sorted data can be faster than unsorted, and it is the mechanism behind Spectre.

The problem

Chapter 11 left us with control hazards. A branch's direction is not known until several stages after it is fetched, but the front end must fetch *something* every cycle.

```
Cost of getting it wrong, by design depth

  pipeline    branch resolved at    flush penalty
  ──────────────────────────────────────────────
  5-stage     stage 3               ~2 cycles
  10-stage    stage 7               ~7 cycles
  15-stage    stage 11              ~15 cycles
  Pentium 4   stage ~20             ~30 cycles

Branches are ~15–25% of instructions in typical code.

  With a 15-cycle penalty and NO prediction:
      CPI = 1 + 0.20 × 15 = 4.0
  With 95% prediction accuracy:
      CPI = 1 + 0.20 × 0.05 × 15 = 1.15

Prediction is not an optimisation. Without it, deep pipelines are
pointless — you would spend all your speed on flushes.
```

Static prediction

The cheapest approach: decide from the instruction alone, with no history.

Heuristic	Rationale	Accuracy
Always not-taken	Simplest; just keep fetching sequentially	~40%
Always taken	Most branches in loops are taken	~60%
Backward taken, forward not-taken	A backward branch is almost always a loop; a forward branch is usually an error path	~70%
Compiler hint	Profile-guided, encoded in the instruction or in layout	~80%

```
/* Linux and GCC let you supply the hint explicitly */
#define likely(x)   __builtin_expect(!!(x), 1)
#define unlikely(x) __builtin_expect(!!(x), 0)

if (unlikely(ptr == NULL))          /* error path: moved out of line     */
        return -EINVAL;             /* so the fall-through is the common */
                                    /* case and stays in the I-cache     */

/* what this actually does: the compiler reorders basic blocks so the
   likely path is contiguous. On modern cores the dynamic predictor
   outperforms the hint within a few iterations — the real benefit is
   INSTRUCTION CACHE LAYOUT, not the prediction itself. */
```

> **WHERE HINTS STILL GENUINELY MATTER**
> On a small in-order core (Cortex-M, Cortex-A53) with a weak or absent dynamic predictor, and on the very first execution of any branch before history exists. In hot loops on a big core, remove them — they add noise and the hardware already knows better. Profile before adding one.

Dynamic prediction

One-bit predictor

Remember what the branch did last time. Keep a table of bits indexed by branch address.

```
   predict = last outcome

   for (i = 0; i < 10; i++) { ... }

   iterations:  T T T T T T T T T N       (N = the final exit)
   prediction:  ? T T T T T T T T T
   correct:     ✗ ✓ ✓ ✓ ✓ ✓ ✓ ✓ ✓ ✗

   Two mispredicts per loop execution: the exit, and then the first
   iteration of the NEXT execution, because the table now says "not taken".

   For a nested loop run many times, that doubling is significant.
```

Two-bit saturating counter

Require two consecutive surprises before changing the prediction. This is the fundamental unit of nearly every real predictor.

```
          taken            taken            taken
      ┌──────────┐     ┌──────────┐     ┌──────────┐
      ▼          │     ▼          │     ▼          │
  ┌──────┐     ┌──────┐     ┌──────┐     ┌──────┐
  │ 00   │     │ 01   │     │ 10   │     │ 11   │
  │ SN   │◄────│ WN   │◄────│ WT   │◄────│ ST   │
  └──────┘     └──────┘     └──────┘     └──────┘
          n-taken      n-taken      n-taken
 strongly       weakly          weakly          strongly
 NOT taken      NOT taken       TAKEN           TAKEN

 predict TAKEN if the high bit is 1.

 Same loop:  T T T T T T T T T N
 now the single N moves ST → WT, still predicting taken.
 Next execution starts correct. ONE mispredict per loop, not two.
```

Correlating and tournament predictors

Two-bit counters cannot capture patterns. Real code has branches that depend on other branches:

```
if (x < 5)  a = 1;      /* branch A */
if (y < 3)  b = 1;      /* branch B */
if (a && b) c = 1;      /* branch C — fully determined by A and B */
```

A **global history register** shifts in the outcome of every branch, forming a pattern. Indexing the counter table by (branch address XOR global history) lets the predictor learn "when the last few branches went TNT, this one is taken".

Predictor	Idea	Typical accuracy
2-bit bimodal	Counter per branch address	~85%
gshare	Index by address XOR global history	~93%
Tournament	Run a local and a global predictor, plus a meta-predictor that learns which to trust per branch	~95%
TAGE	Several tables with different history lengths; the longest matching one wins	~97–99%
Perceptron / neural	A weighted sum over a long history vector	~97–99%

Modern cores use TAGE or perceptron variants with thousands of entries and history lengths in the hundreds. The predictor can be several percent of core area — it is that valuable.

Predicting the target, not just the direction

Knowing a branch is taken is useless without knowing *where*. Three structures handle this:

Structure	Handles	How
BTB — branch target buffer	Direct branches	Cache mapping branch address → last target. Available during fetch, before decode.
Indirect predictor	`BR Xn` — virtual calls, switch tables, function pointers	History-indexed target table; harder, since the target varies
RAS — return address stack	`RET`	A hardware stack: `BL` pushes, `RET` pops. Near-perfect, because calls and returns nest.

TWO WAYS SOFTWARE BREAKS THE RETURN ADDRESS STACK

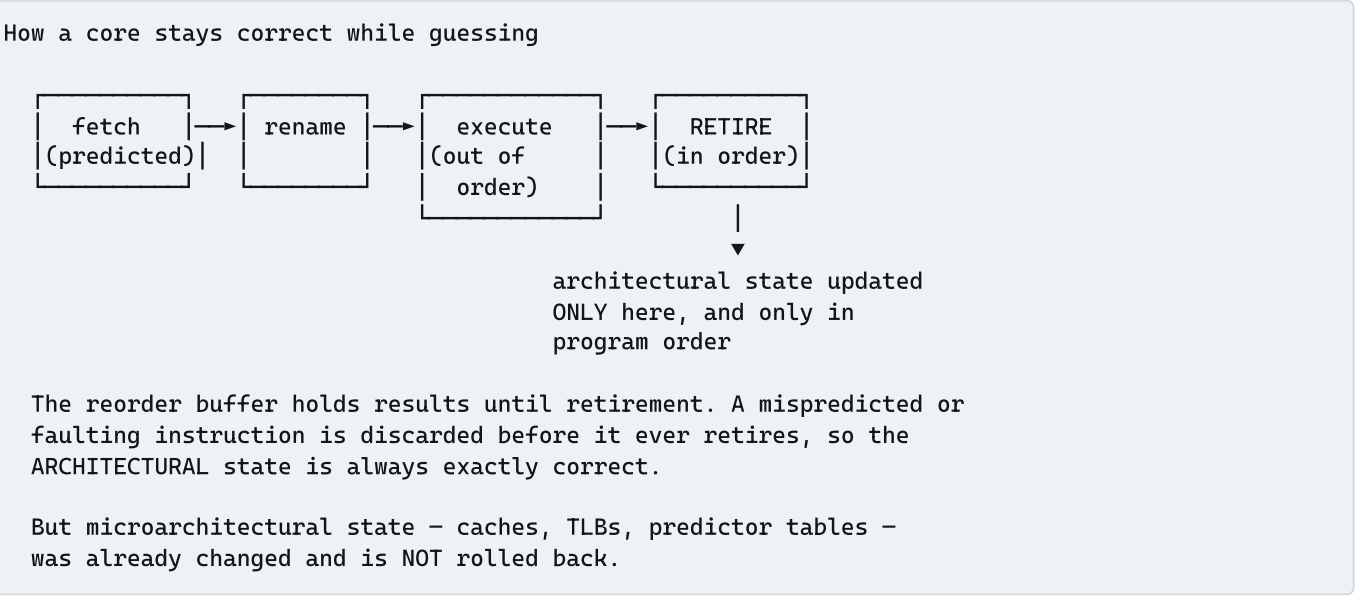
The RAS assumes calls and returns are balanced. Break that assumption and you lose a near-100% predictor:

- **Unbalanced call/return.** `setjmp` / `longjmp`, C++ exception unwinding, coroutine switches and hand-written context switches all return to somewhere the RAS did not predict. The stack stays misaligned for several subsequent returns, so the cost is more than one mispredict.
- **Using `BL` as a plain jump**, or `RET` as an indirect branch. Some hand-written assembly does this to save an instruction; it corrupts the RAS. ARM added `BLR` target hints and `RETAA` partly to keep these paths honest.

Speculation: acting on the guess

Prediction only helps if the processor *proceeds* on it. Modern cores execute far past unresolved branches, and beyond that, speculate on more than branch direction:

Kind	Guess	Recovery when wrong
Control speculation	Which way a branch goes	Flush and refetch
Memory dependence speculation	That a load does not alias an earlier pending store	Replay the load and everything after it
Value prediction	The result of a long-latency operation	Rare in shipping designs
Prefetch speculation	Which cache lines will be needed	No correctness impact — just wasted bandwidth



Spectre and Meltdown

That last line is the whole vulnerability class. Speculation is architecturally invisible and microarchitecturally loud.

```
Spectre variant 1 — bounds check bypass

  if (index < array1_size)          ← attacker trains this to predict TAKEN
          y = array2[array1[index] * 4096];

  1. Attacker calls the function repeatedly with valid indices.
     The predictor learns: this branch is taken.

  2. Attacker calls with index far out of bounds, having evicted
     array1_size from cache so the check is SLOW to resolve.

  3. The core speculates "taken", reads array1[index] — memory it
     must not read — and uses that secret byte to index array2.
     A cache line in array2 is loaded, chosen by the secret value.

  4. The check resolves. Speculation is discarded. y is never written.
     Architecturally, nothing happened.

  5. Attacker times reads across array2. One line is fast.
     Its index reveals the secret byte.

The bounds check was CORRECT. It was simply evaluated too late.
```

Variant	Mechanism	Mitigation
Spectre v1	Bounds check bypass	Index masking + `CSDB`; Linux's `array_index_nospec()`
Spectre v2	Branch target injection — poison the indirect predictor	Retpolines, `BHB` flushing, hardware `CSV2`
Meltdown	Speculative read across the privilege boundary before the permission check retires	KPTI: unmap the kernel from user page tables. Most ARM cores were never vulnerable.
MDS / L1TF	Leakage from internal buffers	Microcode buffer flushes on transitions

```
/* the Linux kernel's Spectre-v1 mitigation, and how to read it */
if (index < size) {
        index = array_index_nospec(index, size);
        /* Expands to a data dependency that forces index to 0 when out
         * of bounds — a mask computed WITHOUT a branch, so speculation
         * cannot bypass it. On arm64:
         *     cmp   x1, x2
         *     csel  x1, x1, xzr, lo     ; a mux, not a branch
         *     csdb                      ; speculation barrier
         */
        val = array[index];
}

/* ARM's speculation control instructions */
    CSDB    // consumption of speculative data barrier
    SSBB    // speculative store bypass barrier
    SB      // full speculation barrier (ARMv8.5)
```

Making your code predictable

```
/* The famous case: this loop is ~6x faster when the data is sorted */
for (i = 0; i < n; i++)
        if (data[i] >= 128)
                sum += data[i];

/* Sorted:   the branch goes one way for a long run — near-perfect prediction.
   Unsorted: 50/50 random — the predictor cannot do better than chance,
             and every other iteration costs a full flush.

   The fix that makes sorting irrelevant: remove the branch. */

for (i = 0; i < n; i++) {
        int mask = -(data[i] >= 128);   /* 0 or -1 (all ones) */
        sum += data[i] & mask;          /* a MUX, chapter 05  */
}
/* compiles to CSEL/CSINC on AArch64 — no branch, constant time */
```

Guideline	Why
Prefer predictable branches over clever ones	A branch taken 99% of the time is nearly free; a 50/50 branch is very expensive
Hoist unpredictable conditions out of hot loops	Split the loop into two predictable loops rather than one unpredictable one
Use branchless selection for random conditions	`CSEL`, arithmetic masks, `min` / `max`
Prefer `switch` over long `else if` chains	A jump table is one indirect branch instead of many conditional ones
Avoid virtual calls in the hottest loops	Indirect branches are the hardest to predict; devirtualise or batch by type
In cryptographic code, never branch on secrets	Timing and predictor state leak the secret — see crypto chapter 19

```
# measure it
perf stat -e branches,branch-misses ./program
#   1,204,000,000  branches
#      63,000,000  branch-misses   #  5.23% of all branches   ← above ~2% is worth investigating

perf record -e branch-misses ./program && perf report   # find WHICH branch
```

How it shows up

Symptom	Cause
Sorted input is several times faster than unsorted	Branch predictability, not cache behaviour
A microbenchmark is far faster than production	The benchmark's branches are trivially predictable; real inputs are not
Performance collapses after adding a rare error check	The branch became unpredictable, or the error path polluted the I-cache
Indirect calls dominate a profile	Indirect predictor misses; consider devirtualisation
A big kernel-upgrade slowdown	Spectre mitigations: retpolines and barriers cost real cycles
Cryptographic timing varies with the key	Secret-dependent branching — a genuine vulnerability
`setjmp`-heavy code has poor branch statistics	Return address stack corruption

Check yourself

✓ Compute CPI for 20% branches with a 15-cycle penalty at 100%, 90% and 99% accuracy.

- ✓ Draw the two-bit saturating counter and explain why it beats one bit on loops.
- ✓ Explain what a global history register adds that a bimodal predictor cannot capture.
- ✓ Name the three target-prediction structures and which branch type each serves.
- ✓ Give two ways software corrupts the return address stack.
- ✓ Explain Spectre v1 in five steps, and say why the bounds check was not the bug.
- ✓ Rewrite a data-dependent conditional sum as branchless code.

The memory hierarchy and locality

The gap between processor speed and memory speed is the dominant fact of modern computing. This chapter explains the illusion built to hide it, and why data layout beats almost every other optimisation you can make.

The problem

You want memory that is large, fast and cheap. Physics permits any two.

Technology	Access time	Typical size	Cost per bit	Why
Register	~0.3 ns (1 cycle)	~1 KB total	Enormous	Flip-flops right beside the ALU
SRAM (cache)	1–20 ns	32 KB – 32 MB	High	6 transistors per bit, no refresh
DRAM	50–100 ns	1–512 GB	Moderate	1 transistor + 1 capacitor, must be refreshed
NAND flash / SSD	50–100 µs	0.1–10 TB	Low	Charge trapped on a floating gate
Hard disk	5–10 ms	1–20 TB	Very low	A spinning platter and a moving arm

```
Put those numbers on a human scale. Scale one CPU cycle to one second:

  L1 cache hit          4 cycles     →  4 seconds
  L2 cache hit         12 cycles     →  12 seconds
  L3 cache hit         40 cycles     →  40 seconds
  DRAM                200 cycles     →  3 minutes 20 seconds
  SSD read       ~200,000 cycles     →  2.5 days
  Disk seek   ~20,000,000 cycles     →  8 months

A DRAM access is not "a bit slower". Relative to the core, it is a
coffee break. Everything in this chapter exists to avoid taking it.
```

Locality: the property that makes caching work

A cache is only useful if past accesses predict future ones. Real programs oblige, in two distinct ways:

THE TWO LOCALITIES

Temporal locality — if you accessed an address, you will probably access it again soon. Loop counters, the stack top, a hot data structure, function code inside a loop.

Spatial locality — if you accessed an address, you will probably access a nearby one soon. Array traversal, struct field access, sequential instruction fetch.

Caches exploit temporal locality by *keeping* recently used data, and spatial locality by *fetching a whole line* rather than a single word. Code with neither gets no benefit at all — which is why a random-access hash table over a large working set can be slower than a linear scan of an array containing the same data.

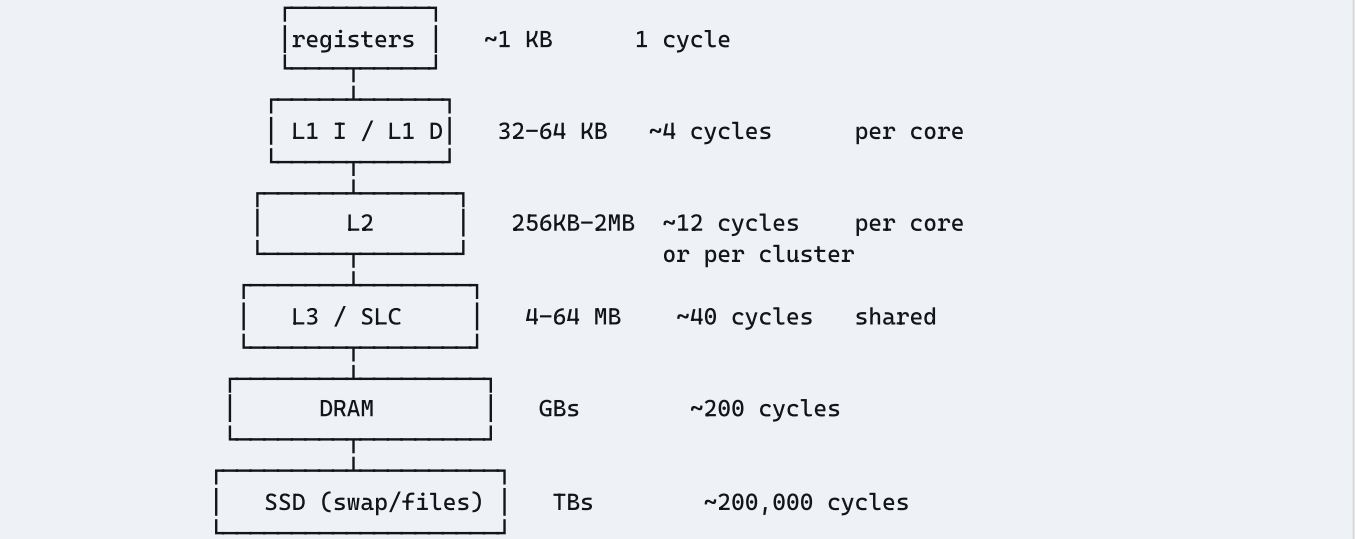
```
/* excellent locality — this is nearly free */
for (i = 0; i < n; i++)
        sum += a[i];        /* spatial: consecutive addresses
                               temporal: sum and i stay in registers */

/* terrible locality */
for (i = 0; i < n; i++)
        sum += a[perm[i]];  /* random order: every access a likely miss */

/* the classic demonstration: same work, 10x difference */
for (i = 0; i < N; i++)          for (j = 0; j < N; j++)
  for (j = 0; j < N; j++)          for (i = 0; i < N; i++)
    total += m[i][j];                total += m[i][j];

/* left: row-major, walks memory sequentially — one miss per 16 elements
   right: strides by a whole row — one miss per ELEMENT               */
```

The hierarchy



```
Each level is a CACHE for the level below it, and each is roughly
10x larger and 3–5x slower than the one above.

The same principle appears again at every scale: the page cache caches
the disk, a CDN caches an origin server, a TLB caches page table walks.
Once you see the pattern you will find it everywhere in systems.
```

Inclusive, exclusive and the "not on the critical path" question

Policy	Meaning	Trade-off
Inclusive	Everything in L1 is also in L2	Coherency is simple: snoop L3 and you know what the cores hold. Wastes capacity.
Exclusive	A line lives at exactly one level	Maximum effective capacity; coherency needs more bookkeeping.
Non-inclusive	Neither guaranteed	The common compromise on ARM designs

Quantifying it

```
Average Memory Access Time

  AMAT = hit_time + miss_rate × miss_penalty

  With a hierarchy, recurse:

  AMAT = t_L1 + m_L1 × (t_L2 + m_L2 × (t_L3 + m_L3 × t_DRAM))

  Worked example:
      t_L1 = 4,   m_L1 = 5%
      t_L2 = 12,  m_L2 = 40%     (of L1 misses)
      t_L3 = 40,  m_L3 = 50%     (of L2 misses)
      t_DRAM = 200

  AMAT = 4 + 0.05 × (12 + 0.40 × (40 + 0.50 × 200))
       = 4 + 0.05 × (12 + 0.40 × 140)
       = 4 + 0.05 × 68
       = 7.4 cycles

  Now halve the L1 miss rate to 2.5% (better data layout):
  AMAT = 4 + 0.025 × 68 = 5.7 cycles — a 23% improvement in ALL
  memory access time, from changing nothing but how data is arranged.
```

> **WHY THE MISS RATE MATTERS MORE THAN THE HIT TIME**
> Look at the leverage in that equation. Reducing L1 hit time from 4 to 3 cycles is a heroic hardware change worth ~13%. Halving the miss rate is often a source-level change worth ~23%. This is the arithmetic behind the rule of thumb that **data layout beats instruction-level optimisation** — and it is why profiling tools report cache misses so prominently.

The three kinds of miss

Type	Cause	Cure
Compulsory (cold)	First ever access to a line — nothing could have been cached	Prefetching; larger lines. Unavoidable in principle.
Capacity	The working set is larger than the cache	Shrink the working set: blocking/tiling, smaller data types, better packing
Conflict	Too many hot lines map to the same set, even though the cache is not full	Higher associativity, or change the alignment/stride of your data (chapter 14)

A fourth appears on multi-core: **coherence misses**, where another core invalidated your line. Covered in chapter 15.

Prefetching

A miss costs 200 cycles only if you wait for it. If the line arrives before you ask, the cost is zero.

Kind	Mechanism	Catches
Next-line	Fetch line N+1 whenever N is fetched	Sequential scans, instruction fetch
Stride	Detect a constant stride and extrapolate	Array walks, matrix rows, struct arrays

Kind	Mechanism	Catches
Software	`PRFM PLDL1KEEP, [addr]` — an explicit hint	Pointer chasing, irregular patterns the hardware cannot see

```
/* software prefetch: useful when you know the future and hardware does not */
for (n = list; n; n = n->next) {
        __builtin_prefetch(n->next);    /* start fetching the NEXT node   */
        process(n->data);               /* while we work on this one      */
}

/* prefetch distance matters — too close and it has not arrived,
   too far and it is evicted before use. Tune by measurement.        */
#define DIST 8
for (i = 0; i < n; i++) {
        __builtin_prefetch(&a[i + DIST]);
        heavy_work(a[i]);
}
```

PREFETCHING IS NOT FREE

Every prefetch consumes memory bandwidth and a cache line's worth of capacity. Aggressive prefetching on a bandwidth-saturated system makes things *worse* by evicting useful data and competing for the memory controller. Measure; do not assume. On modern cores the hardware stride prefetcher already handles regular patterns better than you will by hand — reserve software prefetch for genuinely irregular access.

Designing for the hierarchy

Structure of arrays versus array of structures

```
/* AoS — natural to write, poor for scanning one field */
struct particle { float x, y, z, vx, vy, vz; int id; float mass; };
struct particle p[100000];              /* 32 bytes each               */

for (i = 0; i < n; i++) p[i].x += p[i].vx;
/* each 64-byte line holds 2 particles, and you use 8 of its 64 bytes.
   87% of every line fetched is wasted bandwidth. */

/* SoA — awkward to write, excellent for scanning */
struct particles {
        float x[100000], y[100000], z[100000];
        float vx[100000], vy[100000], vz[100000];
};
for (i = 0; i < n; i++) ps.x[i] += ps.vx[i];
/* every byte of every fetched line is used, and it VECTORISES —
   the compiler can now emit NEON/SVE operating on 4–8 elements at once */
```

Blocking (tiling)

```
/* naive matrix multiply: B is walked column-wise — a miss per element */
for (i = 0; i < N; i++)
  for (j = 0; j < N; j++)
    for (k = 0; k < N; k++)
      C[i][j] += A[i][k] * B[k][j];

/* blocked: work on tiles small enough that A, B and C tiles all fit
   in L1 simultaneously. Same arithmetic, dramatically fewer misses. */
for (ii = 0; ii < N; ii += BS)
 for (jj = 0; jj < N; jj += BS)
  for (kk = 0; kk < N; kk += BS)
   for (i = ii; i < ii+BS; i++)
    for (j = jj; j < jj+BS; j++)
     for (k = kk; k < kk+BS; k++)
      C[i][j] += A[i][k] * B[k][j];

/* choose BS so 3 * BS * BS * sizeof(float) < L1 size.
   For 32 KB L1 and floats: BS ≈ 50, so 32 or 48 in practice.
   This is the single most important optimisation in dense linear
   algebra, and therefore in machine learning kernels — see AI ch. 04. */
```

Hot/cold splitting

```
/* before: rarely-used fields evict useful data from every line */
struct conn {
        int fd;  int state;  uint64_t bytes;      /* hot: touched per packet */
        char peer_name[64]; time_t created;       /* cold: touched on error  */
        struct sockaddr_storage addr;             /* cold                    */
};

/* after: the hot struct is small, so more connections fit per line */
struct conn {
        int fd;  int state;  uint64_t bytes;
        struct conn_cold *cold;                   /* one pointer           */
};
```

Measuring it

```
perf stat -e cache-references,cache-misses,\
L1-dcache-loads,L1-dcache-load-misses,\
LLC-loads,LLC-load-misses,dTLB-load-misses ./program

perf record -e cache-misses ./program && perf report   # which line misses?

# on ARM, the PMU exposes the same counters by architectural name
perf list | grep -i cache

# a quick empirical map of your machine's hierarchy: time a pointer
# chase over increasing working-set sizes and look for the step changes.
# The steps land exactly at your L1, L2 and L3 capacities.
```

How it shows up

Symptom	Cause
Performance drops sharply past a specific input size	The working set exceeded a cache level

Symptom	Cause
Swapping loop order changes runtime by 10×	Row-major versus column-major traversal
Linked list is far slower than an array with identical contents	No spatial locality, plus dependent loads (chapter 11)
Adding a field to a struct slows an unrelated loop	The struct crossed a cache-line boundary, halving elements per line
Profile shows high IPC but poor wall-clock throughput	Memory-bandwidth-bound; the core is busy waiting efficiently
A microbenchmark is much faster than production	The benchmark's working set fits in cache; production's does not
Aligning an array to 64 bytes gives a measurable speedup	Removed lines split across two cache lines

Check yourself

- ✓ State the two kinds of locality and give a code example of each.
- ✓ Compute AMAT for a three-level hierarchy and show which term dominates.
- ✓ Name the three classic miss types and the cure for each.
- ✓ Explain why row-major traversal beats column-major, in terms of cache lines.
- ✓ Convert an array-of-structs loop to structure-of-arrays and say what two things improve.
- ✓ Explain blocking and how to choose the block size from cache capacity.
- ✓ Say when software prefetching helps and when it hurts.

Cache organisation and policies

Chapter 13 said caches work. This chapter opens one up: how an address finds its line, why associativity exists, what happens on a write, and why two arrays exactly 4 KB apart can destroy your performance.

The problem

A cache holds a small subset of a huge address space. Two questions must be answered on every access, in about one cycle:

1. Given an address, **where would that line be** if it were cached?
2. **Is it actually there**, or is this a different address that maps to the same place?

Searching every entry would be correct and far too slow. The answer is to make the location a function of the address, and store enough extra bits to confirm identity.

Cache lines

Caches do not store individual bytes. The unit of transfer and tracking is a **line**, almost universally 64 bytes on ARM and x86.

```
Why 64 bytes and not 4?

  Larger lines:  + exploit spatial locality — fetch neighbours for free
                 + fewer tags to store (less overhead)
                 − more wasted bandwidth if you use only part of it
                 − more false sharing between cores (chapter 15)

  64 bytes is the empirical sweet spot, and it has consequences you
  can measure:

    · a 64-byte struct fits exactly one line — align it and every
      access touches one line instead of two
    · reading 1 byte costs the same as reading 64
    · two variables in the same line are, for coherency purposes,
      THE SAME VARIABLE
```

Address decomposition

An address is split into three fields. This is the whole mechanism.

```
   ┌──────────────┬──────────────┬──────────────┐
   │     TAG      │    INDEX     │    OFFSET    │
   └──────────────┴──────────────┴──────────────┘
      identity       which set     byte within
                     to look in     the line

  OFFSET = log2(line size)          64-byte line  → 6 bits
  INDEX  = log2(number of sets)
  TAG    = everything left over

Worked example: 32 KB, 8-way set-associative, 64-byte lines

  lines total = 32768 / 64        = 512
  sets        = 512 / 8           = 64 sets
  offset bits = log2(64)          = 6
  index bits  = log2(64)          = 6
  tag bits    = 48 - 6 - 6        = 36   (for a 48-bit address)

   47                    12 11    6 5    0
  ┌────────────────────────┬────────┬──────┐
  │          TAG           │ INDEX  │OFFSET│
  └────────────────────────┴────────┴──────┘
```

The lookup

```
  1. Extract INDEX from the address    → select one set
  2. Read all N ways of that set in parallel
  3. Compare each way's stored TAG against the address's TAG,
     and check its VALID bit
  4. Any match → HIT. Use OFFSET to pick bytes from that line.
     No match  → MISS. Choose a victim, evict it, fetch the line.

Steps 2 and 3 happen simultaneously across all ways — that is what
associativity costs in hardware: N comparators and N tag reads per access.
```

Associativity

Organisation	Where a line may go	Cost	Weakness
Direct-mapped (1-way)	Exactly one place	One comparator; fastest, smallest	Two hot addresses with the same index thrash forever, even with the cache 99% empty
N-way set-associative	Any of N ways in one set	N comparators, a replacement policy	Still possible to conflict with N+1 hot lines
Fully associative	Anywhere	One comparator per line — only feasible for tiny structures	Impractical above a few dozen entries; used for TLBs and victim caches

```
Direct-mapped thrashing, made concrete

  32 KB direct-mapped, 64-byte lines → 512 sets
  index = bits [14:6], so addresses 32 KB apart share an index.

  float a[8192], b[8192];        /* 32 KB each, adjacent in memory */
  for (i = 0; i < 8192; i++)
          a[i] += b[i];

  a[i] and b[i] are exactly 32768 bytes apart → SAME SET, every i.
  Each iteration evicts the other. 100% miss rate.
  Padding b by one line makes the miss rate ~6%.

This is a CONFLICT MISS: the cache is nearly empty and still missing.
```

THE POWER-OF-TWO STRIDE TRAP

This is not a historical curiosity — it bites constantly in numerical and image code. Any array whose row stride is a large power of two makes column traversal land on the same few sets.

```
float m[1024][1024];              /* row stride = 4096 bytes */
for (j = 0; j < 1024; j++)
        for (i = 0; i < 1024; i++)
                sum += m[i][j];   /* every access strides 4096 bytes */

/* With a 4096-byte set span, all 1024 accesses in the inner loop map
   to the same set. An 8-way cache holds 8 of them. Miss rate ≈ 100%.

   Fix: pad the row.  */
float m[1024][1024 + 16];         /* stride is now 4160 — indices spread */
```

The same effect explains why FFT and matrix libraries pad their leading dimensions, and why a benchmark can slow down 5× when you round an array size up to a power of two.

How much associativity is enough?

Empirically, an N-way cache of size S has about the same miss rate as a direct-mapped cache of size 2S, with diminishing returns past 8 ways. Typical modern designs: L1 4- or 8-way (latency-sensitive), L2 8- to 16-way, L3 16-way or more.

Replacement policy

Policy	Idea	Note
LRU	Evict the least recently used way	Good, but exact LRU needs log2(N!) bits per set — only practical for small N
Pseudo-LRU	A binary tree of "which half was used more recently"	N−1 bits per set; nearly as good. The common real choice.
Random	Pick a way at random	Cheap, and immune to pathological patterns. Used in some ARM L1s.
RRIP / DRRIP	Predict re-reference interval; insert streaming data as "evict soon"	Handles scans that would otherwise flush the whole cache

> **WHY LRU FAILS ON SCANS**
> Stream an array larger than the cache and LRU evicts everything useful in favour of data you will never touch again. This is why `madvise(MADV_DONTNEED)`, non-temporal stores (`STNP` on AArch64) and RRIP-style policies exist: they let a bulk copy pass through without destroying the working set of everything else.

Write policies

Two independent decisions, giving four combinations — and the choice is directly visible in your page tables.

Decision	Options
On a write hit	**Write-back**: update the line, mark it dirty, write to memory only on eviction. **Write-through**: update the line *and* memory every time.
On a write miss	**Write-allocate**: fetch the line first, then write into it. **No-write-allocate**: send the write straight to memory.

```
Write-back + write-allocate   ← the standard pairing, and the default
                                for Normal memory on ARM
  + far less memory traffic (repeated writes coalesce in the cache)
  + a write miss followed by more writes to the same line is cheap
  - memory is stale until eviction → this is exactly why DMA needs
    cache maintenance (chapter 15, and the SMMU chapter)
  - a dirty line must be written out on eviction, adding latency

Write-through + no-write-allocate
  + memory is always current → simple for DMA and for coherency
  + no dirty bits to track
  - every store goes to memory; needs a write buffer to be tolerable

The DIRTY bit is the whole difference. It is why a cache flush is
sometimes a no-op and sometimes writes megabytes to DRAM.
```

```
/* On ARM this is not a fixed property of the cache — it is chosen
   per page, via the AttrIndx field of the translation descriptor
   indexing into MAIR_EL1. See ARM chapters 11 and 14.            */

MAIR slot 0 = 0xFF   /* Normal, Inner+Outer Write-Back, read+write allocate */
MAIR slot 1 = 0x00   /* Device-nGnRnE — never cached at all                 */
MAIR slot 2 = 0x44   /* Normal, Non-cacheable                               */

/* So "is this memory write-back cached?" is a software decision made
   in a page table, not a hardware constant. Getting it wrong for a
   DMA buffer or an MMIO region is a classic driver bug.            */
```

Virtual versus physical indexing

The cache lookup needs an address — but which one, the virtual address the program used or the physical address after translation? Waiting for the MMU adds latency to every access.

Scheme	Index / Tag	Property
PIPT	Physical / Physical	Simplest to reason about; no aliasing. But the TLB lookup is on the critical path.
VIVT	Virtual / Virtual	Fastest, but must be flushed on every context switch and suffers aliasing. Largely abandoned.

Scheme	Index / Tag	Property
VIPT	Virtual / Physical	**The standard.** Index with the virtual address (available immediately) while the TLB produces the physical tag in parallel. Both finish together.

```
Why VIPT works, and its constraint

  Page offset bits are IDENTICAL in the virtual and physical address —
  translation only changes the page number.

   47                      12 11        0
  ┌──────────────────────────┬────────────┐
  │      page number         │  offset    │   ← offset is untranslated
  └──────────────────────────┴────────────┘
                             └──────┬─────┘
                                    │ if INDEX+OFFSET fit inside here,
                                    │ indexing with the VA is identical
                                    │ to indexing with the PA

  Constraint:  (cache size / associativity) ≤ page size

  4 KB pages, 64-byte lines → index+offset ≤ 12 bits
  32 KB cache: needs 8-way to keep each way at 4 KB.

This is precisely why L1 caches are "32 KB, 8-way" so consistently.
It is not a tuning choice — it is forced by the 4 KB page size.
Going to a 64 KB L1 requires 16 ways, or larger pages, or accepting
aliasing and handling it in software.
```

Inspecting a real machine

```
# Linux exposes the full cache topology
lscpu -C
#  NAME ONE-SIZE ALL-SIZE WAYS TYPE        LEVEL SETS
#  L1d       64K     512K    4 Data            1  256
#  L1i      128K       1M    4 Instruction     1  512
#  L2         4M      32M    8 Unified         2 8192
#  L3        16M      16M   16 Unified         3 16384

# or directly
cat
/sys/devices/system/cpu/cpu0/cache/index0/{level,type,size,ways_of_associativity,coherency_line_
size}

getconf -a | grep CACHE
```

```
/* the constant every performance-sensitive program needs */
#include <unistd.h>
long line = sysconf(_SC_LEVEL1_DCACHE_LINESIZE);   /* usually 64 */

/* C++17 gives it portably at compile time */
#include <new>
alignas(std::hardware_destructive_interference_size) struct counter { ... };

/* Linux kernel */
struct foo {
        int hot;
} ____cacheline_aligned;
```

How it shows up

Symptom	Cause
Rounding an array dimension to a power of two slows things 5×	Conflict misses from a power-of-two stride; pad the row
Two arrays are fine separately, terrible together	They map to the same sets; offset one allocation
Performance changes when an unrelated global is added	Alignment shifted, changing which sets your data lands in
A big `memcpy` slows down everything afterwards	The copy evicted the working set; use non-temporal stores
Aligning a struct to 64 bytes gives a free speedup	It no longer straddles two lines
A DMA buffer reads back stale data	Write-back cache holds the dirty line; memory has not been updated
Peripheral registers behave erratically	MMIO mapped as Normal cacheable instead of Device
L1 is always 32 KB and 8-way on every chip you check	The VIPT constraint against a 4 KB page

Check yourself

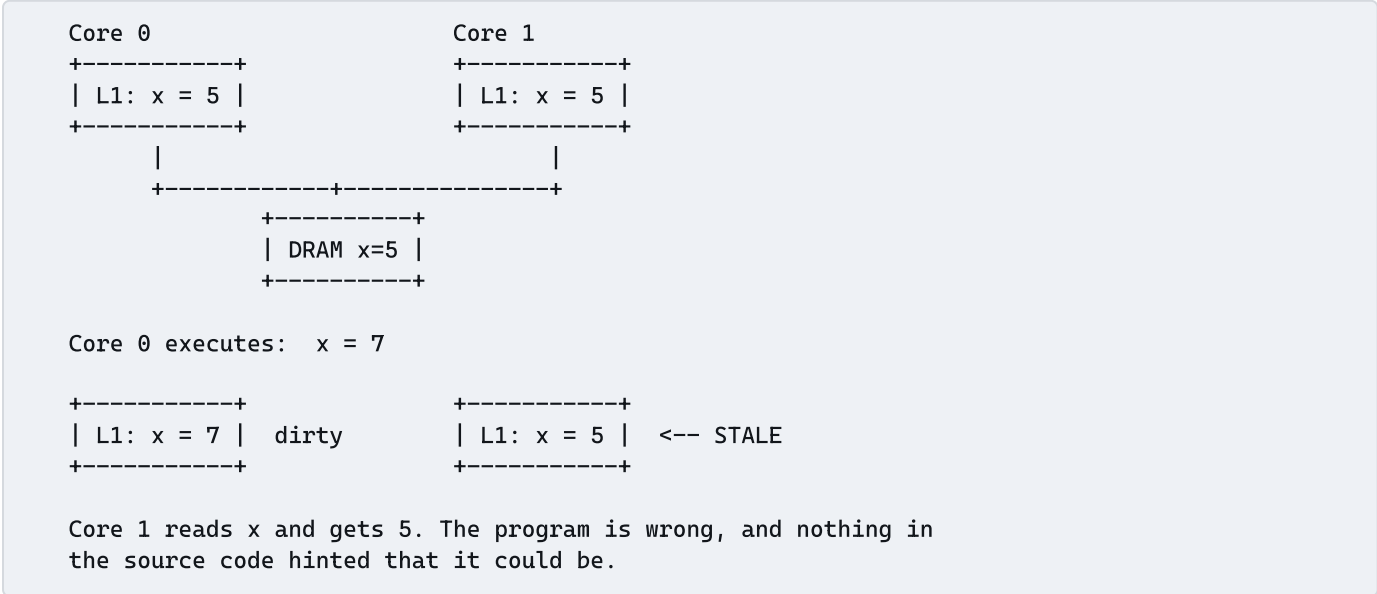
- ✓ Split a 48-bit address into tag/index/offset for a 64 KB, 4-way, 64-byte-line cache.
- ✓ Explain a conflict miss and construct two arrays that thrash a direct-mapped cache.
- ✓ Say why associativity helps and why 8-way is a common stopping point.
- ✓ Give the four write-policy combinations and which ARM uses for Normal memory.
- ✓ Explain the dirty bit and connect it to why DMA needs cache maintenance.
- ✓ Derive the VIPT constraint and use it to explain why L1 caches are 32 KB, 8-way.
- ✓ Explain why padding a matrix row can be a large optimisation.

Cache coherence and memory consistency

Two words that sound like synonyms and are not. Coherence is about one location seen by many caches; consistency is about the order of operations across different locations. Confusing them is the root of most multi-core bugs.

The problem

Give each core its own cache (chapter 13) and you have created a correctness problem: the same location now exists in several places at once, with different values.



Coherence: one location, many caches

THE COHERENCE GUARANTEE

A memory system is coherent if, for any *single* location:

1. A read returns the value of the most recent write to that location.
2. All observers agree on the *order* of writes to it (write serialisation).

Note what this does not say: nothing about the relative ordering of accesses to *different* locations. That is consistency, and it is a separate guarantee that hardware does *not* give you by default.

MESI

Each cache line carries a state. Cores watch — "snoop" — each other's transactions and change state accordingly.

State	Meaning	Others may hold it?	Memory current?
M — Modified	I have it and I changed it	No	No — I must write back
E — Exclusive	I have it, unmodified, and only I have it	No	Yes
S — Shared	I have it, unmodified, others may too	Yes	Yes
I — Invalid	No usable copy	—	—

```
The transitions that matter

  Core 0 reads x, nobody else has it   ->  I -> E
  Core 1 then reads x                  ->  Core 0: E -> S,  Core 1: I -> S
  Core 0 writes x                      ->  broadcast INVALIDATE
                                           Core 1: S -> I
                                           Core 0: S -> M
  Core 1 reads x again                 ->  Core 0 must SUPPLY the data
                                           (or write it back first)
                                           Core 0: M -> S,  Core 1: I -> S

The E state exists purely as an optimisation: if only you hold a clean
line, you may write it without broadcasting anything. Without E, every
first write to a private variable would need a bus transaction.

MOESI adds O (Owned): a dirty line may be shared, with one owner
responsible for eventual write-back. Saves memory traffic.
```

On ARM this rides the interconnect protocols from chapter 17 — ACE for smaller systems, CHI for large ones. Broadcast snooping does not scale past a modest core count, so large designs use a **directory**: a structure recording which caches hold which lines, so invalidations go point-to-point instead of to everyone.

False sharing

Coherence operates on *lines*, not variables. Two unrelated variables in the same 64-byte line are indistinguishable to the protocol.

```
/* looks perfectly parallel. It is not. */
struct counters {
        uint64_t a;    /* thread 0 increments this */
        uint64_t b;    /* thread 1 increments this */
};                     /* both in ONE cache line   */

/* Thread 0 writes a  -> invalidates the line in thread 1's cache
   Thread 1 writes b  -> invalidates the line in thread 0's cache
   ...forever. The line ping-pongs between cores every iteration.

   Measured effect: often 10-100x SLOWER than one thread doing both
   increments. You added a core and went backwards.               */

/* the fix: give each its own line */
struct counters {
        alignas(64) uint64_t a;
        alignas(64) uint64_t b;
};

/* portable spellings */
_Alignas(64)                                        /* C11           */
alignas(std::hardware_destructive_interference_size) /* C++17         */
____cacheline_aligned                               /* Linux kernel  */
__attribute__((aligned(64)))                        /* GCC / Clang   */
```

THE SIGNATURE OF FALSE SHARING

Unmistakable once you know it: **throughput gets worse as you add threads**, and the working set is tiny. Confirm with `perf c2c record` / `perf c2c report`, which names the exact cache lines suffering cross-core contention and the source lines touching them. Usual victims: per-thread statistics arrays, adjacent lock structures, and the head and tail pointers of a ring buffer.

Consistency: many locations, what order?

Coherence is not enough. Consider two *different* variables:

```
/* both start at 0 */

/* Core 0 */                    /* Core 1 */
data = 42;                      while (flag == 0)
flag = 1;                               ;
                                use(data);      /* may read 0! */
```

Every location is coherent. Yet core 1 can observe `flag == 1` while still reading `data == 0`. Coherence never promised anything about ordering *between* addresses.

Why the reordering happens

Source	What it does
Compiler	Reorders or eliminates accesses it can prove safe *single-threaded*
Store buffer	A write retires into a buffer; other cores cannot see it yet. The store to `data` can still be sitting there when `flag`'s store drains.
Out-of-order execution	Loads issue as soon as their address is known, possibly before earlier loads
Cache hierarchy	Invalidations reach different cores at different times
Interconnect	Messages take different routes and arrive out of order

Memory models, strong to weak

Model	Guarantee	Used by
Sequential consistency	One global order consistent with each program's order	No real hardware — too slow. It is the model beginners assume.
TSO (total store order)	Only store→load may be reordered; the store buffer is the sole relaxation	x86-64, SPARC
Weak / relaxed	Almost anything may be reordered unless you say otherwise	**ARM**, RISC-V, PowerPC

WHY THIS BITES WHEN PORTING FROM X86

Lock-free code that ran correctly on x86 for years can fail on ARM. x86's TSO happens to forbid the reorderings naive code depends on; ARM's weak model does not. *The code was always wrong* — x86 merely hid it. It will not reproduce reliably either: it depends on timing, core count and load, so it surfaces in production rather than in test. This is the most common serious porting bug from x86 to ARM.

Restoring order

```
Fixed with barriers

  /* Core 0 */                    /* Core 1 */
  data = 42;                      while (flag == 0)
  DMB ISHST;   <- prior stores            ;
  flag = 1;       visible before    DMB ISHLD;  <- no later load may
                  later stores                    float above this
                                   use(data);

Fixed with acquire / release - cheaper, and the modern idiom

  /* Core 0 */                    /* Core 1 */
  data = 42;                      while (LDAR(flag) == 0)   <- acquire
  STLR(flag, 1);   <- release             ;
                                  use(data);

  STLR: no EARLIER access may be reordered after it
  LDAR: no LATER   access may be reordered before it

Together they form a RELEASE-ACQUIRE PAIR: everything core 0 did
before the release is visible to core 1 after the acquire. This is
the fundamental synchronisation building block, and every mutex,
every channel and every lock-free queue is built out of it.
```

```
/* portable C11 / C++11 - compiles to LDAR/STLR on ARM, and to plain
   loads and stores on x86, where TSO already provides the ordering  */
#include <stdatomic.h>

_Atomic int flag = 0;
int data = 0;

/* producer */
data = 42;
atomic_store_explicit(&flag, 1, memory_order_release);

/* consumer */
while (atomic_load_explicit(&flag, memory_order_acquire) == 0)
        ;
use(data);                      /* guaranteed to see 42 */

/* Linux kernel spellings of the same idea */
smp_store_release(&flag, 1);
if (smp_load_acquire(&flag)) use(data);
smp_mb();  smp_rmb();  smp_wmb();      /* full / read / write barrier  */
READ_ONCE(x);  WRITE_ONCE(x, v);       /* stop the COMPILER only       */
```

`memory_order`	Guarantee	Cost on ARM
`relaxed`	Atomicity only, no ordering	Free — a plain atomic op
`acquire`	Later accesses cannot move before it	`LDAR`
`release`	Earlier accesses cannot move after it	`STLR`
`acq_rel`	Both, for read-modify-write	`LDAXR` / `STLXR` or `CAS`
`seq_cst`	Plus a single global total order	Most expensive — and the default if you omit the argument

Coherence with devices

Cores are kept coherent by hardware. Devices may not be — and whether they are is a property of the SoC, not something you may assume.

```
Non-coherent DMA: the two failure modes

  CPU writes a buffer, then starts a device READ
    · the data is dirty in L1; DRAM still holds the old bytes
    · the device reads DRAM -> gets garbage
    -> software must CLEAN (flush) the cache first

  Device WRITES a buffer, then the CPU reads it
    · the CPU may still hold a stale clean copy in L1
    · the CPU reads its cache -> gets old data
    -> software must INVALIDATE the cache first

  On ARM:  DC CVAC (clean), DC IVAC (invalidate), DC CIVAC (both)

Coherent DMA: the device participates in the coherency protocol
(ACE-Lite or CHI; marked `dma-coherent` in the device tree). No
maintenance needed - but never assume it, check.
```

```
/* Which is exactly why you NEVER hand a device a raw kmalloc pointer.
   The DMA API knows whether this device is coherent and emits the
   right maintenance - or correctly emits none.                      */

dma_addr_t d = dma_map_single(dev, buf, len, DMA_TO_DEVICE);
/* ... the device owns the buffer here; the CPU must not touch it ... */
dma_unmap_single(dev, d, len, DMA_TO_DEVICE);

/* peek mid-transfer, correctly */
dma_sync_single_for_cpu(dev, d, len, DMA_FROM_DEVICE);
inspect(buf);
dma_sync_single_for_device(dev, d, len, DMA_FROM_DEVICE);
```

Measuring coherence traffic

```
# find false sharing and cross-core line contention
perf c2c record ./program
perf c2c report --stdio
#   reports HITM (hit-modified) events: a load that hit a line
#   modified in ANOTHER core's cache - the fingerprint of sharing

# ARM PMU events worth watching
perf stat -e mem_access,l2d_cache_wb,bus_access_shared ./program

# quick triage: if throughput DROPS as you add threads and the working
# set is tiny, it is almost certainly false sharing
```

How it shows up

Symptom	Cause
Adding threads makes a parallel program slower	False sharing; pad to cache-line boundaries

Symptom	Cause
Lock-free code works on x86, fails on ARM	Missing barriers, previously hidden by TSO
A bug appears only under load on many cores	The reordering window widened; the ordering was never guaranteed
A flag is set but the data it guards is stale	Missing release/acquire pairing
DMA reads zeros or old data	Cache not cleaned before the device read
DMA results never become visible to the CPU	Cache not invalidated after the device write
Adding a `printf` makes the bug vanish	Timing changed; the race is still there
`volatile` did not fix a multi-threaded bug	`volatile` constrains the compiler, not the hardware. It is not a barrier and never was.

Check yourself

- ✓ State the difference between coherence and consistency in one sentence each.
- ✓ Walk two cores through the MESI states for read, read, write, read.
- ✓ Explain why the E state exists.
- ✓ Construct a false-sharing example, fix it, and say how you would detect it.
- ✓ Explain why the flag/data example can fail even with perfect coherence.
- ✓ Give the release-acquire pairing and state exactly what it guarantees.
- ✓ Say why lock-free code tested on x86 may fail on ARM.
- ✓ Name the two cache-maintenance operations non-coherent DMA needs, and when each applies.

Virtual memory as an architectural idea

Every address your program uses is a lie the hardware maintains. This chapter covers why that indirection exists and how it works in general; ARM chapter 12 and OS chapter 12 cover the specific mechanics.

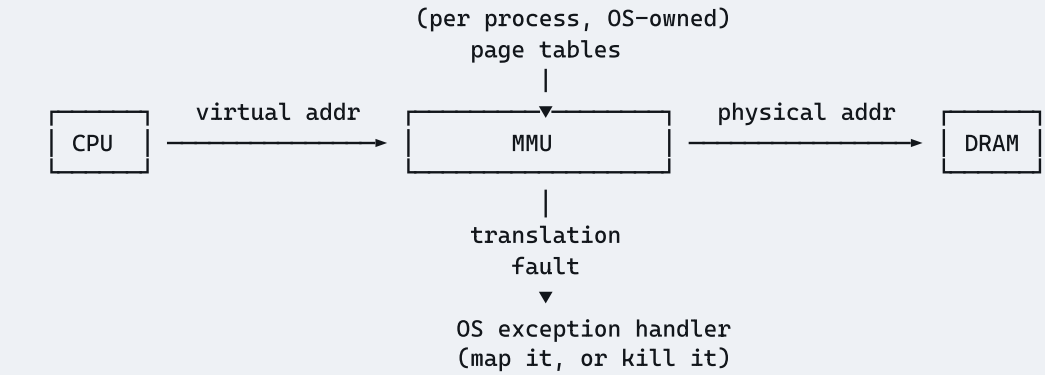
The problem

Before virtual memory, a program's addresses were physical addresses. Four consequences, all bad:

Problem	Consequence
No protection	Any program can read or write any other program's memory, and the OS's. One bug takes down everything.
No relocation	A program compiled to load at 0x10000 must load there. Two such programs cannot coexist.
Fragmentation	Free memory exists but not contiguously, so a large allocation fails while plenty is free.
Hard capacity limit	The working set must fit in physical RAM. No overcommit, no demand loading, no swap.

THE IDEA

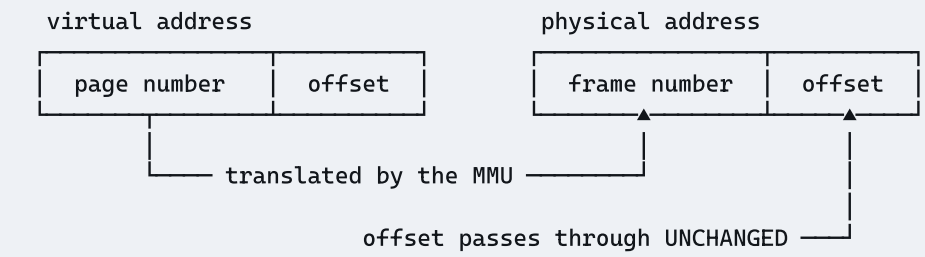
Insert a hardware translation step between the address a program emits and the address that reaches memory. Software sees **virtual addresses**; the memory system sees **physical addresses**; a per-process mapping table, controlled by the OS and consulted by hardware, connects them. Every problem above dissolves at once.



The MMU sits inside the core, in the memory stage of the pipeline (chapter 11). Every load, store and instruction fetch goes through it.

Pages: the unit of mapping

Mapping every byte individually would need a table larger than memory. So the address space is divided into fixed-size **pages**, and only the page number is translated.



```
Page size 4 KB  -> offset is 12 bits
Page size 16 KB -> offset is 14 bits
Page size 64 KB -> offset is 16 bits

Because the offset is untranslated, the low bits of a virtual and a
physical address are IDENTICAL. This single fact is what makes VIPT
caches possible (chapter 14) - the cache can start its lookup before
translation finishes.
```

Choosing a page size

	Small pages (4 KB)	Large pages (2 MB, 1 GB)
Internal fragmentation	Low — little waste per allocation	High — a 1-byte allocation can pin 2 MB
Page table size	Large — many entries	Small
TLB reach	Poor — 1024 entries cover 4 MB	Excellent — 1024 entries cover 2 GB
Fault granularity	Fine — demand paging works well	Coarse — one fault pulls in 2 MB
Typical use	General purpose	Databases, VMs, the kernel's own linear map, ML workloads

Most systems support several sizes simultaneously — Linux calls the large ones *huge pages*, ARM calls the intermediate levels *blocks*. The trade-off is always fragmentation against TLB reach.

Page tables

A flat array indexed by page number is the obvious design and is immediately impossible:

```
  48-bit address space, 4 KB pages
      2^48 / 2^12 = 2^36 pages = 68,719,476,736 entries
      x 8 bytes each = 512 GB of page table.  Per process.

The fix: exploit sparseness. Almost all of that space is unmapped, so
use a MULTI-LEVEL tree and simply omit the empty subtrees.

  VA[47:39] -> L0 entry -> points to an L1 table  (or is INVALID)
  VA[38:30] -> L1 entry -> points to an L2 table
  VA[29:21] -> L2 entry -> points to an L3 table
  VA[20:12] -> L3 entry -> the physical frame + permissions
  VA[11:0]  -> offset within the frame

A process using 8 MB needs only a handful of tables, not 512 GB.
An INVALID entry at any level prunes an entire subtree in one step.
```

Structure	How it works	Trade-off
Multi-level (radix) tree	Fixed fan-out per level, indexed by address bits	The universal choice: x86-64, ARM, RISC-V. Cost is one memory access per level on a miss.

Structure	How it works	Trade-off
Inverted page table	One entry per *physical* frame, hashed by VA	Size proportional to RAM, not address space. Awkward for shared memory. Used historically on PowerPC.
Hashed page table	Hash the VA into a bucket chain	Compact but variable-latency lookups

What an entry carries besides an address

A translation entry is not just a pointer. The permission and attribute bits are where most of the architecture's power lives:

Field	Purpose	What it enables
Valid	Is this mapping present?	Demand paging, swap, lazy allocation
Read / Write	Access permission	Read-only data, copy-on-write
Execute-never	May instructions be fetched here?	W^X — the single most effective anti-exploit measure
Privilege	User-accessible, or kernel only?	The user/kernel boundary itself
Accessed / Dirty	Has it been read? written?	Page replacement policy; knowing what must be written back
Memory attributes	Cacheable? Device? Shareable?	MMIO correctness, DMA buffers (ARM ch. 11)
Global / ASID	Shared across processes, or tagged	Avoiding a full TLB flush on context switch

> **THE INSIGHT WORTH CARRYING FORWARD**
>
> Protection and translation are the *same mechanism*. The hardware must consult the table on every access to find the physical address, so checking permissions at the same time is free. That is why virtual memory is the foundation of process isolation rather than a separate feature — and why a system without an MMU (a Cortex-M) needs an entirely different protection scheme, the MPU.

The TLB

A four-level walk costs four memory accesses. Doing that on every load would make every access five times slower. So translations are cached in the **Translation Lookaside Buffer**.

```
Typical structure

  L1 TLB    32–64 entries, fully associative, ~1 cycle
            often split: separate iTLB and dTLB
  L2 TLB    1024–2048 entries, set-associative, ~10 cycles
  miss      -> hardware page table walker -> up to 4 memory accesses
               (each of which may itself hit or miss in the caches)

TLB reach = entries x page size
  1024 entries x 4 KB  =   4 MB   <- easily exceeded
  1024 entries x 2 MB  =   2 GB   <- why huge pages help so much

A TLB miss on a workload with a large random working set can cost
more than the cache miss that follows it.
```

Context switches and tagging

Each process has its own mapping, so naively a context switch invalidates every TLB entry — and the new process then takes hundreds of misses warming it back up. Two mechanisms avoid this:

- **Address space identifiers.** Tag each entry with the owning process (ARM calls it *ASID*, x86 calls it *PCID*). Entries from several processes coexist; a switch just changes the current tag.
- **Global entries.** Kernel mappings are identical in every process, so they are marked global and match regardless of tag — no reload after a system call.

> **SOFTWARE MUST INVALIDATE; HARDWARE WILL NOT NOTICE**
> The TLB is a cache with *no coherence protocol*. If you modify a page table entry, the stale translation lives on until you explicitly invalidate it. On a multi-core system you must invalidate on *every* core that might hold it — a "TLB shootdown", which on ARM is a broadcast `TLBI` and on x86 requires an inter-processor interrupt. Forgetting this produces the classic "works on one core, fails on four" bug, and shootdown cost is a real scalability limit for `munmap`-heavy workloads.

Page faults: the useful exception

A translation failure traps to the OS, which decides what it means. Most faults are not errors — they are how features get implemented.

Fault	OS response	Feature it implements
Valid bit clear, page is on disk	Read it in, update the entry, retry	Demand paging and swap
Valid bit clear, never touched	Allocate a zero page now	Lazy allocation — why `malloc` of 1 GB is instant
Write to a read-only shared page	Copy it, make the copy writable, retry	Copy-on-write — why `fork()` is cheap
Access flag clear	Set it and retry	Tracking which pages are in use, for replacement
Write to a clean page	Set dirty, retry	Knowing which pages need writing back
Genuinely unmapped, or permission violation	SIGSEGV / bug check	Protection — catching the actual bug

```
The demand-paging round trip

  1. Instruction issues a load            VA -> MMU
  2. TLB miss -> page table walk
  3. Entry invalid -> PAGE FAULT exception, precise
  4. Hardware saves the faulting address and cause, enters the OS
  5. OS looks up its own record of what SHOULD be at that address
  6. Allocates a frame, reads from disk if needed, writes the entry
  7. Invalidates the stale TLB entry
  8. Returns from the exception
  9. The SAME instruction re-executes, and now succeeds

Step 9 is why the exception must be PRECISE (chapter 11). The core
must be able to restart the faulting instruction as though nothing
had happened - which constrains the whole out-of-order design.
```

What the indirection buys, beyond protection

Capability	Mechanism
Shared libraries	One physical copy of libc mapped into every process at whatever address suits it
Memory-mapped files	File pages mapped directly; reads become faults, writes become dirty pages

Capability	Mechanism
Guard pages	An unmapped page below each stack turns overflow into a clean fault instead of silent corruption
ASLR	Randomised mapping addresses make exploit gadget locations unpredictable
Contiguity from fragments	Physically scattered frames appear as one contiguous buffer
Overcommit	Promise more address space than you have RAM, back it only on use
Virtualisation	A second translation stage under the first (ARM ch. 16)
Device isolation	The same idea applied to DMA — the IOMMU (security ch. 02)

And what it costs

- **Latency** on every access, hidden by the TLB but never zero.
- **Memory** for the tables themselves, plus the walker's own cache pressure.
- **Determinism.** A page fault can take microseconds to milliseconds. This is why hard real-time systems lock pages (`mlockall`) or avoid an MMU entirely — see OS chapter 19.
- **Shootdown cost** on many-core systems.
- **A side channel.** Timing differences between mapped and unmapped pages leak layout information, which is what defeats naive ASLR.

Seeing it on a real system

```
# the virtual layout of a running process
cat /proc/self/maps
#   aaaab7c40000-aaaab7c48000 r-xp 00000000 fe:01 1234  /usr/bin/cat
#   aaaab7c57000-aaaab7c58000 r--p 00007000 fe:01 1234  /usr/bin/cat
#   ffff9c7f0000-ffff9c811000 r-xp 00000000 fe:01 5678  /lib/ld-linux.so
#   ffffe3d21000-ffffe3d42000 rw-p 00000000 00:00 0     [stack]
#              ^ permissions: r/w/x and p=private or s=shared

# per-page physical detail
cat /proc/self/smaps            # Rss, Pss, dirty pages, huge pages per mapping

# fault counts: minor = no disk, major = disk read required
/usr/bin/time -v ./program 2>&1 | grep -i fault
ps -o min_flt,maj_flt -p $$

# TLB pressure
perf stat -e dTLB-load-misses,iTLB-load-misses,dtlb_walk,itlb_walk ./program
```

How it shows up

Symptom	Cause
`malloc` of a huge block succeeds instantly, then crashes on write	Lazy allocation plus overcommit; memory was never really reserved
First touch of each page is slow, later touches fast	Demand paging — one minor fault per page
Huge pages give a large speedup on a big-working-set program	TLB reach, not cache behaviour
A latency spike of milliseconds in an otherwise fast loop	A major fault: the OS went to disk
Page table change works on one core, fails on four	Missing TLB shootdown

Symptom	Cause
A driver reads garbage from a peripheral	Mapped with the wrong memory attributes, not the wrong address
Stack overflow gives a clean crash rather than corruption	The guard page did its job
Real-time task misses a deadline occasionally	An unlocked page faulted; use `mlockall()`

Check yourself

- ✓ Give the four problems virtual memory solves, and say which one is about security.
- ✓ Explain why the page offset is not translated, and one thing that fact makes possible.
- ✓ Compute the size of a flat page table for a 48-bit space, and explain how a multi-level tree avoids it.
- ✓ List six fields in a page table entry besides the frame number, and what each enables.
- ✓ Define TLB reach and explain why huge pages help large working sets.
- ✓ Explain why the TLB needs explicit invalidation and what a shootdown is.
- ✓ Name four features implemented by *deliberately* taking a page fault.
- ✓ Explain why virtual memory complicates hard real-time systems.

I/O, buses and interconnects

A CPU that cannot talk to the world is a heater. This chapter covers how software reaches a device, the three ways data moves, and what actually travels on the wires between blocks — which turns out to matter enormously for security.

How software reaches a device

Two historical approaches. Only one survives in modern designs.

	Port-mapped I/O	Memory-mapped I/O
Address space	Separate, small (x86: 64 KB)	Shared with memory
Instructions	Dedicated: `IN`, `OUT`	Ordinary `LDR` / `STR`
Protection	A separate permission mechanism	The MMU, for free
Used by	Legacy x86 only	**ARM, RISC-V, and everything modern**

MEMORY-MAPPED I/O

Peripheral registers are assigned addresses in the same physical address space as DRAM. Writing to a UART is the same instruction as writing to RAM; only the address differs. Everything follows from this: device access is protected by page tables, translated by the MMU, and subject to the same memory-attribute rules as any other access.

```
A physical memory map is a static, chip-designer decision

  0x0000_0000  +--------------------------+
               |  Boot ROM                |
  0x1000_0000  +--------------------------+
               |  On-chip SRAM            |
  0x4000_0000  +--------------------------+
               |  Peripheral region       |
               |    0x4000_0000  UART0    |   each block usually gets
               |    0x4000_1000  UART1    |   at least one 4 KB page,
               |    0x4000_2000  I2C0     |   so it can be mapped and
               |    0x4800_0000  GIC      |   protected independently
  0x8000_0000  +--------------------------+
               |  DRAM                    |
               +--------------------------+

The 4 KB granularity is not an accident: it is the page size, so that
one driver can be given exactly one peripheral and nothing else.
```

Why MMIO must not be cached

```
/* Device registers are not memory. They have SIDE EFFECTS. */

status = regs->FIFO;    /* reading POPS a byte from the FIFO      */
regs->CTRL = START;     /* writing STARTS a physical operation    */
n = regs->COUNT;        /* the value changes without any write    */

/* If this region were cached and speculatable:
     - a speculative read could drain a FIFO nobody asked to read
     - a cached read would return a stale count forever
     - a write could sit in a dirty line and never reach the device
     - two writes could be merged, or reordered

   Hence a distinct memory TYPE (ARM: Device-nGnRnE), not merely
   "uncached". See ARM chapter 11.                                */

/* And hence: never dereference an MMIO pointer directly. */
u32 v = readl(base + STATUS);       /* Linux                       */
writel(v | ENABLE, base + CTRL);    /* includes the right barriers */
```

The three ways data moves

	Polling	Interrupts	DMA
Mechanism	CPU spins reading a status bit	Device signals; CPU takes an exception	Device moves data to/from memory itself
CPU cost	100% while waiting	Only on events, plus entry/exit overhead	Near zero; one interrupt on completion
Latency	Lowest and most deterministic	Interrupt latency, typically µs	Setup cost amortised over a large transfer
Best for	Very short waits; early boot before interrupts exist; hard real-time	Most peripherals	Bulk: network, storage, display, cameras
Hazard	Wastes power; can hang forever — always bound the loop	Storms if you fail to clear at the source	Coherency and address translation

```
/* polling, done correctly - ALWAYS with a timeout */
ret = readl_poll_timeout(base + STATUS, val,
                         val & STATUS_READY,   /* condition            */
                         10,                   /* µs between polls     */
                         1000);                /* µs before giving up  */
if (ret)
        return -ETIMEDOUT;      /* the device is wedged; say so
                                   rather than hanging the kernel */
```

Why DMA changes everything

```
Without DMA                      With DMA

  device -> CPU register           device -> memory, directly
         -> memory                 CPU is not involved at all

  every byte costs instructions    one setup + one interrupt

But now a SECOND entity issues addresses onto the interconnect, and
it never passed through the CPU's MMU. Two consequences:

  1. COHERENCY. The device sees DRAM; the CPU sees its cache.
     (chapter 15)

  2. PROTECTION. Every isolation guarantee built with page tables
     has a hole in it, because the device's transactions were never
     checked. This is why the IOMMU/SMMU exists.
     (security track, chapters 02-07)
```

Bus topologies

```
Shared bus            one set of wires, arbitration decides who drives
                      + simple, cheap, easy to snoop
                      - one transaction at a time; does not scale
                      e.g. classic AHB, I2C, older PCI

Crossbar              every master connected to every slave
                      + full parallelism between disjoint pairs
                      - area grows as N x M
                      e.g. small AXI interconnects

Network on chip       routers and links, packets find their way
  (NoC / mesh)        + scales to dozens of masters
                      - variable latency, needs flow control
                      e.g. ARM CMN, CHI-based fabrics

Point to point        dedicated serial links, switched
  (serial)            + very high bandwidth per pin, hot-pluggable
                      - protocol complexity, serialisation latency
                      e.g. PCIe, USB, Ethernet
```

Parallel gave way to serial

Counter-intuitively, one differential pair beats 64 parallel wires. Parallel buses are limited by *skew* — bits on different wires arrive at slightly different times, and the clock period must exceed the worst skew. Serial links embed the clock in the data, eliminating skew entirely, and then use equalisation and error correction to push the rate far higher. This is why PCIe replaced PCI, SATA replaced PATA, and USB replaced the parallel port.

AMBA: the ARM family

Protocol	Character	Typical use
APB	Simple, no bursts, one transfer at a time, low power	Slow peripheral registers: UART, I2C, GPIO, timers
AHB	Single shared bus, pipelined, supports bursts	Simpler SoCs, Cortex-M systems
AXI	Five independent channels, out-of-order via IDs, high throughput	The workhorse: memory controllers, DMA, GPU
ACE	AXI plus coherency snooping	Coherent CPU clusters

Protocol	Character	Typical use
ACE-Lite	Can snoop others but is not snooped	I/O-coherent DMA masters
CHI	Packet-based, scalable mesh, credit flow control	Large multi-core and server-class SoCs

```
AXI's five channels are independent, which is the whole point

  master                                        slave
    |--- AW: write address ------------------------->|
    |--- W:  write data ---------------------------->|
    |<-- B:  write response ------------------------|
    |--- AR: read address ------------------------->|
    |<-- R:  read data ----------------------------|

Because address and data are separate channels, a master can issue
many addresses before any data returns - OUTSTANDING TRANSACTIONS.
Because responses carry an ID, they may return OUT OF ORDER.

This is how a memory system hides 200-cycle DRAM latency: keep
dozens of requests in flight rather than waiting for each.
```

What travels besides address and data

THIS LIST IS THE FOUNDATION OF THE ENTIRE SECURITY TRACK

An AXI transaction carries far more than an address:

- `AxADDR` — the physical address.
- `AxID` — the master's transaction ID, from which the SoC derives a **master ID** or **StreamID**: *who is asking*.
- `AxPROT[1]` — the **NS bit**: Secure or Non-secure. One wire, and it is the entirety of TrustZone's bus-level enforcement.
- `AxPROT[0]` — privileged or unprivileged. `AxPROT[2]` — instruction or data.
- `AxCACHE` — cacheability and bufferability, derived from the page table's memory attributes.
- `AxLEN`, `AxSIZE`, `AxBURST` — the shape of the burst.

So the `NS` and `AttrIndx` fields you set in a page table descriptor are not abstractions — they become *physical signals*, and hardware downstream (the SMMU, the TZASC, the XPU) makes allow/deny decisions from them. Setting a bit in a descriptor is setting a wire on the interconnect.

External buses worth recognising

Bus	Wires	Speed	Character
I2C	2 (SDA, SCL)	100 kHz – 3.4 MHz	Addressed, multi-drop, open-drain. Slow and cheap: sensors, EEPROMs, PMICs.
SPI	4 (MOSI, MISO, SCK, CS)	1–100 MHz	Full duplex, one chip-select per device. Flash, displays, radios.
UART	2 (TX, RX)	9.6 k – 4 M baud	Asynchronous, no clock line, point-to-point. The debug console.
USB	Differential pair(s)	12 Mb/s – 40 Gb/s	Host-controlled, enumerable, hot-pluggable, powered.
PCIe	1–16 lanes	2–64 GB/s	Switched point-to-point, enumerable, DMA-capable, MSI interrupts.
CAN	2 (differential)	1–8 Mb/s	Multi-master, priority arbitration, robust. Automotive and industrial.

Bus	Wires	Speed	Character
Ethernet	Pairs	10 Mb/s – 800 Gb/s	Packet switched, and increasingly used inside vehicles too.

Discoverable versus described

```
DISCOVERABLE buses can be probed. Software asks, hardware answers.

  PCIe: read the configuration space at each bus/device/function
        -> vendor ID, device ID, class, BAR sizes
  USB:  the host requests descriptors from every device it detects

  -> the OS matches a driver against the reported IDs, automatically.

NON-DISCOVERABLE buses cannot. There is no way to ask address
0x40001000 whether a UART lives there - and a wrong guess may hang
the bus or trigger a side effect.

  On-SoC peripherals, I2C and SPI slaves are all in this category.

  -> the hardware must be DESCRIBED to software out of band:
       device tree (embedded Linux, ARM)
       ACPI tables  (servers, Windows on ARM, x86)
       board files  (legacy, deprecated)

This distinction is exactly why the device tree exists, and why an
embedded Linux driver looks so different from a PCIe driver.
```

Getting an interrupt from a device to a core

```
Wired interrupt (traditional)

  device asserts a physical line -> interrupt controller -> core
  · limited by pin count, so lines get shared
  · shared lines mean every handler must check "is it mine?"
    and return "not mine" if not

Message-signalled interrupt (MSI / MSI-X, and ARM's LPIs)

  device performs a WRITE to a special address, carrying a payload
  · no dedicated wires at all - it is just a bus transaction
  · thousands of distinct interrupts per device
  · no sharing, so no "is it mine?" ambiguity
  · arrives IN ORDER with the DMA data it refers to, which removes
    a classic race: with a wired interrupt the signal can arrive
    before the data it announces has landed in memory
```

The interrupt controller itself — priority, masking, routing to a specific core, security grouping — is covered in ARM chapters 23 and 24.

Inspecting a real system

```
# who owns which physical address range
cat /proc/iomem
#   40000000-40000fff : serial@40000000
#   80000000-bfffffff : System RAM

# interrupt counts per CPU — is the handler actually firing?
cat /proc/interrupts

# enumerate discoverable buses
lspci -vv          # BARs, capabilities, link speed, MSI config
lsusb -t           # topology tree

# non-discoverable hardware, as described to the kernel
ls /proc/device-tree/
dtc -I fs -O dts /proc/device-tree | less

# DMA and IOMMU groupings
ls /sys/kernel/iommu_groups/*/devices/
```

How it shows up

Symptom	Cause
Register reads return all zeros or all ones	Device unclocked or unpowered, wrong base address, or a bus firewall denying access
Writes appear to have no effect	Region mapped cacheable instead of Device; or a write-1-to-clear register
Device works in the debugger, fails at speed	Missing barriers between register writes, or a required delay
Reading a status register consumes data	Side-effecting register plus speculative or repeated reads
Interrupt fires continuously, system unresponsive	Not cleared at the device before acknowledging the controller
Interrupt never fires	Wrong number, wrong trigger type, masked, or not enabled at the device
DMA lands in the wrong place	Device programmed with a virtual or physical address instead of the DMA address
Interrupt arrives before the DMA data is visible	Wired-interrupt race; MSI avoids it by construction
PCIe device enumerates but its driver never binds	Vendor/device ID not in the driver's match table
On-SoC peripheral is invisible to Linux	Missing or `status = "disabled"` device tree node

Check yourself

- ✓ Explain memory-mapped I/O and one thing it gets for free from the MMU.
- ✓ Give three reasons MMIO must not be cached or speculated.
- ✓ Compare polling, interrupts and DMA on CPU cost, latency and failure mode.
- ✓ Explain the two problems DMA creates and name the hardware that solves each.
- ✓ Say why AXI separates address and data channels, and what that enables.
- ✓ List what an AXI transaction carries besides address and data, and why security depends on it.
- ✓ Explain discoverable versus described buses and why the device tree exists.
- ✓ Give two advantages of MSI over a wired shared interrupt.

Measuring performance: CPI, Amdahl and roofline

Optimisation without measurement is superstition. This chapter gives you the three models that let you predict what an optimisation is worth *before* you spend a week on it, and the counters that tell you where the time actually went.

The performance equation

Everything starts here. Runtime decomposes into exactly three factors, and every optimisation you will ever make attacks one of them.

```
                instructions        cycles           seconds
   time  =    ─────────────────  ×  ─────────────  ×  ─────────
                  program           instruction        cycle

                     ↑                  ↑                ↑
                  algorithm,           CPI             1 / clock
                  compiler,         (the micro-         frequency
                  ISA                architecture)

Who controls each factor:

  instruction count   you (algorithm, data structures), the compiler,
                      the ISA (CISC does more per instruction)
  CPI                 the microarchitecture, but YOU influence it
                      heavily through cache and branch behaviour
  clock period        the process node, the pipeline depth, power
                      and thermal limits (chapter 20)
```

> **THE TRAP THIS EQUATION EXPOSES**
>
> These factors are not independent, so a "win" on one can be a loss overall. Deepening the pipeline raises the clock but worsens CPI on every mispredict. A CISC instruction lowers the instruction count but may take more cycles. Vectorising cuts instruction count but may increase memory traffic. **Only end-to-end wall-clock time is real.** This is why "we reduced instruction count by 30%" is not a result — it is a hypothesis.

Why MIPS and clock speed are useless as comparisons

```
MIPS = instruction count / (runtime × 10^6)

/* Fails because: */
- a compiler that emits MORE, simpler instructions scores HIGHER
  while running slower
- different ISAs do different amounts of work per instruction
- one core at 3 GHz with CPI 4 loses to one at 2 GHz with CPI 1

/* The same applies to FLOPS in isolation, and to clock speed.
   The only honest comparison is: the same real workload,
   measured end to end, on both machines. */
```

CPI, and where the cycles go

The useful form splits CPI into a base plus the stalls you can attack:

```
   CPI = CPI_ideal + Σ (stall events per instruction × penalty)

Worked example — a memory-bound loop

   CPI_ideal                              = 0.5   (2-wide superscalar)
   L1 D-miss:   4% × 12 cycles            = 0.48
   L2 miss:     1% × 40 cycles            = 0.40
   LLC miss:    0.5% × 200 cycles         = 1.00
   branch miss: 2% × 15 cycles            = 0.30
   ──────────────────────────────────────────────
   CPI                                    = 2.68

Read the table, not the total. The LLC misses alone cost more than
everything else combined, and they are 0.5% of accesses.

Halving the LLC miss rate:      CPI 2.68 -> 2.18   (19% faster)
Perfect branch prediction:      CPI 2.68 -> 2.38   (11% faster)
Doubling the issue width:       CPI 2.68 -> 2.43   ( 9% faster)

The expensive-and-rare event wins. This is why profiling by
COUNT is misleading and profiling by COST is correct.
```

The reciprocal, **IPC** (instructions per cycle), is what most tools report. IPC above ~2 on a wide core suggests you are compute-bound; IPC below ~0.5 almost always means you are waiting on memory.

Amdahl's law: the ceiling on any optimisation

```
   If a fraction p of runtime is improved by a factor s:

                        1
   speedup  =  ──────────────────
                (1 − p) + p / s

The part you did NOT improve sets a hard ceiling:

   max speedup = 1 / (1 − p)     even with s = ∞

Examples, and the intuition they should install:

   p = 0.95, s = ∞   ->  20x     ceiling
   p = 0.90, s = ∞   ->  10x
   p = 0.75, s = ∞   ->   4x
   p = 0.50, s = ∞   ->   2x     <- half the code, infinite speedup,
                                    and you barely double performance

   p = 0.90, s = 2   ->  1.82x
   p = 0.90, s = 10  ->  5.26x
   p = 0.90, s = 100 ->  9.17x   <- 10x more effort for 1.7x more gain
```

> **WHAT AMDAHL ACTUALLY TELLS YOU TO DO**
>
> **Profile first, always.** A 10× improvement to code that is 5% of runtime yields 4.7% overall. A 30% improvement to code that is 80% of runtime yields 26%. Engineers routinely spend weeks on the former because it was the interesting problem. Measure, find the largest *p*, and attack that — then re-measure, because the profile changes as soon as you succeed.

Gustafson's counterpoint

Amdahl assumes a fixed problem size. In practice, more capable machines get used on bigger problems, and the parallel fraction often grows with problem size while the serial part stays constant. A weather model on a 1000-core cluster does not run the same simulation faster; it runs a finer grid. Both laws are correct — they answer different questions. Ask which one your situation is: *fixed work, want it sooner* (Amdahl) or *fixed time, want more work* (Gustafson).

The roofline model

The single most useful mental model for deciding whether to optimise compute or memory.

```
   Arithmetic intensity  I = FLOPs performed / bytes moved from DRAM

   Attainable GFLOP/s = min( peak_compute,  I × peak_bandwidth )

  GFLOP/s
    ▲
    │                     ┌──────────────── peak compute (the flat roof)
    │                    /
    │                   /
    │                  /  ← the slanted roof: I × peak bandwidth
    │                 /
    │                /
    │               /
    └──────────────┴──────────────────────────────────────► arithmetic intensity
                   ▲
            ridge point:  I = peak_compute / peak_bandwidth

   LEFT of the ridge  -> MEMORY BOUND.  Faster arithmetic buys nothing.
                         Improve locality, blocking, data layout,
                         compression, or fuse operations.

   RIGHT of the ridge -> COMPUTE BOUND. Bandwidth is not the issue.
                         Vectorise, use more cores, better algorithms.
```

```
/* Compute the intensity of your kernel and place it on the roofline. */

/* vector add: c[i] = a[i] + b[i]   over floats */
   FLOPs  = 1 per element
   bytes  = 12 per element  (read a, read b, write c)
   I      = 0.083 FLOP/byte        -> deeply MEMORY BOUND

/* dot product: s += a[i] * b[i] */
   FLOPs  = 2 per element
   bytes  = 8 per element
   I      = 0.25                   -> still memory bound

/* dense matrix multiply, N x N, properly blocked */
   FLOPs  = 2 N^3
   bytes  ≈ 3 N^2  (each matrix read/written once, if it fits in cache)
   I      ≈ 2N / 3                 -> grows with N: COMPUTE bound

/* This is exactly why blocked matrix multiply is the canonical
   optimisation, and why machine-learning kernels are written as
   matrix multiplies whenever possible - it moves them to the right
   of the ridge. See AI chapter 04.                                  */
```

A TYPICAL RIDGE POINT TODAY

A modern core might reach 100 GFLOP/s with 25 GB/s of bandwidth per core — a ridge at I = 4 FLOP/byte. Most real code sits at I between 0.1 and 1. **The majority of programs are memory bound**, which is why chapters 13 to 15 matter more for performance than instruction-level tricks, and why hardware keeps adding cache rather than ALUs.

Hardware performance counters

Every modern core has a PMU that counts microarchitectural events. This is ground truth, not inference.

```
# the standard first look
perf stat ./program

#   12,405,281,113  cycles                    #  2.98 GHz
#   18,204,113,782  instructions              #  1.47  insn per cycle
#    3,201,554,231  branches
#       62,119,882  branch-misses             #  1.94% of all branches
#    1,905,332,110  cache-references
#      210,553,901  cache-misses              # 11.05% of cache refs

# read it in this order:
#   IPC < 0.5      -> stalled; find out on what
#   IPC 0.5 - 1.5  -> mixed
#   IPC > 2        -> compute bound; algorithmic work is next
#   branch-misses > 2%      -> chapter 12
#   cache-miss rate high    -> chapters 13-14

# then localise it
perf record -g ./program && perf report      # which functions
perf record -e cache-misses ./program        # which lines miss
perf annotate                                # which instruction

# ARM-specific detail
perf stat -e l1d_cache_refill,l2d_cache_refill,dtlb_walk,\
stall_frontend,stall_backend ./program

# stall_frontend high  -> instruction supply: I-cache, branch mispredicts
# stall_backend  high  -> data supply or execution: D-cache, dependencies
```

Top-down analysis

Rather than guessing, classify every issue slot into one of four buckets. Intel formalised this as Top-Down; ARM's equivalent uses the stall counters above.

```
   every cycle's issue slots
            |
      ┌─────┴──────┐
   retiring     not retiring
   (useful)          |
            ┌────────┴─────────┐
      bad speculation      stalled
      (mispredicts,          |
       machine clears)   ┌───┴────┐
                      frontend    backend
                      bound       bound
                      (I-cache,   (D-cache, DRAM,
                       decode,     execution ports,
                       branch)     dependencies)

Whichever bucket dominates tells you which chapter to reread:
  frontend bound  -> code layout, I-cache, chapter 12
  backend bound   -> data layout, chapters 13-15
  bad speculation -> chapter 12
  retiring high   -> you are done tuning; change the algorithm
```

Benchmarking honestly

Mistake	Why it lies	Fix
Measuring once	Noise from scheduling, frequency, other load	Many runs; report median and spread, not the best
Reporting the mean	One outlier dominates it	Median plus p95/p99, which is what users feel
Cold vs warm confusion	First run pays page faults and cache misses	Decide which you are measuring, and say so
Dead code elimination	The compiler deletes work whose result is unused	Consume the result; use a benchmark framework's `DoNotOptimize`
Unrealistic input	Tiny inputs fit in cache; sorted inputs predict perfectly	Use production-shaped data
Frequency scaling	Turbo and thermal throttling move the clock mid-run	Pin the governor, or measure cycles rather than seconds
Ignoring variance across cores	big.LITTLE cores differ several-fold	Pin with `taskset`
Optimising the benchmark	You improved the measurement, not the product	Confirm the win on the real workload

```
# make the machine quiet before you trust a number
sudo cpupower frequency-set -g performance     # fix the governor
taskset -c 2 ./program                          # pin to one core
sudo sh -c 'echo 3 > /proc/sys/vm/drop_caches'  # cold-start measurement

# measure cycles, not seconds, when the clock may move
perf stat -e cycles,instructions -r 20 ./program   # 20 runs, with stddev
```

Latency versus throughput

These are different goals and optimising one routinely harms the other. Be explicit about which you are being paid for.

	Latency	Throughput
Question	How long does one operation take?	How many per second?
Improved by	Shorter critical path, fewer dependent steps, avoiding queues	Batching, pipelining, parallelism, larger buffers
Harmed by	Batching (you wait for the batch to fill)	Small transfers, per-item overhead
Report as	Median, p95, p99, max	Operations or bytes per second
Matters most for	Interrupt handlers, control loops, interactive UI, RTOS	Bulk data, network, storage, batch compute

Little's Law connects them: $L = \lambda W$ — items in flight equal arrival rate times time in system. Raising throughput by adding queueing necessarily raises latency. In hard real-time work (OS chapter 19) only the *worst case* counts, and average throughput is irrelevant.

A workflow that works

1. **Establish a reliable measurement** of the thing you actually care about. If you cannot measure it repeatably, stop here — everything downstream is guesswork.
2. **Profile** to find where time goes. Use cost, not call count.
3. **Apply Amdahl** to the profile. Compute the best possible payoff for each candidate before you start.
4. **Classify the bottleneck** with counters or roofline: memory, compute, branch, frontend, I/O.
5. **Fix the largest one**, and only that one.
6. **Re-measure.** Confirm the predicted gain appeared. If it did not, your model was wrong — that is valuable information.
7. **Re-profile.** The bottleneck has moved. Repeat until the remaining gain is not worth the complexity.
8. **Keep the benchmark in CI** so the win does not silently regress.

How it shows up

Symptom	Cause
A big optimisation produced a tiny overall gain	Amdahl: you improved a small fraction of runtime
Vectorising gave no speedup at all	Memory bound — left of the roofline ridge
Adding cores stopped helping past four	Serial fraction, shared bandwidth, or lock contention
The benchmark improved, production did not	Unrepresentative input or a cache-resident working set
Results vary 20% between runs	Frequency scaling, core migration, other load
IPC is high but the program is slow	Executing a lot of unnecessary instructions — an algorithmic problem
IPC is very low with few cache misses	Long dependency chains, or frontend bound
Average latency is fine, users complain	You reported the mean; they experience p99

Check yourself

- ✓ Write the performance equation and say who controls each factor.

- ✓ Explain why MIPS and clock speed are not valid comparisons.
- ✓ Given a CPI breakdown, identify which stall to attack and predict the gain.
- ✓ Compute the maximum speedup when 80% of runtime is improvable.
- ✓ Define arithmetic intensity and compute it for a vector add and a matrix multiply.
- ✓ Explain what being left of the roofline ridge means for your next move.
- ✓ Name four benchmarking mistakes and how to avoid each.
- ✓ Explain why improving throughput can worsen latency.

Parallelism: ILP, SIMD, SMT and multicore

Clock speeds stopped rising around 2005. Everything since has come from doing more things at once. This chapter covers the four kinds of parallelism, which ones are free, which ones you must ask for, and why "add more cores" stops working.

Why parallelism became the only option

```
Dynamic power in CMOS:      P ≈ C × V² × f

  Raising frequency f raises power linearly — and requires raising
  voltage V to keep switching fast enough, which raises power by the
  SQUARE. So a 20% clock increase can cost ~70% more power.

  ~2005: the "power wall". Air cooling caps a chip around 100–150 W.
  Frequencies flattened at 3–4 GHz and have stayed there for 20 years.

  Meanwhile transistor counts kept doubling. The only way to spend
  them was on MORE UNITS rather than FASTER ones:

     more execution units per core        -> ILP
     wider registers                      -> SIMD
     more thread contexts per core        -> SMT
     more cores                           -> multicore
     specialised units                    -> accelerators, NPUs

This is the entire shape of modern computing, and it is a
consequence of one equation.
```

Flynn's taxonomy

	Single data	Multiple data
Single instruction	**SISD** — a classic scalar core	**SIMD** — one instruction, many elements: NEON, SVE, AVX, GPUs
Multiple instruction	**MISD** — essentially unused, except for redundant lockstep cores in safety systems	**MIMD** — multicore, multiprocessor, clusters

Instruction-level parallelism

Independent instructions in a single stream, executed simultaneously. **You do not ask for this — the hardware finds it.**

Technique	What it does	Covered in
Pipelining	Overlaps stages of consecutive instructions	ch. 11
Superscalar issue	Issues 2–8 instructions per cycle to different units	here
Out-of-order execution	Runs instructions as operands become ready, not in program order	ch. 11
Register renaming	Removes false (write-after-read/write) dependencies	ch. 11
Speculation	Executes past unresolved branches	ch. 12

```
What limits ILP, and what you can do about it

  TRUE DEPENDENCIES. A dependent chain cannot be parallelised at all.

     s = 0;
     for (i = 0; i < n; i++)
             s += a[i];        <- every add waits for the previous one
                                  4-cycle FP add latency = 4 cycles/element
                                  no matter how wide the core is

  Break the chain with accumulators - the single highest-value ILP
  optimisation available to a programmer:

     s0 = s1 = s2 = s3 = 0;
     for (i = 0; i < n; i += 4) {
             s0 += a[i];   s1 += a[i+1];      <- four INDEPENDENT chains
             s2 += a[i+2]; s3 += a[i+3];         now the 4-cycle latencies
     }                                           overlap
     s = (s0 + s1) + (s2 + s3);

  Typical result: ~4x faster, from an unchanged instruction count.

  Note the reassociation: this changes floating-point results
  (chapter 03), which is exactly why the compiler will NOT do it for
  you unless you pass -ffast-math. On integers it does it freely.
```

Beyond ~4-wide issue, ILP hits diminishing returns: real code simply does not contain enough independent work, and the hardware to find more grows quadratically. That is why cores stopped getting wider and started getting more numerous.

Data-level parallelism: SIMD

One instruction, several data elements. Cheap in hardware — one instruction fetch and decode drives many ALUs — but you or your compiler must express it.

```
   scalar                          SIMD (128-bit, 4 x float32)

   c[0] = a[0] + b[0];             ┌─────┬─────┬─────┬─────┐  a
   c[1] = a[1] + b[1];             ├─────┼─────┼─────┼─────┤
   c[2] = a[2] + b[2];             │  +  │  +  │  +  │  +  │  b
   c[3] = a[3] + b[3];             ├─────┼─────┼─────┼─────┤
                                   └─────┴─────┴─────┴─────┘  c
   4 instructions                  1 instruction

  ARM NEON      128-bit fixed        V0-V31
  ARM SVE/SVE2  128-2048, scalable   Z0-Z31 + predicates P0-P15
  x86 AVX2      256-bit
  x86 AVX-512   512-bit

SVE's key idea is VECTOR LENGTH AGNOSTIC code: the same binary runs
optimally on 128-bit and 512-bit implementations, because the loop is
written against a runtime length with predication for the tail.
No recompilation, no dispatch table.
```

```
/* Four ways to get SIMD, in order of preference */

/* 1. Let the compiler do it. Write clean, obviously independent loops. */
void add(float *restrict c, const float *a, const float *b, int n) {
        for (int i = 0; i < n; i++)
                c[i] = a[i] + b[i];
}
/* -O3 -march=armv8-a+simd emits NEON automatically.
   `restrict` is what makes it legal: it promises the arrays do not
   overlap, so the compiler may reorder the accesses. Without it the
   compiler must assume c may alias a, and vectorisation is unsafe. */

/* Check whether it actually happened - do not assume: */
//   gcc -O3 -fopt-info-vec-missed   (tells you WHY it did not)

/* 2. OpenMP, when the compiler needs permission */
#pragma omp simd
for (int i = 0; i < n; i++) c[i] = a[i] + b[i];

/* 3. Intrinsics: explicit, portable across compilers, readable */
#include <arm_neon.h>
for (int i = 0; i < n; i += 4) {
        float32x4_t va = vld1q_f32(a + i);
        float32x4_t vb = vld1q_f32(b + i);
        vst1q_f32(c + i, vaddq_f32(va, vb));
}

/* 4. Hand-written assembly. Rarely justified; hard to maintain. */
```

WHY YOUR LOOP DID NOT VECTORISE

The compiler must *prove* the transformation is safe. Common blockers, roughly in order of frequency: possible pointer aliasing (fix with `restrict`); a loop-carried dependency; a data-dependent early exit or `break`; function calls that cannot be inlined; a non-contiguous or indirect access pattern (`a[idx[i]]`); floating-point reassociation that would change results; and a trip count unknown at compile time combined with expensive tail handling. Ask the compiler with `-fopt-info-vec-missed` rather than guessing — it will name the reason.

SIMD DOES NOT RESCUE A MEMORY-BOUND LOOP

Vector add has an arithmetic intensity of about 0.08 FLOP/byte — far left of the roofline ridge (chapter 18). Making the arithmetic 4× faster changes nothing when you are waiting on DRAM. Vectorise things that are compute bound, or fix the memory behaviour first. This is the most common reason a carefully vectorised loop shows no improvement.

Thread-level parallelism on one core: SMT

Simultaneous multithreading keeps two or more architectural contexts in one physical core, so when one thread stalls the other uses the idle execution units.

Duplicated per thread	Shared between threads
Architectural registers, program counter, exception state	Execution units, caches, TLBs, branch predictors, memory bandwidth

```
Typical gain: 10–30%, for maybe 5% extra area. Excellent value —
when the threads stall a lot and do not fight over cache.

When SMT HURTS:
  · both threads are compute bound and already saturating the units
  · they have large, distinct working sets, so each halves the other's
    effective cache
  · latency matters: your thread now shares a core with an unknown
    neighbour, so worst-case timing becomes unpredictable
  · SECURITY: sharing caches and predictors is a side channel. Threads
    can observe each other. Cloud providers and hardened systems often
    disable SMT entirely for this reason.

ARM's application cores generally do NOT implement SMT — the design
choice has been more, simpler cores instead. Some Neoverse and
specialised ARM cores do. x86 calls it Hyper-Threading.
```

Multicore

```
Homogeneous                     Heterogeneous (big.LITTLE, DynamIQ)

  4x identical cores              2x big  (wide, OoO, high power)
  simple scheduling               4x LITTLE (narrow, in-order, efficient)
                                  same ISA, very different performance

  Heterogeneity buys energy efficiency: run background work on the
  LITTLE cores at a fraction of the power, migrate to big under load.

  What it costs YOU:
    · benchmark results depend on which core you landed on
    · a thread can migrate mid-measurement
    · worst-case timing analysis must assume the slowest core
    · pin with taskset when measuring anything (chapter 18)
```

Why adding cores stops helping

Limit	Mechanism	What to do
Amdahl's serial fraction	The sequential part never shrinks	Parallelise more of it, or accept the ceiling
Lock contention	Threads serialise on a shared lock	Finer-grained locks, per-CPU data, lock-free structures, RCU
Memory bandwidth	All cores share one memory controller	Improve locality; reduce bytes moved (ch. 13)
Cache coherence traffic	Shared lines ping-pong between cores	Pad to line boundaries; avoid shared writes (ch. 15)
False sharing	Unrelated variables in one cache line	Align per-thread data to 64 bytes
Load imbalance	One thread finishes last; the rest idle	Dynamic scheduling, work stealing, smaller chunks
Synchronisation overhead	Barriers and joins cost more than the work	Coarser tasks; fewer barriers
Power and thermal	All-core turbo is lower than single-core turbo	Nothing — it is physics (ch. 20)

> **NEGATIVE SCALING IS A SPECIFIC, DIAGNOSABLE BUG**
>
> If throughput *decreases* as you add threads, you are almost certainly looking at false sharing or lock contention — not at a fundamental limit. Confirm with `perf c2c` and lock profiling before concluding the problem is not parallelisable. Genuine bandwidth saturation flattens the curve; contention bends it downwards.

Parallel programming models

Model	Shape	Good for	Hazard
Shared memory threads	pthreads, `std::thread`	Fine-grained work on one machine	Races, deadlock, false sharing
Task / work stealing	OpenMP tasks, TBB, Rayon	Irregular and recursive work	Task granularity too fine
Data parallel	`#pragma omp parallel for`	Regular loops over arrays	Load imbalance; false sharing at chunk edges
Message passing	MPI, channels, actors	Distributed memory; no shared state by construction	Message overhead; harder to load balance
SPMD / GPU	CUDA, OpenCL, Vulkan compute	Massive regular data parallelism	Divergence, transfer cost, memory coalescing
Pipeline	Stages connected by queues	Streaming; heterogeneous stages	The slowest stage sets throughput

```
/* the same loop, three ways */

/* data parallel */
#pragma omp parallel for schedule(dynamic, 64) reduction(+:sum)
for (int i = 0; i < n; i++)
        sum += heavy(a[i]);
/* `dynamic` handles imbalance when heavy() varies per element;
   `reduction` gives each thread a private accumulator and combines
   them at the end - which is exactly the false-sharing fix from
   chapter 15, done for you.                                    */

/* explicit threads with per-thread state, padded */
struct alignas(64) partial { double sum; };
std::vector<partial> parts(nthreads);        /* one cache line each */

/* pipeline */
stage1 -> queue -> stage2 -> queue -> stage3
/* throughput = 1 / max(stage time). Balance the stages, and size
   the queues to absorb jitter without adding needless latency.   */
```

Measuring parallel efficiency

```
speedup    S(n) = T(1) / T(n)
efficiency E(n) = S(n) / n          # 1.0 = perfect

# plot efficiency against thread count. The SHAPE is diagnostic:
#   flat near 1.0           -> scaling well, keep going
#   gradual decline         -> Amdahl's serial fraction, or bandwidth
#   sharp knee              -> a resource saturated: bandwidth or a lock
#   DECREASING below 1 core -> false sharing or contention. A bug.

perf stat -e cycles,instructions ./program          # per-thread IPC
perf c2c record ./program                           # false sharing
perf lock record ./program && perf lock report      # lock contention
perf record -e sched:sched_switch                   # migration, imbalance
```

How it shows up

Symptom	Cause
4 threads give 1.3× speedup	Large serial fraction, or bandwidth saturation
Throughput falls as threads are added	False sharing or lock contention
Vectorised loop shows no gain	Memory bound; SIMD was never the bottleneck
Compiler refuses to vectorise a simple loop	Possible aliasing — add `restrict`
Manual unrolling with accumulators gives 4×	You broke a true dependency chain — an ILP win
Results differ between scalar and vector versions	Floating-point reassociation (ch. 03)
Benchmark varies 3× between runs	Thread landed on a LITTLE core; pin it
Disabling SMT made a latency-sensitive service faster	Contention and unpredictable sharing on the physical core
All-core workload runs at a lower clock than single-core	Power and thermal budget (ch. 20)

Check yourself

- ✓ Explain from $P \approx CV^2f$ why clock speeds stopped rising.
- ✓ Give the four kinds of parallelism and say which require programmer effort.
- ✓ Show how multiple accumulators break a dependency chain, and why the compiler will not do it for floats.
- ✓ Explain what `restrict` promises and why vectorisation needs it.
- ✓ Explain why SIMD does not help a memory-bound loop.
- ✓ Say what SMT duplicates, what it shares, and give two reasons to disable it.
- ✓ List five reasons adding cores stops helping, and how you would distinguish them.
- ✓ Interpret an efficiency-versus-threads curve that decreases below 1.0.

Power, energy and thermal limits

Power is the constraint that shapes every modern design decision — why clocks stopped rising, why phones have big and LITTLE cores, why your laptop is fast for ten seconds. For battery-powered embedded work it is often the primary specification, not an afterthought.

Power versus energy

TWO DIFFERENT QUANTITIES, TWO DIFFERENT GOALS

Power (watts) is the instantaneous rate. It determines heat, and therefore cooling, package and thermal throttling.

Energy (joules = watts × seconds) is the total consumed. It determines battery life.

They pull in different directions. Running twice as fast at three times the power *saves* energy if the device can then sleep — the "race to idle" strategy. Deciding which you are optimising is the first question in any power discussion, and getting it wrong wastes months.

Where the power goes

```
   P_total  =  P_dynamic  +  P_static

   P_dynamic = α × C × V² × f        switching: charging and
                                      discharging gate capacitance
        α  activity factor — fraction of gates toggling per cycle
        C  capacitance — grows with transistor count and wire length
        V  supply voltage
        f  clock frequency

   P_static  = I_leak × V            leakage: current through
                                      transistors that are "off"

Two facts follow, and they explain most of modern computing:

  1. V is SQUARED. Halving the voltage quarters dynamic power.
     But lower voltage means slower switching, so f must drop too.
     Reducing both gives roughly CUBIC savings — this is the entire
     basis of dynamic voltage and frequency scaling.

  2. Leakage grows as transistors shrink and as temperature rises,
     and it is paid whenever the circuit is powered at all — even
     idle. At modern nodes it can be 30–40% of total power. Hence
     POWER GATING: physically disconnect unused blocks, do not
     merely stop clocking them.
```

Why performance costs so much more than it returns

```
/* Approximate, but the shape is right and it is the shape that matters. */

  frequency   voltage   dynamic power   relative performance
  ──────────────────────────────────────────────────────────

   1.0 GHz     0.7 V        1.0 x             1.0 x
   1.5 GHz     0.8 V        1.96 x            1.5 x
   2.0 GHz     0.9 V        3.31 x            2.0 x
   2.5 GHz     1.05 V       5.63 x            2.5 x
   3.0 GHz     1.2 V        8.82 x            3.0 x

   3x the performance costs ~9x the power.
   Or, read the other way: HALF the frequency at reduced voltage
   costs about ONE EIGHTH the power.

This is why:
  · a LITTLE core at 1 GHz does background work at a tiny fraction
    of the energy a big core would spend
  · two cores at 1.5 GHz beat one at 3 GHz on both power AND
    throughput — when the work parallelises
  · "turbo" is a short-duration exception, not a sustainable state
```

The three walls

Wall	What happened	Consequence
Power wall (~2005)	Air cooling caps a chip at roughly 100–150 W; frequency scaling hit that ceiling	Clocks flattened at 3–4 GHz. Performance now comes from parallelism (ch. 19).
End of Dennard scaling (~2006)	Historically, shrinking transistors let voltage drop proportionally, keeping power per area constant. Below ~1 V, threshold voltage and leakage stopped that.	More transistors no longer come with free power savings.
Dark silicon	You can fit more transistors on a die than you can afford to switch simultaneously	Chips are full of specialised blocks — video codecs, NPUs, crypto engines — used one at a time. Specialisation became the way to spend transistors.

> **WHY ACCELERATORS EXIST**
>
> A fixed-function block doing one job — H.265 decode, AES, convolution — can be 10 to 1000× more energy efficient than a general-purpose core doing the same work, because it eliminates instruction fetch, decode, register file traffic and speculation. Dark silicon makes that trade obviously worthwhile: the block costs area, which is cheap, and saves energy, which is not. This is why a modern SoC is mostly *not* CPU, and why NPUs appeared in phones.

How hardware saves power

Technique	Mechanism	Attacks	Wake cost
Clock gating	Stop the clock to an idle block	Dynamic (f → 0)	~free, a cycle
Power gating	Disconnect the supply entirely	Dynamic *and* leakage	State is lost; µs to ms to restore
DVFS	Scale voltage and frequency together to match demand	Dynamic, cubically	µs; voltage rails settle slowly

Technique	Mechanism	Attacks	Wake cost
Heterogeneous cores	Migrate work to an efficient core	Dynamic	Migration + cache warm-up
Retention states	Low voltage that preserves SRAM contents but cannot run	Leakage, partially	Faster than full power-off
Race to idle	Finish fast, then enter a deep sleep state	Total energy	Depends on wake latency
Accelerators	Fixed-function hardware for hot workloads	Energy per operation	Setup and data movement

Idle states are a hierarchy, and deeper is not always better

```
ACPI C-states / ARM idle states — deeper saves more, wakes slower

  C0 / running     executing instructions
  C1 / WFI         clock gated, caches live          wake: ~ns
  C2               deeper clock gating               wake: ~µs
  C3               L1/L2 flushed, caches off         wake: ~10s of µs
  C6+ / power off  core powered down, state saved    wake: ~100s of µs
                   to always-on memory

  ARM's WFI (wait for interrupt) and WFE (wait for event) are the
  instructions that request this; PSCI CPU_SUSPEND selects the depth.

THE BREAK-EVEN CALCULATION that governs every idle decision:

  entering a state costs E_transition and T_wake.
  It is only worth entering if the expected idle time exceeds

        T_breakeven = E_transition / (P_shallow - P_deep)

  An OS governor predicts the next wake (from timers and past
  behaviour) and picks the deepest state whose break-even it clears.
  Predict wrong and you spend MORE energy than you saved.
```

> **WHY A PERIODIC TIMER IS EXPENSIVE OUT OF PROPORTION TO ITS WORK**
>
> A task that wakes every 1 ms to do nothing prevents the system from ever reaching a deep idle state. The work is negligible; the *lost sleep* is not. This is why Linux has a tickless kernel (`NO_HZ`), why timer coalescing and deferrable timers exist, and why a single badly written polling loop can halve a device's battery life. When profiling power, count *wakeups*, not CPU percentage — `powertop` exists precisely to show you this.

Thermal behaviour

```
   T_junction = T_ambient + P × R_thermal

     R_thermal = thermal resistance, °C per watt, from junction to air.
     Determined by package, heatsink, airflow, and PCB copper.

A phone SoC might have R_thermal ≈ 15 °C/W with no heatsink.
     5 W sustained  ->  75 °C above ambient  ->  throttling.

Which is why:

   · sustained performance is often HALF of burst performance
   · a benchmark's first 10 seconds do not predict the next 10 minutes
   · thermal throttling is a PERFORMANCE bug you cannot fix in software
   · leakage rises with temperature, and leakage generates heat —
     a positive feedback loop that must be actively broken by
     throttling, or the part destroys itself
```

Concept	Meaning
TDP	Thermal Design Power — what the cooling must remove. Not maximum power, and not average power. A design target, frequently misread as a spec.
Sustained vs burst	Short bursts exploit thermal mass; sustained load is limited by $R_{thermal}$
Throttling	Firmware reduces frequency and voltage when a temperature limit is hit
Thermal mass	Heat capacity that buys time before the limit is reached — why turbo works at all
Hot spots	Temperature is not uniform; the GPU corner may throttle while the die average looks fine

What software controls

```
Ranked by leverage. The top of this list dwarfs the bottom.

  1. DO LESS WORK.
     A better algorithm saves energy in every term at once. No power
     technique competes with not executing the instructions.

  2. MOVE LESS DATA.
     Energy per operation, roughly, at a modern node:
        32-bit integer add          ~0.1 pJ
        32-bit float multiply       ~1 pJ
        32-bit SRAM (cache) read    ~5 pJ
        32-bit DRAM read           ~200 pJ   <- 2000x the add
        wireless transmit, per bit  ~1000 pJ

     A DRAM access costs more energy than a thousand arithmetic
     operations. Cache optimisation (chapters 13-14) is therefore
     ALSO the most effective power optimisation available to you.

  3. SLEEP MORE, AND DEEPER.
     Batch work. Coalesce timers. Use interrupts, never polling.
     Minimise wakeups, not just CPU time.

  4. USE THE RIGHT UNIT.
     Offload to an accelerator, or to a LITTLE core.

  5. LET THE GOVERNOR DO ITS JOB.
     Do not pin frequency to maximum "for consistency" outside
     of a measurement session.
```

```
/* polling versus interrupts, in energy terms */

/* BAD: the core never sleeps, the whole SoC stays in a shallow state */
while (!(readl(base + STATUS) & READY))
        ;

/* BETTER: sleep until the hardware says something happened */
wait_event_interruptible(dev->wq, dev->ready);

/* In bare metal, WFI is the whole idea: */
    while (!ready) {
        __asm__ volatile("wfi");   /* clock-gate until an interrupt */
    }

/* Batching beats spreading: 100 wakeups doing 1 unit of work each
   costs far more than 1 wakeup doing 100 units, because each wakeup
   pays the transition energy and blocks deep idle.               */
```

Measuring power

```
# Linux: where are the wakeups coming from?
sudo powertop                    # per-process wakeups/second and estimated power
sudo powertop --auto-tune        # applies known-good power settings

# what state is the CPU actually in?
cpupower monitor                 # residency in each C-state and P-state
cat /sys/devices/system/cpu/cpu0/cpufreq/scaling_cur_freq
cat /sys/devices/system/cpu/cpu0/cpufreq/scaling_governor

# thermal zones and trip points
cat /sys/class/thermal/thermal_zone*/type
cat /sys/class/thermal/thermal_zone*/temp     # millidegrees C

# on-die energy counters, where available
perf stat -e power/energy-pkg/ ./program

# battery-powered embedded work: an external measurement is
# ground truth. A current-sense resistor plus a scope, or a
# purpose-built power analyser, shows the wakeup pattern directly
# in a way no software counter can.
```

Power in embedded design

Class	Budget	Dominant concern
Energy harvesting	µW	Sleep current. The device is asleep >99.9% of the time; active power barely matters.
Coin-cell sensor	10 µA average	Duty cycle and radio energy per packet
Wearable	mW	Wakeup frequency; always-on sensing on a low-power island
Phone	1–8 W	Thermal limits, big.LITTLE scheduling, display and radio
Automotive / industrial	W–kW	Thermal reliability over a wide temperature range

```
/* Average current for a duty-cycled sensor — the calculation that
   determines whether a product ships.                              */

   sleep current      2 µA
   active current     8 mA
   active time        20 ms per reading
   reading interval   10 s

   duty cycle = 0.020 / 10 = 0.2%
   I_avg = 0.002 × 8000 µA + 0.998 × 2 µA
         = 16 µA + 2 µA = 18 µA

   225 mAh coin cell / 0.018 mA ≈ 12,500 hours ≈ 1.4 years

   Now suppose a firmware bug leaves the radio in idle at 200 µA:
   I_avg = 218 µA  ->  43 days.

   Same code, same features, 12x shorter life. Sleep current is
   almost always the number that decides the product.            */
```

How it shows up

Symptom	Cause
Benchmark is fast for 10 s then drops 40%	Thermal throttling; the burst exploited thermal mass
All-core workload runs at a lower clock than single-core	Power budget shared across cores
Battery life is a fraction of the calculation	Sleep current higher than assumed, or a peripheral left enabled
Device never enters deep idle	A periodic timer or polling loop preventing it
Performance varies between identical units	Silicon variation, cooling differences, or ambient temperature
Results differ between runs at the same nominal frequency	DVFS transitions and core migration
Cache optimisation reduced power measurably	DRAM accesses cost ~2000× an ALU operation
An accelerator is slower but the battery lasts longer	Optimising energy, not latency — often the correct trade
Timing analysis fails on a big.LITTLE system	Worst case must assume the LITTLE core at its lowest frequency

Check yourself

- ✓ State the difference between power and energy, and give a case where they conflict.
- ✓ Write the dynamic power equation and explain why voltage is the important term.
- ✓ Explain why 3× frequency costs roughly 9× power.
- ✓ Describe the power wall, the end of Dennard scaling and dark silicon, and what each caused.
- ✓ Distinguish clock gating from power gating and say what each attacks.
- ✓ Give the break-even condition for entering a deeper idle state.
- ✓ Explain why a 1 ms periodic timer is expensive out of proportion to its work.
- ✓ Compare the energy of an integer add and a DRAM access, and say what that implies for optimisation.
- ✓ Compute average current for a duty-cycled sensor and show why sleep current dominates.

TRACK COMPLETE

That closes the computer architecture track. You now have the vocabulary every other track on this site assumes: binary representation, logic, the stored-program model, pipelines, the memory hierarchy, coherence, virtual memory, I/O, and the performance and power models used to reason about all of it.

From here, the C track makes these ideas concrete in a language, and the ARM track makes them concrete in a real architecture.

TRACK

The C language

C is the language of every kernel, driver and bootloader on this site. This track covers it to the depth a systems programmer actually needs.

20 chapters

The C abstract machine and translation phases

C does not describe what your processor does. It describes a hypothetical machine, and the compiler must only produce a program that *behaves as if* that machine ran it. Everything confusing about C — optimisation surprises, undefined behaviour, `volatile` — follows from this one idea.

What C actually is

Beginners learn C as "portable assembly": each statement becomes a few instructions. That model is wrong, and it will mislead you for years.

> **THE AS-IF RULE**
>
> The C standard defines an **abstract machine** with its own rules for evaluation, storage and side effects. A conforming implementation must reproduce the abstract machine's *observable behaviour* — and nothing else is guaranteed. Observable behaviour is:
>
> - accesses to `volatile` objects, exactly as written;
> - data written to files at program termination;
> - interactive input and output prompts, appearing before the reads they prompt.
>
> Everything else — how many instructions, which registers, whether a variable exists at all, in what order independent computations happen — is the compiler's business.

```
/* You wrote this: */
int f(void) {
        int a = 10;
        int b = 20;
        int c = a * b;
        int d[100];
        for (int i = 0; i < 100; i++) d[i] = i;
        return c;
}

/* GCC -O2 emits this: */
f:
        mov     w0, #200
        ret

/* The array, the loop, and the variables never existed. Nothing about
   them was observable, so the abstract machine permits their removal.
   The compiler is not "cheating" — it is doing exactly what C says. */
```

Why this matters immediately

You expect	The abstract machine says	Consequence
A loop that reads a hardware register will re-read it	Nothing changed the object, so one read suffices	Infinite loop unless you use `volatile` (ch. 10)
Zeroing a password buffer before `free` will happen	The buffer is dead afterwards; the store is unobservable	The `memset` is deleted; secrets remain in memory

You expect	The abstract machine says	Consequence
Signed overflow wraps like the hardware does	Signed overflow is undefined; assume it never happens	Your overflow check is deleted (ch. 15)
Two writes to different globals happen in order	Neither is observable in isolation	Another core sees them reordered (CA ch. 15)
Local variables live on the stack	Storage is only required if the address is taken	They live in registers; a debugger shows <optimized out>

THE MENTAL SHIFT

Stop asking "what instructions will this produce?" and start asking **"what am I permitted to assume?"** The compiler is not your adversary, but it is a strict contract lawyer: it will use every freedom the standard grants. Code that relies on unguaranteed behaviour works until the day you raise the optimisation level, change compilers, or upgrade GCC — and then fails in production.

The eight translation phases

The standard defines translation as a sequence of phases. Knowing them explains a whole class of otherwise baffling errors.

```
1  Map physical source characters to the source character set.
   Trigraphs (??= for #) replaced. Removed in C23; good riddance.

2  Splice lines ending in backslash-newline.
   -> why a stray space AFTER the backslash in a multi-line macro
      breaks it: the backslash is no longer at end of line.

3  Decompose into preprocessing tokens and whitespace.
   Comments become a single space HERE — so a comment cannot be
   produced by a macro, and /* */ inside a string literal is text.

4  Execute preprocessing directives, expand macros, and recursively
   process #include files. Phases 1-4 run again on each header.
   -> #include is literal text substitution. Nothing more.

5  Convert escape sequences and characters in literals to the
   execution character set.

6  Concatenate adjacent string literals.
   -> "abc" "def" becomes "abcdef". This is why the PRIu32 macros
      work:  printf("%" PRIu32 "\n", x)

7  COMPILE. Tokens are analysed syntactically and semantically,
   and translation units become object code.

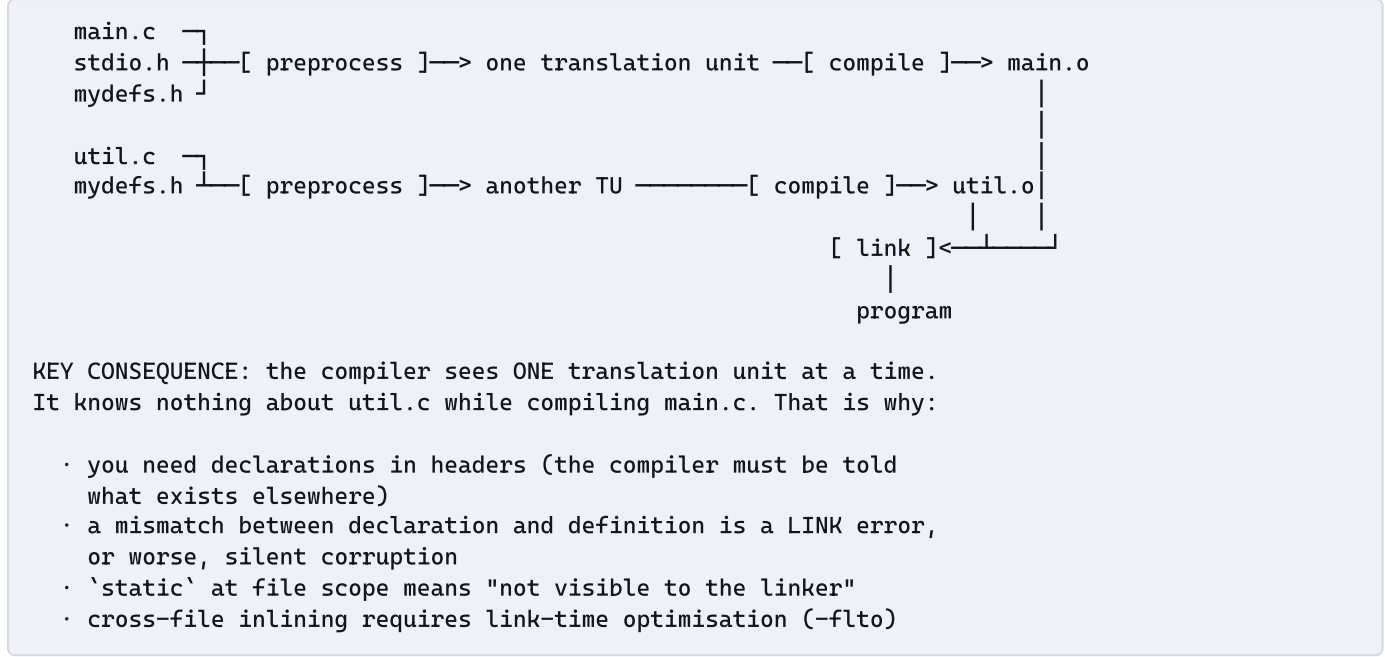
8  LINK. Resolve external references; combine translation units
   and library components into the final image.
```

```
/* Phase 2 in action — the classic multi-line macro bug */
#define SWAP(a, b) do {  \
        int t = (a);     \
        (a) = (b);       \ <-- one trailing space here
        (b) = t;         \
} while (0)
/* error: unterminated argument list / stray '\'
   because the line no longer ends in backslash-newline.       */

/* Phase 6 in action — adjacent literal concatenation */
#include <inttypes.h>
printf("count = %" PRIu32 " items\n", n);
/* PRIu32 expands to "u" (or "lu"), and phase 6 glues the three
   literals into one format string. This is how the standard makes
   printf portable across platforms with different int widths.  */
```

The translation unit

C's unit of compilation is one source file *after preprocessing* — the file plus every header it included, textually pasted in.



```
KEY CONSEQUENCE: the compiler sees ONE translation unit at a time.
It knows nothing about util.c while compiling main.c. That is why:

  · you need declarations in headers (the compiler must be told
    what exists elsewhere)
  · a mismatch between declaration and definition is a LINK error,
    or worse, silent corruption
  · `static` at file scope means "not visible to the linker"
  · cross-file inlining requires link-time optimisation (-flto)
```

```
/* the classic silent disaster this enables */

/* a.c */                          /* b.c */
int counter;                       extern short counter;   /* WRONG type */
void inc(void) { counter++; }      void reset(void) { counter = 0; }

/* Each TU compiles cleanly. The linker matches them by NAME only.
   b.c writes 2 bytes where a.c expects 4. Result: corruption that
   depends on endianness and layout.

   The fix is structural, not a matter of care: declare it ONCE, in a
   header, and include that header in BOTH files — including the one
   that defines it, so the compiler checks the definition against
   the declaration.                                                  */

/* counter.h */
extern int counter;
void inc(void);
void reset(void);
```

Sequencing and the abstract machine's clock

The abstract machine does not execute one statement at a time in a simple order. It has **sequence points** (C99) or, more precisely, a *sequenced-before* relation (C11).

Guaranteed sequenced	NOT sequenced
End of a full expression (the `;`)	Between function arguments
Between `&&` and `||` operands	Between the two operands of `+`, `*`, `=`
Between `,` operator operands	Between subexpressions generally
Before a function call's body runs	Two calls in one expression: order unspecified
Between `?:` condition and the chosen branch	

```
/* Undefined behaviour: i modified twice with no sequencing between */
i = i++ + 1;
a[i] = i++;
f(i++, i++);          /* also: argument evaluation order is unspecified */

/* Well defined, because && sequences its operands */
if (p != NULL && p->field > 0)      /* p->field is not evaluated if p is NULL */

/* Unspecified but NOT undefined: the order of the two calls */
printf("%d %d\n", g(), h());        /* g may run before or after h */

/* This is why the "clever" one-liner is a genuine bug, not a style
   issue. There is no "what it does on my compiler" — the standard
   permits anything, including formatting your disk, and in practice
   different optimisation levels give different answers.          */
```

Objects, values and lvalues

Term	Meaning
Object	A region of storage whose contents can represent values. Not "an instance of a class" — C has no classes.

Term	Meaning
Value	The meaning of an object's contents, as interpreted by its type
Lvalue	An expression that designates an object. "Locator value" — it has an address.
Rvalue	Informally, the value of an expression. The standard says "value of an expression".
Effective type	The type through which an object may be accessed. Violating it breaks strict aliasing (ch. 15).
Lifetime	The span during which storage is guaranteed reserved. Using an object outside its lifetime is undefined.

```
int x = 5;
int *p = &x;

x        /* lvalue: designates the object x        */
*p       /* lvalue: designates the object x        */
x + 1    /* not an lvalue: designates no object    */
&x       /* not an lvalue: the address is a value  */

x = 10;      /* fine: lvalue on the left  */
x + 1 = 10;  /* error: not an lvalue      */

/* Arrays are lvalues that are NOT assignable — a distinct category
   the standard calls "non-modifiable lvalue". Hence: */
int a[10], b[10];
a = b;       /* error, even though both are lvalues */
```

The abstract machine's memory model

```
C guarantees FOUR storage durations, not "the stack and the heap".
Where they physically live is the implementation's choice.

  static        exists for the whole program run
                globals, file-scope and function-scope `static`
                zero-initialised if not explicitly initialised
                -> typically .data and .bss

  thread        one instance per thread (_Thread_local, C11)
                -> typically thread-local storage blocks

  automatic     exists from block entry to block exit
                ordinary local variables
                INDETERMINATE unless you initialise them
                -> typically registers or the stack; often neither,
                   if the optimiser can prove no storage is needed

  allocated     from malloc/calloc/realloc until free
                -> typically the heap

The words "stack" and "heap" appear NOWHERE in the C standard. A
freestanding implementation (chapter 20) may have no heap at all.
```

Hosted versus freestanding

The standard defines two conformance levels, and the distinction is exactly the one that matters for kernel and bare-metal work.

	Hosted	Freestanding
Entry point	`main()` with the standard signature	Implementation-defined — `_start`, `Reset_Handler`, `DriverEntry`
Library	The complete standard library	Only headers with no runtime: `<stddef.h>`, `<stdint.h>`, `<stdbool.h>`, `<limits.h>`, `<stdarg.h>`, `<float.h>`, `<iso646.h>`, `<stdalign.h>`, `<stdnoreturn.h>`
Examples	Application on Linux or Windows	Linux kernel, bootloaders, Cortex-M firmware, UEFI

```
# building freestanding — what these flags actually mean
aarch64-none-elf-gcc \
    -ffreestanding \      # do not assume the standard library exists
    -nostdlib \           # do not link libc or the startup files
    -fno-builtin \        # do not replace calls with builtin versions
    -fno-stack-protector \
    -c main.c

# -fno-builtin matters more than it looks. Without it, GCC may turn
# a hand-written loop into a call to memcpy() — which does not exist
# in your freestanding image. Linker error, in a function you never
# called. The Linux kernel builds with -ffreestanding for this reason.
```

Standard versions

Standard	Worth knowing for
C89 / C90	Declarations at the top of a block only; no `//` comments. Still mandated in some safety-critical and legacy codebases.
C99	`//` comments, declarations anywhere, `<stdint.h>`, `<stdbool.h>`, `inline`, VLAs, designated initialisers, compound literals, `restrict`
C11	`_Atomic`, `_Thread_local`, `_Static_assert`, `_Alignas` / `_Alignof`, anonymous structs and unions, a real memory model
C17	Bug fixes only; no new features
C23	`nullptr`, `constexpr`, `typeof`, binary literals, `[[attributes]]`, `bool` / `static_assert` as keywords, trigraphs removed

```
# always state the standard explicitly; the default varies by compiler version
gcc -std=c11 -pedantic       # strict ISO C11
gcc -std=gnu11               # C11 plus GNU extensions (the Linux kernel uses gnu11/gnu17)

# GNU extensions you WILL meet in kernel code, and should recognise
typeof(x) tmp;                       /* now standard in C23    */
({ int a = f(); a * a; })            /* statement expressions  */
__attribute__((packed, aligned(4)))
[0 ... 15] = 0                       /* range initialisers     */
```

How it shows up

Symptom	Cause
Code works at `-O0`, breaks at `-O2`	You relied on behaviour the abstract machine does not guarantee
A polling loop never exits	Missing `volatile`; the compiler hoisted the load

Symptom	Cause
A debugger reports `<optimized out>`	The variable was never given storage — it was not observable
Multi-line macro fails with "stray backslash"	Trailing whitespace after the line continuation (phase 2)
Clean compile, wrong values at runtime across files	Mismatched declaration and definition; no shared header
`i = i++ + 1` differs between compilers	Undefined behaviour, not implementation choice
Link error for `memcpy` you never called	The compiler generated it; build with `-fno-builtin`
A `memset` that scrubs a key is deleted	Dead store elimination; use `memset_s` or a `volatile` pointer

Check yourself

- ✓ State the as-if rule and list what counts as observable behaviour.
- ✓ Explain why a compiler may delete an entire loop, and when it may not.
- ✓ Name the eight translation phases and one bug each of phases 2, 4 and 6 explains.
- ✓ Define a translation unit and explain why a type mismatch across files can pass the build.
- ✓ Give three expressions that are undefined because of missing sequencing.
- ✓ Name the four storage durations and say which are initialised for you.
- ✓ State two differences between hosted and freestanding, and why `-fno-builtin` matters.

Types, ranks and integer promotion

C silently converts operand types before almost every operation. The rules are precise, mostly invisible, and responsible for a remarkable share of real security vulnerabilities. This chapter makes them explicit.

The types, and what is actually guaranteed

C does not fix the size of its integer types. It fixes *minimum ranges*, and leaves the rest to the implementation.

Type	Guaranteed minimum	Typical LP64 (Linux/ARM64)	Typical LLP64 (Windows x64)
`char`	8 bits	8	8
`short`	16 bits	16	16
`int`	16 bits	32	32
`long`	32 bits	**64**	**32**
`long long`	64 bits	64	64
`void *`	—	64	64

THE SINGLE MOST EXPENSIVE ASSUMPTION IN C

`long` is 64-bit on Linux and macOS, and 32-bit on Windows. Code that stores a pointer or a file offset in a `long` compiles cleanly on both and silently truncates on one. Every large port between these platforms has hit this. The rule: **never use `long` when you mean "64 bits"** — use `int64_t`, and use `size_t` / `uintptr_t` for sizes and pointer-sized integers.

The types you should actually use

```
#include <stdint.h>
#include <stddef.h>
#include <inttypes.h>

/* exact width — use these for anything that touches hardware,
   a file format, or the wire. They are optional in the standard
   but present on every platform you will meet.                  */
int8_t  int16_t  int32_t  int64_t
uint8_t uint16_t uint32_t uint64_t

/* at-least width, possibly faster than the exact type */
int_least32_t   int_fast32_t

/* pointer-sized integers */
intptr_t  uintptr_t          /* a pointer fits in these           */
ptrdiff_t                    /* result of subtracting pointers    */

/* sizes and counts */
size_t                       /* result of sizeof; unsigned        */
ssize_t                      /* POSIX: a size or -1 for error     */

/* printing them portably — this is what <inttypes.h> is for */
printf("%" PRIu32 " %" PRIx64 "\n", a, b);
printf("%zu %td %p\n", sz, diff, (void *)ptr);
/* %zu for size_t, %td for ptrdiff_t, and cast to void* for %p —
   all three are required, and all three are commonly got wrong.  */
```

Integer promotion

> **THE RULE**
>
> In almost any arithmetic context, any operand of a type whose rank is lower than `int` — `char`, `short`, `_Bool`, bitfields — is first converted to `int`, if `int` can represent all its values. Otherwise to `unsigned int`.
>
> This happens *before* the operator is applied, and it happens whether you want it or not.

```
uint8_t a = 200, b = 100;

uint8_t c = a + b;
/* What happens:
     a is promoted to int -> 200
     b is promoted to int -> 100
     the addition is done in int -> 300      (NO wraparound here)
     the result is converted back to uint8_t -> 300 % 256 = 44
   So c == 44, but the intermediate value really was 300.        */

/* This matters when you check for overflow: */
if (a + b > 255)     /* TRUE — the comparison is done in int */
        handle_overflow();
/* ...which is what you wanted. But: */
if ((uint8_t)(a + b) < a)
        handle_overflow();   /* also works, and is the usual idiom */
```

```
/* The classic promotion surprise */
uint16_t x = 0xFFFF;
uint16_t y = ~x;                 /* what is y? */

/* Step by step:
     x promotes to int:        0x0000FFFF
     ~ applied in int:         0xFFFF0000   (int is 32-bit)
     converted back to uint16: 0x0000
   y == 0. Which is what you wanted, by luck.

   But this one is not luck: */
if (~x == 0xFFFF0000) ...        /* comparing uint16_t against int */

/* And this is a real bug: */
uint32_t z = ~x;                 /* z == 0xFFFF0000, NOT 0x0000FFFF */
/* Because ~x was computed in int, not in uint16_t. */
```

The usual arithmetic conversions

Once both operands are at least `int`, they are brought to a *common type*:

```
  1. If either is a floating type, convert to the larger floating type
     (long double > double > float).

  2. Otherwise, integer promotion is applied to both.

  3. If both have the same type, done.

  4. If both are signed, or both unsigned: convert to the HIGHER RANK.
     rank: long long > long > int > short > char

  5. MIXED SIGNEDNESS — where the bugs live:

     a) If the UNSIGNED type has rank >= the signed type's rank,
        the signed operand is converted to UNSIGNED.
                    <-- this is the dangerous case

     b) Otherwise, if the signed type can represent all values of
        the unsigned type, the unsigned operand is converted to
        SIGNED.

     c) Otherwise, both are converted to the unsigned version of
        the signed type.
```

RULE 5A, AND THE VULNERABILITY IT CREATES

```
int len = -1;
if (len < sizeof(buffer))         /* sizeof yields size_t: UNSIGNED */
        memcpy(buffer, src, len);

/* len is converted to size_t.
   -1 as an unsigned 64-bit value is 18446744073709551615.
   The comparison is FALSE... no wait — it is 18446744073709551615 <
   sizeof(buffer)? No. So the branch is not taken. Lucky.

   Now flip the comparison, which is just as natural to write: */

if (len > sizeof(buffer))
        return -EINVAL;           /* NOT taken: -1 became huge?  no —
                                     huge > sizeof, so it IS taken.  */

/* The point is that you cannot reason about it at a glance, and the
   answer changes with the direction of the comparison and the types
   involved. Compare a signed length against a signed limit, or
   validate that the length is non-negative FIRST:                  */

if (len < 0 || (size_t)len > sizeof(buffer))
        return -EINVAL;
```

CVE databases are full of this pattern. Compile with `-Wsign-compare` (included in `-Wextra`) and treat every warning as a bug, not noise.

```
/* another everyday instance of the same rule */
for (int i = 0; i < strlen(s) - 1; i++)   /* strlen returns size_t */
        ...
/* If s is empty: strlen(s) is 0, and 0 - 1 in size_t is SIZE_MAX.
   The loop runs about 18 quintillion times. */

/* fix: compute the bound once, in a signed type, or restructure */
size_t n = strlen(s);
for (size_t i = 0; i + 1 < n; i++)        /* no subtraction below zero */
        ...
```

Signed versus unsigned: choosing deliberately

	Signed	Unsigned
Overflow	**Undefined behaviour** — the compiler assumes it cannot happen	Defined: wraps modulo 2^N
Optimisation	Better: the compiler can assume `i + 1 > i`	Worse: must handle wraparound
Comparison against the other	Dangerous — see above	
Right shift	Implementation-defined for negatives (arithmetic in practice)	Defined: logical, fills with zero
Use for	Quantities that can meaningfully be negative; loop indices that count down	Bit manipulation, hardware registers, sizes, hashes, modular arithmetic

```
/* Signed overflow is UB, and the optimiser acts on it: */
int check(int x) {
        return x + 1 > x;        /* compiles to `return 1;` */
}
/* Because signed overflow "cannot happen", x + 1 > x is always true.
   Your overflow check is deleted. See chapter 15.                  */

/* Unsigned wraps predictably, which is why hardware code uses it: */
uint32_t elapsed = now - start;   /* correct even when `now` wrapped */

/* Countdown loops with unsigned indices are a perennial bug: */
for (size_t i = n - 1; i >= 0; i--)   /* i >= 0 is ALWAYS true */
        ...                            /* infinite loop         */

for (size_t i = n; i-- > 0; )          /* correct idiom          */
        use(a[i]);
```

The three character types

```
/* char, signed char and unsigned char are THREE DISTINCT TYPES.
   Whether plain `char` is signed is implementation-defined:
       x86, ARM on Windows/macOS  -> signed
       ARM on Linux, PowerPC      -> UNSIGNED
   This has broken more ports than almost anything else.        */

char c = 200;            /* signed char: this is -56. unsigned: 200 */
if (c == 200) ...        /* false on ARM Linux, true on x86         */

/* The classic getchar() bug: */
char c;
while ((c = getchar()) != EOF)   /* WRONG */
        process(c);
/* getchar returns int so it can return 256 distinct byte values PLUS
   EOF (-1). Storing it in char loses that distinction: on a signed-
   char platform, byte 0xFF becomes -1 and terminates the loop early;
   on an unsigned-char platform the loop NEVER terminates because c
   can never equal -1.                                              */

int c;                           /* correct */
while ((c = getchar()) != EOF)
        process((unsigned char)c);

/* Rules that keep you out of trouble:
     - use `unsigned char` for raw bytes and buffers
     - use `char` only for actual text
     - cast to unsigned char before passing to <ctype.h> functions:
           isalpha((unsigned char)c);
       passing a negative char there is undefined behaviour        */

/* -funsigned-char / -fsigned-char force it, but relying on a flag
   makes your code non-portable in a different way. Be explicit. */
```

Conversion rules

Conversion	Behaviour
Narrowing to unsigned	Well defined: modulo 2^N. `(uint8_t)300` is 44.

Conversion	Behaviour
Narrowing to signed	Value fits: preserved. Does not fit: **implementation-defined** (in practice, truncation with the top bit becoming the sign)
Signed → unsigned	Well defined: add 2^N until in range. `(unsigned)-1` is `UINT_MAX`.
Unsigned → signed	Fits: preserved. Does not fit: implementation-defined
Integer → float	Rounded if not exactly representable (CA ch. 03)
Float → integer	**Truncates toward zero.** Out of range or NaN is *undefined*.
Anything → `_Bool`	0 becomes false, anything else true. Not truncation.

```
(int)3.99      ->  3      /* truncation, not rounding      */
(int)-3.99     -> -3      /* toward zero, not toward -inf  */
(int)1e30      ->  UNDEFINED — does not fit in int
(_Bool)256     ->  1      /* not 0! _Bool is not a narrow int */

/* rounding, when you actually want it */
#include <math.h>
lround(3.5)    ->  4
(int)(x + 0.5) ->  wrong for negatives, and for x near the .5 boundary
```

Writing overflow checks that survive the optimiser

```
/* WRONG: relies on signed overflow, which is UB, so it is deleted */
if (a + b < a) overflow();

/* RIGHT 1: compiler builtins. Portable across GCC and Clang,
   and they map to the CPU's flags — one instruction. */
int result;
if (__builtin_add_overflow(a, b, &result))
        return -EOVERFLOW;

/* RIGHT 2: check before the operation, using the type's limits */
#include <limits.h>
if (b > 0 && a > INT_MAX - b) return -EOVERFLOW;
if (b < 0 && a < INT_MIN - b) return -EOVERFLOW;

/* RIGHT 3: for sizes, use unsigned and check the wrap — defined behaviour */
size_t total = n * size;
if (n != 0 && total / n != size)
        return -EOVERFLOW;              /* the classic malloc guard */

/* Linux kernel helpers that do exactly this */
check_add_overflow(a, b, &res);
array_size(n, size);          /* saturates to SIZE_MAX on overflow */
struct_size(p, member, n);
```

Compiler flags that catch these

```
gcc -Wall -Wextra \
    -Wsign-compare \        # signed/unsigned comparison — enable and OBEY
    -Wconversion \          # implicit narrowing conversions (noisy but valuable)
    -Wsign-conversion \
    -Wshadow \
    -Wcast-align \
    -Wpointer-arith \
    -Wstrict-overflow=5 \   # warn where the optimiser assumes no overflow
    -fno-strict-overflow    # ...or make signed overflow defined (wraps)

# find them at runtime instead
gcc -fsanitize=undefined -fsanitize=signed-integer-overflow
# UBSan reports the exact file, line and values at the moment it happens.
# Run your test suite under it — it costs a few percent and finds real bugs.
```

How it shows up

Symptom	Cause
A length check passes for a negative length	Signed converted to unsigned in the comparison
Loop over `strlen(s) - 1` runs forever on an empty string	`size_t` underflow
An overflow check compiles to `return 1`	Signed overflow is UB; the check was deleted
Code works on x86, misbehaves on ARM Linux	Plain `char` signedness differs
`getchar` loop stops early or never stops	Return value stored in `char` instead of `int`
Pointer truncated on Windows, fine on Linux	`long` is 32-bit under LLP64
`~x` on a `uint16_t` gives a huge number	Promotion to `int` before the operator
`printf("%d", sizeof(x))` prints garbage	Wrong conversion specifier; use `%zu`
Countdown loop with `size_t` never ends	`i >= 0` is always true for unsigned

Check yourself

- ✓ State what C guarantees about the size of `int` and `long`, and give the LP64/LLP64 difference.
- ✓ Explain integer promotion and predict the value of `~x` for a `uint16_t`.
- ✓ Walk through the usual arithmetic conversions for `int` versus `size_t`.
- ✓ Write a length check that is safe against a negative input.
- ✓ Explain why signed overflow being UB is useful to the optimiser and dangerous to you.
- ✓ Give the correct countdown-loop idiom for an unsigned index.
- ✓ Explain the `getchar` bug and why it fails differently on two platforms.
- ✓ Write a multiplication overflow check that the optimiser cannot remove.

Operators, precedence and evaluation order

Precedence decides how an expression is *parsed*. Evaluation order decides *when* each part runs. C fixes the first completely and leaves much of the second deliberately unspecified — and confusing the two produces bugs that change with the optimisation level.

The precedence table

```
Highest to lowest. Learn the shape, not the numbers.

 1  postfix        a[i]  f()  a.b  p->b  a++  a--  (type){init}    L→R
 2  unary          ++a  --a  +a  -a  !a  ~a  (type)a  *p  &a
                   sizeof  _Alignof                                R→L
 3  multiplicative *  /  %                                         L→R
 4  additive       +  -                                            L→R
 5  shift          <<  >>                                          L→R
 6  relational     <  <=  >  >=                                    L→R
 7  equality       ==  !=                                          L→R
 8  bitwise AND    &                                               L→R
 9  bitwise XOR    ^                                               L→R
10  bitwise OR     |                                               L→R
11  logical AND    &&                                              L→R
12  logical OR     ||                                              L→R
13  conditional    ?:                                              R→L
14  assignment     =  +=  -=  *=  /=  %=  <<=  >>=  &=  ^=  |=     R→L
15  comma          ,                                               L→R
```

THE FOUR PRECEDENCE MISTAKES THAT ACTUALLY HAPPEN

Every one of these compiles without a word from the compiler unless you enable warnings.

```
/* 1. Bitwise operators bind LOOSER than comparison.
      This is C's oldest design mistake, inherited from B. */
if (x & MASK == 0)          /* parsed as  x & (MASK == 0)  ->  x & 0  ->  0 */
if ((x & MASK) == 0)        /* what you meant                              */

/* 2. Shift binds looser than arithmetic. */
x << 2 + 3                  /* parsed as  x << (2 + 3)  =  x << 5 */
(x << 2) + 3                /* what you probably meant             */

/* 3. Dereference binds looser than postfix ++. */
*p++                        /* parsed as  *(p++)   - increment the POINTER  */
(*p)++                      /* increment the VALUE                          */

/* 4. Assignment inside a condition, without parentheses. */
while (c = getchar() != EOF)      /* c = (getchar() != EOF)  ->  c is 0 or 1 */
while ((c = getchar()) != EOF)    /* correct                                 */
```

Build with `-Wparentheses` (in `-Wall`) and it will flag most of these. The habit that removes the whole class: **parenthesise whenever mixing categories** — bitwise with comparison, shift with arithmetic, assignment inside a condition. Clarity costs nothing.

Precedence is not evaluation order

> **THE DISTINCTION**
> `a() + b() * c()` — precedence says the multiplication groups first, so the result is `a() + (b() * c())`. It says *nothing* about which function runs first. The compiler may call them in any order, and different optimisation levels genuinely produce different orders.

```
/* UNSPECIFIED: legal, but the order may vary. Do not depend on it. */
printf("%d %d\n", g(), h());        /* g and h in either order      */
int x = f() + g();                  /* likewise                     */
a[i()] = b[j()];                    /* likewise                     */

/* UNDEFINED: the standard imposes no requirements at all.
   Two modifications, or a modification and a read, of the same
   object with no sequencing between them.                          */
i = i++ + 1;
a[i] = i++;
i = ++i + i++;
f(i++, i++);

/* These are not "compiler-dependent" — they are BROKEN. The compiler
   may produce anything, and modern compilers exploit that to
   optimise. Enable -Wsequence-point (in -Wall).                     */
```

Where C does guarantee order

Construct	Guarantee	Why it matters
`&&` and `||`	Left evaluated fully first; right only if needed	Short-circuit guards: `if (p && p->x)`
`?:`	Condition first; then exactly one branch	Safe division: `d ? n/d : 0`
`,` operator	Left evaluated and discarded, then right	Multiple side effects in a `for` header
End of full expression	All side effects complete before the next statement	The basic sanity guarantee
Function call	All arguments evaluated before the body runs	But not in any particular order among themselves
C11 assignment	Right operand sequenced before the left in a compound assignment's read-modify-write	Makes `a[i++] += 1` defined in C11

```
/* Short-circuit is a guarantee you can build on */
if (p != NULL && p->len > 0 && p->data[0] == 'x')   /* safe, in order */
if (i < n && a[i] == target)                         /* bounds check first */
if (denom == 0 || total / denom > limit)             /* no divide by zero  */

/* The comma operator, used properly — rare outside for-headers */
for (i = 0, j = n - 1; i < j; i++, j--)
        swap(&a[i], &a[j]);

/* Note: the comma in a function call is a SEPARATOR, not the comma
   operator, and imposes no ordering.                               */
f(a, b);          /* separator: no sequencing between a and b */
f((a, b));        /* comma OPERATOR: one argument, b, after evaluating a */
```

Bitwise operators in practice

Op	Effect	Idiom
`&`	AND	Test or clear bits: `x & MASK`, `x &= ~BIT`
`|`	OR	Set bits: `x |= BIT`
`^`	XOR	Toggle bits: `x ^= BIT`; also equality-to-zero test
`~`	NOT	Build inverse masks: `~(1u << n)`
`<<`	Left shift	Multiply by 2^n; build masks
`>>`	Right shift	Divide by 2^n (unsigned); extract fields

SHIFT IS A MINEFIELD OF UNDEFINED BEHAVIOUR

```
x << n     /* UB if n < 0, or n >= width of the PROMOTED type of x */
x >> n     /* same                                                  */

int x = 1;
x << 32;              /* UB: int is 32 bits, so n must be 0..31      */
x << 31;              /* UB in C: shifting into the sign bit of a
                         signed type overflows. Use unsigned.        */

1 << 31               /* UB — `1` is int                            */
1u << 31              /* fine — unsigned int                        */
1ull << 40            /* fine — need the wide literal for wide shifts */

uint64_t mask = 1 << bit;     /* BUG if bit >= 32: the shift happens
                                 in int, THEN widens                */
uint64_t mask = 1ULL << bit;  /* correct                            */

/* Right shift of a NEGATIVE signed value is implementation-defined:
   arithmetic (sign-extending) on every real compiler, but not
   guaranteed. Use unsigned types for bit work — always.            */
```

The rule that avoids all of it: **do bit manipulation in unsigned types, with suffixed literals** (`1u`, `1ul`, `1ull`) wide enough for the shift.

```
/* the standard field extract/insert idioms */
#define FIELD_MASK(hi, lo)   (((1ull << ((hi) - (lo) + 1)) - 1) << (lo))
#define FIELD_GET(reg, hi, lo)  (((reg) & FIELD_MASK(hi, lo)) >> (lo))
#define FIELD_SET(reg, hi, lo, v) \
        (((reg) & ~FIELD_MASK(hi, lo)) | (((uint64_t)(v) << (lo)) & FIELD_MASK(hi, lo)))

/* Linux provides these properly, with compile-time checking: */
#include <linux/bitfield.h>
#define CTRL_SPEED  GENMASK(5, 2)
val = FIELD_GET(CTRL_SPEED, reg);
reg = (reg & ~CTRL_SPEED) | FIELD_PREP(CTRL_SPEED, 3);
```

Logical versus bitwise

```
/* && and & are NOT interchangeable, and the difference bites. */

if (p && p->valid)     /* safe: p->valid only evaluated if p is non-NULL */
if (p &  p->valid)      /* CRASH: both sides always evaluated;
                              and it computes a bitwise AND of a pointer   */

/* Type of the result differs too */
!x           /* int: 0 or 1                     */
~x           /* same type as promoted x         */
a && b       /* int: 0 or 1                     */
a &  b       /* the common type of a and b      */

/* A subtle one: !! forces a value to exactly 0 or 1 */
#define BOOL(x)  (!!(x))
flags |= BOOL(cond) << FLAG_SHIFT;    /* without !!, a value of 6 would
                                         shift into the wrong bits      */
```

Division, modulo and negative numbers

```
/* Since C99, integer division truncates TOWARD ZERO, and
   the sign of % follows the DIVIDEND.                    */

 7 /  2  ==  3       7 %  2 ==  1
-7 /  2  == -3      -7 %  2 == -1     /* not +1 */
 7 / -2  == -3       7 % -2 ==  1
-7 / -2  ==  3      -7 % -2 == -1

/* Identity that always holds:  (a/b)*b + a%b == a  */

/* So the "is it even" test is fine, but a naive modulo bucket is not: */
if (x % 2 == 1)          /* FALSE for negative odd x, which gives -1 */
if (x % 2 != 0)          /* correct */

/* Mapping into 0..n-1 for possibly-negative x: */
int idx = ((x % n) + n) % n;

/* Division by zero is UNDEFINED, not a trap you can rely on.
   INT_MIN / -1 is also undefined - the result does not fit.  */
if (b == 0 || (a == INT_MIN && b == -1))
        return -EINVAL;
```

sizeof and friends

```
sizeof(type)      /* parentheses required for a type    */
sizeof expr       /* parentheses optional for an expression */

/* sizeof does NOT evaluate its operand (except for VLAs) */
int i = 0;
size_t n = sizeof(i++);       /* i is still 0 — this is a compile-time
                                 operation, and a common interview trap */

/* Result type is size_t: unsigned. Chapter 02 explains why that matters. */
if (sizeof(a) - sizeof(b) > 0)   /* ALWAYS true — unsigned never negative */

/* The array-length macro, and why it is not safe on a pointer */
#define ARRAY_SIZE(a)  (sizeof(a) / sizeof((a)[0]))

int a[10];
ARRAY_SIZE(a);                /* 10, correct */

void f(int a[10]) {
        ARRAY_SIZE(a);        /* WRONG: `a` is a POINTER here (chapter 05).
                                 Gives sizeof(int*)/sizeof(int) = 2       */
}

/* Linux's version fails to COMPILE on a pointer, which is far better: */
#define ARRAY_SIZE(arr) \
        (sizeof(arr) / sizeof((arr)[0]) + __must_be_array(arr))

/* C11 alignment operators */
_Alignof(double)              /* alignment requirement, in bytes */
_Alignas(64) char buf[128];   /* force alignment — cache lines, DMA */
```

Compound assignment and increment

```
/* Compound assignment evaluates the left operand ONCE. This matters
   when it has side effects or is expensive.                        */
a[f()] += 1;          /* f() called once            */
a[f()] = a[f()] + 1;  /* f() called twice, in unspecified order */

/* It also performs an implicit conversion back, which can hide narrowing */
uint8_t x = 200;
x += 100;             /* computed in int (300), truncated back to 44
                         — no warning without -Wconversion             */

/* Pre versus post increment */
int i = 5;
j = i++;      /* j = 5, i = 6 — yields the OLD value */
j = ++i;      /* j = 7, i = 7 — yields the NEW value */

/* In C, on scalars, there is no performance difference: the compiler
   discards the unused old value. The habit of preferring ++i comes
   from C++, where the operand may be a heavy iterator object.       */
```

How it shows up

Symptom	Cause
A flag test is always false	`x & MASK == 0` — missing parentheses

Symptom	Cause
A loop reads one character then stops	`while (c = getchar() != EOF)`
Pointer advances when you meant to increment a value	`*p++` versus `(*p)++`
A shift produces 0 or garbage for large bit numbers	`1 << n` with `n >= 32`; needs `1ull`
`ARRAY_SIZE` returns 2 inside a function	The array parameter decayed to a pointer
Modulo bucket index is negative	`%` follows the sign of the dividend
Expression gives different results at `-O0` and `-O2`	Undefined behaviour from unsequenced modification
A size comparison is always true	`sizeof` yields unsigned; the subtraction wrapped
Crash on a null check that looks correct	`&` used where `&&` was meant — no short circuit

Check yourself

- ✓ Explain the difference between precedence and evaluation order, with an example of each mattering.
- ✓ Parse `x & MASK == 0` and say what it actually computes.
- ✓ Name the four constructs where C guarantees left-to-right evaluation.
- ✓ Give three ways a shift expression can be undefined, and the rule that avoids all of them.
- ✓ Explain why `uint64_t m = 1 << 40;` is wrong.
- ✓ Predict `-7 % 2` and write a correct positive-modulo helper.
- ✓ Explain why `sizeof(i++)` leaves `i` unchanged.
- ✓ Say why `ARRAY_SIZE` fails on a function parameter and how Linux prevents it.

Pointers from first principles

A pointer is a value that designates an object. That is all. Every difficulty people have with pointers comes from confusing the pointer with the thing it points to, or from reading declarations in the wrong direction. Both are fixable in an afternoon.

The mental model

```
Memory is a numbered array of bytes. An object occupies a run of them.
A pointer is a value that identifies where an object begins, together
with a TYPE that says how to interpret what is there.

   address:   0x1000   0x1004   0x1008   0x100C
              +--------+--------+--------+--------+
   memory:    |   42   |  ...   |  0x1000|  ...   |
              +--------+--------+--------+--------+
                  ^                |
                  |                |
                  x                p        int *p = &x;

   x     the object.        value 42.
   &x    its address.        value 0x1000.
   p     a pointer object.   value 0x1000, stored at 0x1008.
   *p    the object at that address.   value 42.
   &p    the address of the pointer itself.  value 0x1008.

The TYPE matters as much as the address:
   int *p     -> "reading 4 bytes here gives an int"
   char *c    -> "reading 1 byte here gives a char"
   Two pointers can hold the same address and mean different things.
```

THE TWO OPERATORS, SAID PRECISELY

`&x` — "the address of x". Turns an object into a pointer value.
`*p` — "the object that p points to". Turns a pointer value back into an object.

They are inverses: `*&x` is `x`. Read `*` aloud as **"the thing at"**, never as "pointer" — that single habit clears up most confusion.

Reading declarations

C declaration syntax mirrors *use*, not structure. The reliable technique is the spiral rule: start at the identifier, then move right when you can, left when you must.

```
   int *p;              p is a pointer to int
   int **p;             p is a pointer to a pointer to int
   int p[10];           p is an array of 10 ints
   int *p[10];          p is an ARRAY of 10 pointers to int
   int (*p)[10];        p is a POINTER to an array of 10 ints
   int *f(void);        f is a function returning pointer to int
   int (*f)(void);      f is a POINTER to a function returning int
   int (*f[5])(void);   f is an array of 5 pointers to functions
                          returning int
   int *(*f)(int *);    f is a pointer to a function taking int*
                          and returning int*

Why the parentheses: [] and () bind TIGHTER than *.
   int *p[10]    ==  int *(p[10])    array of pointers
   int (*p)[10]                      pointer to array

When it gets hard, stop and use a typedef. Professional code does.

   typedef int (*handler_fn)(struct device *, void *);
   handler_fn table[16];        /* obviously an array of handlers */

   cdecl(1) or `cdecl explain ...` will read any declaration aloud.
```

Where `const` goes

```
/* Read RIGHT TO LEFT from the identifier. const applies to what is
   immediately to its LEFT — unless it is leftmost, then to the right. */

const int *p;          /* p: pointer to const int   */
int const *p;          /* identical to the above    */
int *const p;          /* p: const pointer to int   */
const int *const p;    /* const pointer to const int */

const int *p;          *p = 5;   /* ERROR: object is const   */
                       p = &y;   /* fine: pointer is mutable */

int *const p = &x;     *p = 5;   /* fine: object is mutable  */
                       p = &y;   /* ERROR: pointer is const  */

/* The east-const style makes the rule uniform, which is why many
   codebases now prefer it:
        int const *p;        rather than  const int *p;
   Either is fine — be consistent.                          */
```

Pointer arithmetic

> **ARITHMETIC IS IN UNITS OF THE POINTED-TO TYPE, NOT BYTES**
>
> `p + 1` advances by `sizeof(*p)` bytes. This is what makes `a[i]` and `*(a + i)` equivalent, and it is why `void *` arithmetic is not standard C.

```
int a[5] = {10, 20, 30, 40, 50};
int *p = a;              /* points at a[0] */

p + 1                    /* a[1] — address advances by 4 bytes  */
*(p + 2)                 /* 30                                   */
p[2]                     /* identical: p[2] is *(p + 2) BY DEFINITION */
2[p]                     /* also 30 — legal, and a good argument for
                            why you should never write it        */

int *q = &a[4];
q - p                    /* 4 — a ptrdiff_t, in ELEMENTS not bytes */
(char *)q - (char *)p    /* 16 — in bytes                          */

/* void* arithmetic is a GNU extension (treats it as char*). It is
   used throughout the Linux kernel but is not portable ISO C.     */
void *v = p;
v + 1;                   /* GCC: +1 byte. MSVC/strict ISO: error   */
```

What arithmetic is legal

```
   int a[5];
   +----+----+----+----+----+----+
   |a[0]|a[1]|a[2]|a[3]|a[4]| ** |
   +----+----+----+----+----+----+
     ^                         ^
    &a[0]                   a + 5  = "one past the end"

  LEGAL:   any pointer from &a[0] to a+5 inclusive
           comparing any two of them
           dereferencing anything EXCEPT a+5

  UNDEFINED:  computing a - 1     (before the start)
              computing a + 6     (past one-past-the-end)
              dereferencing a + 5
              comparing pointers into DIFFERENT objects with < >

  The one-past-the-end rule is what makes the standard loop idiom
  legal, and it is why `end` pointers work at all:

      for (int *p = a; p != a + 5; p++)
              use(*p);
```

```
/* This looks fine and is undefined behaviour: */
for (int *p = &a[4]; p >= a; p--)     /* the final p-- computes a-1 */
        use(*p);

/* correct backwards iteration */
for (int *p = a + 5; p-- != a; )
        use(*p);
/* or just use an index */
for (size_t i = 5; i-- > 0; )
        use(a[i]);
```

Null pointers

```
int *p = NULL;        /* NULL is ((void*)0) or 0, implementation's choice */
int *p = 0;           /* the null pointer CONSTANT — same thing           */
int *p = nullptr;     /* C23, and clearer                                 */

if (p)                /* idiomatic: tests against null       */
if (p != NULL)        /* identical, more explicit            */

/* Dereferencing NULL is UNDEFINED, not "crashes with a segfault".
   On a system with memory at address 0 — many microcontrollers, and
   the x86 real-mode interrupt vector table — it silently reads
   garbage or corrupts something important.                      */

/* And the optimiser exploits it. This is a real Linux kernel CVE
   pattern (CVE-2009-1897):                                      */
struct s *p = get();
int x = p->field;          /* dereference implies p is non-NULL... */
if (p == NULL)             /* ...so the compiler DELETES this check */
        return -EINVAL;

/* Always check BEFORE dereferencing. The order is not stylistic. */

/* NULL is not necessarily all-zero bits. memset(&p, 0, sizeof p)
   is not guaranteed to produce a null pointer, though it does on
   every platform you will meet. Use explicit initialisation.      */
```

void pointers and generic code

```
/* void* is "a pointer to something unspecified". It converts to and
   from any OBJECT pointer type without a cast.                     */

void *v = &x;            /* implicit, fine                */
int *p = v;              /* implicit in C (NOT in C++)     */
int *p = (int *)v;       /* explicit — required in C++, harmless in C */

*v;                      /* ERROR: cannot dereference, size unknown  */

/* This is the mechanism behind every generic C API: */
void *malloc(size_t);
void *memcpy(void *dst, const void *src, size_t n);
int qsort_cmp(const void *a, const void *b);

/* qsort's comparator: the standard idiom for recovering the type */
static int cmp_int(const void *a, const void *b)
{
        int x = *(const int *)a;
        int y = *(const int *)b;
        return (x > y) - (x < y);    /* avoids overflow of x - y */
}
qsort(arr, n, sizeof(int), cmp_int);

/* Do NOT cast the result of malloc in C.
      int *p = malloc(n * sizeof *p);        // correct, idiomatic
   The cast is required in C++, unnecessary in C, and historically
   it hid the missing-prototype bug. Note `sizeof *p` rather than
   `sizeof(int)` — it stays correct if the type of p changes.    */
```

> **VOID* DOES NOT MEAN "FUNCTION POINTER"**
> The standard guarantees conversion between `void *` and object pointers only. Converting a function pointer through `void *` is not guaranteed — on architectures where code and data addresses differ in width or format it genuinely breaks. POSIX requires it to work for `dlsym()`, which is why that API is a documented wart. Keep function pointers in function pointer types.

Pointers to pointers

```
/* Reason 1: modifying a caller's pointer */
void alloc_buf(char **out, size_t n)
{
        *out = malloc(n);        /* write through to the caller's pointer */
}
char *buf;
alloc_buf(&buf, 100);

/* C is strictly pass-by-value. To let a function change your pointer,
   you must pass a pointer TO it. There is no other mechanism.      */

/* Reason 2: arrays of pointers — argv is the canonical example */
int main(int argc, char **argv)
/*                 char *argv[]  — identical in a parameter list */
{
        for (int i = 0; i < argc; i++)
                puts(argv[i]);
}

/* Reason 3: the linked-list deletion trick that removes all the
   special cases. Worth studying until it is obvious.             */
void remove_if(struct node **head, int target)
{
        struct node **pp = head;          /* pointer to the link itself */
        while (*pp) {
                struct node *entry = *pp;
                if (entry->value == target) {
                        *pp = entry->next;    /* unlink, whatever pp points to */
                        free(entry);
                } else {
                        pp = &entry->next;
                }
        }
}
/* No head-versus-middle special case, no `prev` pointer, no NULL
   checks for the previous node. Linus Torvalds has cited this as
   the difference between understanding pointers and not.          */
```

The four ways pointers go wrong

Fault	What it is	Detection
Dangling	Points to storage whose lifetime ended	ASan, Valgrind, KASAN
Wild	Uninitialised — contains garbage	MSan, `-Wuninitialized`, always initialise
Out of bounds	Past the end of the object	ASan, `-fsanitize=bounds`
Type-punned illegally	Accessed through an incompatible type	`-Wstrict-aliasing`, ch. 15

```
/* Dangling: returning a pointer to an automatic object */
char *bad(void)
{
        char buf[64];
        sprintf(buf, "hello");
        return buf;          /* buf's lifetime ends HERE */
}                            /* -Wreturn-local-addr catches this one */

/* Dangling: use after free */
free(p);
p->field = 1;                /* undefined; may silently work for a while */
free(p);                     /* double free: heap corruption            */

/* The discipline that prevents it: */
free(p);
p = NULL;                    /* now a later use crashes loudly and
                                a second free() is a no-op            */

/* Dangling: a pointer into a container that reallocated */
int *p = &vec->data[0];
vec_push(vec, x);            /* may realloc and move the buffer */
*p = 5;                      /* dangling - a very common real bug */

/* Wild: uninitialised */
int *p;                      /* contains whatever was on the stack */
*p = 5;                      /* undefined                          */
int *p = NULL;               /* at least it will fault predictably  */
```

restrict: promising no aliasing

```
/* Without restrict, the compiler must assume dst and src may overlap,
   so it cannot keep values in registers across the loop.          */
void copy(int *dst, const int *src, size_t n)
{
        for (size_t i = 0; i < n; i++)
                dst[i] = src[i];      /* must reload src[i] each time */
}

/* restrict promises: within this scope, the object accessed through
   this pointer is not accessed through any other pointer.          */
void copy(int *restrict dst, const int *restrict src, size_t n)
{
        for (size_t i = 0; i < n; i++)
                dst[i] = src[i];      /* now vectorisable */
}

/* This is why memcpy() and memmove() are two functions:
       memcpy  - arguments are restrict; overlapping is UNDEFINED
       memmove - handles overlap correctly, and is slower for it

   Breaking a restrict promise is undefined behaviour with no
   diagnostic. Only use it where you genuinely control both
   pointers. See chapter 10.                                      */
```

Finding pointer bugs

```
# AddressSanitizer — use-after-free, out-of-bounds, double free.
# Roughly 2x slowdown; run your whole test suite under it.
gcc -fsanitize=address -fno-omit-frame-pointer -g prog.c

# MemorySanitizer — reads of uninitialised memory (Clang only)
clang -fsanitize=memory -fno-omit-frame-pointer -g prog.c

# UndefinedBehaviorSanitizer — null deref, bad shifts, overflow
gcc -fsanitize=undefined -g prog.c

# Valgrind — no rebuild required, but ~20x slower
valgrind --leak-check=full --track-origins=yes ./prog

# Static analysis, free and fast
gcc -fanalyzer -Wall -Wextra prog.c
clang --analyze prog.c

# In the kernel: KASAN, KMSAN, and CONFIG_DEBUG_OBJECTS
```

How it shows up

Symptom	Cause
Crash far from the faulty code	Heap corruption from an earlier out-of-bounds write
Works in debug, crashes in release	Uninitialised pointer that happened to hold a valid address
Function returns garbage strings	Returned a pointer to a local buffer
Value changes without being assigned	Another pointer aliases it; or a dangling write
A null check is optimised away	You dereferenced before checking
Iterator invalidated after an append	Container reallocated; the old pointer dangles
Pointer arithmetic advances by the wrong amount	Arithmetic is in elements; check the pointer's type
`void *` arithmetic fails to compile	GNU extension; cast to `char *` for portability
Second `free()` corrupts the heap	Double free; set the pointer to NULL after freeing

Check yourself

- ✓ Explain `&` and `*` in one sentence each and say why they are inverses.
- ✓ Read aloud: `int *(*f[5])(char *)`.
- ✓ Give the difference between `const int *p` and `int *const p`.
- ✓ Explain why `p + 1` may advance by 8 bytes, and what determines it.
- ✓ State the one-past-the-end rule and show a loop that violates it.
- ✓ Explain why a null check placed after a dereference can be deleted.
- ✓ Write the pointer-to-pointer linked-list removal and say what special cases it eliminates.
- ✓ Explain what `restrict` promises and why `memcpy` and `memmove` both exist.

Arrays, decay and pointer arithmetic

"Arrays are pointers" is the most repeated falsehood in C teaching. Arrays and pointers are different types with different sizes and different semantics. They are connected by one specific rule — decay — and understanding exactly where it applies and where it does not resolves nearly every array confusion.

Arrays are not pointers

```
int a[10];
int *p = a;

sizeof(a)      /* 40 — the whole array          */
sizeof(p)      /* 8  — one pointer              */

&a             /* type int(*)[10] — pointer to array of 10 int */
&p             /* type int**                                   */

&a + 1         /* advances 40 bytes — past the whole array     */
&p + 1         /* advances 8 bytes                             */

a = p;         /* ERROR: an array is not assignable            */
p = a;         /* fine: decay                                   */
```

THE DECAY RULE, STATED EXACTLY

In most expression contexts, an expression of type "array of T" is converted to "pointer to T", pointing at the first element.

The four exceptions — the only places an array stays an array:

1. Operand of `sizeof`
2. Operand of `&` (address-of)
3. Operand of `_Alignof`
4. A string literal used to initialise a character array

Everywhere else — assignment, arithmetic, comparison, function arguments — the array decays.

```
char s[] = "hello";      /* exception 4: initialises the array,
                            so s is 6 bytes and MUTABLE          */
char *t  = "hello";      /* decay: t points at a string LITERAL,
                            which you must not modify            */

s[0] = 'H';              /* fine                                 */
t[0] = 'H';              /* UNDEFINED — literals may be in ROM,
                            and on many targets they are         */

/* Declare pointers to literals as const to make the compiler help: */
const char *t = "hello";
t[0] = 'H';              /* now a compile error, as it should be  */
```

Array parameters are a lie

```
These four declarations are IDENTICAL. The compiler rewrites all of
them to the last one.

    void f(int a[10]);
    void f(int a[100]);
    void f(int a[]);
    void f(int *a);        <- what the compiler actually sees

Consequences you must internalise:

  · sizeof(a) inside f is sizeof(int*), NOT the array size
  · the bound in the declaration is documentation, nothing more
  · the compiler will NOT check that you passed 10 elements
  · you must pass the length separately. Always.
```

```
/* the bug this causes, constantly */
void process(int a[10])
{
        size_t n = sizeof(a) / sizeof(a[0]);   /* 8/4 = 2, not 10 */
        for (size_t i = 0; i < n; i++)          /* processes 2 elements */
                ...
}
/* -Wsizeof-pointer-div warns about exactly this. Enable it. */

/* the correct signature */
void process(int *a, size_t n);
void process(size_t n, int a[n]);    /* C99: documents intent, and
                                        some compilers can check it */

/* C99 static array parameters — a promise of a minimum size.
   GCC and Clang will warn if you pass fewer or pass NULL.        */
void process(int a[static 10]);      /* "at least 10 elements"    */
```

Multidimensional arrays

```
C has no 2-D arrays. It has arrays OF arrays, stored contiguously
in row-major order.

    int m[3][4];

    memory layout, 48 bytes, one contiguous block:
    +--------------+--------------+--------------+
    | m[0][0..3]   | m[1][0..3]   | m[2][0..3]   |
    +--------------+--------------+--------------+
     ^              ^
     m[0]           m[1]        each is an int[4]

    m           type int(*)[4] after decay — pointer to a ROW
    m[0]        type int[4], decays to int*
    m[0][0]     type int
    *(*(m+1)+2) == m[1][2]

    sizeof(m)      48    the whole thing
    sizeof(m[0])   16    one row
    sizeof(m[0][0]) 4    one element

  The address computation the compiler emits for m[i][j]:
      base + (i * 4 + j) * sizeof(int)
  The COLUMN COUNT is baked into the type. That is why it cannot be
  omitted in a parameter declaration.
```

```
/* passing a 2-D array: all but the FIRST bound are required */
void f(int m[3][4]);      /* rewritten to int (*m)[4]  */
void f(int m[][4]);       /* same                      */
void f(int (*m)[4]);      /* what it really is         */
void f(int **m);          /* WRONG — a different type entirely */

/* C99 VLA parameters make it general and self-documenting */
void f(size_t rows, size_t cols, int m[rows][cols])
{
        m[i][j] = 0;      /* indexing works naturally */
}

/* the portable pre-C99 alternative: flatten it yourself */
void f(int *m, size_t rows, size_t cols)
{
        m[i * cols + j] = 0;
}
```

> **`INT **` IS NOT A 2-D ARRAY**
>
> An `int[3][4]` is one contiguous 48-byte block. An `int **` is a pointer to an array of pointers, each pointing to a separately allocated row — four allocations, scattered in memory, and an extra dereference per access. They are incompatible types and behave differently for cache locality (CA ch. 13). Passing one where the other is expected is a type error that a cast will silence and then crash.

Allocating arrays

```
/* 1-D: straightforward. Note `sizeof *a` rather than `sizeof(int)`. */
int *a = malloc(n * sizeof *a);
if (!a) return -ENOMEM;

/* Guard the multiplication — n * size can overflow (chapter 02) */
if (n > SIZE_MAX / sizeof *a) return -EOVERFLOW;
int *a = malloc(n * sizeof *a);
/* or */
int *a = calloc(n, sizeof *a);     /* calloc checks internally, and zeroes */

/* 2-D contiguous — ONE allocation, best locality, index arithmetic */
int (*m)[COLS] = malloc(rows * sizeof *m);
m[i][j] = 0;                        /* natural syntax, contiguous storage */
free(m);

/* 2-D "jagged" — N+1 allocations, worse locality, but rows may differ
   in length and can be reallocated independently                    */
int **m = malloc(rows * sizeof *m);
for (size_t i = 0; i < rows; i++)
        m[i] = malloc(cols * sizeof **m);
/* ...and you must free every row before freeing m */

/* Flat with manual indexing — one allocation, works pre-C99,
   and the shape is a runtime value                                  */
int *m = malloc(rows * cols * sizeof *m);
#define M(i, j) m[(i) * cols + (j)]
```

Variable-length arrays

```
void f(size_t n)
{
        int a[n];          /* C99 VLA: size determined at runtime */
        ...
}                          /* automatically freed at scope exit    */

/* Attractive, and largely a trap in systems code: */
```

Problem	Detail
Stack overflow	A large or attacker-controlled `n` silently blows the stack. No error, no diagnostic — just corruption or a crash. Kernel stacks are 8–16 KB.
No failure path	Unlike `malloc`, there is no way to detect that allocation failed
Optional	Made optional in C11; MSVC has never supported them
Hidden cost	Prevents some optimisations; the frame size becomes dynamic
Banned	The Linux kernel removed all VLAs in 2018 and builds with `-Wvla`. MISRA C forbids them.

```
/* Use them only for VLA PARAMETERS, which are pure documentation
   and generate no allocation:                                  */
void matmul(size_t n, size_t m, double a[n][m]);   /* good use     */

/* Otherwise: a fixed bound with a check, or heap allocation */
if (n > MAX_ITEMS) return -EINVAL;
int a[MAX_ITEMS];
/* or */
int *a = malloc(n * sizeof *a);
```

Flexible array members

```
/* The idiomatic way to allocate a header plus a variable-length
   payload in ONE allocation. C99 standardised it.              */
struct packet {
        uint32_t len;
        uint8_t  type;
        uint8_t  data[];        /* flexible array member - must be LAST,
                                   and cannot be the only member       */
};

struct packet *p = malloc(sizeof *p + payload_len);
p->len = payload_len;
memcpy(p->data, payload, payload_len);
/* one allocation, one free, contiguous, cache-friendly */

/* sizeof(struct packet) does NOT include data[] - it is 8 here.
   Guard the addition against overflow:                         */
if (payload_len > SIZE_MAX - sizeof *p) return -EOVERFLOW;

/* Linux provides helpers that do this correctly: */
p = kmalloc(struct_size(p, data, payload_len), GFP_KERNEL);

/* The old pre-C99 hack you will still meet, and should not copy: */
uint8_t data[1];        /* "struct hack" - technically UB to index past [0] */
uint8_t data[0];        /* GNU extension, same idea                          */
```

Bounds are never checked

```
int a[10];
a[10] = 0;        /* one past the end - undefined, and usually silent */
a[-1] = 0;        /* also undefined                                    */
a[1000000] = 0;   /* also undefined; may or may not fault              */

/* C performs NO bounds checking, ever. `a[i]` is defined as
   `*(a + i)` and that is all the compiler does.

   This is the root of the buffer overflow, which remains one of the
   most exploited vulnerability classes in existence - because on the
   stack, writing past an array reaches the saved return address.   */
```

```
Stack layout during a classic overflow

   higher addresses
   +---------------------+
   | saved return address|  <-- overwrite this and you control the PC
   +---------------------+
   | saved frame pointer |
   +---------------------+
   | char buf[64]        |  <-- gets(buf) writes as much as it is given
   +---------------------+
   lower addresses

Mitigations, none of which are a substitute for correct code:

  stack canaries    -fstack-protector-strong   detect on return
  non-executable stack                          make the payload harder
  ASLR                                          make addresses unknown
  FORTIFY_SOURCE    -D_FORTIFY_SOURCE=2        compile/run-time checks
  ASan              -fsanitize=address          catch it in testing
```

```
/* the discipline */
#define ARRAY_SIZE(a)  (sizeof(a) / sizeof((a)[0]))    /* on real arrays only */

for (size_t i = 0; i < ARRAY_SIZE(a); i++)   /* never a hardcoded bound */
        use(a[i]);

/* validate every index that came from outside */
if (idx >= ARRAY_SIZE(table))
        return -EINVAL;
return table[idx];

/* pass length with pointer, always */
void process(const uint8_t *data, size_t len);

/* and in security-sensitive code, mask rather than branch, so the
   check survives speculation (see CA chapter 12): */
idx = array_index_nospec(idx, ARRAY_SIZE(table));
```

Arrays of characters versus strings

```
/* A "string" in C is a convention, not a type: a char array whose
   contents end with '\0'.                                        */

char a[6] = "hello";      /* 5 chars + terminator - exactly fits  */
char b[5] = "hello";      /* legal in C! No terminator. NOT a string.
                             Passing b to strlen() runs off the end. */
char c[]  = "hello";      /* size 6, deduced - prefer this        */

sizeof("hello")   /* 6 - includes the terminator */
strlen("hello")   /* 5 - does not                */

/* This distinction is the source of a large fraction of C's
   buffer bugs. Chapter 06 covers string handling in full.     */
```

How it shows up

Symptom	Cause
`ARRAY_SIZE` returns 2 or 8 inside a function	The parameter decayed to a pointer
Writing to a string literal crashes	`char *s = "..."`; literals are read-only
Passing a 2-D array to `int **` gives garbage	Incompatible types; a cast hid the error
Stack smashing detected, at a random later point	Buffer overflow caught by the canary on return
Crash only with large input	VLA stack overflow, or a fixed buffer overrun
Struct with trailing array reads garbage	`sizeof` did not include the flexible member; allocation too small
`strlen` returns an enormous number	Missing null terminator; the array was exactly the string length
Off-by-one that only shows under ASan	Reading `a[n]`; the byte was harmlessly padding in release builds
Backwards loop crashes on the last iteration	Computing a pointer before the start of the array

Check yourself

- ✓ Give four differences between `int a[10]` and `int *p`.
- ✓ State the decay rule and its four exceptions.
- ✓ Explain why `void f(int a[10])` does not check the size, and what to write instead.
- ✓ Draw the memory layout of `int m[3][4]` and explain why the column count is part of the type.
- ✓ Give three ways to allocate a 2-D array and the trade-off of each.
- ✓ List three reasons the Linux kernel banned VLAs.
- ✓ Write a struct with a flexible array member and allocate it safely.
- ✓ Explain how an array overflow reaches the return address, and name three mitigations.

Strings and buffer safety

C has no string type. It has a convention — a byte array ending in a zero — and a library of functions that trust you to have got the sizes right. This chapter covers the convention, why the classic functions are dangerous, and what to use instead.

The convention

```
A C string is a contiguous sequence of characters terminated by '\0'.

   char s[] = "hello";

   index:   0    1    2    3    4    5
          +----+----+----+----+----+----+
          | h  | e  | l  | l  | o  | \0 |
          +----+----+----+----+----+----+
   size:  6 bytes.   length: 5 characters.

Every consequence of C string handling follows from this:

  · LENGTH IS NOT STORED. strlen() walks the array counting bytes,
    so it is O(n) and it must find a terminator or run off the end.
  · The terminator costs one byte that is easy to forget.
  · A string cannot contain a zero byte. Binary data needs a
    pointer + length, never a "string".
  · Nothing knows the CAPACITY of the buffer but you.
```

```
char a[6] = "hello";     /* exactly fits: 5 + terminator          */
char b[5] = "hello";     /* LEGAL C: no terminator. Not a string.  */
char c[]  = "hello";     /* size 6, deduced — prefer this          */
char d[10] = "hi";       /* remaining bytes zero-filled            */

sizeof("hello")          /* 6 — a compile-time array size         */
strlen("hello")          /* 5 — a runtime walk                    */

/* strlen on b runs past the end of the array: undefined behaviour,
   and in practice it returns whatever happens to follow in memory. */
```

The functions that should not exist

Function	Problem	Verdict
`gets()`	No way to specify a size. Unconditionally exploitable.	**Removed from C11.** Never use it.
`strcpy()`	Writes until the source terminator; no destination bound	Only when you have proven the size
`strcat()`	Same, plus it must walk the destination first	Same
`sprintf()`	Unbounded output	Use `snprintf()`
`strncpy()`	**Does not always terminate**, and zero-pads the whole buffer	Almost never what you want — see below
`strncat()`	The size argument is the *remaining space*, not the buffer size — universally misused	Avoid
`strtok()`	Modifies its input and holds global state; not reentrant	`strtok_r()`, or write your own

Function	Problem	Verdict
`atoi()`	No error reporting at all; UB on overflow	`strtol()` with full checking

STRNCPY IS NOT A SAFE STRCPY

```
char dst[8];
strncpy(dst, "hello world", sizeof dst);
/* dst now contains: h e l l o _ w o
   NO terminator. Any subsequent strlen(dst) or printf("%s") runs
   off the end of the buffer.                                      */

strncpy(dst, "hi", sizeof dst);
/* dst contains: h i \0 \0 \0 \0 \0 \0
   It zero-filled ALL remaining bytes — O(n) regardless of input.  */

/* strncpy was designed in 1979 for fixed-width, non-terminated
   records in early UNIX directory entries. It was never a
   "safe strcpy" and using it as one creates bugs.                */

/* If you must use it, terminate explicitly: */
strncpy(dst, src, sizeof dst - 1);
dst[sizeof dst - 1] = '\0';
```

What to use instead

snprintf — the portable workhorse

```
char buf[64];
int n = snprintf(buf, sizeof buf, "%s: %d", name, value);

/* snprintf ALWAYS terminates (when size > 0), and returns the length
   it WOULD have written. That return value is how you detect
   truncation — and it is why the return is not the bytes written.  */

if (n < 0)
        return -EIO;                    /* encoding error          */
if ((size_t)n >= sizeof buf)
        return -ENAMETOOLONG;           /* truncated               */

/* The classic bug: using the return value as a length blindly */
char buf[16];
int n = snprintf(buf, sizeof buf, "%s", long_string);
memcpy(other, buf, n);          /* n may EXCEED sizeof buf — overflow */

/* correct */
size_t len = (n < 0) ? 0 : ((size_t)n < sizeof buf ? (size_t)n : sizeof buf - 1);
```

strlcpy and strlcat — when available

```
/* From OpenBSD; in glibc since 2.38, and in the Linux kernel.
   They always terminate and return the length they TRIED to create,
   so truncation is detectable with one comparison.               */

size_t r = strlcpy(dst, src, sizeof dst);
if (r >= sizeof dst)
        return -ENAMETOOLONG;           /* truncated */

/* strscpy() is the kernel's preferred variant: it returns the
   number of bytes copied, or -E2BIG on truncation — an error code
   rather than a length you must compare.                         */
ssize_t r = strscpy(dst, src, sizeof dst);
if (r < 0)
        return r;
```

A comparison you can act on

Function	Always terminates?	Detects truncation?	Cost
`strcpy`	Yes	No bound at all	O(len)
`strncpy`	**No**	No	O(size) — always pads
`snprintf`	Yes	Yes, via return	Format parsing overhead
`strlcpy`	Yes	Yes, via return	O(src len) — reads all of src
`strscpy` (Linux)	Yes	Yes, returns `-E2BIG`	O(min(src, size))
`memcpy` + manual	You do it	You do it	Fastest, most error-prone

Parsing numbers correctly

```
/* atoi has no error reporting whatsoever and is UB on overflow. */
int n = atoi(s);          /* returns 0 for "abc" AND for "0" */

/* strtol, used properly — this is the full, correct pattern */
#include <stdlib.h>
#include <errno.h>
#include <limits.h>

int parse_int(const char *s, int *out)
{
        char *end;
        errno = 0;                      /* MUST clear it first */

        long v = strtol(s, &end, 10);    /* explicit base: 10, never 0
                                            unless you want "0x" and
                                            octal to be accepted      */

        if (end == s)          return -EINVAL;   /* no digits at all  */
        if (*end != '\0')      return -EINVAL;   /* trailing garbage  */
        if (errno == ERANGE)   return -ERANGE;   /* out of long range */
        if (v < INT_MIN || v > INT_MAX) return -ERANGE;  /* out of int */

        *out = (int)v;
        return 0;
}

/* Note the four distinct failure modes. Any parser that does not
   distinguish them will accept input it should reject.           */

/* Kernel equivalents, which get this right for you: */
kstrtoint(s, 10, &val);
kstrtoul(s, 0, &val);
```

Bytes, characters and encodings

```
A `char` is a BYTE. It is not a character.

  UTF-8 encodes a code point in 1 to 4 bytes:

    'A'   U+0041   -> 0x41                    1 byte
    'é'   U+00E9   -> 0xC3 0xA9               2 bytes
    '中'  U+4E2D   -> 0xE4 0xB8 0xAD          3 bytes
    '😜'  U+1F600  -> 0xF0 0x9F 0x98 0x80      4 bytes

  So for a UTF-8 string:
     strlen()  gives BYTES, not characters
     s[i]      indexes a byte, possibly mid-character
     toupper() on a byte of a multi-byte sequence is meaningless
     truncating at a byte boundary can produce invalid UTF-8

  What is still safe on UTF-8 without decoding:
     · comparing for equality (memcmp)
     · searching for an ASCII substring (UTF-8 is self-synchronising:
       a multi-byte sequence never contains an ASCII byte)
     · concatenation
     · sorting by byte order == sorting by code point order

  What is NOT safe: length in characters, indexing, case conversion,
  truncation, reversing, normalisation-sensitive comparison.
```

```
/* Practical advice for systems code:
     - treat text as opaque UTF-8 bytes and pass it through
     - validate UTF-8 at the boundary if you must interpret it
     - never truncate a UTF-8 string at an arbitrary byte offset
     - do not use wchar_t: it is 16-bit on Windows and 32-bit on
       Linux, which makes it useless for portable code
     - if you need real Unicode handling, use ICU or utf8proc     */

/* truncating UTF-8 safely: back up to a leading byte */
size_t utf8_truncate(const char *s, size_t max)
{
        size_t n = strnlen(s, max);
        while (n > 0 && (s[n] & 0xC0) == 0x80)   /* 10xxxxxx = continuation */
                n--;
        return n;
}
```

The ctype trap

```
#include <ctype.h>

char c = get_byte();
if (isalpha(c))          /* UNDEFINED if c is negative */

/* The <ctype.h> functions take an int that must be representable as
   `unsigned char` or equal EOF. On platforms where plain char is
   signed (x86 Linux, Windows), byte 0xE9 becomes -23, and the
   implementation indexes a lookup table out of bounds.           */

if (isalpha((unsigned char)c))     /* correct — always cast */

/* Also: these are locale-dependent. In systems code that parses
   protocols, write explicit checks instead:                      */
static inline bool is_digit(char c)  { return c >= '0' && c <= '9'; }
static inline bool is_alpha(char c)  { return (c|32) >= 'a' && (c|32) <= 'z'; }
```

Handling secrets in buffers

```
/* This does not work: */
void check_password(const char *input)
{
        char key[32];
        derive_key(key, input);
        use(key);
        memset(key, 0, sizeof key);   /* DEAD STORE — the compiler
                                         removes it, because key is
                                         never read again (chapter 01) */
}

/* Portable-ish fixes, in order of preference: */

memset_s(key, sizeof key, 0, sizeof key);      /* C11 Annex K, optional */
explicit_bzero(key, sizeof key);               /* BSD, glibc 2.25+      */
SecureZeroMemory(key, sizeof key);             /* Windows               */
memzero_explicit(key, sizeof key);             /* Linux kernel          */

/* If you have none of them, force it through a volatile pointer: */
static void *(*const volatile memset_ptr)(void *, int, size_t) = memset;
memset_ptr(key, 0, sizeof key);

/* And compare secrets in CONSTANT TIME — never with memcmp, which
   returns as soon as it finds a difference and thereby leaks how
   many bytes matched. See the cryptography track.               */
static int ct_memcmp(const void *a, const void *b, size_t n)
{
        const unsigned char *x = a, *y = b;
        unsigned char diff = 0;
        for (size_t i = 0; i < n; i++)
                diff |= x[i] ^ y[i];       /* no early exit */
        return diff;                        /* 0 == equal    */
}
```

Compiler and runtime hardening

```
# FORTIFY_SOURCE: replaces str/mem functions with checked versions
# when the destination size is known at compile time. Nearly free.
gcc -O2 -D_FORTIFY_SOURCE=3 -Wall -Wextra

# stack canaries
gcc -fstack-protector-strong

# warn about format-string problems, including non-literal formats
gcc -Wformat=2 -Wformat-security

# catch overflows in testing
gcc -fsanitize=address -g

# static analysis
gcc -fanalyzer                # GCC 10+, finds many string bugs
```

FORMAT STRING VULNERABILITIES

```
printf(user_input);              /* CATASTROPHIC */
/* If user_input contains %s the program reads an arbitrary pointer;
   %n WRITES to memory. This is a full compromise, not a crash.   */

printf("%s", user_input);        /* correct — the format is a literal */

/* -Wformat-security flags any call where the format is not a
   literal. Treat it as an error, not a warning.                  */
```

How it shows up

Symptom	Cause
`strlen` returns a huge number	Missing terminator — often from `strncpy`
Output has trailing garbage	Buffer not terminated; `%s` read past the end
"stack smashing detected" on return	Canary caught a buffer overflow
Truncation goes unnoticed until data is corrupt downstream	Return value of `snprintf` / `strlcpy` ignored
Crash copying a string that "obviously fits"	Forgot the terminator byte in the size calculation
Non-ASCII input crashes or misbehaves	`<ctype.h>` called with a negative `char`
String length differs from displayed characters	UTF-8 — bytes, not characters
A key remains in memory after being zeroed	Dead store elimination removed the `memset`
Program leaks memory contents when given `%x` input	Format string vulnerability
`atoi("abc")` silently yields 0	No error reporting; use `strtol`

Check yourself

- ✓ Explain why `strlen` is O(n) and what that implies for loops that call it.
- ✓ Give two distinct reasons `strncpy` is not a safe `strcpy`.
- ✓ Explain what `snprintf` returns and how to detect truncation correctly.

- ✓ Write a fully correct integer parser using `strtol`, naming all four failure modes.
- ✓ Say what remains safe to do with UTF-8 without decoding it, and what does not.
- ✓ Explain the `<ctype.h>` negative-`char` bug.
- ✓ Explain why `memset` on a key buffer may be deleted, and give two fixes.
- ✓ Show a format string vulnerability and its one-character fix.

Structs, unions, padding and alignment

Structs are how C describes memory layout — for data structures, for hardware register blocks, and for wire protocols. The compiler inserts invisible padding to satisfy alignment, and if you do not know where it goes, you will write structs that are twice the size they need to be and protocol parsers that silently corrupt data.

Alignment

THE REQUIREMENT

Every type has an **alignment**: a power of two that its address must be a multiple of. Typically alignment equals size for scalar types — a 4-byte `int` must sit at an address divisible by 4.

The hardware imposes this. On ARM, an unaligned access to *Device* memory always faults; on Normal memory it usually works but may be slower or split into two bus transactions. On some architectures it faults everywhere. In C, forming or dereferencing a misaligned pointer is undefined behaviour regardless of what the hardware would do.

```
#include <stdalign.h>

alignof(char)      /* 1  */
alignof(short)     /* 2  */
alignof(int)       /* 4  */
alignof(double)    /* 8  */
alignof(void *)    /* 8 on 64-bit */
alignof(max_align_t)  /* the strictest fundamental alignment: 16 typically */

/* A struct's alignment is the LARGEST alignment among its members.
   Its size is always a multiple of its alignment.               */
```

Padding, member by member

```
struct bad {
        char  a;      /* offset 0                  */
                      /* offsets 1-3: PADDING      */
        int   b;      /* offset 4  (must be /4)    */
        char  c;      /* offset 8                  */
                      /* offsets 9-11: TAIL PADDING */
};                    /* sizeof == 12, alignof == 4 */

  byte:   0    1    2    3    4    5    6    7    8    9   10   11
        +----+----+----+----+----+----+----+----+----+----+----+----+
        | a  | ..pad.. |         b         | c  |    ..pad..       |
        +----+----+----+----+----+----+----+----+----+----+----+----+

Two kinds of padding, for two different reasons:

  INTERNAL padding aligns the NEXT member.
  TAIL padding makes sizeof a multiple of alignof, so that in an
  ARRAY of this struct, every element is correctly aligned.

Reorder largest-to-smallest and both shrink:

struct good {
        int   b;      /* offset 0 */
        char  a;      /* offset 4 */
        char  c;      /* offset 5 */
                      /* offsets 6-7: tail padding */
};                    /* sizeof == 8 — 33% smaller */
```

```
/* Inspect any struct's real layout — do not guess */
#include <stddef.h>
printf("size=%zu align=%zu b@%zu c@%zu\n",
       sizeof(struct bad), alignof(struct bad),
       offsetof(struct bad, b), offsetof(struct bad, c));

/* Or have the compiler print it for you */
//   gcc -Wpadded              warns wherever padding is inserted
//   pahole ./binary           shows every struct's holes (from dwarves)
//   clang -Xclang -fdump-record-layouts
```

WHY LAYOUT MATTERS BEYOND SIZE

A struct that fits in one 64-byte cache line costs one miss; one that straddles two costs two (CA ch. 14). In the Linux kernel, shrinking a frequently allocated struct below a slab size class is a measurable performance win. `pahole` exists precisely because this is worth doing systematically — and it is a routine kind of upstream patch.

packed: powerful and dangerous

```
struct __attribute__((packed)) wire {
        uint8_t  type;
        uint32_t length;      /* now at offset 1 — MISALIGNED */
        uint16_t flags;
};                            /* sizeof == 7, alignof == 1     */

/* This removes all padding. It also creates a real hazard: */

struct wire *w = (struct wire *)buffer;
uint32_t len = w->length;    /* compiler knows this is packed, so it
                                emits byte loads + shifts. Correct,
                                but slower.                          */

uint32_t *p = &w->length;    /* -Waddress-of-packed-member:
                                a plain uint32_t* implies 4-byte
                                alignment, which this is NOT.
                                Dereferencing p is UB and FAULTS on
                                strict-alignment targets.            */
```

THE PACKED-STRUCT RULES

1. **Never take the address of a packed member** and store it in a normal pointer. Enable `-Waddress-of-packed-member` and treat it as an error.
2. **Never pass a packed member by reference** to a function expecting an aligned pointer.
3. **Packed does not fix endianness.** It controls padding only. A wire protocol still needs explicit byte-order conversion.
4. **Prefer explicit serialisation** for protocols. Packed structs work, but they trade a portability problem you can see for one you cannot.

```
/* The robust alternative: explicit serialisation. Slightly more
   code, and immune to padding, alignment AND endianness.        */

static size_t wire_parse(const uint8_t *b, size_t n, struct msg *out)
{
        if (n < 7) return 0;
        out->type   = b[0];
        out->length = ((uint32_t)b[1] << 24) | ((uint32_t)b[2] << 16) |
                      ((uint32_t)b[3] <<  8) |  (uint32_t)b[4];   /* big endian */
        out->flags  = ((uint16_t)b[5] <<  8) |  (uint16_t)b[6];
        return 7;
}

/* Or use the standard conversions when you do use a struct: */
#include <arpa/inet.h>          /* htonl, ntohl, htons, ntohs      */
#include <endian.h>             /* htobe32, le32toh, ... (glibc)   */
val = be32toh(w->length);       /* kernel: be32_to_cpu()           */
```

Structs for hardware registers

```
/* The idiomatic MMIO register block: every member volatile, gaps
   declared explicitly, and a static assertion on the layout.    */

struct uart_regs {
        volatile uint32_t DR;         /* 0x00 data                */
        volatile uint32_t RSR;        /* 0x04 receive status      */
        uint32_t          _pad0[4];   /* 0x08-0x14 reserved       */
        volatile uint32_t FR;         /* 0x18 flags               */
        uint32_t          _pad1;      /* 0x1C                     */
        volatile uint32_t IBRD;       /* 0x20 integer baud rate   */
};

_Static_assert(sizeof(struct uart_regs) == 0x24, "uart_regs layout");
_Static_assert(offsetof(struct uart_regs, FR) == 0x18, "FR offset");

#define UART0 ((struct uart_regs *)0x40000000u)

/* Why the static asserts: a silent padding change - from a member
   type edit, a compiler upgrade, or a different ABI - would shift
   every subsequent register. The assert turns a runtime mystery
   into a build failure.                                          */

/* Note: do NOT pack a register-block struct. The registers are
   naturally aligned by design; packing only invites the compiler
   to emit byte accesses, which most peripherals reject.        */
```

Unions

```
/* All members share the same storage, starting at offset 0.
   sizeof is the largest member; alignof is the strictest.     */

union value {
        uint32_t u;
        float    f;
        uint8_t  bytes[4];
};                              /* sizeof == 4 */

/* Legal use 1: saving space when only one member is live at a time,
   with a tag to say which. This is a "tagged union".            */
struct variant {
        enum { V_INT, V_FLOAT, V_PTR } kind;
        union {
                int64_t i;
                double  d;
                void   *p;
        } u;
};

/* Legal use 2: type punning. In C — unlike C++ — reading a member
   other than the one last written is DEFINED, since C99 TC3.    */
union { float f; uint32_t bits; } cvt = { .f = 1.0f };
printf("%08x\n", cvt.bits);        /* 3f800000 — well defined in C */

/* The alternative that is always correct in both languages: */
uint32_t bits;
memcpy(&bits, &f, sizeof bits);    /* compiles to zero instructions
                                      at -O2; the compiler recognises
                                      the idiom                     */

/* What is NOT legal: punning through incompatible POINTERS.
   That violates strict aliasing — see chapter 15.               */
uint32_t bits = *(uint32_t *)&f;   /* UB. Do not do this.          */

/* Anonymous unions and structs (C11) — very common in kernel code */
struct packet {
        uint8_t type;
        union {                        /* no member name needed */
                struct { uint16_t a, b; } pair;
                uint32_t raw;
        };
};
p.raw = 0;  p.pair.a = 1;             /* accessed directly */
```

Bitfields

```
struct flags {
        unsigned int enable   : 1;
        unsigned int mode     : 3;
        unsigned int priority : 4;
        unsigned int          : 0;    /* force to next storage unit */
        unsigned int count    : 16;
};
```

BITFIELDS ARE UNSUITABLE FOR HARDWARE AND WIRE FORMATS

Almost everything about them is implementation-defined:

- **Allocation order** within a storage unit — MSB-first or LSB-first — is up to the ABI, so the same struct describes different bits on big- and little-endian targets.
- **Straddling** a storage-unit boundary is implementation-defined.
- **The underlying type**: only `int`, `signed int`, `unsigned int` and `_Bool` are portable. Plain `int` bitfields may be signed or unsigned — always write `unsigned`.
- **Access is not atomic.** Reading or writing one bitfield may read-modify-write the whole storage unit, so two threads updating adjacent bitfields can lose an update — even though they touch "different variables". The C11 memory model bounds this, but it still surprises people.
- **You cannot take the address** of a bitfield.

For registers and protocols, use explicit masks and shifts. They are portable, greppable, and generate the same code.

```
/* Do this instead */
#define CTRL_ENABLE      (1u << 0)
#define CTRL_MODE_SHIFT  1
#define CTRL_MODE_MASK   (0x7u << CTRL_MODE_SHIFT)

reg = (reg & ~CTRL_MODE_MASK) | ((mode << CTRL_MODE_SHIFT) & CTRL_MODE_MASK);
reg |= CTRL_ENABLE;

/* Linux provides checked helpers */
#include <linux/bitfield.h>
#define CTRL_MODE  GENMASK(3, 1)
reg = (reg & ~CTRL_MODE) | FIELD_PREP(CTRL_MODE, mode);
mode = FIELD_GET(CTRL_MODE, reg);
```

Initialisation

```
struct point { int x, y, z; };

struct point a = {1, 2, 3};          /* positional               */
struct point b = {1};                /* y and z are ZERO, not garbage */
struct point c = {0};                /* whole struct zeroed      */
struct point d = { };                /* C23; GNU extension before */

/* Designated initialisers (C99) — use these. They survive member
   reordering, document intent, and zero everything unmentioned. */
struct point e = { .x = 1, .z = 3 };          /* y == 0 */

/* Essential for sparse structs, which is why kernel code is full
   of them: */
static const struct file_operations fops = {
        .owner   = THIS_MODULE,
        .open    = my_open,
        .read    = my_read,
        .release = my_release,
        /* every other member is NULL — safely and explicitly */
};

/* Compound literals (C99): an unnamed object you can take the
   address of. Lifetime is the enclosing block.               */
send(&(struct point){ .x = 1, .y = 2 });
configure((struct cfg){ .baud = 115200, .bits = 8 });
```

Structs cannot be compared

```
struct point a, b;
if (a == b)                    /* COMPILE ERROR — no == for structs */

if (memcmp(&a, &b, sizeof a) == 0)   /* compiles, and is WRONG */

/* memcmp compares the PADDING BYTES too, and padding contents are
   indeterminate. Two structs with identical members can compare
   unequal. Assignment copies padding unpredictably; a struct built
   field-by-field has different padding from one from an initialiser.

   Correct: compare member by member.                              */
static bool point_eq(const struct point *a, const struct point *b)
{
        return a->x == b->x && a->y == b->y && a->z == b->z;
}

/* The same reasoning applies to HASHING a struct and to sending one
   over a wire: padding bytes may leak stale stack contents — a real
   information-disclosure class in kernel ioctl handlers. Always
   memset the whole struct before filling it, when it crosses a
   trust boundary.                                                 */
struct info out;
memset(&out, 0, sizeof out);      /* not just = {0} on all paths */
out.a = ...;
copy_to_user(u, &out, sizeof out);
```

container_of

```
/* Given a pointer to a member, recover the enclosing struct.
   This is how intrusive data structures work throughout the kernel. */

#define container_of(ptr, type, member) \
        ((type *)((char *)(ptr) - offsetof(type, member)))

struct task {
        int              pid;
        struct list_head list;     /* embedded, not a pointer */
        char             name[16];
};

/* Given a struct list_head *node from a generic list walk: */
struct task *t = container_of(node, struct task, list);

/* Why this is better than a `void *data` pointer in the node:
     - no extra allocation per element
     - no extra indirection on access
     - one object can be on SEVERAL lists at once, each with its
       own embedded node
   The cost is that it is pointer arithmetic the compiler cannot
   type-check, which is why the kernel's version adds a
   __same_type() assertion.                                      */
```

How it shows up

Symptom	Cause
`sizeof` a struct is larger than the sum of its members	Padding — reorder members largest first
A wire protocol parses correctly on x86, wrongly on ARM	Endianness, or a bitfield's implementation-defined order
Fault when dereferencing a pointer to a packed member	Misaligned pointer; strict-alignment target
Register writes go to the wrong offsets after a compiler upgrade	Padding changed; add `_Static_assert` on offsets
Two identical-looking structs compare unequal	`memcmp` including indeterminate padding
Kernel leaks stack bytes to userspace	Padding in a struct copied out without being zeroed
Concurrent updates to adjacent bitfields lose one	Read-modify-write of the shared storage unit
Struct grew and throughput dropped	It now spans two cache lines
Uninitialised member despite an initialiser	Positional initialiser missing a member — use designated form

Check yourself

- ✓ Compute the size and layout of `struct { char a; int b; char c; }` and reorder it optimally.
- ✓ Explain the difference between internal and tail padding, and why tail padding must exist.
- ✓ Give three rules for using packed structs safely, and say what packed does *not* fix.
- ✓ Write a register-block struct with static assertions and explain what they protect against.
- ✓ Explain why type punning through a union is legal in C but a pointer cast is not.
- ✓ List four implementation-defined properties of bitfields.
- ✓ Explain why `memcmp` on structs is wrong, and what to do instead.

- ✓ Write `container_of` and explain why intrusive lists use it.

Bit manipulation

Embedded work is bit work. Every hardware register is a packed collection of fields, every protocol header is bit-aligned, and every flag set is a bitmask. This chapter is the complete idiom set, plus the traps that make bit code subtly wrong.

Ground rules

FOUR RULES THAT PREVENT MOST BIT BUGS

1. **Use unsigned types.** Signed shifts, signed overflow and sign extension are all undefined or implementation-defined. There is no upside.
2. **Suffix your literals.** `1u`, `1ul`, `1ull` — a bare `1` is an `int`, and `1 << 40` is undefined behaviour.
3. **Parenthesise.** Bitwise operators bind looser than comparison (ch. 03).
4. **Name your masks.** A bare `0x38` in a shift is unreviewable.

Single-bit operations

```
#define BIT(n)  (1u << (n))        /* for <32-bit fields          */
#define BIT_ULL(n) (1ull << (n))   /* when n may reach 32 or more */

x |=  BIT(n);                /* set        */
x &= ~BIT(n);                /* clear      */
x ^=  BIT(n);                /* toggle     */
if (x & BIT(n)) ...          /* test       */

/* conditionally set or clear without a branch */
x = (x & ~BIT(n)) | ((-(unsigned)cond) & BIT(n));
/* -(unsigned)cond is 0x00000000 or 0xFFFFFFFF — a mask from a bool */

/* the same idea, more readable */
if (cond) x |=  BIT(n);
else      x &= ~BIT(n);
```

THE SHIFT TRAPS, AGAIN

```
1 << 31            /* UB: shifting into the sign bit of an int */
1u << 31           /* fine                                     */
1 << 32            /* UB: n must be < width of the type        */
1ull << 40         /* fine                                     */

uint64_t m = 1 << bit;      /* BUG for bit >= 32: computed in int,
                               THEN widened                      */
uint64_t m = 1ull << bit;   /* correct                           */

x >> n             /* if x is signed and negative, the result is
                      implementation-defined (arithmetic shift in
                      practice, but do not rely on it)          */

/* And a shift by a variable that can equal the width: */
uint32_t mask = (1u << width) - 1;    /* UB when width == 32 */
uint32_t mask = width >= 32 ? ~0u : (1u << width) - 1;   /* safe */
uint32_t mask = (uint32_t)((1ull << width) - 1);          /* also safe */
```

Multi-bit fields

```
A 32-bit control register, as a TRM would document it:

  31    24 23  20 19        8 7    4 3  1  0
 +--------+------+-----------+------+----+--+
 | RESVD  | MODE |  DIVISOR  | PRIO |RSV |EN|
 +--------+------+-----------+------+----+--+

  EN       bit  0
  PRIO     bits 7:4
  DIVISOR  bits 19:8
  MODE     bits 23:20

Turn each field into a shift and a mask, once, at the top of the file.
```

```
#define CTRL_EN            BIT(0)
#define CTRL_PRIO_SHIFT    4
#define CTRL_PRIO_MASK     (0xFu   << CTRL_PRIO_SHIFT)
#define CTRL_DIV_SHIFT     8
#define CTRL_DIV_MASK      (0xFFFu << CTRL_DIV_SHIFT)
#define CTRL_MODE_SHIFT    20
#define CTRL_MODE_MASK     (0xFu   << CTRL_MODE_SHIFT)

/* extract */
unsigned prio = (reg & CTRL_PRIO_MASK) >> CTRL_PRIO_SHIFT;

/* insert - ALWAYS clear before OR-ing, and mask the value so an
   out-of-range input cannot corrupt neighbouring fields          */
reg = (reg & ~CTRL_PRIO_MASK) |
      ((prio << CTRL_PRIO_SHIFT) & CTRL_PRIO_MASK);

/* generic helpers, if you have no library */
#define FIELD_MASK(hi, lo)  (((1ull << ((hi) - (lo) + 1)) - 1) << (lo))
#define FIELD_GET(r, hi, lo)  (((r) & FIELD_MASK(hi, lo)) >> (lo))
#define FIELD_SET(r, hi, lo, v) \
        (((r) & ~FIELD_MASK(hi, lo)) | \
         (((uint64_t)(v) << (lo)) & FIELD_MASK(hi, lo)))
```

```
/* Linux's version, which you should copy the design of: the mask is
   the single source of truth and the shift is derived from it, so
   the two can never disagree.                                      */
#include <linux/bitfield.h>

#define CTRL_PRIO  GENMASK(7, 4)      /* 0x000000F0 */
#define CTRL_DIV   GENMASK(19, 8)
#define CTRL_MODE  GENMASK(23, 20)

prio = FIELD_GET(CTRL_PRIO, reg);
reg  = (reg & ~CTRL_PRIO) | FIELD_PREP(CTRL_PRIO, prio);

/* FIELD_PREP checks at COMPILE TIME that the value fits in the
   field and that the mask is a contiguous run of bits. That is
   the whole reason to prefer it over hand-rolled shifts.       */
```

Register access semantics

Type	Meaning	Correct access
RW	Read/write	Read-modify-write is fine
RO	Read only	Never write
WO	Write only; reads return garbage	Never read-modify-write — keep a shadow copy
W1C	Write 1 to clear	Write only the bits you want cleared
W1S	Write 1 to set	Same
RC	Read clears	Read exactly once and keep the value

```
/* W1C is the one people get wrong. */
reg |= IRQ_DONE;             /* WRONG: read-modify-write on W1C.
                                The read returns ALL pending bits, and
                                writing them back clears interrupts you
                                have not handled yet — silently losing
                                events.                              */

writel(IRQ_DONE, base + STATUS);   /* correct: write ONLY that bit */

/* Write-only registers need a shadow, because you cannot read back */
static uint32_t ctrl_shadow;
static void ctrl_update(uint32_t set, uint32_t clr)
{
        ctrl_shadow = (ctrl_shadow & ~clr) | set;
        writel(ctrl_shadow, base + CTRL);
}
```

Counting, finding and rounding

```
/* Use the builtins. They map to single instructions (CLZ, RBIT,
   CNT on ARM) and are far faster than a loop.                  */

__builtin_popcount(x)        /* number of set bits, unsigned int  */
__builtin_popcountll(x)      /* ...long long                      */
__builtin_clz(x)             /* count leading zeros  - UB if x==0 */
__builtin_ctz(x)             /* count trailing zeros - UB if x==0 */
__builtin_ffs(x)             /* find first set, 1-based, 0 if x==0 */
__builtin_parity(x)          /* 1 if an odd number of bits set    */

/* C23 standardises these in <stdbit.h>: */
stdc_count_ones(x)  stdc_leading_zeros(x)  stdc_trailing_zeros(x)
stdc_bit_width(x)   stdc_bit_ceil(x)       stdc_has_single_bit(x)

/* Linux equivalents that handle zero safely */
hweight32(x)   fls(x)   ffs(x)   __ffs(x)   ilog2(x)
```

```
/* Derived idioms - worth recognising instantly */

x & (x - 1)               /* clear the LOWEST set bit             */
x & -x                    /* ISOLATE the lowest set bit           */
x | (x - 1)               /* set all bits below the lowest set bit */
!(x & (x - 1)) && x       /* is x a power of two?                 */

/* iterate over set bits efficiently */
while (mask) {
        int bit = __builtin_ctzll(mask);
        handle(bit);
        mask &= mask - 1;          /* clear the one we just did */
}

/* round up to a multiple of a power of two */
#define ALIGN_UP(x, a)    (((x) + (a) - 1) & ~((a) - 1))
#define ALIGN_DOWN(x, a)  ((x) & ~((a) - 1))
#define IS_ALIGNED(x, a)  (((x) & ((a) - 1)) == 0)
/* NOTE: these require `a` to be a power of two. Assert it. */

/* round up to the next power of two */
static uint32_t next_pow2(uint32_t x)
{
        return x <= 1 ? 1 : 1u << (32 - __builtin_clz(x - 1));
}

/* ceiling division without floating point */
#define DIV_ROUND_UP(n, d)  (((n) + (d) - 1) / (d))
```

Byte order

```
/* Endianness is about the order of BYTES within a multi-byte value.
   It matters whenever bytes cross a boundary: a network, a file,
   another chip.                                                    */

uint32_t v = 0x12345678;

/* little endian (ARM, x86): low byte first  */   78 56 34 12
/* big endian ("network order"):             */   12 34 56 78

/* Never swap by hand with a cast — use the standard conversions. */
#include <arpa/inet.h>    /* htonl htons ntohl ntohs           */
#include <endian.h>       /* htobe32 htole32 be32toh le32toh   */

uint32_t on_wire = htobe32(v);       /* host -> big endian     */
uint32_t host    = be32toh(on_wire); /* big endian -> host     */

/* Linux kernel, with type annotations that sparse checks: */
__be32 x = cpu_to_be32(v);
v = be32_to_cpu(x);
/* Declaring the field as __be32 and building with `make C=1` makes
   a missing conversion a WARNING rather than a silent bug.      */

/* the builtins, if you need a raw swap */
__builtin_bswap16(x)  __builtin_bswap32(x)  __builtin_bswap64(x)

/* On a little-endian host these conversions compile to a single
   REV instruction; on a big-endian host they compile to nothing.
   There is no reason to avoid them.                             */
```

> **ENDIANNESS IS NOT THE SAME AS BIT ORDER**
>
> Within a byte, bit numbering is a documentation convention, not a hardware property — `x & 1` is the least significant bit everywhere. Endianness only reorders *bytes*. But a bitfield spanning a byte boundary is affected by both, which is one more reason bitfields are unsuitable for wire formats (ch. 07).

Bitmaps

```
/* A bitmap over N items, packed into words. */
#define BITS_PER_WORD   (8 * sizeof(unsigned long))
#define BITMAP_WORDS(n) (((n) + BITS_PER_WORD - 1) / BITS_PER_WORD)

unsigned long map[BITMAP_WORDS(1024)];

static inline void bm_set(unsigned long *m, size_t i)
{ m[i / BITS_PER_WORD] |=  1ul << (i % BITS_PER_WORD); }

static inline void bm_clear(unsigned long *m, size_t i)
{ m[i / BITS_PER_WORD] &= ~(1ul << (i % BITS_PER_WORD)); }

static inline bool bm_test(const unsigned long *m, size_t i)
{ return m[i / BITS_PER_WORD] & (1ul << (i % BITS_PER_WORD)); }

/* find the first zero bit - an allocator in four lines */
static size_t bm_find_free(const unsigned long *m, size_t n)
{
        for (size_t w = 0; w < BITMAP_WORDS(n); w++)
                if (~m[w])
                        return w * BITS_PER_WORD + __builtin_ctzl(~m[w]);
        return n;                   /* none free */
}

/* Linux has a complete, tested API - use it in kernel code:
     DECLARE_BITMAP, set_bit, clear_bit, test_and_set_bit,
     find_first_zero_bit, bitmap_weight, for_each_set_bit

   Note that set_bit() and friends are ATOMIC; __set_bit() is not.
   Choosing wrongly gives you a lost-update race under concurrency. */
```

Branchless and constant-time code

```
/* Two reasons to avoid branching on data:
     1. performance, when the branch is unpredictable (CA ch. 12)
     2. SECURITY, when the data is secret — branch timing leaks it */

/* select without a branch */
uint32_t mask = -(uint32_t)cond;          /* 0 or 0xFFFFFFFF */
result = (a & mask) | (b & ~mask);        /* cond ? a : b     */

/* min and max */
int min = b ^ ((a ^ b) & -(a < b));

/* absolute value, without a branch */
int mask = x >> (sizeof(int) * 8 - 1);    /* 0 or -1 (arithmetic shift) */
int abs  = (x + mask) ^ mask;

/* constant-time comparison — never use memcmp on secrets */
static int ct_eq(const uint8_t *a, const uint8_t *b, size_t n)
{
        uint8_t d = 0;
        for (size_t i = 0; i < n; i++)
                d |= a[i] ^ b[i];         /* no early exit */
        return d == 0;
}

/* The compiler may still reintroduce a branch. In real cryptographic
   code, verify the generated assembly, or use a vetted library.
   See the cryptography track, chapter 19.                          */
```

How it shows up

Symptom	Cause
A flag test is always false	`x & MASK == 0` — precedence
Setting bit 32 or higher does nothing	`1 << n` computed in `int`
Writing one field corrupts a neighbouring one	Missing mask on the value, or missing clear before OR
Interrupts are silently lost	Read-modify-write on a W1C status register
Reading a register changes system behaviour	Read-clear semantics; you read it twice
Protocol works locally, fails across the network	Missing byte-order conversion
Struct-based parser breaks on a different compiler	Bitfield allocation order is implementation-defined
Mask computation gives 0 for full width	`(1u << 32) - 1` is undefined
Two threads updating flags lose an update	Non-atomic read-modify-write; use `set_bit` or an atomic
Password comparison leaks timing	`memcmp` returns early on the first difference

Check yourself

- ✓ Give the four ground rules for bit code and the bug each prevents.
- ✓ Write set, clear, toggle and test for a single bit, safely for bit numbers up to 63.
- ✓ Extract and insert a 4-bit field at bits 7:4, masking the input value.
- ✓ Explain W1C semantics and why read-modify-write breaks it.

- ✓ Explain what `x & (x - 1)` and `x & -x` compute.
- ✓ Write a safe full-width mask expression for a runtime width of 0–32.
- ✓ Explain when byte-order conversion is needed and name the correct functions.
- ✓ Write a constant-time equality check and say why `memcmp` is unsuitable.

Storage duration, scope and linkage

Three independent properties that every identifier in C has, and that beginners routinely merge into one vague notion of "global". Separating them explains `static`'s two unrelated meanings, why `extern` exists, and what actually ends up in each section of your binary.

Three orthogonal questions

Property	Question it answers	Values
Storage duration	When does the object exist?	static, automatic, thread, allocated
Scope	Where is the name visible in the source?	file, block, function, function-prototype
Linkage	Do declarations in different translation units refer to the same object?	external, internal, none

```
They are independent. All eight useful combinations occur:

  int g;                     file scope, external linkage, static duration
  static int s;              file scope, INTERNAL linkage, static duration
  void f(void) {
      int a;                 block scope, no linkage, AUTOMATIC duration
      static int c;          block scope, no linkage, STATIC duration
      extern int g;          block scope, external linkage
      _Thread_local int t;   thread duration
      int *p = malloc(4);    p is automatic; *p has ALLOCATED duration
  }

The word `static` means two completely different things depending on
where it appears. That is a genuine wart in the language, not
something you are failing to understand.
```

Storage duration

Automatic

```
void f(void)
{
        int a;              /* INDETERMINATE — not zero */
        int b = 0;          /* explicitly initialised    */
        char buf[1024];     /* 1 KB of stack             */
}                           /* all cease to exist here    */

/* Reading an uninitialised automatic object is undefined behaviour,
   not "reads garbage". The compiler may assume it never happens.
   -Wuninitialized and -fsanitize=memory catch it.               */

/* Lifetime ends at the closing brace, INCLUDING inner blocks: */
int *p;
{
        int x = 5;
        p = &x;
}
*p;                         /* dangling: x's lifetime ended        */

/* Stack size is finite and often small:
     Linux userspace thread   8 MB default
     Linux KERNEL stack       8–16 KB    <- total, for the whole call chain
     Cortex-M firmware        1–8 KB
   Which is why kernel code never puts large buffers on the stack,
   and why VLAs are banned there (chapter 05).                    */
```

Static

```
int g_count;                /* zero-initialised, guaranteed */
static int s_flag = 1;
const char msg[] = "hi";

void f(void)
{
        static int calls = 0;    /* initialised ONCE, before main();
                                    retains its value between calls */
        calls++;
}

/* Static objects with no explicit initialiser are ZERO-initialised.
   This is a guarantee, unlike automatic storage.                  */

/* The initialiser must be a CONSTANT EXPRESSION — evaluated at
   translation time, not at run time:                             */
static int a = 5;              /* fine                    */
static int b = 5 * 3;          /* fine: constant folded   */
static int c = f();            /* ERROR in C (legal in C++) */
static int d = another_static; /* ERROR: not a constant     */
```

STATIC DURATION AND REENTRANCY

A function-local `static` makes the function **non-reentrant**: two threads, or an interrupt handler and mainline code, share that one object. This is why `strtok`, `asctime` and `gmtime` all have `_r` variants, and why a "just cache it in a static" optimisation is a concurrency bug waiting for a second thread. Use a caller-supplied buffer, or `_Thread_local`.

Thread

```
#include <threads.h>
_Thread_local int errno_like;      /* C11; one instance per thread   */
thread_local int x;                 /* C23 spelling / <threads.h>     */
__thread int y;                     /* GCC extension, widely used     */

/* Cost: access needs a TLS lookup — cheap but not free, and in
   shared libraries it can require a function call the first time.
   In the Linux kernel the equivalent is per-CPU data:            */
DEFINE_PER_CPU(int, my_counter);
this_cpu_inc(my_counter);       /* no locking needed: it is ours */
```

Allocated

```
void *p = malloc(n);            /* lifetime: from malloc to free     */
/* Covered fully in chapter 14. The key point here is that the
   POINTER has automatic duration while the OBJECT has allocated
   duration — two different lifetimes, and confusing them is
   exactly what a memory leak or a dangling pointer is.          */
```

Linkage, and what the linker sees

Linkage	Meaning	How to get it
External	One object shared across all translation units	File-scope declaration without `static`
Internal	One object per translation unit; invisible to the linker	File-scope `static`
None	Not shared at all	Block-scope objects, function parameters, `typedef`s

```
/* util.c */
int  public_counter;              /* external: visible everywhere    */
static int private_state;         /* internal: only this file        */
static void helper(void) { }      /* internal: not in the symbol table */
void api_function(void) { }       /* external                        */

/* main.c */
extern int public_counter;        /* refers to util.c's object       */
/* extern int private_state; */   /* LINK ERROR: undefined symbol    */
```

WHY `STATIC` AT FILE SCOPE IS GOOD PRACTICE, NOT JUST HIDING

- **Prevents name collisions** across the whole program — a real problem in large C codebases with no namespaces.
- **Enables optimisation.** The compiler can see every use of an internal-linkage function, so it can inline it aggressively, clone it, change its calling convention, or delete it entirely if unused.
- **Documents intent** — this is an implementation detail, not API.
- **Shrinks the symbol table** and the exported surface.

Rule: **everything at file scope should be `static` unless it is declared in a header.** Build with `-Wmissing-prototypes` to catch violations mechanically.

Declaration versus definition

```
/* A DECLARATION introduces a name and its type.
   A DEFINITION additionally allocates storage or supplies a body.
   You may declare a thing many times; you may define it once.    */

extern int x;               /* declaration                       */
int x;                      /* definition (tentative - see below) */
int x = 5;                  /* definition with initialiser        */

void f(void);               /* declaration (prototype)            */
void f(void) { }            /* definition                         */

/* The C-specific wrinkle: a TENTATIVE definition. */
int x;          /* at file scope, with no initialiser, this is a
                   "tentative definition". Several are allowed in
                   ONE translation unit and collapse into one.    */

/* Across translation units, C90 compilers accepted multiple
   tentative definitions and merged them - the "common symbol"
   model. GCC 10 changed the default to -fno-common, so this is
   now an error, as it always should have been:                */

/* a.c */  int counter;
/* b.c */  int counter;      /* error: multiple definition of `counter' */

/* THE CORRECT PATTERN, and the only one you should use: */

/* counter.h */
extern int counter;          /* declaration only, in the header */

/* counter.c */
#include "counter.h"         /* include your OWN header - this is
                                what makes the compiler check the
                                definition against the declaration */
int counter = 0;             /* the single definition             */
```

Header discipline

```
/* my_module.h */
#ifndef MY_MODULE_H
#define MY_MODULE_H            /* include guard — always            */

#include <stddef.h>            /* headers must be self-contained:
                                  include what YOU need, so the
                                  user need not guess the order    */

struct my_thing;               /* forward declaration is enough if
                                  callers only handle pointers      */

extern int my_global;                      /* declaration       */
int  my_init(void);                         /* declaration       */
void my_process(struct my_thing *, size_t);

/* An inline function in a header needs care in C (unlike C++): */
static inline int my_helper(int x) { return x * 2; }
/* `static inline` gives every TU its own copy with internal
   linkage. It always works, and is what you want 99% of the time.
   Plain `inline` in C requires exactly one TU to also provide an
   `extern inline` definition, which is a rule almost nobody
   remembers correctly.                                          */

#endif /* MY_MODULE_H */
```

Put in the header	Keep in the .c file
Declarations of public functions	Definitions
`extern` declarations of public variables	The one definition
Types callers must know the size of	Types callers only hold pointers to (opaque)
Macros and constants that are part of the API	Internal macros
`static inline` helpers, if small and hot	Everything else

```
/* Opaque types: the single most useful encapsulation technique in C */

/* device.h — callers see only a pointer */
struct device;                          /* incomplete type      */
struct device *device_create(void);
int  device_read(struct device *, void *, size_t);
void device_destroy(struct device *);

/* device.c — the layout is private */
struct device {
        int fd;
        char name[64];
        struct buffer *buf;
};

/* Callers cannot allocate one on the stack, cannot access members,
   and cannot break when you change the layout. The whole struct is
   an implementation detail. This is how every good C library is
   structured — FILE*, pthread_t and struct device in the kernel
   are all this pattern.                                          */
```

Where objects actually land

```
   ELF sections, and what maps to each

   .text     code, read-only, executable
             functions, and const data on some targets

   .rodata   read-only data
             string literals, const arrays, jump tables
             -> writing here faults (chapter 05)

   .data     initialised read-write static-duration objects
             int g = 5;
             -> occupies space in the BINARY (the initial values
                must be stored somewhere)

   .bss      zero-initialised static-duration objects
             int g;  static char buf[1<<20];
             -> occupies NO space in the binary, only a size.
                The loader (or startup code) zeroes it.
                This is why a 1 MB zeroed array costs nothing on disk.

   stack     automatic-duration objects
   heap      allocated-duration objects
```

```
# see it for yourself
size ./program
#    text    data     bss     dec     hex filename
#   12345     456   10240   23041    5a01 ./program

nm -C --size-sort ./program | tail -20     # largest symbols
nm ./program | grep ' [bB] '               # bss symbols
readelf -S ./program                       # section headers
objdump -t ./program                        # full symbol table

# in embedded work, `size` is a build-gate metric: .text must fit
# in flash and .data + .bss must fit in RAM.

# placing objects in a specific section, for linker scripts
__attribute__((section(".fast_code"))) void isr(void) { }
__attribute__((section(".noinit")))    uint32_t boot_count;
```

Initialisation order

```
/* Within one translation unit, static objects are initialised in
   declaration order — but in C they are all constant expressions,
   so there is no ordering hazard as there is in C++.

   What DOES have an ordering problem is constructor attributes: */

__attribute__((constructor))       void setup(void)   { }
__attribute__((constructor(101)))  void setup_early(void) { }
__attribute__((destructor))        void teardown(void) { }

/* Order ACROSS translation units is unspecified (priority values
   help, but only within one link unit). Do not build dependencies
   between constructors in different files.

   The robust pattern is explicit initialisation from main(), or
   lazy initialisation guarded by a flag:                          */

static bool ready;
static void ensure_init(void)
{
        if (!ready) { do_init(); ready = true; }
}
/* ...and note that this is NOT thread safe. For that you need
   call_once (C11) or pthread_once.                                */

#include <threads.h>
static once_flag once = ONCE_FLAG_INIT;
call_once(&once, do_init);
```

How it shows up

Symptom	Cause
"multiple definition of X" at link time	A variable defined in a header, or in two .c files
"undefined reference to X"	Declared but never defined; or defined `static` in another file
Two modules corrupt each other's data	Same external name in both; should have been `static`
Value changes unexpectedly between calls	A function-local `static` you forgot about
Function misbehaves when called from two threads	Non-reentrant: shared `static` state
Returned pointer contains garbage	Pointer to an automatic object whose lifetime ended
Binary is huge for a program with little code	Large initialised arrays in `.data`; make them zero-init or `const`
Works with GCC 9, fails to link with GCC 10	`-fno-common` became the default; fix the tentative definitions
Constructor runs before something it depends on	Cross-TU initialisation order is unspecified
Stack overflow in kernel or firmware	Large automatic buffer; kernel stacks are 8–16 KB

Check yourself

- ✓ Name the three orthogonal properties and give an example of each combination that matters.
- ✓ Explain `static`'s two distinct meanings and where each applies.
- ✓ Say which objects are zero-initialised for you and which are indeterminate.

- ✓ Explain why a function-local `static` makes a function non-reentrant.
- ✓ Give the correct header/source pattern for a shared global and say why the .c file includes its own header.
- ✓ Explain what a tentative definition is and why `-fno-common` changed things.
- ✓ Describe the opaque-type pattern and what it buys.
- ✓ Say which section a 1 MB zeroed array lands in and why it does not bloat the binary.

const, volatile and restrict

Three qualifiers, three completely different jobs. `const` is a promise you make to the compiler; `volatile` is a promise the compiler makes to you; `restrict` is a promise you make that the compiler cannot verify. Each is routinely misunderstood, and `volatile` especially so.

const

WHAT IT MEANS

`const` says "*I will not modify this object through this expression.*" It is a type-system constraint, checked at compile time. It does **not** mean the object is immutable, and it does **not** mean the value is a compile-time constant.

```
/* Placement — read right to left from the identifier */
const int *p;          /* pointer to const int: *p is read-only     */
int const *p;          /* identical                                  */
int *const p;          /* const pointer: p itself cannot be reseated */
const int *const p;    /* both                                       */

const int *p = &x;
*p = 5;                /* error: object is const through p           */
p = &y;                /* fine                                       */
x = 5;                 /* FINE — x itself is not const               */

/* That last line is the point: const on a pointer restricts what
   YOU may do through that pointer, not what the object is.       */
```

Where const earns its place

```
/* 1. API documentation the compiler enforces */
size_t strlen(const char *s);          /* will not modify s          */
void *memcpy(void *dst, const void *src, size_t n);   /* src is read */

/* 2. Genuinely read-only data goes in .rodata, saving RAM —
      which on a microcontroller is the scarce resource         */
static const uint8_t font_table[4096] = { ... };   /* flash, not RAM */

/* 3. Catching mistakes at compile time */
void process(const struct config *cfg)
{
        cfg->retries = 3;      /* error — caught immediately         */
}
```

THREE THINGS CONST IS NOT

1. **Not a compile-time constant.** `const int n = 10; int a[n];` is a VLA in C, not a fixed array. Use `#define`, an `enum`, or C23's `constexpr` for array bounds and case labels.
2. **Not immutability.** Casting it away and writing is undefined *only if the object was originally defined const*. Writing through a cast to a non-const object is legal — which is why `const` cannot be relied on for security.
3. **Not deep.** `const struct s *p` makes `p->field` const, but if `field` is a pointer, `*p->field` is still writable. C has no transitive const.

```
/* The const-correctness annoyance you will hit: C, unlike C++, does
   not implicitly convert `T**` to `const T**`. This is by design —
   allowing it would let you smuggle a const pointer into a
   non-const one — but it means some correct code needs a cast.   */
void f(const char **p);
char *argv[10];
f(argv);                    /* warning: incompatible pointer type */
f((const char **)argv);     /* explicit, and safe here            */
```

volatile

WHAT IT MEANS

`volatile` tells the compiler: *this object may change by means outside this program's control, so perform every access exactly as written — do not cache it in a register, do not eliminate it, do not duplicate it, and do not reorder it relative to other volatile accesses.*

It constrains the **compiler**. It says nothing to the CPU or the memory system.

```
/* Without volatile, this is an infinite loop at -O2 */
uint32_t *status = (uint32_t *)0x40000018;
while (!(*status & READY))     /* nothing in the loop changes *status,
        ;                         so the compiler loads it ONCE, or
                                  deletes the loop entirely          */

/* With volatile, the load happens every iteration */
volatile uint32_t *status = (volatile uint32_t *)0x40000018;
while (!(*status & READY))
        ;
```

The three legitimate uses

Use	Why
Memory-mapped I/O	Hardware changes the value; reads and writes have side effects
Variables modified by a signal handler	Must be `volatile sig_atomic_t`; the handler runs outside normal flow
Variables modified across `setjmp` / `longjmp`	Non-volatile locals have indeterminate values after a `longjmp`

VOLATILE IS NOT FOR THREADS

This is the most persistent misconception in C. `volatile` gives you *none* of what concurrent code needs:

- **No atomicity.** `volatile int x; x++;` is still a load, an add and a store. Two threads can still lose an update.
- **No memory ordering.** Volatile accesses are ordered relative to *each other*, but not relative to ordinary accesses, and the *hardware* is free to reorder everything anyway on a weakly ordered machine like ARM (CA ch. 15).
- **No visibility guarantee.** Nothing forces the store out of the store buffer or invalidates another core's cache line.

For threads, use `_Atomic` / `<stdatomic.h>`, or your platform's primitives. Linus Torvalds' well-known essay on this is `Documentation/process/volatile-considered-harmful.rst` in the kernel tree — it is worth reading.

```
/* WRONG — a classic that appears to work until it does not */
volatile bool done = false;
volatile int  result;

void producer(void) { result = compute(); done = true; }
void consumer(void) { while (!done) ; use(result); }
/* On ARM the two stores may become visible in either order, so the
   consumer can see done==true and a stale result. volatile did
   nothing to prevent it.                                          */

/* RIGHT — C11 atomics */
#include <stdatomic.h>
atomic_bool done = false;
int result;                             /* plain int is fine now */

void producer(void)
{
        result = compute();
        atomic_store_explicit(&done, true, memory_order_release);
}
void consumer(void)
{
        while (!atomic_load_explicit(&done, memory_order_acquire))
                ;
        use(result);                    /* guaranteed to see it   */
}
```

volatile in MMIO, done properly

```
/* volatile alone is not sufficient for device registers either —
   it stops the COMPILER reordering, not the CPU or the bus.     */

/* Bare metal: pair it with barriers where ordering matters */
static inline void mmio_write32(uintptr_t a, uint32_t v)
{
        *(volatile uint32_t *)a = v;
        __asm__ volatile("dsb sy" ::: "memory");   /* if it must land */
}

/* In an OS, use the accessors — they get this right for you: */
writel(val, base + CTRL);        /* Linux: volatile + barriers      */
readl(base + STATUS);
writel_relaxed(val, base + CTRL);  /* no barrier, when order is
                                      genuinely irrelevant           */
WRITE_REGISTER_ULONG(reg, val);  /* Windows                          */

/* Never hand-roll MMIO access in kernel code. The accessors also
   encode endianness and, on some architectures, special
   instructions that a plain volatile store would not use.       */
```

The volatile-qualified struct pattern

```
/* Correct: every member volatile */
struct uart_regs {
        volatile uint32_t DR;
        volatile uint32_t FR;
};

/* Also correct, and shorter: qualify the pointer */
struct uart_regs { uint32_t DR; uint32_t FR; };
volatile struct uart_regs *u = (volatile struct uart_regs *)BASE;

/* WRONG: qualifying the pointer variable rather than the target */
struct uart_regs *volatile u;      /* the POINTER is volatile;
                                      the registers are not!      */
```

restrict

WHAT IT MEANS

`restrict` on a pointer promises: *within the lifetime of this pointer, the object it points to will not be accessed through any other pointer.* It is a promise **you** make. The compiler cannot check it, and breaking it is undefined behaviour with no diagnostic.

It applies only to pointers, and it exists purely to enable optimisation.

```
/* Without restrict, the compiler must assume a and b may overlap */
void add(int *a, const int *b, size_t n)
{
        for (size_t i = 0; i < n; i++)
                a[i] += b[i];
}
/* Every iteration must RELOAD b[i], because the previous store to
   a[i] might have modified it. No vectorisation possible.       */

/* With restrict, the promise unlocks it */
void add(int *restrict a, const int *restrict b, size_t n)
{
        for (size_t i = 0; i < n; i++)
                a[i] += b[i];
}
/* Now the compiler can load a block of b, load a block of a, add
   them with SIMD, and store. Typically 4-8x faster.             */
```

```
/* The canonical illustration: two functions, one difference. */
void *memcpy (void *restrict dst, const void *restrict src, size_t n);
void *memmove(void       *dst, const void       *src, size_t n);

/* memcpy's arguments are restrict: overlapping is UNDEFINED, and
   glibc's memcpy really does misbehave on overlap — it copies in
   whatever order is fastest, including backwards.

   memmove handles overlap correctly and pays for it.

   If you are not certain the buffers are disjoint, use memmove. The
   "memcpy is faster" reasoning is not worth a corruption bug.   */
```

HOW TO BREAK A RESTRICT PROMISE WITHOUT NOTICING

```
void f(int *restrict a, int *restrict b);
int arr[10];
f(arr, arr);              /* UB — same object through both        */
f(arr, arr + 5);          /* UB if the accessed ranges overlap    */

/* Aliasing through a struct member is easy to miss: */
void g(struct s *restrict p, int *restrict q);
g(&obj, &obj.field);      /* UB — q points inside *p              */

/* Rule of thumb: only use restrict on parameters of leaf functions
   whose callers you control, or where the API contract explicitly
   forbids overlap (and is documented as doing so).             */
```

Combining qualifiers

```
/* const volatile — real and useful: a hardware register that the
   device updates but software must never write.               */
const volatile uint32_t *status = (const volatile uint32_t *)0x40000018;
uint32_t s = *status;      /* fine: reads happen every time      */
*status = 0;               /* compile error: correctly rejected  */

/* Typical for: status registers, free-running counters, ID registers */

/* volatile const is the same thing; order does not matter.       */

/* restrict + const is common in read-only source parameters */
void transform(float *restrict out, const float *restrict in, size_t n);
```

_Atomic, for completeness

```
#include <stdatomic.h>

_Atomic int counter;               /* C11 type qualifier         */
atomic_int counter;                /* the convenience typedef     */

atomic_fetch_add(&counter, 1);     /* atomic read-modify-write   */
atomic_load(&counter);
atomic_store(&counter, 0);
atomic_compare_exchange_strong(&p, &expected, desired);

/* _Atomic gives you what volatile does not:
     - indivisibility of read-modify-write
     - a memory ordering model you can reason about
     - the compiler emits LDAXR/STLXR or LSE atomics on ARM

   Note: atomic operations on large types may be implemented with a
   lock. Check with:                                          */
atomic_is_lock_free(&obj);
ATOMIC_INT_LOCK_FREE               /* compile-time: 0, 1 or 2    */
```

Need	Use	Not
Hardware register	`volatile` + barriers, or MMIO accessors	`_Atomic`
Shared between threads	`_Atomic` or a lock	`volatile`
Set by a signal handler	`volatile sig_atomic_t` or `atomic_int`	plain `int`
Read-only API parameter	`const`	—
Non-overlapping buffers	`restrict`	—
Compile-time constant	`#define`, `enum`, C23 `constexpr`	`const`

How it shows up

Symptom	Cause
Polling loop hangs at `-O2`, works at `-O0`	Missing `volatile` on the status register
Register writes never reach the device	Missing `volatile`, or missing barrier
Thread sees a stale value despite `volatile`	`volatile` is not a memory barrier; use atomics

Symptom	Cause
Counter loses increments under load	`volatile` does not make `++` atomic
`const int n` rejected as an array bound	Not a compile-time constant in C; use `enum` or `#define`
Corruption when source and destination overlap	`memcpy` with overlapping buffers; use `memmove`
Vectorisation silently disabled	Possible aliasing; add `restrict`
Wrong results after adding `restrict`	The promise was false — the buffers do alias
Warning converting `char**` to `const char**`	C does not allow it implicitly; cast explicitly
Struct members not treated as volatile	Qualified the pointer variable instead of the pointee

Check yourself

- ✓ Distinguish `const int *p`, `int *const p` and `const int *const p`.
- ✓ Give three things `const` does not provide.
- ✓ Explain exactly what `volatile` constrains, and what it does not.
- ✓ Give the three legitimate uses of `volatile`.
- ✓ Explain, with an example, why `volatile` is wrong for thread communication.
- ✓ Write a correct MMIO write and say why `volatile` alone is insufficient.
- ✓ State the `restrict` promise and show two ways to break it accidentally.
- ✓ Explain why both `memcpy` and `memmove` exist.
- ✓ Give a case where `const volatile` is exactly right.

Functions, calling conventions and varargs

A function call is a contract between two pieces of code that may have been compiled separately. This chapter covers what C guarantees about that contract, what the ABI adds, and why varargs is the least safe thing in the language.

C is pass-by-value, always

THERE ARE NO EXCEPTIONS

Every argument is copied into the function. The function receives a private copy and cannot modify the caller's object. "Pass by reference" in C is a convention: you pass a *copy of a pointer*, and the function modifies what that pointer designates.

```
void bad_swap(int a, int b) { int t = a; a = b; b = t; }
/* modifies copies; the caller sees nothing */

void good_swap(int *a, int *b) { int t = *a; *a = *b; *b = t; }
good_swap(&x, &y);
/* the POINTERS are still passed by value — but they point at the
   caller's objects, so writing through them is visible.        */

/* This is also why you need a pointer-to-pointer to change a
   caller's pointer (chapter 04):                               */
void alloc(char **out) { *out = malloc(100); }

/* And why passing a large struct by value is a real cost: */
void f(struct big s);          /* copies sizeof(struct big) bytes */
void f(const struct big *s);   /* copies 8 bytes                  */
/* Rule of thumb: pass by pointer above ~2 machine words, and use
   const to document that you will not modify it.               */
```

Prototypes matter

```
/* THREE different declarations, and only one is right in modern C */

int f();              /* pre-C23: UNSPECIFIED number of arguments.
                         No checking at all. C23: same as (void).  */
int f(void);          /* takes NO arguments. Checked.              */
int f(int, char *);   /* full prototype. Checked.                  */

/* With `int f();` the compiler cannot check your call site: */
f(1, 2, 3);           /* accepted; arguments passed per default
                         promotions; behaviour undefined if the
                         definition disagrees                      */

/* This is why every C project should build with: */
//   -Wstrict-prototypes    warn on ()
//   -Wmissing-prototypes   warn on a non-static function with no
//                          prior prototype (catches typos in names)
//   -Wold-style-definition

/* And why implicit declaration is fatal. Pre-C99, calling an
   undeclared function assumed it returned int:               */
double x = sqrt(2.0);       /* without #include <math.h>: assumed to
                               return int, so x gets garbage      */
/* C99 removed implicit declarations. GCC 14 and Clang 16 finally
   made it a hard error by default. If you see
   "implicit declaration of function", you are missing a header -
   never silence it with a cast.                                  */
```

The calling convention

C says nothing about *how* arguments reach the callee. That is defined by the platform ABI, and it is what makes separately compiled code interoperate.

```
AArch64 (AAPCS64) - the convention on every ARM64 system

  X0-X7    integer/pointer arguments 1-8, and return value in X0
  X8       indirect result pointer (for large struct returns)
  X9-X15   caller-saved temporaries
  X16,X17  IP0/IP1 - reserved for linker veneers
  X18      platform register (TLS on Windows; reserved on some OSes)
  X19-X28  CALLEE-saved: if you use them, save and restore them
  X29      FP  frame pointer
  X30      LR  link register - the return address, set by BL
  SP       stack pointer, must be 16-byte aligned at every call
  V0-V7    floating point / SIMD arguments and return
  V8-V15   callee-saved (lower 64 bits only)

  Arguments beyond 8 go on the stack, right to left.

x86-64 System V (Linux, macOS)
  RDI RSI RDX RCX R8 R9  integers;  XMM0-7 floats;  RAX returns

x86-64 Microsoft
  RCX RDX R8 R9 only - just four register arguments, plus a
  32-byte "shadow space" the caller must reserve.

  This is why calling convention mismatches are a real bug class
  in cross-platform code and in hand-written assembly.
```

```
/* what a function's prologue and epilogue are actually doing */
my_func:
        stp     x29, x30, [sp, #-32]!   /* push FP and LR, SP -= 32   */
        mov     x29, sp                 /* establish the frame        */
        stp     x19, x20, [sp, #16]     /* save callee-saved regs     */
        ...
        ldp     x19, x20, [sp, #16]     /* restore                     */
        ldp     x29, x30, [sp], #32     /* pop, SP += 32               */
        ret                             /* branch to X30               */

/* The 16-byte SP alignment requirement is not advisory. Violating
   it faults on any instruction that assumes it, and produces
   corruption that looks random. Hand-written assembly gets this
   wrong constantly.                                          */
```

Variadic functions

```
#include <stdarg.h>

int sum(int count, ...)
{
        va_list ap;
        va_start(ap, count);           /* last NAMED parameter */

        int total = 0;
        for (int i = 0; i < count; i++)
                total += va_arg(ap, int);   /* type must be correct */

        va_end(ap);                     /* required */
        return total;
}
sum(3, 10, 20, 30);
```

WHY VARARGS IS THE LEAST SAFE CONSTRUCT IN C

- **No type checking whatsoever.** `va_arg(ap, int)` on a `double` argument reads the wrong bytes from the wrong place. There is no diagnostic.
- **No count.** The function cannot know how many arguments it received. You must encode it in a named parameter or a sentinel — and if the caller lies, you read past the argument area.
- **Default argument promotions apply** and surprise people: `float` becomes `double`, and anything narrower than `int` becomes `int`. So `va_arg(ap, char)` and `va_arg(ap, float)` are always wrong.
- `NULL` **is not a pointer.** Passing bare `NULL` as a variadic sentinel may pass a 32-bit `0` where a 64-bit pointer is expected. Write `(void *)NULL`.

```
/* the promotion traps */
f(1, 'a', 3.14f);
        va_arg(ap, char)    /* WRONG: promoted to int   -> use int    */
        va_arg(ap, float)   /* WRONG: promoted to double -> use double */
        va_arg(ap, short)   /* WRONG                    -> use int    */

/* the sentinel trap */
execl("/bin/ls", "ls", NULL);          /* may pass 32-bit 0 */
execl("/bin/ls", "ls", (char *)NULL);  /* correct           */

/* Getting the compiler to help with printf-like functions: */
void my_log(const char *fmt, ...)
        __attribute__((format(printf, 1, 2)));
/* Now -Wformat checks your call sites exactly as it does printf's.
   Add this to every logging function you write - it is free, and
   it catches a genuinely common bug class.                      */

/* Forwarding varargs requires the v-variants: */
void my_log(const char *fmt, ...)
{
        va_list ap;
        va_start(ap, fmt);
        vfprintf(stderr, fmt, ap);      /* NOT fprintf(...) */
        va_end(ap);
}

/* Reusing a va_list after it has been consumed is UB. Copy it: */
va_list ap2;
va_copy(ap2, ap);
int len = vsnprintf(NULL, 0, fmt, ap);   /* measure */
char *buf = malloc(len + 1);
vsnprintf(buf, len + 1, fmt, ap2);       /* format  */
va_end(ap2);
```

ALTERNATIVES WORTH PREFERRING

Pass an array plus a count. Use a struct with designated initialisers. In C11, use `_Generic` for type-safe dispatch. Variadic macros (`__VA_ARGS__`) are checked because they expand into real calls — prefer them for logging wrappers. Reserve genuine varargs for `printf`-shaped APIs, and always attach the `format` attribute.

_Generic: type-safe dispatch

```
/* C11's answer to "I want one name for several types" */
#define abs(x) _Generic((x),        \
        int:         abs,           \
        long:        labs,          \
        long long:   llabs,         \
        float:       fabsf,         \
        double:      fabs,          \
        default:     fabs           \
)(x)

/* Selection happens at COMPILE TIME on the static type of the
   controlling expression. The unselected branches are not even
   evaluated, so this is zero-cost.                          */

/* A practical use: type-safe printing helpers */
#define print(x) _Generic((x),              \
        int:          print_int,            \
        const char *: print_str,            \
        char *:       print_str,            \
        double:       print_double          \
)(x)
```

inline and noreturn

```
/* `static inline` in a header — use this, essentially always */
static inline int max(int a, int b) { return a > b ? a : b; }

/* Plain `inline` in C has a rule almost nobody applies correctly:
   an inline definition provides no external definition, so exactly
   one TU must also provide `extern inline` (C99) or a non-inline
   definition. Get it wrong and you get "undefined reference".
   `static inline` sidesteps the whole problem.                  */

/* inline is a HINT. These are not: */
__attribute__((always_inline)) static inline void f(void);
__attribute__((noinline))      void g(void);

/* noreturn lets the compiler drop the return path and improves
   warnings about uninitialised variables after a call.        */
#include <stdnoreturn.h>
noreturn void panic(const char *msg);          /* C11 */
[[noreturn]] void panic(const char *msg);      /* C23 */
__attribute__((noreturn)) void panic(const char *);   /* GCC */
```

Attributes worth knowing

Attribute	Effect
`format(printf, m, n)`	Enables `-Wformat` checking on your own logging functions
`warn_unused_result`	Warns if the return value is ignored — essential for functions that can fail
`nonnull(1, 2)`	Documents and checks that parameters must not be NULL
`malloc`	Tells the optimiser the returned pointer does not alias anything
`pure` / `const`	No side effects / depends only on arguments — enables CSE

Attribute	Effect
`cleanup(fn)`	Calls `fn` when the variable goes out of scope — RAII in C
`weak`	The symbol may be overridden; used for optional hooks in firmware
`section("name")`	Place in a specific linker section

```
/* cleanup gives you scope-based resource management in plain C.
   The Linux kernel adopted this in 6.5 and it is spreading fast. */
static inline void free_ptr(void *p) { free(*(void **)p); }
#define _cleanup_free_ __attribute__((cleanup(free_ptr)))

void f(void)
{
        _cleanup_free_ char *buf = malloc(100);
        if (!buf) return;                  /* freed automatically */
        if (error) return;                 /* freed automatically */
        ...
}                                          /* freed automatically */

/* This removes the goto-ladder for the common single-resource case.
   It is a GCC/Clang extension, not ISO C.                          */
```

Recursion and stack budgets

```
/* Recursion is fine in application code and dangerous in systems code.
   Kernel stacks are 8-16 KB TOTAL for the entire call chain; an
   interrupt handler may nest on top of it.                         */

/* Estimate a frame's size: */
//   objdump -d prog | grep 'sub.*sp'      look for the prologue
//   gcc -fstack-usage                     emits a .su file per TU
//   gcc -Wstack-usage=1024                warn above a threshold

/* Convert recursion to iteration with an explicit stack when depth
   is input-dependent — an attacker-controlled depth is a denial of
   service at best.                                                 */

/* Tail calls MAY be optimised into a jump, but C does not
   guarantee it. Do not rely on TCO for correctness.            */
```

How it shows up

Symptom	Cause
Function modifies its argument but the caller sees no change	Pass-by-value; you need a pointer
"implicit declaration of function"	Missing header; the return type is assumed `int`
Float return value is garbage	Missing prototype, so the wrong register was read
`printf("%d", 3.14)` prints nonsense	Varargs has no type checking
Variadic function reads garbage after N arguments	Count or sentinel was wrong
Crash only on 64-bit	Bare `NULL` as a variadic sentinel
"undefined reference" for an `inline` function	Plain `inline` without an external definition; use `static inline`
Stack corruption in hand-written assembly	SP not 16-byte aligned, or a callee-saved register clobbered

Symptom	Cause
Passing a big struct is unexpectedly slow	Copied by value; pass a `const` pointer
Kernel stack overflow with deep recursion	8–16 KB total; convert to iteration

Check yourself

- ✓ Explain why C has no pass-by-reference, and how the effect is achieved.
- ✓ Give the difference between `int f()` and `int f(void)` and why it matters.
- ✓ Name the AArch64 argument registers, the callee-saved set, and the stack alignment rule.
- ✓ List four reasons varargs is unsafe.
- ✓ Explain default argument promotions and give two `va_arg` types that are always wrong.
- ✓ Show how to make the compiler type-check your own logging function.
- ✓ Explain why `static inline` is preferred over plain `inline` in headers.
- ✓ Describe the `cleanup` attribute and the problem it solves.

Function pointers and dispatch tables

Function pointers are how C does polymorphism, callbacks, plugins and state machines. Every driver interface in Linux and Windows is a struct of function pointers. Once the declaration syntax stops being frightening, the patterns are straightforward — and they are everywhere.

Declaration syntax

```
   int  f(int);            a function taking int, returning int
   int (*p)(int);          a POINTER to such a function
   int *g(int);            a function returning int*  - different!

The parentheses around *p are mandatory, because () binds tighter
than *. Without them you get "function returning a pointer".

   int (*fns[4])(int);     an array of 4 such pointers
   int (*(*p)[4])(int);    a pointer to such an array
   int (*f(void))(int);    a function returning a function pointer

At the third line, stop and use a typedef. Everyone does.
```

```
/* Two ways to name the type. Learn to read both. */
typedef int  handler_t(int);       /* the FUNCTION type      */
typedef int (*handler_ptr_t)(int); /* the POINTER type       */

handler_ptr_t p = my_func;
handler_t    *q = my_func;         /* equivalent, and arguably clearer */

/* Modern style prefers naming the function type and adding * at use,
   because it keeps the pointer-ness visible:                        */
typedef int compare_fn(const void *, const void *);
void sort(void *base, size_t n, size_t sz, compare_fn *cmp);
```

Taking and calling

```
int add(int a, int b) { return a + b; }

int (*op)(int, int) = add;      /* the & is optional...   */
int (*op)(int, int) = &add;     /* ...both are identical  */

int r = op(2, 3);               /* call: the * is optional */
int r = (*op)(2, 3);            /* ...both are identical   */

/* A function name in an expression decays to a pointer, exactly
   like an array name (chapter 05). That is why both spellings
   work. Pick one and be consistent; `op(2,3)` is more common.  */

/* Comparison and null are meaningful */
if (op == add)  ...
if (op != NULL) op(1, 2);

/* But arithmetic is NOT. You cannot do op + 1, and sizeof on a
   function type is undefined.                                   */
```

FUNCTION POINTERS ARE NOT OBJECT POINTERS

The standard guarantees conversion between `void *` and *object* pointers only. Converting a function pointer through `void *` is not guaranteed by ISO C — on architectures where code addresses have a different size or format it genuinely breaks. POSIX requires it to work so that `dlsym()` can exist, which is why that API is a documented wart. Keep function pointers in function-pointer types, and use a union or a POSIX-blessed cast if you truly must.

Callbacks

```
/* The standard library's own example */
int cmp_int(const void *a, const void *b)
{
        int x = *(const int *)a, y = *(const int *)b;
        return (x > y) - (x < y);       /* avoids overflow of x - y */
}
qsort(arr, n, sizeof arr[0], cmp_int);

/* THE design rule for callback APIs: always carry a user context.
   Without it, callers are forced into global state.            */

/* BAD - no context */
void for_each(int *a, size_t n, void (*fn)(int));

/* GOOD - an opaque pointer threaded through */
void for_each(int *a, size_t n, void (*fn)(int, void *), void *ctx)
{
        for (size_t i = 0; i < n; i++)
                fn(a[i], ctx);
}

struct acc { long total; };
static void add_to(int v, void *ctx) { ((struct acc *)ctx)->total += v; }

struct acc a = {0};
for_each(arr, n, add_to, &a);

/* This is why qsort_r/qsort_s exist: plain qsort has no context
   parameter, so comparators that need extra state must use a
   global - which is not reentrant or thread safe.             */
```

Dispatch tables: polymorphism in C

```
/* A struct of function pointers IS a vtable. This is exactly how
   C++ virtual functions are implemented, written out by hand.  */

struct file_ops {
        int     (*open)(struct file *);
        ssize_t (*read)(struct file *, void *, size_t);
        ssize_t (*write)(struct file *, const void *, size_t);
        int     (*close)(struct file *);
};

struct file {
        const struct file_ops *ops;     /* the vtable pointer */
        void *private_data;             /* the "derived" state */
};

/* Each implementation supplies its own table. Designated
   initialisers mean unimplemented operations are NULL.       */
static const struct file_ops disk_ops = {
        .open  = disk_open,
        .read  = disk_read,
        .write = disk_write,
        .close = disk_close,
};
static const struct file_ops socket_ops = {
        .open  = sock_open,
        .read  = sock_read,
        /* .write and .close are NULL */
};

/* Generic code dispatches without knowing the type: */
ssize_t file_read(struct file *f, void *buf, size_t n)
{
        if (!f->ops->read)
                return -ENOSYS;         /* ALWAYS check for NULL */
        return f->ops->read(f, buf, n);
}

/* Note `const struct file_ops *` — the table lives in .rodata,
   so it cannot be corrupted by a stray write, and it is shared
   by every instance rather than copied per object.           */
```

```
Why this is the shape of every OS driver interface

   struct file                struct file_ops (in .rodata)
   +----------------+         +---------------------------+
   | ops  ----------|-------> | open   -> disk_open       |
   | private_data   |         | read   -> disk_read       |
   +----------------+         | write  -> disk_write      |
                              | close  -> disk_close      |
   struct file                +---------------------------+
   +----------------+
   | ops  ----------|-------> (socket_ops)
   | private_data   |
   +----------------+

  One generic VFS layer, many implementations, no switch statement,
  and new implementations can be added without touching the core.

  Linux: struct file_operations, struct net_device_ops,
         struct platform_driver
  Windows: the WDF EvtIo* callbacks and the WDM MajorFunction array
  Both are this pattern.
```

Jump tables and state machines

```
/* Replacing a long switch with a table — O(1), and data-driven */

typedef void (*cmd_fn)(const char *args);

struct command {
        const char *name;
        cmd_fn      handler;
        const char *help;
};

static const struct command commands[] = {
        { "read",  cmd_read,  "read a register"  },
        { "write", cmd_write, "write a register" },
        { "dump",  cmd_dump,  "dump memory"      },
};

static int dispatch(const char *name, const char *args)
{
        for (size_t i = 0; i < ARRAY_SIZE(commands); i++)
                if (strcmp(commands[i].name, name) == 0) {
                        commands[i].handler(args);
                        return 0;
                }
        return -EINVAL;
}
/* Adding a command is one table row. The help text, the parser and
   the dispatcher all stay unchanged — this is the main practical
   benefit over a switch.                                          */
```

```
/* A state machine as a table of transitions */
typedef enum { S_IDLE, S_RUNNING, S_ERROR, S_COUNT } state_t;
typedef enum { E_START, E_STOP, E_FAULT, E_COUNT } event_t;

typedef state_t (*transition_fn)(void *ctx);

static const transition_fn table[S_COUNT][E_COUNT] = {
        [S_IDLE]    = { [E_START] = on_start,  [E_FAULT] = on_fault },
        [S_RUNNING] = { [E_STOP]  = on_stop,   [E_FAULT] = on_fault },
        [S_ERROR]   = { [E_STOP]  = on_reset },
};

state_t step(state_t s, event_t e, void *ctx)
{
        transition_fn fn = table[s][e];
        return fn ? fn(ctx) : s;        /* NULL = ignore the event */
}
/* The table IS the specification. It can be reviewed against a
   state diagram directly, which nested switches cannot.        */
```

Weak symbols and optional hooks

```
/* Firmware pattern: provide a default that the application may
   override, with no function pointer and no runtime cost.     */

__attribute__((weak)) void board_init(void) { /* default: nothing */ }

int main(void)
{
        board_init();          /* calls the app's version if it
                                  defined one, else the default   */
}

/* The linker resolves this at link time: a strong definition
   anywhere replaces the weak one. Used heavily in CMSIS and
   vendor SDKs for interrupt vectors:                          */
__attribute__((weak)) void TIM1_IRQHandler(void) { default_handler(); }
```

Safety and security

FUNCTION POINTERS ARE AN ATTACK SURFACE

An attacker who can overwrite a function pointer controls the program counter. This is why:

- **Keep vtables in `.rodata`** — declare them `const`. A read-only page cannot be corrupted by a heap or stack overflow.
- **Always NULL-check** before calling through a pointer. A partially initialised struct is a jump to address 0.
- **Validate indices** into dispatch tables before use, and mask rather than branch in security-sensitive paths (CA ch. 12).
- **Modern mitigations exist**: ARM Pointer Authentication (`PACIASP` / `AUTIASP`) signs return addresses and can sign function pointers; Branch Target Identification (`BTI`) requires indirect branch targets to be marked; Control Flow Integrity (`-fsanitize=cfi`) checks that the target has the right type.

```
/* Build with the hardening on, on aarch64: */
gcc -mbranch-protection=standard    /* PAC + BTI */
clang -fsanitize=cfi -flto -fvisibility=hidden

/* Defensive dispatch */
static int call_op(struct file *f, int op_index)
{
        if (op_index < 0 || (size_t)op_index >= ARRAY_SIZE(f->ops->table))
                return -EINVAL;                   /* bounds check    */
        cmd_fn fn = f->ops->table[op_index];
        if (!fn)
                return -ENOSYS;                   /* NULL check      */
        return fn(f);
}
```

Performance

Call kind	Cost	Why
Direct call	Cheapest; often inlined away entirely	Target known at compile time
Indirect call, well predicted	A few cycles	The indirect branch predictor learns a stable target
Indirect call, unpredictable	10–20 cycles	Mispredict flushes the pipeline (CA ch. 12)
Indirect call with CFI	Plus a type check	Worth it in security-relevant code

The real cost is usually not the branch — it is that an indirect call is an **optimisation barrier**. The compiler cannot inline it, cannot propagate constants through it, and must assume it clobbers memory. In a hot inner loop, hoisting the dispatch outside the loop, or specialising the loop per implementation, is often a large win.

```
/* dispatch per element — the pointer blocks all optimisation */
for (size_t i = 0; i < n; i++)
        ops->process(&a[i]);

/* dispatch once — now each branch can be inlined and vectorised */
if (ops->process == fast_process)
        for (size_t i = 0; i < n; i++) fast_process(&a[i]);
else
        for (size_t i = 0; i < n; i++) ops->process(&a[i]);
```

How it shows up

Symptom	Cause
Declaration will not compile	Missing parentheses: `int *f(int)` vs `int (*f)(int)`
Jump to address 0	Called through an unset function pointer; NULL-check first
Callback needs global state	API lacks a context parameter
Crash after a struct is reallocated	Stored pointer to a member; the vtable moved
Wrong function called, or immediate crash	Signature mismatch — the pointer type lied
Works with GCC, fails with a different ABI	Casting between incompatible function pointer types
Profile dominated by indirect branch misses	Unpredictable virtual dispatch; specialise the loop
Exploit overwrites a vtable	Table was writable; declare it `const`

Symptom	Cause
`dlsym` result will not convert cleanly	ISO C does not guarantee `void*` to function pointer

Check yourself

- ✓ Declare a pointer to a function taking `const void *` and returning `int`, then an array of five of them.
- ✓ Explain why `&f` and `f` are interchangeable, and `(*p)()` and `p()` too.
- ✓ Say why converting a function pointer through `void *` is not portable.
- ✓ Design a callback API and explain why the context parameter is not optional.
- ✓ Write a dispatch-table struct and show how NULL entries are handled.
- ✓ Explain why the ops table should be `const`.
- ✓ Name three hardware or compiler mitigations for function-pointer corruption.
- ✓ Explain why an indirect call in a hot loop can cost more than the branch itself.

The preprocessor

The preprocessor is a text substitution engine that runs before the compiler sees anything. It knows nothing about types, scopes or expressions. That ignorance is the source of both its power and every macro bug you will ever write.

The mental model

> **IT IS A SEPARATE LANGUAGE**
> Preprocessing happens in translation phase 4 (ch. 01), operating on *preprocessing tokens*. There are no variables, no types and no scopes — only names, replacement lists and conditional inclusion. By the time the compiler runs, every macro has vanished.

```
# See exactly what the compiler receives. Do this whenever a macro
# misbehaves — it turns a mystery into an obvious text problem.
gcc -E file.c | less
gcc -E -P file.c            # -P strips the line markers
gcc -E -dM - < /dev/null    # every predefined macro on this target
gcc -E -dM file.c | sort    # every macro visible in this TU
```

#include

```
#include <stdio.h>      /* search the SYSTEM include path first  */
#include "myheader.h"   /* search relative to THIS file first,
                           then fall back to the system path     */

/* It is literal text substitution. The entire file's contents are
   pasted at this point, and phases 1-4 run on them recursively.  */

# where does it look?
gcc -I dir      # add dir to the quoted AND angle search path
gcc -isystem d  # add d as a system dir (suppresses warnings from it)
gcc -E -v -     # print the actual search paths in order
```

Include guards

```
/* Every header needs one, or a struct definition included twice
   becomes a redefinition error.                                  */
#ifndef MYMODULE_H
#define MYMODULE_H
...
#endif /* MYMODULE_H */

/* #pragma once is shorter, supported by every compiler you will
   meet, and is not standard. It also behaves better with symlinks
   and hard links, where a guard macro can be duplicated.       */
#pragma once

/* Use whichever your project already uses. Do not mix them. */
```

HEADER HYGIENE THAT PAYS FOR ITSELF

- **Self-contained.** A header must compile on its own — include everything it needs. Test it mechanically: `gcc -fsyntax-only header.h`.
- **Minimal.** Forward-declare (`struct foo;`) rather than including, when callers only handle pointers. This is the single biggest lever on build times in large C projects.
- **Include your own header first** in the matching `.c` file. If it is not self-contained, you find out immediately.
- **No `using`-style pollution.** Do not define short unprefixed macros (`MAX` , `OK` , `ERROR`) in a public header — they will collide.

Object-like macros

```
#define BUFFER_SIZE 1024
#define PI 3.14159265358979
#define DEVICE_NAME "uart0"

/* Prefer these to `const int` for array bounds and case labels,
   because in C a const object is NOT a constant expression
   (chapter 10).                                                */
char buf[BUFFER_SIZE];

/* But for typed constants, an enum is better: it is visible to the
   debugger, obeys scope, and is type-checked.                    */
enum { BUFFER_SIZE = 1024 };
enum state { S_IDLE, S_RUN, S_DONE };

/* C23 finally gives a real alternative: */
constexpr int buffer_size = 1024;
```

Function-like macros, and the four rules

```
/* WRONG — every one of these is a real bug */
#define SQUARE(x) x * x
#define MAX(a, b) a > b ? a : b

SQUARE(2 + 3)      /* -> 2 + 3 * 2 + 3  = 11, not 25 */
10 / SQUARE(2)     /* -> 10 / 2 * 2     = 10, not 2.5 */
MAX(1, 2) + 1      /* -> 1 > 2 ? 1 : 2 + 1 = 3, not 3... by luck */
```

THE FOUR RULES

1. **Parenthesise every parameter** where it appears.
2. **Parenthesise the whole replacement.**
3. **Evaluate each parameter exactly once**, or document that you do not.
4. **Wrap multi-statement macros** in `do { } while (0)`.

```
/* Rules 1 and 2 */
#define SQUARE(x) ((x) * (x))
#define MAX(a, b) (((a) > (b)) ? (a) : (b))

/* Rule 3 is the one you cannot fix with parentheses: */
MAX(i++, j++)      /* one of them is incremented TWICE */
SQUARE(f())        /* f() is CALLED TWICE              */

/* GNU statement expressions solve it — used throughout Linux: */
#define MAX(a, b) __extension__ ({      \
        __auto_type _a = (a);           \
        __auto_type _b = (b);           \
        _a > _b ? _a : _b;              \
})
/* Each argument is evaluated exactly once into a temporary. The
   leading underscores avoid capturing a caller's variable named
   `a`. Not ISO C, but available in GCC and Clang.             */

/* Rule 4: why do/while(0) rather than braces alone */
#define LOG(msg) do { timestamp(); puts(msg); } while (0)

if (x) LOG("hi"); else other();
/* With bare braces this would be:
       if (x) { ... };  else other();
   — a stray semicolon before else, which is a syntax error.
   do/while(0) makes the macro a single statement that REQUIRES
   a trailing semicolon, so it composes exactly like a function
   call.                                                       */
```

Stringification and pasting

```
#define STR(x)   #x            /* # turns a parameter into a string */
#define XSTR(x)  STR(x)        /* the extra level forces expansion  */

#define VERSION 42
STR(VERSION)     /* "VERSION"  — # does NOT expand its argument */
XSTR(VERSION)    /* "42"       — the outer call expands it first */

/* This two-level idiom is essential and non-obvious. The same
   applies to token pasting:                                    */

#define CAT(a, b)   a##b       /* ## joins two tokens          */
#define XCAT(a, b)  CAT(a, b)

#define PREFIX dev
CAT(PREFIX, _init)     /* PREFIX_init — not expanded           */
XCAT(PREFIX, _init)    /* dev_init                             */

/* A practical use: generating parallel declarations */
#define DEFINE_ACCESSOR(name, type)                     \
        static type get_##name(void) { return name; }   \
        static void set_##name(type v) { name = v; }

DEFINE_ACCESSOR(baud, uint32_t)   /* get_baud / set_baud */

/* And a debug macro that shows both expression and value */
#define TRACE(expr) \
        printf("%s:%d: %s = %d\n", __FILE__, __LINE__, #expr, (expr))
TRACE(x + y);         /* main.c:42: x + y = 7 */
```

Variadic macros

```
#define LOG(fmt, ...) fprintf(stderr, fmt, __VA_ARGS__)
LOG("x=%d\n", x);
LOG("hello\n");        /* ERROR: __VA_ARGS__ is empty, leaving a
                          trailing comma                        */

/* Three fixes, in order of preference: */

/* 1. C23 / C++20: __VA_OPT__ — standard and clean */
#define LOG(fmt, ...) fprintf(stderr, fmt __VA_OPT__(,) __VA_ARGS__)

/* 2. GNU: ##__VA_ARGS__ deletes the preceding comma if empty */
#define LOG(fmt, ...) fprintf(stderr, fmt, ##__VA_ARGS__)

/* 3. Portable: require at least the format, forward the rest */
#define LOG(...) fprintf(stderr, __VA_ARGS__)

/* Counting arguments — a classic trick worth recognising */
#define NARGS(...) NARGS_(__VA_ARGS__, 5, 4, 3, 2, 1, 0)
#define NARGS_(_1, _2, _3, _4, _5, N, ...) N
NARGS(a, b, c)        /* 3 */
```

Conditional compilation

```
#if defined(__aarch64__)
        /* ARM64 */
#elif defined(__x86_64__)
        /* x86-64 */
#else
#       error "unsupported architecture"
#endif

#ifdef DEBUG
#       define DBG(...) printf(__VA_ARGS__)
#else
#       define DBG(...) ((void)0)
#endif

/* Prefer #if over #ifdef when the macro has a VALUE — it catches
   the case where the config system defines it to 0:            */
#if CONFIG_FEATURE_X        /* 0 is false; undefined is also false */
#ifdef CONFIG_FEATURE_X     /* TRUE even when defined to 0!        */

/* Useful predefined macros */
__FILE__  __LINE__  __func__  __DATE__  __TIME__
__STDC__  __STDC_VERSION__       /* 201112L = C11, 202311L = C23 */
__GNUC__  __clang__  __ARM_ARCH  __BYTE_ORDER__
__has_include(<threads.h>)       /* C23; GCC/Clang earlier        */
__has_attribute(cleanup)
__has_builtin(__builtin_expect)
```

IFDEF SPRAWL IS A MAINTENANCE DISEASE

```
/* BAD: the logic is unreadable and only one branch is ever compiled,
   so the others silently rot.                                  */
void send(void)
{
#ifdef LINUX
        write(fd, buf, n);
#elif defined(WINDOWS)
        WriteFile(h, buf, n, &w, NULL);
#endif
}

/* BETTER: isolate platform code behind one interface, implemented
   in separate FILES selected by the build system. Then every
   line compiles on its platform and the logic stays readable. */

/* port.h */
int port_send(const void *buf, size_t n);
/* port_linux.c, port_win.c — chosen in the Makefile */

/* Where a conditional is unavoidable, prefer one that keeps both
   branches compiled: */
if (IS_ENABLED(CONFIG_FEATURE_X))    /* Linux idiom: a real `if`,
        do_x();                         evaluated at compile time,
                                        but both sides type-check  */
```

Compile-time assertions

```
#include <assert.h>

/* C11: fails the BUILD, not the program. Free, and enormously
   valuable for layout assumptions.                             */
static_assert(sizeof(struct packet) == 16, "packet layout changed");
static_assert(sizeof(void *) == 8, "64-bit only");
static_assert(CHAR_BIT == 8, "assumes 8-bit bytes");
_Static_assert(offsetof(struct regs, FR) == 0x18, "FR offset");

/* Pre-C11 idiom you will still meet in older code */
#define STATIC_ASSERT(c, name) \
        typedef char static_assert_##name[(c) ? 1 : -1]

/* Put these next to every struct that describes hardware or a wire
   format (chapter 07). A compiler upgrade or an ABI change that
   shifts padding then becomes a build failure instead of a
   runtime mystery.                                             */
```

X-macros

```
/* One list, many derived artefacts, guaranteed in sync. This is the
   most useful advanced preprocessor technique.                  */

#define ERROR_LIST                      \
        X(ERR_NONE,    0, "success")    \
        X(ERR_TIMEOUT, 1, "timed out")  \
        X(ERR_NOMEM,   2, "out of memory")

/* generate the enum */
#define X(name, val, str) name = val,
enum error { ERROR_LIST };
#undef X

/* generate the string table from the SAME list */
#define X(name, val, str) [val] = str,
static const char *const error_strings[] = { ERROR_LIST };
#undef X

const char *strerr(enum error e)
{
        return (size_t)e < ARRAY_SIZE(error_strings)
                ? error_strings[e] : "unknown";
}

/* Adding an error is ONE line. The enum and the strings can never
   drift apart — which is exactly the bug this prevents.        */
```

Prefer the alternatives

Instead of	Use	Why
`#define MAX_N 10`	`enum { MAX_N = 10 };`	Typed, scoped, visible in the debugger
A short function macro	`static inline`	Type-checked, single evaluation, debuggable, same code generated
`#define SQUARE(x)`	`static inline int square(int)`	No double evaluation, no parenthesis traps
Type-dispatch macros	`_Generic` (ch. 11)	Compile-time, type-safe
`#ifdef` around logic	`if (IS_ENABLED(...))` or separate files	Both branches keep compiling
`#define DEBUG_PRINT`	A real logging function with the `format` attribute	Format checking

Macros remain irreplaceable for: include guards, conditional compilation, stringification and pasting, capturing `__FILE__`/`__LINE__` at the call site, X-macros, and anything that must work in a constant expression.

Debugging macros

```
# the first thing to do, always
gcc -E problem.c | grep -A5 'my_macro'

# clang-format the output to make it readable
gcc -E -P problem.c | clang-format

# see where a macro was defined
gcc -E -dD problem.c | grep 'define MY_MACRO'

# a macro redefined with a different value
gcc -Wall            # -Wmacro-redefined / "redefined" warning

# check a header is self-contained
gcc -fsyntax-only -x c myheader.h

# undefine from the command line
gcc -UDEBUG -DLOG_LEVEL=3
```

How it shows up

Symptom	Cause
Arithmetic macro gives a wrong result in an expression	Missing parentheses around parameters or the whole body
A side effect happens twice	Parameter used more than once in the replacement
Syntax error at `else`	Multi-statement macro not wrapped in `do { } while (0)`
Stringified macro shows the name, not the value	Missing the second expansion level
Trailing comma error with no variadic arguments	Need `__VA_OPT__` or `##__VA_ARGS__`
Feature enabled despite being configured off	`#ifdef` on a macro defined to `0`; use `#if`
"redefinition of struct" errors	Missing include guard
Header compiles in one file, fails in another	Not self-contained; depends on include order
Enum and its string table drift apart	Two hand-maintained lists; use an X-macro
Register offsets wrong after a compiler upgrade	No `static_assert` on the layout

Check yourself

- ✓ Explain why the preprocessor cannot type-check anything.
- ✓ Give the four macro rules and a bug each one prevents.
- ✓ Explain why `do { } while (0)` is the correct wrapper.
- ✓ Show why stringification needs two macro levels.
- ✓ Give the difference between `#ifdef X` and `#if X`.
- ✓ Write an X-macro generating an enum and a matching string table.
- ✓ Write a `static_assert` guarding a hardware struct's layout.
- ✓ Name three things macros are still the right tool for.

Dynamic memory and its failure modes

C gives you four functions and no safety net. Every use-after-free, double free, leak and heap overflow in the history of computing came through this interface. This chapter covers using it correctly, the ownership discipline that makes it tractable, and why embedded systems often ban it outright.

The four functions

```
void *malloc(size_t size);              /* uninitialised            */
void *calloc(size_t n, size_t size);    /* zeroed, checked multiply */
void *realloc(void *p, size_t size);    /* resize, may move         */
void  free(void *p);                    /* release; free(NULL) is a no-op */

/* correct malloc usage */
int *p = malloc(n * sizeof *p);    /* `sizeof *p`, not sizeof(int) —
                                      stays correct if the type changes */
if (!p)
        return -ENOMEM;            /* ALWAYS check                      */

/* Do NOT cast the result in C. The cast is required in C++, is
   noise in C, and historically hid the missing-prototype bug.    */
```

THE MULTIPLICATION IS THE VULNERABILITY

```
void *p = malloc(n * sizeof(struct item));
/* If n is attacker-controlled and large, n * sizeof(...) WRAPS.
   You allocate 16 bytes, then write n elements into it.
   This is a textbook heap overflow.                          */

/* calloc checks the multiplication internally — use it: */
void *p = calloc(n, sizeof(struct item));

/* or check explicitly */
if (n > SIZE_MAX / sizeof(struct item))
        return -EOVERFLOW;

/* or use a builtin */
size_t bytes;
if (__builtin_mul_overflow(n, sizeof(struct item), &bytes))
        return -EOVERFLOW;

/* Linux kernel helpers that do this for you: */
kmalloc_array(n, size, GFP_KERNEL);
kcalloc(n, size, GFP_KERNEL);
kmalloc(struct_size(p, items, n), GFP_KERNEL);   /* flexible arrays */
```

realloc, and the leak everyone writes once

```
/* WRONG: if realloc fails it returns NULL and the ORIGINAL block
   is still allocated — you have just leaked it and lost the data. */
p = realloc(p, new_size);
if (!p) return -ENOMEM;      /* the old block is now unreachable */

/* RIGHT: keep the original until you know the new one exists */
void *tmp = realloc(p, new_size);
if (!tmp) {
        free(p);             /* or keep using p — your choice, but
                                make it deliberately */
        return -ENOMEM;
}
p = tmp;

/* Other realloc facts worth knowing:
     realloc(NULL, n)  == malloc(n)
     realloc(p, 0)     is implementation-defined in C17 and
                       UNDEFINED in C23 — never rely on it as free
     the block MAY MOVE, so every pointer into it is invalidated  */

/* That last point causes real bugs: */
int *elem = &vec->data[3];
vec_push(vec, x);            /* may realloc */
*elem = 5;                   /* DANGLING — store an index, not a pointer */
```

Ownership: the discipline that makes this work

> **EVERY ALLOCATION HAS EXACTLY ONE OWNER**
>
> The owner is responsible for freeing it. Ownership may be *transferred*, but it is never shared implicitly. Write down, in the function's documentation or its name, who owns what. C gives you no enforcement, so the convention is all you have — which is precisely why it must be explicit.

```
/* Document ownership in the API. These are the three patterns: */

/* 1. Caller owns — the function borrows */
size_t parse(const char *input, struct result *out);
/*     ^ const: we only read it        ^ caller-provided storage */

/* 2. Callee allocates, caller owns — transfer OUT */
struct buffer *buffer_create(size_t n);   /* caller must
void buffer_destroy(struct buffer *b);       call destroy */

/* 3. Callee takes ownership — transfer IN */
void queue_push(struct queue *q, char *msg);   /* q now owns msg;
                                                  caller must not
                                                  free or reuse it */
/* Make this obvious in the name if it is not obvious from context: */
void queue_push_owned(struct queue *q, char *msg);

/* Matching create/destroy pairs, consistently named, are the single
   most effective convention in C memory management:            */
foo_create / foo_destroy
foo_alloc  / foo_free
foo_new    / foo_delete        /* pick ONE style per project */
```

Patterns that reduce the surface

The goto cleanup ladder

```
/* Idiomatic C, and the reason `goto` is not banned in kernel code.
   Resources are released in exactly reverse order of acquisition. */
int setup(struct dev *d)
{
        int ret;

        d->buf = malloc(SIZE);
        if (!d->buf)
                return -ENOMEM;

        d->fd = open_device();
        if (d->fd < 0) {
                ret = d->fd;
                goto err_free;
        }

        ret = start_thread(d);
        if (ret)
                goto err_close;

        return 0;

err_close:
        close(d->fd);
err_free:
        free(d->buf);
        d->buf = NULL;
        return ret;
}
/* Labels named for what they UNDO, not where they are. One exit
   point per resource. This scales to a dozen resources without
   nesting.                                                      */
```

Scope-based cleanup

```
/* GCC/Clang `cleanup` attribute — RAII in C. Adopted by the Linux
   kernel in 6.5 and spreading through systemd and glib.       */
static inline void freep(void *p) { free(*(void **)p); }
#define _cleanup_free_ __attribute__((cleanup(freep)))

int process(void)
{
        _cleanup_free_ char *buf = malloc(1024);
        if (!buf)
                return -ENOMEM;

        if (early_error)
                return -EIO;        /* freed automatically */

        return 0;                   /* freed automatically */
}

/* Linux 6.5+ provides this properly, with type safety: */
#include <linux/cleanup.h>
struct foo *f __free(kfree) = kmalloc(sizeof(*f), GFP_KERNEL);
guard(mutex)(&lock);                /* unlocked on scope exit */
```

Arena and pool allocation

```
/* When many objects share a lifetime, allocate them from one arena
   and free the whole arena at once. No per-object bookkeeping, no
   leaks, and dramatically faster.                                  */

struct arena { char *base; size_t size, used; };

void *arena_alloc(struct arena *a, size_t n)
{
        n = (n + 15) & ~(size_t)15;             /* align to 16 */
        if (a->used + n > a->size)
                return NULL;
        void *p = a->base + a->used;
        a->used += n;
        return p;
}
void arena_reset(struct arena *a) { a->used = 0; }   /* frees everything */

/* Ideal for: per-request server allocations, compiler AST nodes,
   parsing, frame-based game logic. The tradeoff is that you cannot
   free individual objects — which is exactly what removes the
   use-after-free class.                                            */

/* A fixed-size POOL is the embedded variant: pre-allocate N objects,
   hand them out from a free list, never fragment.                  */
```

The failure modes

Bug	What happens	Detection
Leak	Memory never freed; process grows until OOM	ASan (`LeakSanitizer`), Valgrind
Use after free	Reads garbage, or writes into a reallocated object	ASan, Valgrind, KASAN
Double free	Corrupts allocator metadata; often exploitable	ASan, glibc's own checks
Heap overflow	Writes past the block into adjacent data or metadata	ASan, `_FORTIFY_SOURCE`
Invalid free	Freeing a stack pointer, an interior pointer, or a non-pointer	ASan, glibc
Mismatched allocator	`free` on `new`, or `kfree` on `vmalloc`	Review; some checkers
Uninitialised read	`malloc` memory contains old data	MSan, Valgrind
Fragmentation	Free memory exists but no contiguous block is large enough	Long-running tests; arena/pool design

```
/* The habits that prevent most of these */

free(p);
p = NULL;         /* a later use crashes loudly; a second free is a no-op */

/* Free in the same layer that allocated. If a function allocates
   on some paths and not others, that is a design smell.        */

/* Never free something you did not allocate, and never hand a
   pointer to a different allocator:                            */
kfree(vmalloc_ptr);        /* kernel: corrupts the slab allocator */

/* Zero sensitive data before freeing (chapter 06) — and remember
   plain memset may be optimised away.                          */
explicit_bzero(key, sizeof key);
free(key);
```

Finding them

```
# AddressSanitizer — the default choice. ~2x slower; run everything under it.
gcc -fsanitize=address -fno-omit-frame-pointer -g prog.c
ASAN_OPTIONS=detect_leaks=1:abort_on_error=1 ./prog

# MemorySanitizer — uninitialised reads (Clang only, needs all deps rebuilt)
clang -fsanitize=memory -fno-omit-frame-pointer -g prog.c

# Valgrind — no rebuild, ~20x slower, finds slightly different things
valgrind --leak-check=full --show-leak-kinds=all --track-origins=yes ./prog

# glibc's built-in checks, free at runtime
MALLOC_CHECK_=3 ./prog
MALLOC_PERTURB_=165 ./prog      # fill freed memory with a pattern

# static analysis
gcc -fanalyzer                  # GCC 10+; finds many leaks and UAFs
clang --analyze
cppcheck --enable=all

# in the kernel
CONFIG_KASAN=y  CONFIG_DEBUG_KMEMLEAK=y  CONFIG_DEBUG_OBJECTS=y
```

Why embedded systems restrict or ban it

Problem	Consequence in an embedded context
Fragmentation	Over weeks of uptime, allocation fails despite free memory. No way to recover without a reboot.
Non-determinism	`malloc` has no bounded worst-case time. Unacceptable in a hard real-time path.
No recovery path	What does a brake controller *do* when `malloc` returns NULL?
Unbounded footprint	Static analysis cannot prove the system fits in RAM
Silent failure	Heap corruption in a system with no MMU corrupts anything, anywhere

```
/* The standard alternatives, in rough order of preference: */

/* 1. Static allocation — everything sized at build time */
static struct session sessions[MAX_SESSIONS];
static uint8_t rx_buffer[MAX_FRAME];
/* The linker tells you at BUILD TIME whether it fits. */

/* 2. Fixed-size pools */
static struct msg pool[64];
static uint64_t pool_used;             /* a bitmap */
struct msg *msg_alloc(void)
{
        int i = __builtin_ffsll(~pool_used) - 1;
        if (i < 0) return NULL;
        pool_used |= 1ull << i;
        return &pool[i];
}

/* 3. Allocate only at init, never at runtime — the MISRA and
      DO-178C compromise. Startup allocation is deterministic
      because nothing has fragmented yet.                      */

/* MISRA C:2012 Rule 21.3 bans malloc/calloc/realloc/free outright
   in safety-critical code. AUTOSAR and DO-178C impose similar
   restrictions.                                               */
```

What the allocator is doing

```
A typical glibc heap block

   +-----------+-----------------------------+---------+
   |  header   |        your data            | padding |
   |  size,    |  <- malloc returns THIS     |         |
   |  flags    |                             |         |
   +-----------+-----------------------------+---------+
    8-16 bytes

  · malloc(1) really costs 32 bytes. Many tiny allocations are
    mostly overhead — a reason to use pools or arenas.
  · The header sits immediately BEFORE your data, which is why a
    single-byte underflow corrupts allocator metadata, and why
    that is so often exploitable.
  · free() reads that header to learn the size. Passing an
    interior pointer therefore reads garbage as a size.
  · Freed blocks go on size-class free lists ("bins"); adjacent
    free blocks are coalesced. This is where fragmentation lives.
  · Large requests (>128 KB by default) go straight to mmap and
    are returned to the OS on free — which is why RSS sometimes
    drops after free and sometimes does not.

Alternative allocators worth knowing: jemalloc and tcmalloc
(better multithreaded scaling), mimalloc, and for embedded,
TLSF (bounded worst-case time) and FreeRTOS heap_4/heap_5.
```

How it shows up

Symptom	Cause
Crash far from the faulty code	Heap corruption from an earlier overflow

Symptom	Cause
"free(): invalid pointer"	Double free, interior pointer, or a stack address
"malloc(): corrupted top size"	Heap overflow overwrote allocator metadata
Process RSS grows without bound	Leak — or fragmentation preventing return to the OS
Works with small input, corrupts with large	Size calculation overflowed
Data changes after a container append	`realloc` moved the block; stored pointer dangles
Leak only on the error path	Missing cleanup in an early return; use the goto ladder
Memory lost when an allocation fails	`p = realloc(p, n)` overwrote the original pointer
Long-running device eventually fails to allocate	Fragmentation; switch to pools
Values differ between debug and release	Reading uninitialised `malloc` memory

Check yourself

- ✓ Write a correct allocation of `n` items with the overflow check.
- ✓ Show the `realloc` leak and the correct form.
- ✓ Name the three ownership patterns and how you would document each in an API.
- ✓ Write a goto cleanup ladder for three resources, in the right order.
- ✓ Explain what the `cleanup` attribute does and what problem it solves.
- ✓ Explain when an arena allocator is the right choice and what it gives up.
- ✓ Give four reasons embedded systems ban dynamic allocation, and two alternatives.
- ✓ Explain why a one-byte heap underflow is often exploitable.

Undefined, unspecified and implementation-defined behaviour

Three categories that sound similar and differ enormously. One is a portability note, one is a harmless choice, and one means the standard imposes no requirements at all — and modern optimisers act on that fact in ways that delete your safety checks.

The three categories

Category	Meaning	Must be documented?	Example
Implementation-defined	The implementation chooses, and must document its choice. Behaviour is consistent.	Yes	Size of `int`; whether plain `char` is signed; right shift of a negative value
Unspecified	The implementation chooses from several valid options, and need not document or be consistent.	No	Order of evaluation of function arguments; padding byte contents
Undefined	**The standard imposes no requirements whatsoever.** Anything may happen, including nothing, including time travel.	No	Signed overflow, null dereference, out-of-bounds access, data race

WHY UB IS NOT "WHATEVER THE HARDWARE DOES"

The common intuition — "signed overflow wraps, because the CPU wraps" — is wrong, and dangerously so. The compiler does not translate your code to instructions; it reasons about your code *assuming undefined behaviour never occurs*, and uses that assumption to justify transformations. If UB does occur, the assumptions were false, and the conclusions drawn from them can be arbitrary.

Crucially, the effects are **not local**. UB can cause code *before* the offending statement to misbehave, because the optimiser propagates the assumption backwards.

Optimisations that delete your code

```
/* 1. The overflow check that vanishes */
bool check(int a, int b) { return a + b < a; }
/* Signed overflow is UB, so the compiler assumes a + b never
   overflows. If it never overflows, a + b < a is equivalent to
   b < 0. And with -fstrict-overflow it may simplify further.
   GCC compiles the classic form `a + b < a` to `b < 0` — which
   is not the check you wrote.                                  */

/* 2. The null check that vanishes  (Linux CVE-2009-1897) */
struct tun *tun = ptr;
struct sock *sk = tun->sk;          /* dereference implies non-NULL */
if (!tun)                            /* ...so this is dead code     */
        return -EINVAL;              /* DELETED by the optimiser    */
/* Result: a null dereference that the author had explicitly
   guarded against. Order matters: check FIRST, then dereference. */

/* 3. The infinite loop that vanishes */
while (1) { }
/* A loop with no side effects and no exit is UB in C11 (6.8.5p6).
   The compiler may assume it terminates and delete it, letting
   control fall through to whatever follows.                     */

/* 4. The bounds check that vanishes */
int f(int *p, int i)
{
        int x = p[i];                /* implies i is in bounds...  */
        if (i < 0 || i >= 10)        /* ...so this is redundant    */
                return -1;
        return x;
}

/* 5. Unreachable code becomes reachable */
int f(int x)
{
        if (x > 0) return 1;
        if (x < 0) return -1;
        if (x == 0) return 0;
        /* no return here — falling off the end of a non-void
           function is UB, so the compiler may emit anything,
           including running into the NEXT function.            */
}
```

The UB you will actually hit

Undefined behaviour	Correct approach
Signed integer overflow	`__builtin_add_overflow`, or use unsigned, or check against `INT_MAX`
Division by zero; `INT_MIN / -1`	Check both before dividing
Shift ≥ width, or negative shift count	Mask the count; use unsigned types (ch. 08)
Out-of-bounds array access	Bounds-check every externally supplied index
Null pointer dereference	Check before, never after
Use after free; double free	Set to NULL after freeing (ch. 14)
Reading an uninitialised object	Initialise at declaration
Strict aliasing violation	`memcpy` or a union (below)

Undefined behaviour	Correct approach
Misaligned pointer access	`memcpy`; never cast a byte pointer to a wider type
Unsequenced modification (`i = i++`)	Split into statements (ch. 03)
Data race	`_Atomic` or a lock — `volatile` is not enough
Falling off the end of a non-void function	Return on every path; `-Wreturn-type`
Modifying a string literal	`const char *` for literals
`memcpy` with overlapping ranges	`memmove`
Passing a negative `char` to `<ctype.h>`	Cast to `unsigned char`
Freeing a non-heap or interior pointer	Free exactly what was allocated

Strict aliasing

> **THE RULE**
> An object may only be accessed through an lvalue of a *compatible* type, a signed/unsigned variant of it, a qualified version, an aggregate containing it, or **any character type**. Accessing an object through an incompatible pointer type is undefined.
>
> The rule exists so the compiler can assume that a `float *` and an `int *` never refer to the same storage — which allows it to keep values in registers across stores. Without it, every store through any pointer would invalidate every cached load.

```
/* The classic violation — "type punning" through a pointer cast */
float f = 1.0f;
uint32_t bits = *(uint32_t *)&f;      /* UNDEFINED */

/* At -O2 this may read a stale register, or reorder relative to the
   store to f, and it genuinely misbehaves on real compilers.     */

/* CORRECT 1: memcpy. Compiles to zero instructions at -O2 — the
   compiler recognises the idiom.                                 */
uint32_t bits;
memcpy(&bits, &f, sizeof bits);

/* CORRECT 2: a union. Legal in C (since C99 TC3), NOT in C++. */
union { float f; uint32_t u; } cvt = { .f = 1.0f };
uint32_t bits = cvt.u;

/* CORRECT 3: character types may alias anything — this is how
   serialisation code is allowed to work at all.               */
unsigned char *bytes = (unsigned char *)&f;
for (size_t i = 0; i < sizeof f; i++) put(bytes[i]);

/* An escape hatch, if you have inherited code you cannot fix: */
gcc -fno-strict-aliasing      /* the Linux kernel builds with this */

/* But note it costs real performance, and it is a workaround, not
   a fix. New code should be alias-correct.                     */
```

Alignment travels with aliasing

```
/* This is a second, independent bug in the same line of code */
uint8_t buf[100];
uint32_t v = *(uint32_t *)(buf + 1);    /* misaligned AND aliasing */

/* On ARM with strict alignment this faults; on x86 it is merely
   slow; and either way the compiler may assume 4-byte alignment
   and emit an instruction that requires it.                    */

/* Correct: */
uint32_t v;
memcpy(&v, buf + 1, sizeof v);          /* alignment-safe, alias-safe,
                                           and compiles to one unaligned
                                           load where the target allows */
```

Finding UB

```
# UndefinedBehaviorSanitizer — the single most valuable tool here.
# Reports the exact file, line and values at the moment it happens.
gcc -fsanitize=undefined -fno-sanitize-recover=all -g prog.c

# individual checks, if you want them separately
-fsanitize=signed-integer-overflow
-fsanitize=shift
-fsanitize=bounds
-fsanitize=alignment
-fsanitize=null
-fsanitize=object-size
-fsanitize=bool,enum
-fsanitize=float-cast-overflow

# combine with ASan for memory UB
gcc -fsanitize=address,undefined -g prog.c

# compile-time help
gcc -Wall -Wextra -Wstrict-aliasing=3 -Wcast-align \
    -Wstrict-overflow=5 -Wsequence-point -Wreturn-type \
    -Wuninitialized -Wnull-dereference -fanalyzer

# make some UB defined, where you must
-fwrapv               # signed overflow wraps (kills the optimisation
                      # AND the check-deletion behaviour)
-fno-strict-aliasing  # disable the aliasing assumption
-fno-delete-null-pointer-checks
# The Linux kernel uses all three. They are a pragmatic choice for
# a huge legacy codebase — not a licence to write UB in new code.
```

> **RUN YOUR ENTIRE TEST SUITE UNDER UBSAN AND ASAN**
> This is the highest-value habit in this chapter. UB is invisible until the day an optimiser or a compiler upgrade exposes it, and by then it is a production incident. Sanitizers cost a few times the runtime in CI and find these bugs the day they are written. Both are in GCC and Clang; there is no reason not to.

Unspecified behaviour worth knowing

```
/* Legal, but the choice is not documented and may vary. */

f(g(), h());              /* order of g and h: unspecified        */
a[i++] = i;               /* actually UNDEFINED — unsequenced      */
p1 < p2                   /* comparing pointers into different
                             objects: unspecified                  */
padding bytes             /* contents are unspecified — which is
                             why memcmp on structs is wrong
                             (chapter 07)                          */
malloc(0)                 /* may return NULL or a unique pointer   */

/* Do not write code that depends on any of these, but note that
   unlike UB, they cannot make unrelated code misbehave.        */
```

Implementation-defined behaviour worth knowing

Behaviour	Typical values	How to be portable
Size of `int`, `long`	32/64 vs 32/32	`<stdint.h>` fixed-width types
Plain `char` signedness	Signed on x86, unsigned on ARM Linux	Say `signed` / `unsigned` explicitly
Right shift of a negative value	Arithmetic everywhere in practice	Use unsigned types
Conversion of out-of-range value to signed	Truncation	Check the range first
Bitfield allocation order	Varies with ABI and endianness	Masks and shifts (ch. 07)
Struct padding	Varies with ABI	`static_assert` on offsets
`NULL`'s representation	All-zero bits, universally	Do not `memset` pointers to zero and assume NULL

How to think about it

```
The bargain C makes:

  The standard leaves things undefined so implementations can be
  FAST on wildly different hardware — one's-complement machines,
  word-addressed machines, machines that trap on overflow. The
  optimiser gets to assume the programmer stayed inside the lines.

  The programmer's side of the bargain is to STAY INSIDE THE LINES.

  What makes this hard in practice:
    · UB is silent — no warning by default
    · effects are non-local and can appear far from the cause
    · behaviour can change with optimisation level, compiler
      version, inlining decisions, or unrelated edits
    · "it worked before" is evidence of nothing

  The practical response is not to memorise the standard. It is:
    1. enable the sanitizers, in CI, on every test
    2. enable the warnings, and treat them as errors
    3. learn the ~15 UB cases in the table above by heart
    4. when something behaves differently at -O2 than at -O0,
       suspect UB FIRST, not a compiler bug
```

How it shows up

Symptom	Cause
Works at `-O0`, fails at `-O2`	UB the optimiser is now exploiting
A safety check appears to be skipped	Deleted because it was provably dead given a UB assumption
Behaviour changes after a compiler upgrade	New optimisation exploiting existing UB
Adding an unrelated `printf` "fixes" it	Inlining or register allocation changed; UB is still there
Type punning gives stale values	Strict aliasing violation
Fault reading a struct field from a byte buffer	Misaligned access; use `memcpy`
Overflow detection never triggers	Signed overflow check optimised away
Program continues past a fatal error	Fell off the end of a non-void function
Different results on ARM and x86	Implementation-defined `char` signedness, or UB
Loop that should never end runs once	Side-effect-free infinite loop assumed to terminate

Check yourself

- ✓ Define the three categories and give an example of each.
- ✓ Explain why UB effects are not local to the offending line.
- ✓ Show why `a + b < a` is not a valid overflow check, and write one that is.
- ✓ Explain the null-check deletion bug and the ordering rule that prevents it.
- ✓ State the strict aliasing rule and give three legal ways to type-pun.
- ✓ Explain why `*(uint32_t *)(buf + 1)` has two separate defects.
- ✓ Name the sanitizer flags you would put in CI and what each catches.

✓ Explain what `-fwrapv` does and why the kernel uses it.

The standard library for systems programmers

The C standard library is small, old, and uneven. Some of it is indispensable, some is actively harmful, and much of it disappears entirely in freestanding builds. This chapter is a working engineer's map of what to use, what to avoid, and what you lose in the kernel.

The headers, sorted by usefulness

Header	Contents	Freestanding?	Verdict
`<stdint.h>`	Fixed-width integer types	**Yes**	Use constantly
`<stddef.h>`	`size_t`, `ptrdiff_t`, `NULL`, `offsetof`	**Yes**	Use constantly
`<stdbool.h>`	`bool`, `true`, `false`	**Yes**	Use (built in from C23)
`<limits.h>`	`INT_MAX`, `CHAR_BIT`, …	**Yes**	Essential for range checks
`<stdarg.h>`	Varargs machinery	**Yes**	Only for printf-like APIs
`<stdalign.h>`, `<stdnoreturn.h>`	C11 keywords as macros	**Yes**	Useful
`<string.h>`	`mem*`, `str*`	No	Use `mem*`; be careful with `str*` (ch. 06)
`<stdlib.h>`	malloc, strtol, qsort, exit, abs	No	Use selectively
`<stdio.h>`	Files and formatted I/O	No	Heavy; often replaced in embedded
`<inttypes.h>`	`PRIu32` and friends	No	Use whenever you print fixed-width types
`<errno.h>`	`errno` and codes	No	Necessary evil
`<assert.h>`	`assert`, `static_assert`	Partly	`static_assert` always; `assert` carefully
`<stdatomic.h>`	C11 atomics	Mostly	Use for concurrency
`<math.h>`	Floating point	No	Pulls in a large library; often unavailable
`<time.h>`	Clocks and calendars	No	API is dated; see below
`<setjmp.h>`	Non-local jumps	No	Avoid
`<signal.h>`	Signal handling	No	Very restricted; see below
`<locale.h>`, `<wchar.h>`	Locales, wide chars	No	Avoid in systems code

The mem* functions

```
memcpy(dst, src, n)     /* non-overlapping only — restrict (ch. 10) */
memmove(dst, src, n)    /* handles overlap                          */
memset(dst, c, n)       /* c is converted to unsigned char          */
memcmp(a, b, n)         /* byte comparison; NOT for structs (ch. 07)
                           and NOT constant time (ch. 06)           */
memchr(s, c, n)         /* find a byte                              */

/* These are the fastest primitives you have. Modern implementations
   are hand-written SIMD, dispatched by CPU feature at load time.
   Do not write your own copy loop.                                 */

/* The compiler also generates calls to them from ordinary code: */
struct big a = b;            /* may become memcpy */
int arr[1000] = {0};         /* may become memset */
/* Which is why freestanding builds must PROVIDE memcpy/memset even
   if the source never calls them (chapter 20).                  */

/* memset's second argument is an int, converted to unsigned char.
   This does not do what it looks like:                          */
memset(arr, 1, n * sizeof(int));    /* sets every BYTE to 1, giving
                                       0x01010101, not 1          */
/* Only 0 is safe to splat across a multi-byte type. Use a loop
   otherwise, or memset_pattern where available.                 */
```

printf, and its cost

```
/* The format specifiers that matter, and are commonly wrong */
%d %u %x       int / unsigned / hex
%ld %lu        long
%lld %llu      long long
%zu %zd        size_t / ssize_t          <- not %d, not %lu
%td            ptrdiff_t
%p             void * — you MUST cast:  printf("%p", (void *)ptr)
%s             char * — never a non-literal FORMAT (ch. 06)
%f %e %g       double (float is promoted)
%%             a literal percent

/* fixed-width types need <inttypes.h> */
#include <inttypes.h>
printf("%" PRIu32 " %" PRIx64 "\n", a, b);

/* Field width and precision from arguments */
printf("%*d\n", width, value);
printf("%.*s\n", len, str);        /* print exactly len bytes —
                                      useful for non-terminated data */
```

> **PRINTF IS ENORMOUS**
>
> A full `printf` with floating-point support costs roughly 10–40 KB of flash and needs a sizeable stack frame. On a microcontroller with 64 KB of flash that is unacceptable. Options: `-u _printf_float` to omit float support in newlib-nano, a minimal reimplementation (`tinyprintf`, `mpaland/printf`), or a binary logging scheme that sends a format ID plus arguments and reconstructs the text on the host. The kernel's `printk` is its own implementation for exactly these reasons — it also cannot use floating point at all.

errno

```
#include <errno.h>

/* errno is thread-local (a macro expanding to a per-thread lvalue).
   The rules that people get wrong:                                  */

/* 1. It is only meaningful after a function that DOCUMENTS setting
      it, and only when that function reported failure.           */
if (fopen(...) == NULL)
        perror("fopen");            /* correct */

/* 2. A successful call may still CLOBBER errno. Never test errno
      to decide whether something failed.                         */
foo();
if (errno) ...                       /* WRONG */

/* 3. For functions that return a valid value on both success and
      failure (strtol, strtod), you MUST clear errno first:       */
errno = 0;
long v = strtol(s, &end, 10);
if (errno == ERANGE) ...

/* 4. Save it immediately if you do anything else first: */
if (write(...) < 0) {
        int saved = errno;
        cleanup();                   /* may clobber errno */
        return -saved;
}

/* Printing it */
perror("context");                   /* writes "context: message\n" */
fprintf(stderr, "%s\n", strerror(errno));       /* not thread-safe   */
strerror_r(errno, buf, sizeof buf);             /* thread-safe       */
```

The kernel does not use `errno` at all: functions return `0` or a negative errno value directly (`-EINVAL`, `-ENOMEM`). This is a strictly better design — the error is in the return value, so it cannot be clobbered or forgotten — and it is worth adopting in your own C libraries.

assert, and when to use it

```
#include <assert.h>

assert(ptr != NULL);        /* aborts if false; compiled out by NDEBUG */

/* THE RULE: assert on PROGRAMMER errors (invariants that must hold
   if the code is correct). Handle USER and ENVIRONMENT errors with
   real error paths.                                              */

assert(index < ARRAY_SIZE(table));   /* internal invariant — assert */
if (!input_valid(s)) return -EINVAL; /* external input — check      */

/* The classic bug: side effects inside assert */
assert(do_something() == 0);         /* vanishes in release builds! */
int r = do_something();
assert(r == 0);                       /* correct */

/* Give it a message by ANDing a string literal — a widely used trick */
assert(n > 0 && "count must be positive");

/* static_assert costs nothing at runtime and never disappears:  */
static_assert(sizeof(struct hdr) == 8, "header layout");

/* In the kernel: */
BUG_ON(cond);       /* panic — reserve for unrecoverable corruption */
WARN_ON(cond);      /* log a stack trace and CONTINUE — prefer this */
WARN_ON_ONCE(cond);
BUILD_BUG_ON(cond); /* compile time */
```

Time

```
#include <time.h>

/* time_t is seconds since the epoch. On 32-bit systems it overflows
   in 2038 — still a live concern on embedded hardware shipping now.
   Use 64-bit time_t (glibc 2.34+ with _TIME_BITS=64) or your own.  */

/* For MEASURING DURATIONS, never use wall-clock time — it jumps
   backwards with NTP, DST and manual changes.                    */
struct timespec t0, t1;
clock_gettime(CLOCK_MONOTONIC, &t0);
work();
clock_gettime(CLOCK_MONOTONIC, &t1);
double sec = (t1.tv_sec - t0.tv_sec) + (t1.tv_nsec - t0.tv_nsec) / 1e9;

/* Clock choices that matter:
     CLOCK_REALTIME       wall clock; can jump. For timestamps only.
     CLOCK_MONOTONIC      never jumps; may pause in suspend. Durations.
     CLOCK_BOOTTIME       monotonic, includes suspend time.
     CLOCK_PROCESS_CPUTIME_ID   CPU time used, for profiling.       */

/* The C standard's clock() returns CPU time in CLOCKS_PER_SEC
   units and is nearly useless for wall-clock measurement.       */
```

Signals: async-signal-safety

```
/* A signal handler interrupts the program at an arbitrary point,
   possibly in the middle of malloc or printf. Almost nothing is
   safe to call from one.                                          */

/* SAFE inside a handler: a short list, including
     write(), _exit(), signal(), sigaction(), and assignment to a
     volatile sig_atomic_t.

   NOT safe: malloc, free, printf, any stdio, most of libc.      */

static volatile sig_atomic_t got_sigint = 0;

static void handler(int sig) { got_sigint = 1; }   /* that is ALL */

int main(void)
{
        struct sigaction sa = { .sa_handler = handler };
        sigemptyset(&sa.sa_mask);
        sigaction(SIGINT, &sa, NULL);      /* prefer over signal() */

        while (!got_sigint)
                do_work();                  /* the real work happens here */
}

/* The modern alternative on Linux: signalfd() or a self-pipe, which
   turn a signal into a readable file descriptor you can poll —
   removing the async-safety problem entirely.                     */
```

What to avoid outright

Avoid	Why	Instead
`gets()`	Unconditionally exploitable; removed in C11	`fgets`, `getline`
`strcpy`, `strcat`, `sprintf`	Unbounded writes	`snprintf`, `strlcpy`
`strncpy`	May not terminate; always pads	`snprintf`, `strscpy`
`atoi`, `atof`	No error reporting; UB on overflow	`strtol`, `strtod` with checks
`strtok`	Global state; modifies input	`strtok_r`, or hand-written
`rand()`	Poor quality; not thread-safe; never for security	`getrandom()`, `arc4random`, a proper PRNG
`setjmp` / `longjmp`	Skips cleanup; interacts badly with optimisation	Error returns
`system()`	Shell injection	`posix_spawn`, `fork` + `exec`
`alloca()`	Unbounded stack growth; no failure path	Fixed buffer or heap
`gmtime`, `asctime`, `strerror`	Return pointers to static buffers — not reentrant	The `_r` variants

What the kernel gives you instead

Userspace	Linux kernel	Note
`malloc` / `free`	`kmalloc` / `kfree`, `kvmalloc`, `devm_kzalloc`	Needs a GFP flag for context
`printf`	`printk`, `pr_info`, `dev_err`	No floating point
`memcpy`, `strlen`	Same names, kernel implementations	Available
`snprintf`	`snprintf`, `scnprintf`	`scnprintf` returns bytes actually written
`strtol`	`kstrtoint`, `kstrtoul`	Returns an error code, not `errno`
`assert`	`WARN_ON`, `BUG_ON`, `BUILD_BUG_ON`	Prefer `WARN_ON`
`qsort`	`sort()`	In `lib/sort.c`
`errno`	Negative return values	Better design
Floating point	**Forbidden**	FP state is not saved on kernel entry
`time()`	`ktime_get()`, `jiffies`	

How it shows up

Symptom	Cause
`printf("%d", sizeof x)` prints garbage	Wrong specifier for `size_t`; use `%zu`
Crash printing a pointer	`%p` without a `(void *)` cast
Binary too large for flash	`printf` with float support linked in
`errno` reports the wrong error	Clobbered by an intervening call; save it immediately
`strtol` range errors never detected	Forgot `errno = 0` before the call
Assertion has no effect in release	Side effect inside `assert`; `NDEBUG` removed it
Timing measurements occasionally negative	Used wall-clock time; use `CLOCK_MONOTONIC`
Deadlock or corruption inside a signal handler	Called a non-async-signal-safe function
`memset(a, 1, n)` gives 0x01010101	`memset` works on bytes
Undefined reference to `memcpy` in a bare-metal build	The compiler generated a call; provide it (ch. 20)

Check yourself

- ✓ Name the freestanding headers and say why those specific ones require no runtime.
- ✓ Give the correct specifiers for `size_t`, `uint32_t` and a pointer.
- ✓ State the four `errno` rules.
- ✓ Explain when to `assert` and when to return an error.
- ✓ Say why `assert(f() == 0)` is a bug.
- ✓ Explain which clock to use for measuring a duration, and why.
- ✓ List three functions that are safe in a signal handler and explain the constraint.
- ✓ Give five standard functions to avoid and their replacements.

Compiling and linking in practice

Most C build problems are link problems, and most link problems come from not knowing what the linker actually does. This chapter walks the pipeline from source to running image, with the diagnostic commands for each stage.

The pipeline

```
   main.c   util.c   startup.S
      |        |         |
   [ preprocess ]        |          gcc -E    -> .i
      |        |         |
   [  compile   ]        |          gcc -S    -> .s   (assembly)
      |        |         |
   [ assemble  ]  [ assemble ]      gcc -c    -> .o   (object, with
      |        |         |                             relocations)
      +--------+---------+
               |
           [   LINK   ]             ld / gcc  -> executable or .elf
               |                    resolves symbols, assigns final
               |                    addresses, applies relocations
               v
           program.elf
               |
      [ objcopy -O binary ]         -> program.bin (raw image to flash)
               |
      [ load / flash / exec ]

Each arrow can fail in a characteristic way, and knowing which stage
you are in tells you which tool to reach for.
```

```
# run one stage at a time when something is wrong
gcc -E  main.c -o main.i     # preprocessed source - macro problems
gcc -S  main.c -o main.s     # assembly            - codegen questions
gcc -c  main.c -o main.o     # object              - syntax/type errors
gcc main.o util.o -o prog    # link                - symbol errors

gcc -v main.c                # show every subprocess and its arguments
gcc -### main.c              # ...without running them
gcc -save-temps main.c       # keep .i, .s and .o alongside the output
```

Inside an object file

```
An ELF object contains SECTIONS and a SYMBOL TABLE.

  .text      machine code
  .rodata    read-only data: literals, const tables
  .data      initialised writable data
  .bss       zero-initialised data — size only, no bytes in the file
  .symtab    symbols: name, section, offset, size, binding, type
  .rela.*    RELOCATIONS: "patch this offset with the address of
             symbol S once you know it"
  .debug_*   DWARF debug information

Symbol bindings:
  GLOBAL   visible to the linker, may be referenced elsewhere
  LOCAL    file-scope `static` — invisible outside this object
  WEAK     may be overridden by a strong definition elsewhere

Symbol types you will see in nm output:
  T  in .text (defined)          t  local .text
  D  in .data                    d  local .data
  B  in .bss                     b  local .bss
  R  in .rodata
  U  UNDEFINED — needs to come from somewhere else
  W  weak
```

```
# inspect objects
nm util.o                       # symbol table
nm -C --defined-only prog       # only what this file defines
nm prog | grep ' U '            # everything still undefined
nm --size-sort -S prog | tail   # the biggest symbols

readelf -h prog                 # ELF header: type, machine, entry point
readelf -S prog                 # section headers with addresses/sizes
readelf -s prog                 # symbol table, verbose
readelf -d prog                 # dynamic section: NEEDED libraries, RPATH
readelf -r util.o               # relocations

objdump -d prog                 # disassemble
objdump -d --source prog        # interleave source (needs -g)
objdump -t prog                 # symbol table
objdump -s -j .rodata prog      # hex dump of one section

size prog                       # text/data/bss totals — the embedded
                                # build-gate metric
```

The two link errors, and how to read them

Undefined reference

```
/tmp/ccXXXX.o: in function `main':
main.c:(.text+0x18): undefined reference to `helper'
```

Cause	Check
The .c file defining it was not compiled or linked	Is `util.o` on the command line?
It is `static` in the defining file	`nm util.o | grep helper` — lower-case `t` means local

Cause	Check
Name mismatch — a typo, or C++ name mangling	`nm -C`; wrap C headers in `extern "C"`
Library not linked	Add `-lfoo`
Library listed *before* its user	**Order matters** — see below
Declared but never defined anywhere	Prototype in a header with no implementation
Wrong architecture object	`file util.o`
Compiler generated a call you did not write	`memcpy` / `memset` in freestanding builds

LINK ORDER IS NOT COMMUTATIVE

```
gcc -lm main.c        # FAILS: at the time libm is processed, nothing
                      # needs sqrt yet, so it is discarded
gcc main.c -lm        # works

/* The traditional linker makes ONE pass, left to right. When it
   reaches an archive (.a) it pulls in only the members that resolve
   currently-undefined symbols, then moves on. A library placed
   before its user contributes nothing.

   RULE: objects first, then libraries, in dependency order
   (users before providers).

   For circular dependencies between static libraries: */
gcc main.o -la -lb -la               # repeat
gcc main.o -Wl,--start-group -la -lb -Wl,--end-group   # or group them

/* Shared libraries do not have this problem in the same way, but
   keeping the order correct is still the habit to build.       */
```

Multiple definition

```
/usr/bin/ld: util.o:(.bss+0x0): multiple definition of `counter';
             main.o:(.bss+0x0): first defined here
```

```
/* Almost always: a variable DEFINED in a header. */

/* WRONG — every including file gets its own definition */
/* config.h */  int verbose = 0;

/* RIGHT */
/* config.h */  extern int verbose;
/* config.c */  int verbose = 0;

/* GCC 10 made -fno-common the default, so tentative definitions
   across translation units now error instead of silently merging.
   If an old codebase suddenly fails to link after a toolchain
   upgrade, this is why. The fix is the pattern above, not
   -fcommon.                                                    */

/* Also caused by:
     - a function DEFINED in a header without `static inline`
     - the same .c file listed twice in the build
     - a name colliding with libc (e.g. defining your own `index`) */
```

Static and shared libraries

```
# static library — an archive of object files
ar rcs libfoo.a a.o b.o c.o
ar t libfoo.a                   # list members
gcc main.o -L. -lfoo -o prog    # members are COPIED into prog

# shared library — loaded at runtime
gcc -fPIC -c a.c b.c            # position-independent code, required
gcc -shared a.o b.o -o libfoo.so.1.0
ln -s libfoo.so.1.0 libfoo.so.1
ln -s libfoo.so.1 libfoo.so
gcc main.o -L. -lfoo -o prog

# runtime lookup
ldd prog                        # which shared objects it needs
LD_LIBRARY_PATH=. ./prog        # development only
gcc ... -Wl,-rpath,'$ORIGIN/../lib'   # embed a relative search path
ldconfig -p | grep foo          # the system cache
```

	Static (.a)	Shared (.so / .dll)
Binary size	Larger — code is copied in	Smaller
Memory across processes	One copy each	Shared text pages
Deployment	Single self-contained file	Must ship and version the library
Updating the library	Requires relinking everything	Drop-in, if the ABI is stable
Startup cost	None	Dynamic symbol resolution
Call cost	Direct	Through the PLT/GOT — one indirection
Typical in embedded	**Yes** — determinism, no loader	Rare on small systems

Controlling visibility

```
/* By default every non-static symbol in a shared library is
   exported. That is slow (large dynamic symbol table), fragile
   (accidental ABI), and prevents optimisation.                */

gcc -fvisibility=hidden -shared ...     /* hide everything by default */

#define API __attribute__((visibility("default")))
API int  public_function(void);          /* explicitly exported       */
static   int private_helper(void);       /* not even in .symtab       */

/* A version script gives finer control and is what real libraries use */
/* libfoo.map */
FOO_1.0 {
    global: foo_init; foo_run; foo_free;
    local:  *;
};
gcc -shared -Wl,--version-script=libfoo.map ...

/* Benefits: smaller symbol table, faster load, a real ABI boundary,
   and the linker can inline and optimise across hidden symbols.  */
```

Link-time optimisation

```
# Without LTO the compiler sees one translation unit at a time and
# cannot inline across files. LTO defers codegen to link time.
gcc -flto -O2 -c a.c b.c
gcc -flto -O2 a.o b.o -o prog

# Typical gains: 5–20% speed, and often smaller binaries because
# unused code across the whole program can be eliminated.
# Costs: much slower and more memory-hungry links; harder debugging;
# occasionally exposes latent UB that was previously hidden by the
# TU boundary.

# also worth knowing
-ffunction-sections -fdata-sections -Wl,--gc-sections
# puts each function and object in its own section so the linker can
# discard unreferenced ones. Essential in embedded builds; often
# saves 20–40% of image size.

-Wl,--print-gc-sections    # show what was discarded
-Wl,-Map=out.map           # a full map file: what ended up where
                           # THE tool for "why is my binary so big?"
```

Linker scripts

```
/* On a hosted OS the default script is invisible. On bare metal you
   write it, and it defines the entire memory layout.           */

MEMORY {
  FLASH (rx)  : ORIGIN = 0x08000000, LENGTH = 512K
  RAM   (rwx) : ORIGIN = 0x20000000, LENGTH = 128K
}

ENTRY(Reset_Handler)

SECTIONS {
  .text : {
    KEEP(*(.vectors))          /* KEEP survives --gc-sections */
    *(.text*)
    *(.rodata*)
    . = ALIGN(4);
    _etext = .;                /* symbols the C code can reference */
  } > FLASH

  .data : AT (_etext) {        /* LIVES in RAM, STORED in FLASH */
    _data_start = .;
    *(.data*)
    . = ALIGN(4);
    _data_end = .;
  } > RAM

  .bss : {
    _bss_start = .;
    *(.bss*) *(COMMON)
    . = ALIGN(4);
    _bss_end = .;
  } > RAM

  _stack_top = ORIGIN(RAM) + LENGTH(RAM);
}

/* The `AT` directive is why startup code has a copy loop: the
   initial values of .data must be stored somewhere non-volatile,
   then copied to RAM before main(). Chapter 20 shows that loop. */
```

Build systems, minimally

```
# A Makefile that regenerates header dependencies automatically —
# the single most important correctness property of a C build.
CC      := aarch64-linux-gnu-gcc
CFLAGS  := -std=c11 -Wall -Wextra -O2 -MMD -MP
SRCS    := $(wildcard src/*.c)
OBJS    := $(SRCS:.c=.o)
DEPS    := $(OBJS:.o=.d)

prog: $(OBJS)
        $(CC) $^ -o $@ $(LDFLAGS)

-include $(DEPS)        # pulls in "main.o: main.c foo.h bar.h"

clean:
        rm -f $(OBJS) $(DEPS) prog

# -MMD -MP makes the compiler emit a .d file listing every header
# the object depends on. Without it, editing a header does NOT
# trigger a rebuild, and you debug a stale binary. This is the most
# common cause of "impossible" behaviour in hand-written Makefiles.
```

```
# generate compile_commands.json so clangd, clang-tidy and IDEs work
bear -- make
# or with CMake
cmake -B build -DCMAKE_EXPORT_COMPILE_COMMANDS=ON
```

A baseline flag set

```
# warnings — turn them on and treat them as errors
-Wall -Wextra -Wpedantic
-Wshadow -Wconversion -Wsign-conversion
-Wcast-align -Wcast-qual -Wpointer-arith
-Wstrict-prototypes -Wmissing-prototypes -Wold-style-definition
-Wwrite-strings -Wredundant-decls -Wnull-dereference
-Wdouble-promotion -Wformat=2
-Werror                     # in CI, at minimum

# hardening for anything that touches untrusted input
-D_FORTIFY_SOURCE=3 -O2
-fstack-protector-strong
-fstack-clash-protection
-fPIE -pie
-Wl,-z,relro,-z,now
-Wl,-z,noexecstack
-mbranch-protection=standard      # aarch64: PAC + BTI

# development and test builds
-g3 -fno-omit-frame-pointer
-fsanitize=address,undefined
-fanalyzer

# embedded
-ffunction-sections -fdata-sections -Wl,--gc-sections
-ffreestanding -nostdlib -fno-builtin
-Wl,-Map=out.map
```

How it shows up

Symptom	Cause
"undefined reference" to a function you can see	Not linked, `static`, or library order wrong
"undefined reference to `sqrt`"	`-lm` missing, or placed before the user
"multiple definition"	Variable or non-inline function defined in a header
Link fails only after a toolchain upgrade	`-fno-common` became the default
Edits to a header have no effect	Missing `-MMD -MP` dependency generation
Binary far larger than expected	No `--gc-sections`; read the map file
Runs on the build machine, "library not found" elsewhere	`LD_LIBRARY_PATH` dependency; set an RPATH or link statically
Crash before `main` on bare metal	Linker script or startup copy loop wrong
Symbol resolves to the wrong library's version	Search order; check with `ldd` and `-Wl,--trace`
LTO build fails or misbehaves	Latent UB previously hidden by the TU boundary

Check yourself

- ✓ Name the five pipeline stages and the flag that stops after each.
- ✓ Say what a relocation is and why object files need them.
- ✓ Explain why `gcc -lm main.c` fails and `gcc main.c -lm` works.
- ✓ Give three causes of "undefined reference" and the command that distinguishes them.
- ✓ Explain why defining a variable in a header causes "multiple definition".
- ✓ Compare static and shared libraries on four axes.
- ✓ Explain what `--gc-sections` needs from the compiler to be effective.
- ✓ Explain why `.data` is stored in flash but lives in RAM.
- ✓ Say what `-MMD -MP` does and what breaks without it.

Inline assembly and compiler intrinsics

Sometimes C cannot express what you need: a system register, a barrier, an atomic sequence, a SIMD instruction. Inline assembly is the escape hatch — and the most dangerous construct in the language, because a wrong constraint produces code that works until the register allocator changes its mind.

Try these first

Need	Reach for	Before
Bit counting, byte swap	`__builtin_popcount`, `__builtin_bswap32`, `<stdbit.h>`	asm
Atomics	`<stdatomic.h>`, `__atomic_*`	asm
Overflow checks	`__builtin_add_overflow`	asm
SIMD	Auto-vectorisation, then `<arm_neon.h>` intrinsics	asm
Barriers	`atomic_thread_fence`, kernel `smp_mb()`	asm
Cache and TLB maintenance	Kernel/vendor helper functions	asm
System registers	Kernel accessors (`read_sysreg()`)	asm

THE RULE

Inline assembly is a last resort. Intrinsics and builtins give the compiler full visibility — it can schedule, allocate registers, constant-fold and vectorise around them. An `asm` block is opaque: the compiler must trust your description of it, and if that description is wrong, the bug appears only at certain optimisation levels or after unrelated edits.

GCC extended asm

```
asm [volatile] ( "template"
               : output operands
               : input operands
               : clobbers
               );

%0, %1, %2 ...   refer to operands in order, outputs first
%w0              32-bit view of operand 0 (aarch64)
%x0              64-bit view

Constraint letters (aarch64):
  "r"   general register
  "m"   memory operand
  "i"   immediate constant
  "w"   SIMD/FP register
  "0"   must use the same register as operand 0

Modifiers:
  "=r"  write-only output   (assume the old value is dead)
  "+r"  read-write output
  "&r"  EARLYCLOBBER — written before all inputs are consumed
```

```
/* read a system register */
static inline uint64_t read_sctlr(void)
{
        uint64_t v;
        asm volatile("mrs %0, sctlr_el1" : "=r"(v));
        return v;
}

/* write one, then synchronise the pipeline */
static inline void write_sctlr(uint64_t v)
{
        asm volatile("msr sctlr_el1, %0\n\t"
                     "isb"
                     :: "r"(v) : "memory");
}

/* a barrier: no operands at all, only a clobber */
#define dmb_ish()  asm volatile("dmb ish" ::: "memory")

/* arithmetic with input and output */
static inline uint32_t rev32(uint32_t x)
{
        uint32_t r;
        asm("rev %w0, %w1" : "=r"(r) : "r"(x));
        return r;
}
/* ...though you should just use __builtin_bswap32(x). */
```

The four mistakes

1. FORGETTING `VOLATILE`

Without it, the compiler may delete an `asm` whose outputs are unused, hoist it out of a loop, or execute it fewer times than written. Any asm with a *side effect* — writing a system register, touching hardware, a barrier — must be `volatile`.

```
asm("msr daifset, #2");              /* may be DELETED — no outputs */
asm volatile("msr daifset, #2");     /* correct                     */

/* Conversely, a pure computation should NOT be volatile, so the
   compiler can hoist it out of loops and CSE it: */
asm("rev %w0, %w1" : "=r"(r) : "r"(x));   /* pure — leave it hoistable */
```

2. MISSING THE `"MEMORY"` CLOBBER

Tells the compiler that the asm reads or writes memory it cannot see, so it must not cache values in registers across the block, and must not reorder memory accesses past it. Every barrier, every cache operation, and any asm that dereferences a pointer needs it.

```
/* WRONG: the compiler may keep *p in a register across the barrier */
asm volatile("dsb sy");

/* RIGHT */
asm volatile("dsb sy" ::: "memory");

/* A compiler-only barrier, with no instruction at all: */
#define barrier() asm volatile("" ::: "memory")
/* This is exactly what Linux's barrier() is, and what READ_ONCE
   and WRITE_ONCE are built on.                                  */
```

3. NOT DECLARING CLOBBERED REGISTERS

If your asm writes a register the compiler thinks holds a live value, that value is silently destroyed. The symptom is corruption in unrelated code, appearing only at certain optimisation levels.

```
/* WRONG: x9 is clobbered but not declared */
asm volatile("mov x9, #0\n\t"
             "add %0, %1, x9" : "=r"(r) : "r"(x));

/* RIGHT */
asm volatile("mov x9, #0\n\t"
             "add %0, %1, x9" : "=r"(r) : "r"(x) : "x9");

/* BETTER: let the compiler choose the scratch register */
uint64_t tmp;
asm volatile("mov %1, #0\n\t"
             "add %0, %2, %1" : "=r"(r), "=&r"(tmp) : "r"(x));

/* Also clobber "cc" if you modify the condition flags: */
asm volatile("subs %0, %1, #1" : "=r"(r) : "r"(x) : "cc");
```

4. MISSING EARLYCLOBBER

By default the compiler may assign an output and an input to the *same* register, assuming inputs are fully consumed before outputs are written. If your asm writes the output before reading all inputs, you need `&`.

```
/* WRONG: %0 and %1 may be the same register, so writing %0 first
   destroys the input.                                          */
asm("mov %0, #0\n\t"
    "add %0, %0, %1" : "=r"(out) : "r"(in));

/* RIGHT */
asm("mov %0, #0\n\t"
    "add %0, %0, %1" : "=&r"(out) : "r"(in));

/* The bug is invisible until register pressure changes — which is
   why it typically appears months later after an unrelated edit. */
```

Worked examples

```
/* Interrupt masking — the shape used in every RTOS and kernel */
static inline unsigned long irq_save(void)
{
        unsigned long flags;
        asm volatile("mrs %0, daif\n\t"
                     "msr daifset, #2"      /* mask IRQ */
                     : "=r"(flags) :: "memory");
        return flags;
}
static inline void irq_restore(unsigned long flags)
{
        asm volatile("msr daif, %0" :: "r"(flags) : "memory");
}

/* An atomic increment with exclusives — for illustration; in real
   code use <stdatomic.h>, which also selects LSE on newer cores. */
static inline void atomic_inc(int *p)
{
        unsigned long tmp;
        int val;
        asm volatile("1: ldaxr %w0, %2\n\t"
                     "   add   %w0, %w0, #1\n\t"
                     "   stlxr %w1, %w0, %2\n\t"
                     "   cbnz  %w1, 1b"
                     : "=&r"(val), "=&r"(tmp), "+Q"(*p)
                     :: "memory");
}
/* Note: "+Q" is a memory operand with no offset — required for
   exclusives. "1:" and "1b" are LOCAL LABELS, mandatory in inline
   asm because the block may be duplicated by inlining or
   unrolling; a named label would then be defined twice.        */

/* SIMD is far better expressed with intrinsics */
#include <arm_neon.h>
void vadd(float *c, const float *a, const float *b, size_t n)
{
        for (size_t i = 0; i + 4 <= n; i += 4)
                vst1q_f32(c + i, vaddq_f32(vld1q_f32(a + i),
                                           vld1q_f32(b + i)));
}
/* Intrinsics are typed, schedulable, and the compiler can still
   register-allocate around them. Prefer them universally.     */
```

asm goto and basic asm

```
/* Basic asm — no operands. Only safe at FILE SCOPE or when the block
   truly touches nothing. Inside a function it is a trap, because
   the compiler assumes it does nothing.                          */
asm(".section .rodata\n\t.asciz \"build-id\"\n\t.previous");

/* asm goto — can branch to a C label. This is what makes Linux's
   static keys (runtime-patchable branches) possible.            */
static inline bool feature_enabled(void)
{
        asm goto("1: nop\n\t"
                 ".pushsection __jump_table, \"aw\"\n\t"
                 ".quad 1b, %l[l_yes]\n\t"
                 ".popsection"
                 :::: l_yes);
        return false;
l_yes:
        return true;
}
/* The nop is rewritten to a branch at runtime when the feature is
   toggled — zero cost when disabled, and no indirect call.     */
```

Naked functions and startup code

```
/* A naked function has no prologue or epilogue. Used for reset
   handlers and context switches, where the ABI does not apply. */
__attribute__((naked)) void Reset_Handler(void)
{
        asm volatile(
                "ldr r0, =_stack_top\n\t"
                "mov sp, r0\n\t"
                "bl  SystemInit\n\t"
                "bl  main\n\t"
                "b   .");
}
/* Rules: the body must be ENTIRELY asm. No local variables, no C
   statements, no return — the compiler generates nothing around
   it, so anything else has undefined behaviour.               */

/* For anything longer than a few instructions, use a separate .S
   file instead. It is easier to read, easier to debug, and the
   assembler gives better diagnostics.                          */
```

Verify what you wrote

```
# ALWAYS read the generated code after writing inline asm.
gcc -O2 -S file.c -o - | less
gcc -O2 -c file.c && objdump -d file.o

# check at several optimisation levels — constraint bugs are
# optimisation-dependent by nature
for O in 0 1 2 3 s; do gcc -O$O -S f.c -o f.$O.s; done

# godbolt.org (Compiler Explorer) is the fastest way to iterate:
# paste, see the assembly instantly, switch compilers and flags.

# in a running kernel or program
gdb ./prog
(gdb) disassemble /s my_function
(gdb) layout asm
```

TESTING CHECKLIST FOR ANY INLINE ASM

- Compiles and behaves correctly at `-O0`, `-O2`, `-Os`.
- Correct when inlined into several different call sites.
- Correct inside a loop (checks `volatile` and clobbers).
- Correct under high register pressure — call it with many live variables around it.
- Correct with LTO enabled.
- Read the disassembly at least once and confirm the register assignment is what you expect.

Portability

```
/* GCC/Clang syntax is not MSVC syntax. MSVC removed inline asm for
   x64 entirely and offers only intrinsics.                      */

#if defined(__GNUC__)
        asm volatile("dmb ish" ::: "memory");
#elif defined(_MSC_VER)
        __dmb(_ARM64_BARRIER_ISH);      /* MSVC intrinsic */
#endif

/* Isolate every asm block behind a small inline wrapper in one
   header. Then the platform conditionals live in ONE file and the
   rest of the codebase calls a normal-looking function.        */

/* arch.h */
static inline void arch_barrier(void);
static inline uint64_t arch_read_cycles(void);
static inline void arch_irq_disable(void);
```

How it shows up

Symptom	Cause
asm block disappears from the output	Missing `volatile` with unused outputs
Barrier has no effect on ordering	Missing `"memory"` clobber

Symptom	Cause
Unrelated variable corrupted	Undeclared register clobber
Works at `-O0`, breaks at `-O2`	Wrong constraints; register allocation changed
Wrong result when an input equals an output	Missing earlyclobber `&`
"symbol already defined" after inlining	Named label in asm; use local labels `1:` / `1b`
Condition flags wrong after the block	Missing `"cc"` clobber
Crash entering a naked function	Non-asm statements in the body
Fails only with LTO	Cross-TU inlining changed the surrounding register state
32-bit operation on a 64-bit register	Used `%0` where `%w0` was needed

Check yourself

- ✓ Give three alternatives to try before writing inline assembly.
- ✓ Explain when `volatile` is required and when it should be omitted.
- ✓ Explain what the `"memory"` clobber tells the compiler.
- ✓ Write a system-register read with the correct constraints.
- ✓ Explain earlyclobber and construct a case that needs it.
- ✓ Explain why inline asm must use local labels.
- ✓ Say why intrinsics are preferable to asm for SIMD.
- ✓ List the optimisation levels and conditions you would test an asm block under.

Defensive C: MISRA, assertions and static analysis

C gives you no safety net, so the profession built one out of process: coding standards, static analysis, assertions and review discipline. This chapter is what actually works in production, and what is theatre.

Defence in depth

```
Each layer catches what the one before it missed. Cost rises,
and so does the cost of the bugs each one prevents.

  1. LANGUAGE DISCIPLINE     free       consistent idioms, small
                                        functions, clear ownership
  2. COMPILER WARNINGS       free       -Wall -Wextra -Werror
  3. STATIC ANALYSIS         cheap      -fanalyzer, clang-tidy,
                                        cppcheck, commercial tools
  4. CODING STANDARD         process    MISRA, CERT C, kernel style
  5. ASSERTIONS              cheap      invariants checked at runtime
  6. SANITIZERS              CI time    ASan, UBSan, TSan, MSan
  7. UNIT + PROPERTY TESTS   effort     including fuzzing
  8. CODE REVIEW             effort     the only layer that catches
                                        DESIGN errors
  9. FORMAL METHODS          expensive  Frama-C, CBMC — for the code
                                        that must not fail

Most teams do 1, 2 and 8, and skip 3, 5 and 6 — which is precisely
where the cheapest wins are.
```

Warnings are the cheapest layer

```
# the baseline every C project should have
-Wall -Wextra -Wpedantic -Werror

# and the ones -Wall does not include but should
-Wshadow                   # a local hiding an outer name
-Wconversion               # implicit narrowing
-Wsign-conversion
-Wcast-align               # casting to a stricter alignment
-Wcast-qual                # casting away const
-Wpointer-arith
-Wstrict-prototypes        # int f() with no parameter list
-Wmissing-prototypes       # a non-static function with no prototype
-Wold-style-definition
-Wredundant-decls
-Wwrite-strings            # string literals become const char[]
-Wnull-dereference
-Wdouble-promotion         # accidental float->double on an MCU
-Wformat=2 -Wformat-security
-Wvla                      # variable-length arrays (chapter 05)
-Wswitch-enum              # a switch missing an enum value

# Treat warnings as errors in CI from day one. A codebase with
# 400 warnings has zero warnings, because nobody reads them.
```

> **ADOPTING `-WERROR` ON AN EXISTING CODEBASE**
> Do not try to fix everything at once. Enable `-Werror` only for *new* files, or use `-Werror=` for individual warnings you have already cleaned (`-Werror=return-type -Werror=implicit-function-declaration`). Ratchet forward: every warning you clear becomes an error so it can never come back. This converts an impossible cleanup into a steady one.

Static analysis

Tool	Finds	Cost
`gcc -fanalyzer`	Leaks, double free, use-after-free, null deref, some UB — with a path trace	Free; slow compile
`clang --analyze` / `scan-build`	Similar, different strengths; HTML reports	Free
`clang-tidy`	Style, modernisation, bug patterns; many CERT and MISRA checks	Free; needs `compile_commands.json`
`cppcheck`	Broad heuristic checks; MISRA add-on	Free; no build integration needed
`sparse`	Kernel-specific: `__user` / `__iomem` pointer misuse, endianness annotations, lock context	Free; `make C=1`
`smatch`	Kernel flow analysis	Free
Coverity, PVS-Studio, Polyspace, Klocwork	Deeper interprocedural analysis; certification evidence	Commercial

```
# run them in CI, not on developer laptops only
gcc -fanalyzer -Wall -Wextra -c src/*.c
scan-build make
clang-tidy src/*.c -- -Iinclude
cppcheck --enable=all --inconclusive --std=c11 src/

# kernel
make C=1 CHECK=sparse
make C=2 CF=-D__CHECK_ENDIAN__

# Static analysers produce false positives. Triage them, suppress
# with a NARROW comment and a REASON, and never with a blanket
# disable:
/* cppcheck-suppress nullPointer ; p is validated in caller, see #123 */
```

MISRA C

A coding standard for safety-related systems, originating in automotive and now used in medical, industrial and aerospace work. MISRA C:2012 has roughly 175 rules and directives, classified as *mandatory*, *required* or *advisory*.

Representative rule	Rationale
No dynamic memory (21.3)	Fragmentation and non-determinism (ch. 14)
No recursion (17.2)	Stack usage cannot be bounded statically
No `goto` (15.1, advisory)	Control-flow analysability
Single exit per function (15.5, advisory)	Simplifies reasoning; widely disputed

Representative rule	Rationale
Every `if` / `else if` chain ends in `else` (15.7)	Forces you to consider the default case
Every `switch` has a `default` (16.4)	Same
All bodies are compound statements (15.6)	Prevents the dangling-else and "goto fail" class
No implicit conversions that change signedness or width (10.x)	The bug class in chapter 02
Function return values must be used or explicitly discarded (17.7)	Ignored error codes
No `#undef`, restricted `#include` forms (20.x)	Preprocessor predictability

> **AN HONEST ASSESSMENT**
>
> MISRA's genuinely valuable rules are the ones about implicit conversion, uninitialised data, unused return values and undefined behaviour — they encode real bug classes. The controversial ones (single exit, no `goto`) can make error handling *worse* in C, since the `goto` cleanup ladder (ch. 14) is the clearest way to release resources in reverse order.
>
> MISRA is a **deviation-based** process: you are expected to violate rules where justified, and to document why. A team that treats it as an absolute prohibition ends up writing worse code to satisfy a checker. If you are not in a certified domain, adopt the conversion and initialisation rules and skip the structural dogma.

CERT C is the security-focused alternative, organised by vulnerability class rather than by language feature, and is generally a better fit for non-certified projects.

Assertions that earn their place

```
/* The distinction that matters: */
assert(...)      /* PROGRAMMER error — an invariant that must hold
                    if this code is correct. May be compiled out.  */
if (...) return -EINVAL;
                 /* EXTERNAL error — bad input, missing hardware,
                    resource exhaustion. Must ALWAYS be handled.   */

/* Assert on: */
assert(index < ARRAY_SIZE(table));     /* internal index          */
assert(state == STATE_READY);          /* state machine invariant */
assert(mutex_is_held(&lock));          /* locking discipline      */
assert(p != NULL);                     /* internal contract       */

/* Never assert on: user input, file contents, network data,
   hardware responses, or malloc results.                       */
```

```
/* In production embedded systems, assert() calling abort() is often
   wrong — you cannot just stop a motor controller. Define your own: */

#ifdef NDEBUG
#  define ASSERT(c) ((void)0)
#else
#  define ASSERT(c) ((c) ? (void)0 : assert_failed(__FILE__, __LINE__))
#endif

void assert_failed(const char *file, int line)
{
        enter_safe_state();            /* outputs off, brakes on   */
        log_persistent(file, line);    /* survive the reset        */
        system_reset();                /* recover, do not hang     */
}

/* The kernel's spectrum, and when to use each: */
BUILD_BUG_ON(cond);      /* compile time — always prefer this      */
WARN_ON(cond);           /* log a stack trace and CONTINUE — the
                            default choice for a recoverable
                            invariant violation                    */
WARN_ON_ONCE(cond);      /* ...but do not spam the log             */
BUG_ON(cond);            /* panic. Reserve for "continuing would
                            corrupt data". Rarely justified.       */
```

Design by contract

```
/**
 * ring_write() — append bytes to the ring buffer
 * @r:    ring buffer, must be non-NULL and initialised
 * @data: source buffer, must be non-NULL if @len > 0
 * @len:  number of bytes, must be <= ring_space(r)
 *
 * Context: caller must hold r->lock.
 * Return: number of bytes written, or a negative errno.
 */
ssize_t ring_write(struct ring *r, const void *data, size_t len)
{
        ASSERT(r != NULL);
        ASSERT(data != NULL || len == 0);
        ASSERT(lockdep_held(&r->lock));
        ...
}

/* Write the precondition, then assert it. The comment documents;
   the assertion enforces. Either alone is half a contract.     */

/* Let the compiler help where it can: */
void f(int *p) __attribute__((nonnull(1)));
int  g(void)   __attribute__((warn_unused_result));

/* warn_unused_result is enormously valuable on anything that can
   fail. Ignored return values are a top-tier bug source.       */
```

Defensive patterns

```
/* Validate at the trust boundary, once, thoroughly. Do not
   re-validate everywhere internally - that hides which layer owns
   the check and produces inconsistent behaviour.              */

int api_entry(const struct request *req)
{
        /* THE boundary: everything after this point may assume
           the request is well-formed.                          */
        if (!req)                       return -EINVAL;
        if (req->len > MAX_LEN)         return -EMSGSIZE;
        if (req->type >= TYPE_COUNT)    return -EINVAL;
        if (req->len > 0 && !req->data) return -EINVAL;

        return handle(req);             /* internal: asserts only */
}

/* Initialise everything at declaration */
struct config cfg = {0};      /* not: struct config cfg; */
int  ret = -EINVAL;
char *buf = NULL;

/* Const everything you do not modify - it is free documentation
   that the compiler checks.                                    */
static int compute(const struct input *in, struct output *out);

/* Fail closed, not open */
switch (mode) {
case MODE_A: return handle_a();
case MODE_B: return handle_b();
default:     return -EINVAL;      /* not: fall through to A */
}

/* Bound every loop that waits on hardware */
int timeout = 10000;
while (!(readl(base + STATUS) & READY))
        if (--timeout < 0)
                return -ETIMEDOUT;

/* Make illegal states unrepresentable where you can */
typedef struct { int v; } celsius_t;    /* not interchangeable with */
typedef struct { int v; } fahrenheit_t; /* an int, or each other    */
```

Testing C

```
# unit test frameworks that work well in C
#   Unity + CMock  — designed for embedded, no dynamic allocation
#   Check, cmocka, greatest, µnit
#   Criterion      — modern, nice output

# run everything under sanitizers in CI
gcc -fsanitize=address,undefined -g -O1 test.c -o test && ./test

# coverage — measure what the tests actually reach
gcc --coverage test.c && ./test && gcov test.c
lcov --capture --directory . --output-file cov.info
genhtml cov.info --output-directory out
# Aim for branch coverage on error paths specifically. Error paths
# are where the untested bugs live, by definition.

# FUZZING is the highest-value testing for any C code that parses
# input. It routinely finds bugs that unit tests never will.
clang -fsanitize=fuzzer,address parser_fuzz.c -o fuzz
./fuzz corpus/ -max_total_time=600
```

```
/* A libFuzzer harness is four lines. There is no excuse not to
   have one for every parser you write.                         */
int LLVMFuzzerTestOneInput(const uint8_t *data, size_t size)
{
        struct msg m;
        parse_message(data, size, &m);    /* must never crash */
        return 0;
}
```

What review is for

Tools find defects; review finds *wrong designs*. Focus review on what no tool can check:

- ✓ Is the ownership of every allocation clear and documented?
- ✓ Is every error path correct, and does it release what it acquired?
- ✓ Are the locking rules stated, and does this code follow them?
- ✓ What happens on the second call? On a concurrent call? On failure halfway through?
- ✓ Is the trust boundary explicit, and is validation on the right side of it?
- ✓ Are the integer types right, and can any arithmetic overflow?
- ✓ Does the API make misuse difficult, or merely document it?
- ✓ Will this be understandable in two years by someone who was not in this conversation?

How it shows up

Symptom	Missing layer
A bug that a warning would have caught ships	Warnings not enabled, or not errors
Codebase has hundreds of warnings	No `-Werror` ratchet; nobody reads them now
Memory bug found in production, not in test	Sanitizers not in CI

Symptom	Missing layer
Parser crashes on malformed input	No fuzzing
Error path leaks or double-frees	Error paths untested; check branch coverage
Ignored return value causes silent corruption	No `warn_unused_result`
Assertion fires in production and halts a machine	`assert` used for external input
MISRA compliance achieved, quality unchanged	Rules applied as ritual, not for their rationale
Same class of bug recurs across the codebase	Fixed instances, not the pattern; add a lint rule

Check yourself

- ✓ Name the defence layers in order of cost and say which three teams most often skip.
- ✓ Give five warning flags not included in `-Wall` and the bug each catches.
- ✓ Explain how to introduce `-Werror` into a legacy codebase.
- ✓ State the rule for when to assert versus when to return an error.
- ✓ Give two MISRA rules that encode real bug classes and one that is contested, with reasons.
- ✓ Explain where input validation belongs and why not everywhere.
- ✓ Write a libFuzzer harness for a parser.
- ✓ List four questions review should answer that no tool can.

C for freestanding and embedded targets

No operating system, no standard library, no `main()` until you arrange one. This chapter closes the C track by assembling everything into a program that runs on bare hardware — and by being explicit about what you give up.

What freestanding means

	Hosted	Freestanding
Entry point	`main(int, char **)`	Implementation-defined: `Reset_Handler`, `_start`, `DriverEntry`
Library	All of it	Only headers with no runtime component
Startup	`crt0` runs before you	You write it
Heap	Present	Only if you provide one
Examples	Linux/Windows application	Linux kernel, U-Boot, UEFI, Cortex-M firmware

```
/* The nine headers guaranteed in a freestanding implementation.
   Note what they have in common: they define TYPES and MACROS
   only — no functions requiring a runtime.                    */
<stddef.h>   <stdint.h>   <limits.h>   <float.h>   <stdbool.h>
<stdarg.h>   <stdalign.h> <stdnoreturn.h>  <iso646.h>
/* C23 adds <stdbit.h> and a few others. */

/* Everything else — string.h, stdlib.h, stdio.h, math.h — you
   either do without or provide yourself.                      */
```

```
# the flags, and what each one actually prevents
aarch64-none-elf-gcc \
    -ffreestanding \        # do not assume a hosted environment
    -nostdlib \             # do not link libc or crt startup files
    -fno-builtin \          # do not substitute builtin versions of
                            #   library functions...
    -fno-stack-protector \  # ...and do not require __stack_chk_fail
    -fno-common \
    -ffunction-sections -fdata-sections \
    -Wl,--gc-sections \
    -T link.ld

# -fno-builtin matters more than it looks: WITHOUT it GCC may turn
# a struct assignment or an array initialisation into a call to
# memcpy() or memset() that you never wrote and did not provide.
# Even WITH it, some calls can still be generated — so provide
# memcpy, memset, memmove and memcmp regardless.
```

Startup code

```
What crt0 does for you on a hosted system, and what you must do here:

   reset
     |
     1. set the stack pointer
     2. copy .data from its flash load address to RAM
     3. zero .bss
     4. (optional) enable FPU, caches, MPU/MMU
     5. call SystemInit / clock configuration
     6. run any constructors (__attribute__((constructor)))
     7. call main()
     8. if main returns — it should not — loop forever
```

```
startup.c — a complete, portable startup for Cortex-M
```

```c
#include <stdint.h>

/* Symbols defined by the linker script (chapter 17). Their ADDRESSES
   are the values you want, so declare them as arrays or take &.  */
extern uint32_t _etext, _data_start, _data_end, _bss_start, _bss_end;
extern uint32_t _stack_top;

extern int main(void);
void Reset_Handler(void);
void Default_Handler(void);

/* Every handler is weakly aliased to Default_Handler, so the
   application overrides only the ones it cares about (chapter 12). */
#define WEAK_ALIAS __attribute__((weak, alias("Default_Handler")))
void NMI_Handler(void)        WEAK_ALIAS;
void HardFault_Handler(void)  WEAK_ALIAS;
void SysTick_Handler(void)    WEAK_ALIAS;
void UART0_IRQHandler(void)   WEAK_ALIAS;

/* The vector table, placed at address 0 by the linker script.
   KEEP(*(.vectors)) in the script prevents --gc-sections from
   discarding it, since nothing references it.                  */
__attribute__((section(".vectors"), used))
void (*const vector_table[])(void) = {
        (void (*)(void))&_stack_top,   /* initial SP  */
        Reset_Handler,                  /* initial PC  */
        NMI_Handler,
        HardFault_Handler,
        0, 0, 0, 0, 0, 0, 0,            /* reserved    */

        0, 0,
        0,                              /* PendSV      */
        SysTick_Handler,
        UART0_IRQHandler,               /* IRQ 0       */
};

void Reset_Handler(void)
{
        /* 2. copy .data from flash to RAM */
        uint32_t *src = &_etext;
        for (uint32_t *dst = &_data_start; dst < &_data_end; )
                *dst++ = *src++;

        /* 3. zero .bss - this is why static objects are zeroed */
        for (uint32_t *p = &_bss_start; p < &_bss_end; )
                *p++ = 0;

        /* 4-5. hardware bring-up */
        SystemInit();

        /* 6. C++ / constructor support, if used */
        extern void (*__init_array_start[])(void);
        extern void (*__init_array_end[])(void);
        for (void (**f)(void) = __init_array_start;
             f < __init_array_end; f++)
                (*f)();

        /* 7. */
        main();

        /* 8. */
        for (;;)
                __asm__ volatile("wfi");
```

```
}

void Default_Handler(void)
{
        for (;;)
                ;               /* set a breakpoint here — an
                                   unexpected interrupt lands here */
}
```

> **THE COPY LOOP IS NOT OPTIONAL, AND ITS ABSENCE IS SUBTLE**
> Skip step 2 and every initialised global holds garbage. Skip step 3 and every zero-initialised global holds garbage. Both produce behaviour that looks like random corruption, works intermittently, and changes when you add an unrelated variable. If a bare-metal program behaves erratically before it does anything interesting, check the startup code first.

Providing the pieces you need

```
/* The compiler can generate calls to these four even if you never
   write them. Provide them, and mark them used so --gc-sections
   does not remove them before the reference appears.           */

void *memcpy(void *dst, const void *src, size_t n)
{
        unsigned char *d = dst;
        const unsigned char *s = src;
        while (n--) *d++ = *s++;
        return dst;
}

void *memset(void *dst, int c, size_t n)
{
        unsigned char *d = dst;
        while (n--) *d++ = (unsigned char)c;
        return dst;
}

void *memmove(void *dst, const void *src, size_t n)
{
        unsigned char *d = dst;
        const unsigned char *s = src;
        if (d < s) { while (n--) *d++ = *s++; }
        else { d += n; s += n; while (n--) *--d = *--s; }
        return dst;
}

int memcmp(const void *a, const void *b, size_t n)
{
        const unsigned char *x = a, *y = b;
        for (; n--; x++, y++) if (*x != *y) return *x - *y;
        return 0;
}

/* Compile these with -fno-tree-loop-distribute-patterns, or GCC may
   recognise the loop inside memcpy and replace it with a call to
   memcpy — infinite recursion, at -O2 only. This is a genuine and
   frequently-hit trap.                                          */
```

```
/* A minimal printf replacement — a few hundred bytes instead of
   tens of kilobytes (chapter 16).                                  */
static void putc_(char c) { while (UART->FR & FR_TXFF) ; UART->DR = c; }

void print_str(const char *s) { while (*s) putc_(*s++); }

void print_hex(uint32_t v)
{
        print_str("0x");
        for (int i = 28; i >= 0; i -= 4)
                putc_("0123456789abcdef"[(v >> i) & 0xF]);
}

void print_dec(uint32_t v)
{
        char buf[11]; int i = 0;
        if (!v) { putc_('0'); return; }
        while (v) { buf[i++] = '0' + v % 10; v /= 10; }
        while (i--) putc_(buf[i]);
}
/* No format parsing, no varargs, no floating point. Covers 95% of
   embedded logging needs at 1% of the code size.                   */
```

Living without a heap

```
/* Static allocation: the linker verifies it fits, at build time. */
static struct session sessions[MAX_SESSIONS];
static uint8_t rx_buf[MAX_FRAME];

/* Fixed-size pool with a bitmap free list */
#define POOL_N 32
static struct msg pool[POOL_N];
static uint32_t  pool_used;

struct msg *msg_alloc(void)
{
        uint32_t free = ~pool_used;
        if (!free) return NULL;
        int i = __builtin_ctz(free);
        if (i >= POOL_N) return NULL;
        pool_used |= 1u << i;
        return &pool[i];
}
void msg_free(struct msg *m)
{
        pool_used &= ~(1u << (m - pool));
}
/* Deterministic time, no fragmentation, bounded memory, and the
   failure mode is a clean NULL rather than gradual degradation. */

/* If you genuinely need a heap, provide _sbrk for newlib: */
extern uint32_t _heap_start, _stack_top;
void *_sbrk(int incr)
{
        static char *brk = (char *)&_heap_start;
        char *prev = brk;
        if (brk + incr > (char *)&_stack_top - STACK_RESERVE)
                return (void *)-1;      /* out of memory */
        brk += incr;
        return prev;
}
```

Register access, assembled

```
/* Everything from chapters 07, 08 and 10 comes together here. */

struct uart_regs {
        volatile uint32_t DR;         /* 0x00 */
        volatile uint32_t RSR;        /* 0x04 */
        uint32_t          _pad0[4];   /* 0x08 - 0x14 */
        volatile uint32_t FR;         /* 0x18 */
        uint32_t          _pad1;
        volatile uint32_t IBRD;       /* 0x20 */
        volatile uint32_t FBRD;       /* 0x24 */
        volatile uint32_t LCRH;       /* 0x28 */
        volatile uint32_t CR;         /* 0x2C */
};

_Static_assert(offsetof(struct uart_regs, CR) == 0x2C, "CR offset");

#define UART0 ((struct uart_regs *)0x40000000u)

#define FR_TXFF     (1u << 5)
#define CR_UARTEN   (1u << 0)
#define CR_TXE      (1u << 8)

void uart_init(uint32_t baud, uint32_t clk)
{
        UART0->CR = 0;                      /* disable while configuring */
        uint32_t div = (clk * 4) / baud;
        UART0->IBRD = div >> 6;
        UART0->FBRD = div & 0x3F;
        UART0->LCRH = (3u << 5);            /* 8 bits            */
        __asm__ volatile("dsb sy" ::: "memory");   /* land before enable */
        UART0->CR = CR_UARTEN | CR_TXE;
}
```

Interrupts in bare metal

```
/* An ISR is an ordinary C function whose ADDRESS is in the vector
   table. On Cortex-M the hardware saves the caller-saved registers,
   so no special attribute is needed.                              */
void UART0_IRQHandler(void)
{
        uint32_t status = UART0->MIS;
        UART0->ICR = status;            /* W1C: clear at the SOURCE */
        if (status & INT_RX)
                ring_put(&rx_ring, UART0->DR);
}

/* Sharing data with mainline code: volatile is necessary but NOT
   sufficient (chapter 10). Either use atomics, or disable
   interrupts around the critical section.                        */
static volatile uint32_t tick;          /* written by ISR only, and
                                           32-bit aligned, so a single
                                           read is atomic on ARM    */

static _Atomic uint32_t events;         /* read-modify-write: needs
                                           a real atomic            */

/* Critical section, the portable way */
static inline uint32_t irq_save(void)
{
        uint32_t f;
        __asm__ volatile("mrs %0, primask\n\tcpsid i" : "=r"(f) :: "memory");
        return f;
}
static inline void irq_restore(uint32_t f)
{
        __asm__ volatile("msr primask, %0" :: "r"(f) : "memory");
}
/* Save-and-restore, never unconditional enable — otherwise nesting
   two critical sections re-enables interrupts too early.       */
```

The constraints to design around

Constraint	Consequence
Stack is 1–8 KB	No recursion, no VLAs, no large locals. Check with `-fstack-usage`.
No MMU	A wild pointer corrupts anything. Use the MPU where present.
Flash is 32–512 KB	`printf` and `math.h` may not fit. Watch `size` output in CI.
No OS	You write the scheduler, or use a superloop plus interrupts
Often no FPU	Software float is 10–100× slower. Use fixed point.
Watchdog	Must be kicked, and must *not* be kicked from a timer interrupt — that defeats it
Power budget	`WFI` in the idle loop, not a busy wait (CA ch. 20)

```
# the numbers to watch on every build
arm-none-eabi-size firmware.elf
#    text   data    bss    dec    hex
#   24512    108   8192  32812   802c
#   ^flash        ^^^^^^^^^^^^ RAM = data + bss (+ stack + heap)

arm-none-eabi-nm --size-sort -S firmware.elf | tail -20   # biggest symbols
arm-none-eabi-gcc -fstack-usage ...   # per-function stack, in .su files
# Fail the build if any of these exceed budget. It is the only way
# they stay within budget.
```

The two program structures

```
/* 1. Superloop plus interrupts — simple, and adequate far more
      often than people expect.                                  */
int main(void)
{
        hw_init();
        for (;;) {
                if (flag_rx)    { flag_rx = 0;   handle_rx(); }
                if (flag_tick)  { flag_tick = 0; handle_tick(); }
                kick_watchdog();
                __asm__ volatile("wfi");     /* sleep until an interrupt */
        }
}
/* ISRs stay short: set a flag, queue data, return. All real work
   happens in the loop, at a known context, with no reentrancy.  */

/* 2. An RTOS, when you need priorities and blocking */
void task_sensor(void *arg)
{
        for (;;) {
                xQueueReceive(q, &sample, portMAX_DELAY);   /* blocks */
                process(&sample);
        }
}
/* Choose an RTOS when you have several independent activities with
   different deadlines. A superloop is genuinely better when you
   do not — fewer failure modes, no stack-per-task overhead.    */
```

How it shows up

Symptom	Cause
Globals contain garbage before `main` does anything	Missing `.data` copy or `.bss` zero in startup
Undefined reference to `memcpy` you never called	Compiler generated it; provide the function
`memcpy` recurses infinitely at `-O2`	GCC recognised your loop; add `-fno-tree-loop-distribute-patterns`
Vector table missing from the image	`--gc-sections` removed it; use `KEEP()`
Hard fault immediately on reset	Stack pointer or reset vector wrong in the table
Random corruption under load	Stack overflow — no MMU to catch it; add a guard pattern
Interrupt fires repeatedly	Not cleared at the source before returning
Data shared with an ISR is stale	Missing `volatile`, or a non-atomic read-modify-write

Symptom	Cause
Image does not fit in flash	`printf` with float support; use a minimal implementation
Works on the debugger, resets in the field	Watchdog not kicked; debug halts often disable it

Check yourself

- ✓ List the freestanding headers and explain what they have in common.
- ✓ Give the eight steps of startup, in order, and what breaks if you skip steps 2 and 3.
- ✓ Explain why `-fno-builtin` is needed and why it is still not sufficient.
- ✓ Explain the `memcpy` self-recursion trap.
- ✓ Write a fixed-size pool allocator and say what it gives you over `malloc`.
- ✓ Explain why the vector table needs `KEEP()` in the linker script.
- ✓ Write a nesting-safe critical section and say why unconditional enable is wrong.
- ✓ Name the build metrics you would gate on, and where they come from.

TRACK COMPLETE

That closes the C track: the abstract machine, types and conversions, pointers and arrays, memory, undefined behaviour, the toolchain, and finally a program that runs on bare hardware with no runtime underneath it.

Next is operating systems — the concepts Linux, Windows and every RTOS share — which both driver tracks assume.

TRACK

C++

C++ where it earns its place in systems work — and an honest account of the parts to leave switched off.

16 chapters

Why C++ for systems, and what to leave out

C++ gives you real safety improvements over C at genuinely zero runtime cost — and also gives you several features that are wrong for embedded work. Knowing which is which is the whole skill, and it matters more here than in any other domain.

What C++ actually buys

```
THE FEATURES THAT COST NOTHING AT RUN TIME AND PREVENT
REAL BUGS:

  RAII                a resource is released when its owner
                      goes out of scope. No leak, on any
                      path, including exceptions and early
                      returns. This is the single biggest
                      win.
  destructors         deterministic, not garbage collected
  const correctness   enforced by the type system
  references          a pointer that cannot be null and
                      cannot be reseated
  strong typing       no implicit void* conversions; enum
                      class does not decay to int
  templates           one implementation, many types, with
                      no runtime dispatch
  constexpr           computation moved to compile time
  std::array, span    an array that knows its own size
  unique_ptr          ownership expressed in the type
  namespaces          no more my_module_do_thing()
  function overloading and default arguments

AND THE COST OF EACH, honestly: zero, provided you use them
as intended. `std::unique_ptr` compiles to exactly the same
code as a raw pointer plus a manual delete - godbolt it and
see (chapter 14).

WHAT IS *NOT* FREE, and needs a decision:
  exceptions          code size, and a hidden control flow
                      path (chapter 12)
  RTTI / dynamic_cast a type-info table per class
  virtual functions   an indirect call and a vtable pointer
                      per object (chapter 11)
  the iostreams       enormous; often 100 KB+ of code
  std::function       a heap allocation and an indirect call
  dynamic allocation  fragmentation and non-determinism
  std::string, vector heap allocation
```

THE HONEST SUMMARY

C++ is a better C for systems work — *if* you choose a subset deliberately and enforce it. Used without that discipline it produces binaries three times the size with unpredictable timing, which is why some embedded organisations ban it outright. That ban is a reasonable response to the undisciplined case and a poor response to the disciplined one.

Choosing a subset

```
# A configuration that most embedded C++ projects converge on:

    -fno-exceptions             ; chapter 12
    -fno-rtti                   ; no dynamic_cast, no typeid
    -fno-threadsafe-statics     ; if single-threaded init
    -fno-use-cxa-atexit         ; no static destructor
                                ; registration
    -ffunction-sections -fdata-sections
    -Wl,--gc-sections
    -Os or -O2
    -std=c++17 or c++20

# AND THE LIBRARY DECISION:
#   freestanding / no std::     bare metal, tightest control
#   ETL (Embedded Template Library)   fixed-capacity
#                               containers with the STL's
#                               interface
#   the STL, minus the allocating parts
#   full STL                    embedded Linux, where a heap
#                               and megabytes exist

# WHAT TO BAN, and why:
#   iostreams          enormous, and drags in locale
#   std::string        heap; use std::string_view, or a
#                      fixed-size buffer
#   std::function      heap + indirect call; use a function
#                      pointer or a template parameter
#   dynamic_cast       needs RTTI
#   exceptions         see chapter 12
#   new/delete in steady state    preallocate at init
#   std::shared_ptr    atomic refcounts; usually the wrong
#                      ownership model for embedded

# WHAT TO ENCOURAGE:
#   std::array, std::span, std::optional, std::variant
#   constexpr everything that can be
#   enum class
#   RAII wrappers for every hardware resource
#   std::unique_ptr with a custom deleter, for handles
#   templates for compile-time configuration

# WRITE IT DOWN. A one-page "C++ subset" document that says
# what is permitted and why is worth more than any amount of
# individual good judgement, because it survives staff
# changes and makes review objective.
```

RAII, immediately

```
/* THE C VERSION, and every error path is a chance to leak: */
        int do_work(void)
        {
                int fd = open("/dev/thing", O_RDWR);
                if (fd < 0) return -1;

                void *buf = malloc(SIZE);
                if (!buf) { close(fd); return -1; }

                if (configure(fd) < 0) {
                        free(buf); close(fd); return -1;
                }
                if (transfer(fd, buf) < 0) {
                        free(buf); close(fd); return -1;
                }

                free(buf);
                close(fd);
                return 0;
        }

/* THE C++ VERSION: */
        class FileDescriptor {
                int fd_;
        public:
                explicit FileDescriptor(const char *path, int flags)
                        : fd_(::open(path, flags)) {}

                ~FileDescriptor() { if (fd_ >= 0) ::close(fd_); }

                /* non-copyable, movable - chapter 03 */
                FileDescriptor(const FileDescriptor&) = delete;
                FileDescriptor& operator=(const FileDescriptor&)
                        = delete;
                FileDescriptor(FileDescriptor&& o) noexcept
                        : fd_(o.fd_) { o.fd_ = -1; }

                bool valid() const { return fd_ >= 0; }
                int  get()   const { return fd_; }
        };

        int do_work()
        {
                FileDescriptor fd("/dev/thing", O_RDWR);
                if (!fd.valid()) return -1;

                std::array<std::byte, SIZE> buf;   /* NO HEAP */

                if (configure(fd.get()) < 0) return -1;
                if (transfer(fd.get(), buf.data()) < 0)
                        return -1;

                return 0;      /* destructor closes fd, on
                                  EVERY path */
        }

/* THE GENERATED CODE IS IDENTICAL to the C version's happy
   path, plus a close in each exit block - which the C version
   also has, written by hand, four times, with one of them
   eventually forgotten.
```

```
   THIS IS THE ARGUMENT FOR C++ IN SYSTEMS WORK, and it is
   the same argument as Linux's devm_ (Linux chapter 26) and
   WDF's object parenting (Windows chapter 13): make cleanup
   structural rather than remembered.                      */
```

Proving the cost

```
/* Do not take "zero-cost" on trust. Check it (chapter 14). */

/* --- unique_ptr versus a raw pointer --- */
        void f() {
                auto p = std::make_unique<int>(42);
                use(*p);
        }
/* -O2 aarch64: */
        mov     w0, #4
        bl      operator new(unsigned long)
        mov     w1, #42
        str     w1, [x0]
        ...
        bl      operator delete(void*, unsigned long)
/* EXACTLY new/delete. No overhead, no size cost.

/* --- std::array versus a C array --- */
        int sum(std::array<int, 4> a) {
                return a[0]+a[1]+a[2]+a[3];
        }
/* compiles to the same instructions as the C version, and
   `a.size()` is a compile-time constant.

/* --- a template versus a macro --- */
        template<typename T> T max(T a, T b)
                { return a > b ? a : b; }
/* -> one `csel`, same as the macro, but type-safe and with no
   double-evaluation bug.

/* --- WHERE IT IS *NOT* FREE --- */
        std::function<int(int)> f = [x](int y) { return x + y; };
/* -> possibly a heap allocation, and an indirect call through
   a type-erased interface. Replace with a template parameter
   or a plain lambda passed by value:                */
        template<typename F> void apply(F f) { ... }
/* -> the lambda is inlined completely; zero cost.

/* THE RULE: any abstraction whose type is known at compile
   time is free. Anything that ERASES the type - virtual,
   std::function, dynamic_cast - costs an indirection and
   blocks inlining.                                        */
```

Static initialisation

```
/* A C++ global with a non-constant initialiser runs code
   before main (compilers chapter 13). On embedded this needs
   thought.                                                  */

        Device g_device{0x40000000};    /* constructor runs
                                           before main - but
                                           the hardware may
                                           not be initialised
                                           yet!             */

/* THE PROBLEMS:
     1. ORDER across translation units is unspecified
     2. it runs before your clock/PLL setup, potentially
     3. .init_array must be walked by your startup code -
        __libc_init_array() does it, and bare-metal startup
        code must call it
     4. destructors register with __cxa_atexit, which needs
        a heap on some implementations

/* THE FIXES, in order of preference: */

/* (a) make it constexpr - initialised at COMPILE time, ends
       up in .rodata or .data, no code runs:               */
        struct Config { uint32_t rate; uint8_t mode; };
        constexpr Config g_config{48000, 2};

/* (b) construct on first use - ordered by dependency: */
        Device& device() {
                static Device instance{0x40000000};
                return instance;
        }
/* (thread-safe since C++11, via a guard variable and an
   atomic - which is what -fno-threadsafe-statics removes if
   you are single-threaded.)

/* (c) explicit two-phase init - the most common embedded
       pattern: */
        Device g_device;                /* trivially
                                           constructed */
        void system_init() {
                g_device.init(0x40000000);   /* YOU choose
                                                when       */
        }

/* (d) placement new into a static buffer, when you need
       control over both timing and location:              */
        alignas(Device) static std::byte storage[sizeof(Device)];
        Device *dev = new (storage) Device{0x40000000};

/* CHECK WHAT YOU HAVE: */
        readelf -x .init_array prog.elf
        nm prog.elf | grep -i 'global.*ctor\|_GLOBAL__sub_I'
/* An empty .init_array means no static constructors, which is
   the goal for a tightly controlled firmware image.      */
```

The standard versions

Version	What it added that matters here
C++11	`auto`, move semantics, lambdas, `constexpr`, `nullptr`, `enum class`, `unique_ptr`, `array`, `<atomic>`, the memory model
C++14	Relaxed `constexpr`, generic lambdas, `make_unique`
C++17	**`string_view`, `optional`, `variant`, structured bindings, `if constexpr`, guaranteed copy elision**
C++20	`concepts`, ranges, `span`, `consteval`, designated initialisers, three-way comparison, modules
C++23	`expected`, `mdspan`, `print`, deducing `this`

```
/* C++17 IS THE PRACTICAL BASELINE for embedded work in 2026:
   universally supported by the toolchains vendors ship, and
   it contains the features that matter most - if constexpr,
   string_view, optional, and guaranteed copy elision.

   C++20's `concepts` and `span` are worth having where the
   toolchain allows; modules are still not practical in most
   embedded toolchains.

   CHECK WHAT YOUR TARGET SUPPORTS before writing the coding
   standard - a vendor GCC 8 in a BSP constrains you to C++17
   partially, and finding that out after writing the code is
   expensive.                                                */
```

How it shows up

Symptom	Cause
Binary three times larger than the C version	Exceptions, RTTI, iostreams — check the flags
100 KB of code from one `std::cout`	iostreams pulls in locale and the whole facet machinery
Unexpected heap allocation	`std::string`, `std::function`, `std::vector` growth
Crash before `main`	A static constructor touching uninitialised hardware
Static object used before construction	Initialisation order — construct on first use
Link error: `__cxa_atexit` undefined	Static destructors on a freestanding target — `-fno-use-cxa-atexit`
Link error: `__gxx_personality_v0`	Exceptions enabled but no unwinder — `-fno-exceptions`
Unpredictable timing in a control loop	Allocation, or an exception path
Template error message is 200 lines	Normal without concepts; C++20 improves it substantially
Team disagrees about which features to use	No written subset — that is the actual problem

Check yourself

- ✓ List ten C++ features that cost nothing at run time and the bug each prevents.
- ✓ List eight that are not free and say what each costs.
- ✓ Write a defensible embedded C++ subset with flags and library rules.
- ✓ Convert a C function with several error paths into an RAII version.
- ✓ Prove that `unique_ptr` and `std::array` are free, on godbolt.

- ✓ Explain why `std::function` is not, and give two replacements.
- ✓ State the rule for which abstractions are free.
- ✓ Give four ways to avoid dynamic static initialisation.
- ✓ Check whether a binary has any static constructors.
- ✓ Choose a standard version for a project and justify it against the available toolchain.

Classes, encapsulation and RAII

A class is a struct with functions, access control and a guaranteed destructor. That last property — deterministic destruction tied to scope — is what makes C++ worth using for systems code, and this chapter is about applying it to hardware.

A class is a struct that cleans up

```
class Timer {
        volatile uint32_t *base_;       /* private by default */
        uint32_t period_;

public:
        explicit Timer(uintptr_t addr, uint32_t period)
                : base_(reinterpret_cast<volatile uint32_t *>(addr)),
                  period_(period)
        {
                base_[REG_PERIOD] = period_;
                base_[REG_CTRL]   = CTRL_ENABLE;
        }

        ~Timer()
        {
                base_[REG_CTRL] = 0;    /* ALWAYS runs on scope
                                           exit                */
        }

        void restart()      { base_[REG_COUNT] = 0; }
        uint32_t value() const { return base_[REG_COUNT]; }

private:
        static constexpr size_t REG_COUNT  = 0;
        static constexpr size_t REG_PERIOD = 1;
        static constexpr size_t REG_CTRL   = 2;
};

/* `class` members are PRIVATE by default; `struct` members
   are PUBLIC. That is the only difference between the two
   keywords. Use `struct` for plain data, `class` when there
   is an invariant to protect.

/* `explicit` PREVENTS IMPLICIT CONVERSION: */
        void f(Timer t);
        f(0x40000000);          /* without explicit, this
                                   COMPILES and silently
                                   constructs a Timer from an
                                   integer                  */
/* Mark every single-argument constructor `explicit` unless
   the implicit conversion is genuinely wanted. This is a
   real bug class, and the fix costs one word.

/* `const` ON A MEMBER FUNCTION means it does not modify the
   object - and is checked. A const Timer& can call value()
   but not restart(). Mark every member function const that
   can be; it costs nothing and it documents intent
   enforceably.                                          */
```

Initialisation

```
/* MEMBER INITIALISER LISTS initialise; assignment in the body
   default-constructs and THEN assigns.                     */

/* WORSE: */
        Buffer(size_t n) {
                size_ = n;              /* size_ was already
                                           default-initialised */
                data_ = new uint8_t[n]; /* ditto */
        }

/* BETTER: */
        Buffer(size_t n)
                : size_(n), data_(new uint8_t[n]) {}

/* AND FOR A MEMBER WITH NO DEFAULT CONSTRUCTOR, or a const or
   reference member, the initialiser list is the ONLY option:
*/
        class Driver {
                Timer timer_;           /* no default ctor */
                const uint32_t id_;
                Bus& bus_;              /* a reference */
        public:
                Driver(uintptr_t addr, uint32_t id, Bus& b)
                        : timer_(addr, 1000), id_(id), bus_(b) {}
        };

/* THE ORDER TRAP: members are initialised in DECLARATION
   order, NOT in the order they appear in the initialiser
   list.                                                    */
        class Bad {
                int b_;
                int a_;
        public:
                Bad() : a_(1), b_(a_) {}   /* b_ initialised
                                              FIRST, from an
                                              uninitialised a_ */
        };
/* -Wreorder warns. Keep the list in declaration order.

/* DEFAULT MEMBER INITIALISERS (C++11) - usually the clearest:
*/
        class Config {
                uint32_t rate_  = 48000;
                uint8_t  gain_  = 0;
                bool     enabled_ = false;
        public:
                Config() = default;     /* uses the above */
                explicit Config(uint32_t rate) : rate_(rate) {}
                                        /* the others still
                                           get their defaults */
        };

        std::vector<int> b{5, 0};       /* 2 elements: 5 and 0 */
/* Brace initialisation prefers an initializer_list
```

```
    constructor when one exists. Elsewhere braces are better -
    they forbid narrowing conversions:                       */
         int x{3.5};             /* ERROR - narrowing */
         int y(3.5);             /* silently 3 */
```

RAII for hardware

```
/* THE PATTERN: acquire in the constructor, release in the
   destructor. Then correctness does not depend on remembering
   anything.                                                  */

/* --- a critical section --- */
class InterruptLock {
        uint32_t saved_;
public:
        InterruptLock() : saved_(disable_interrupts()) {}
        ~InterruptLock() { restore_interrupts(saved_); }

        InterruptLock(const InterruptLock&) = delete;
        InterruptLock& operator=(const InterruptLock&) = delete;
};

        void update_shared(void)
        {
                InterruptLock lock;     /* interrupts off */

                if (error) return;      /* restored HERE */
                shared_state++;
        }                               /* and HERE */

/* Every exit path restores. There is no `goto out` to forget.

        auto guard = make_scope_exit([&] { cleanup(); });
        ...
        guard.release();        /* commit - do NOT clean up */

/* THE `release()` IS THE USEFUL PART: acquire resources,
   register cleanup for each, and release the guards only when
   everything succeeded. That gives transactional semantics
   with no exception handling at all.                    */
```

WHY THIS BEATS EVERY C ALTERNATIVE

The `goto out` ladder (Linux chapter 26) is correct and requires the author to maintain it as the function changes. `devm_` and WDF parenting solve it for one specific framework. RAII solves it for *every* resource, in the language, checked by the compiler, and the generated code is identical. It is the reason to consider C++ even in a codebase that uses nothing else from it.

Modelling a register block

```
/* A struct mapped onto MMIO gives you named, typed register
   access with no runtime cost.                              */

struct UartRegs {
        volatile uint32_t DR;           /* 0x00 data */
        volatile uint32_t RSR;          /* 0x04 */
        volatile uint32_t _pad0[4];
        volatile uint32_t FR;           /* 0x18 flags */
        volatile uint32_t _pad1;
        volatile uint32_t ILPR;         /* 0x20 */
        volatile uint32_t IBRD;         /* 0x24 */
        volatile uint32_t FBRD;         /* 0x28 */
        volatile uint32_t LCRH;         /* 0x2C */
        volatile uint32_t CR;           /* 0x30 */
};
static_assert(offsetof(UartRegs, CR) == 0x30,
              "register layout mismatch");
static_assert(sizeof(UartRegs) == 0x34);

/* THE static_assert IS THE POINT: get the padding wrong and
   the BUILD fails, rather than the device behaving strangely.
   Put one on every register whose offset you care about.

class Uart {
        UartRegs *regs_;
public:
        explicit Uart(uintptr_t base)
                : regs_(reinterpret_cast<UartRegs *>(base)) {}

        void put(char c) {
                while (regs_->FR & FR_TXFF) { }   /* full */
                regs_->DR = static_cast<uint32_t>(c);
        }

        void write(std::string_view s) {
                for (char c : s) put(c);
        }
};

        Uart uart{0x09000000};
        uart.write("hello\n");

/* GENERATES exactly the same loads and stores as the C
   version - `regs_->DR = c` is one `str`, and the class
   wrapper is entirely compiled away (chapter 14).

/* A SAFER ALTERNATIVE for the field manipulation, using
   templates so the shifts and masks are compile-time
   constants (chapter 07):                                */
template<uint32_t Mask, uint32_t Shift>
struct Field {
        static constexpr uint32_t get(uint32_t reg)
                { return (reg & Mask) >> Shift; }
        static constexpr uint32_t set(uint32_t reg, uint32_t v)
                { return (reg & ~Mask) | ((v << Shift) & Mask); }
};
        using Baud = Field<0x0000FF00, 8>;
        regs_->CR = Baud::set(regs_->CR, 115200 / 16);
```

Static members

```
class Counter {
        static inline int instances_ = 0;   /* C++17: define
                                               IN the class */
        int id_;
public:
        Counter() : id_(instances_++) {}
        ~Counter() { instances_--; }

        static int count() { return instances_; }
        /* a static member function - no `this`, callable as
           Counter::count()                                    */
};

/* BEFORE C++17 a static data member needed a definition in
   exactly one translation unit:                               */
        /* header */  class C { static int x; };
        /* one .cpp */ int C::x = 0;
/* `static inline` removes that, and it is one of C++17's
   most practically useful small features.

/* STATIC CONSTEXPR members need no definition at all and cost
   nothing: */
        class Uart {
                static constexpr uint32_t FR_TXFF = 1u << 5;
                static constexpr size_t   FIFO_DEPTH = 16;
        };
/* Scoped, typed, and compiled away entirely - strictly better
   than a #define in every respect.                          */
```

Hiding the implementation

```
/* THE PROBLEM: a class's private members are in its header,
   so changing them recompiles every user - and exposes
   internals.

/* PIMPL - a pointer to the implementation: */

        /* driver.hpp */
        class Driver {
                struct Impl;
                std::unique_ptr<Impl> impl_;
        public:
                Driver();
                ~Driver();              /* MUST be declared
                                           here and DEFINED in
                                           the .cpp, where
                                           Impl is complete  */
                Driver(Driver&&) noexcept;
                Driver& operator=(Driver&&) noexcept;

                void start();
                int  read();
        };

        /* driver.cpp */
        struct Driver::Impl {
                Uart uart;
                std::array<uint8_t, 256> buffer;
                ...
        };
        Driver::Driver() : impl_(std::make_unique<Impl>()) {}
        Driver::~Driver() = default;    /* here, not in the
                                           header             */
        void Driver::start() { impl_->uart.enable(); }

/* THE COST: a heap allocation and an indirection per call. On
   embedded that is usually too much, and the alternatives
   are:
     · an abstract interface with a factory (a vtable, but no
       extra allocation)
     · fixed-size storage: aligned_storage sized by a
       static_assert against sizeof(Impl)
     · simply accepting that private members are visible in
       the header, which for firmware is normally fine

   USE PIMPL for libraries with a stable ABI. Do not use it
   for firmware.                                          */
```

How it shows up

Symptom	Cause
A member has a garbage value in the constructor	Members initialise in *declaration* order — `-Wreorder`
An integer silently became an object	Non-`explicit` single-argument constructor
A resource leaks despite RAII	The object was copied — delete or implement the copy operations (ch. 03)
Destructor runs twice on the same handle	Same cause
Register writes reordered or elided	Missing `volatile` on the register struct

Symptom	Cause
Device behaves as if registers are shifted	Padding wrong — add `static_assert` on offsets
Two elements instead of five in a vector	Braces selected the `initializer_list` constructor
Narrowing conversion accepted silently	Used `()` instead of `{}`
"incomplete type" error on a Pimpl destructor	Destructor defaulted in the header
Link error on a static data member	No definition — use `static inline` (C++17)

Check yourself

- ✓ State the only difference between `class` and `struct`.
- ✓ Explain why every single-argument constructor should be `explicit`.
- ✓ Explain member initialisation order and the bug it causes.
- ✓ Say when an initialiser list is mandatory.
- ✓ Explain the `{}` versus `()` difference, both ways round.
- ✓ Write RAII wrappers for an interrupt lock, a clock gate and a chip select.
- ✓ Write a scope guard with a `release()` and explain what it enables.
- ✓ Map a register block with a struct and prove the layout with `static_assert`.
- ✓ Explain why `static constexpr` members beat `#define`.
- ✓ Explain Pimpl, its cost, and when not to use it.

Construction, destruction and the rule of zero/three/five

Six functions the compiler may generate for you, and the rules about when it does. Getting these wrong is how an RAII class silently double-frees a resource — and the correct answer is usually to write none of them.

The six special members

```
class Widget {
public:
        Widget();                                /* 1. default
                                                    constructor */
        ~Widget();                               /* 2. destructor */
        Widget(const Widget&);                   /* 3. copy ctor */
        Widget& operator=(const Widget&);        /* 4. copy
                                                    assignment  */
        Widget(Widget&&) noexcept;               /* 5. move ctor */
        Widget& operator=(Widget&&) noexcept;    /* 6. move
                                                    assignment  */
};

/* THE COMPILER GENERATES THESE IMPLICITLY, but the rules for
   WHEN are subtle and consequential:

   DEFAULT CONSTRUCTOR
        generated if you declare NO constructor at all.
        Declare any constructor and it disappears.

   DESTRUCTOR
        always generated unless you declare one.

   COPY CONSTRUCTOR and COPY ASSIGNMENT
        generated unless you declare a MOVE operation.
        DEPRECATED if you declare a destructor or the other
        copy operation - it still happens, with a warning.

   MOVE CONSTRUCTOR and MOVE ASSIGNMENT
        generated ONLY IF you declare NONE of: a destructor,
        either copy operation, or the other move operation.

   THE LAST RULE IS THE TRAP. Write a destructor - which every
   RAII class does - and you SILENTLY LOSE the move
   operations. Your class then falls back to COPYING, which
   for a resource-owning class is exactly wrong.         */
```

THE DEFAULT COPY IS A SHALLOW COPY

```
class FileHandle {
        int fd_;
public:
        explicit FileHandle(const char *p) : fd_(open(p, O_RDONLY)) {}
        ~FileHandle() { close(fd_); }
        /* copy operations are IMPLICITLY GENERATED, and copy
           fd_ verbatim */
};

        FileHandle a("/dev/thing");
        FileHandle b = a;       /* both hold the SAME fd */
        /* both destructors run -> close(fd) TWICE.
           The second close may close a DIFFERENT file that
           reused the descriptor number. */
```

This is the single most common C++ resource bug, and it is silent: no warning, correct-looking code, corruption at a distance. The fix is one of the three rules below.

The three rules

```
/* ---- RULE OF ZERO: the one to aim for ------------------ */
/* If your class has no raw resources, declare NONE of the six
   and let the compiler generate all of them correctly.    */

class Sensor {
        std::unique_ptr<Device> dev_;   /* handles its own
                                           lifetime */
        std::array<uint8_t, 64> buf_;   /* trivially copyable */
        std::string name_;              /* handles its own */
public:
        /* NOTHING. Move works, copy is correctly deleted
           (because unique_ptr is non-copyable), destruction
           is correct.                                       */
};

/* THIS IS THE GOAL. Push resource ownership into members
   that already do it right, and the enclosing class needs no
   special members at all.

/* ---- RULE OF FIVE: when you own a raw resource --------- */
class Buffer {
        uint8_t *data_ = nullptr;
        size_t   size_ = 0;

public:
        explicit Buffer(size_t n)
                : data_(new uint8_t[n]), size_(n) {}

        ~Buffer() { delete[] data_; }

        /* copy: DEEP */
        Buffer(const Buffer& o)
                : data_(new uint8_t[o.size_]), size_(o.size_)
        {
                std::copy_n(o.data_, size_, data_);
        }

        Buffer& operator=(const Buffer& o)
        {
                if (this == &o) return *this;   /* SELF-
                                                   ASSIGNMENT */
                uint8_t *p = new uint8_t[o.size_];  /* allocate
                                                       FIRST  */
                std::copy_n(o.data_, o.size_, p);
                delete[] data_;                 /* then release */
                data_ = p;
                size_ = o.size_;
                return *this;
        }

        /* move: STEAL */
        Buffer(Buffer&& o) noexcept
                : data_(o.data_), size_(o.size_)
        {
                o.data_ = nullptr;      /* leave it DESTRUCTIBLE */
                o.size_ = 0;
        }

        Buffer& operator=(Buffer&& o) noexcept
        {
```

```
                if (this == &o) return *this;
                delete[] data_;
                data_ = o.data_;
                size_ = o.size_;
                o.data_ = nullptr;
                o.size_ = 0;
                return *this;
        }
};

/* THE TWO NON-OBVIOUS REQUIREMENTS:
     1. SELF-ASSIGNMENT must work. `x = x` happens through
        references and aliases more often than you expect.
     2. THE MOVED-FROM OBJECT must be left in a valid,
        destructible state. Not "correct" - just safe to
        destroy and safe to assign to.

/* ---- RULE OF THREE: pre-C++11 ------------------------- */
/* Destructor, copy constructor, copy assignment. If you need
   one, you need all three. Still true; the rule of five just
   adds the move pair.                                       */
```

Saying what you mean

```
/* `= default` and `= delete` make intent explicit and
   checkable.                                              */

/* --- MOVE-ONLY, the right shape for most resource types --- */
class FileHandle {
        int fd_ = -1;
public:
        explicit FileHandle(const char *p) : fd_(open(p, O_RDONLY)) {}
        ~FileHandle() { if (fd_ >= 0) close(fd_); }

        FileHandle(const FileHandle&)            = delete;
        FileHandle& operator=(const FileHandle&) = delete;

        FileHandle(FileHandle&& o) noexcept : fd_(o.fd_)
                { o.fd_ = -1; }
        FileHandle& operator=(FileHandle&& o) noexcept
        {
                if (this != &o) {
                        if (fd_ >= 0) close(fd_);
                        fd_ = o.fd_;
                        o.fd_ = -1;
                }
                return *this;
        }

        int get() const { return fd_; }
};
/* Now `FileHandle b = a;` is a COMPILE ERROR, not a
   double-close. That is the whole point.

/* --- NON-COPYABLE, NON-MOVABLE: a scope guard ----------- */
class InterruptLock {
public:
        InterruptLock();
        ~InterruptLock();

        virtual ~Base() = default;
/* A polymorphic base needs a VIRTUAL destructor, or deleting
   through a Base* does not run the derived destructor. And
   declaring it suppresses the moves, so default them
   explicitly if you want them.                            */
```

> **`NOEXCEPT` ON MOVE OPERATIONS IS NOT DECORATION**
>
> `std::vector` reallocating chooses between moving and copying its elements based on whether the move constructor is `noexcept` — because if a move can throw partway through, the vector cannot restore its previous state. A move constructor that is not marked `noexcept` causes `vector` growth to *copy* every element instead. That is a large, silent performance loss, and the fix is one keyword.

Construction and destruction order

```
class Derived : public Base {
        Member1 m1_;
        Member2 m2_;
public:
        Derived() : Base(), m1_(), m2_() { /* body */ }
};

/* CONSTRUCTION ORDER:
     1. base classes, in declaration order
     2. members, in DECLARATION order
     3. the constructor body

   DESTRUCTION IS EXACTLY REVERSED:
     1. the destructor body
     2. members, in reverse declaration order
     3. base classes, in reverse

   WHICH MEANS: a member declared later may safely depend on
   one declared earlier, and not the other way round. Order
   the declarations to match the dependencies.

/* CALLING A VIRTUAL FUNCTION IN A CONSTRUCTOR: */
class Base {
public:
        Base() { init(); }              /* calls BASE::init */
        virtual void init() { }
};
class Derived : public Base {
        int *p_;
public:
        Derived() : p_(new int) { }
        void init() override { *p_ = 1; }   /* NEVER CALLED
                                               from Base's
                                               ctor - and p_
                                               is not yet
                                               initialised
                                               anyway       */
};
/* During Base's constructor the object IS a Base; the vtable
   pointer has not yet been updated. Same in destructors.
   NEVER call a virtual function from a constructor or
   destructor - use two-phase init if you need it.       */

/* DESTRUCTION OF LOCALS is reverse of construction, which is
   exactly what RAII needs: */
        void f() {
                ClockGate  clk(CLK_UART);   /* 1st */
                Uart       uart(0x9000000); /* 2nd */
                ChipSelect cs(pin);         /* 3rd */
                ...
        }   /* cs released, then uart, then the clock -
               correct: the clock must outlive the device
               that needs it.                          */
```

Copy elision

```
/* The compiler may - and since C++17 for some cases MUST -
   construct an object directly in its destination rather than
   constructing and copying.                                  */

        Buffer make() {
                return Buffer(1024);    /* GUARANTEED elision
                                           since C++17: the
                                           object is
                                           constructed
                                           directly in the
                                           caller's storage */
        }
        Buffer b = make();      /* NO copy, NO move, not even
                                   a call to them            */

/* NAMED RETURN VALUE OPTIMISATION - allowed, not guaranteed:
*/
        Buffer make2() {
                Buffer b(1024);
                b.fill(0);
                return b;       /* NRVO usually elides */
        }

/* AND THE PESSIMISATION TO AVOID: */
        return std::move(b);    /* WORSE - the explicit move
                                   DEFEATS NRVO, forcing an
                                   actual move construction */
/* -Wpessimizing-move warns. Just `return b;` - the compiler
   already treats a returned local as an rvalue.

/* THE MECHANISM (compilers chapter 10): the caller passes a
   hidden pointer in x8, and the callee constructs the result
   there. So a "return by value" of a large object is one
   construction, in place - not a construct-then-copy.

   WHICH MEANS: returning by value is the right default, even
   for large types. The out-parameter idiom C requires is
   unnecessary in C++.                                    */
```

Checking your class

```
/* --- ASK THE TYPE SYSTEM --- */
        static_assert(std::is_nothrow_move_constructible_v<Buffer>);
        static_assert(!std::is_copy_constructible_v<FileHandle>);
        static_assert(std::is_trivially_copyable_v<Point>);
        static_assert(std::is_trivially_destructible_v<Config>);

/* `is_trivially_copyable` matters for embedded: a trivially
   copyable type can be memcpy'd, DMA'd and stored in a
   union safely. Assert it on any type you treat that way.

/* --- WARNINGS THAT CATCH THESE BUGS --- */
        -Wdeprecated-copy               /* implicit copy with a
                                           user destructor   */
        -Wdeprecated-copy-dtor
        -Wnon-virtual-dtor              /* polymorphic base
                                           without one       */
        -Wreorder                       /* initialiser order */
        -Wpessimizing-move
        -Wredundant-move
        -Weffc++                        /* GCC: a broad set of
                                           these             */

/* --- AND clang-tidy --- */
        cppcoreguidelines-special-member-functions
        performance-move-const-arg
        modernize-use-equals-default
        modernize-use-equals-delete
/* Run these. The rule-of-five check in particular finds real
   double-free bugs in existing code.                    */
```

How it shows up

Symptom	Cause
Double free, or a file descriptor closed twice	Implicit shallow copy of a resource-owning class
Use-after-free after passing an object by value	Same
`vector` growth is unexpectedly slow	Move constructor not `noexcept` — it copied instead
A move left the source usable and the destination empty	Move operations not implemented; it copied
Crash on self-assignment	No self-assignment check in copy assignment
Member is garbage in the constructor body	Declaration order versus initialiser list order
A virtual override is not called from a constructor	By design — the vtable is not yet the derived one
Derived destructor never runs	Base destructor not `virtual`
Resources released in the wrong order	Declaration order of members or locals
An expected NRVO did not happen	`return std::move(x)` defeated it
"use of deleted function"	Correct — the class is non-copyable and you tried to copy it

Check yourself

- ✓ Name the six special members and when each is implicitly generated.
- ✓ Explain why declaring a destructor suppresses the move operations, and what follows.

- ✓ Demonstrate the shallow-copy double-free and give three ways to prevent it.
- ✓ State the rules of zero, three and five, and say which to aim for.
- ✓ Write a correct rule-of-five class including self-assignment and moved-from state.
- ✓ Explain why move operations should be `noexcept`.
- ✓ State construction and destruction order, including bases and members.
- ✓ Explain why virtual calls in constructors do not dispatch as expected.
- ✓ Explain guaranteed copy elision and why `return std::move(x)` is wrong.
- ✓ Use type traits and warnings to verify a class's copy/move behaviour.

References, value categories and overload resolution

References, the five value categories, and the rules by which C++ picks one function from several candidates. This is the machinery underneath move semantics and templates, and it is where C++'s apparent unpredictability usually comes from.

References

```
        int x = 42;
        int&  r = x;            /* an lvalue reference - an
                                   ALIAS for x               */
        r = 10;                 /* x is now 10 */

/* PROPERTIES:
     · must be initialised - there is no null reference
     · cannot be reseated - `r = y` assigns to x, it does not
       make r refer to y
     · no separate object exists; the compiler implements it
       as a pointer, usually optimised away entirely

/* CONST REFERENCES bind to more things: */
        const int& cr = 42;     /* binds to a TEMPORARY, and
                                   EXTENDS ITS LIFETIME to
                                   that of cr                */
        int& bad = 42;          /* ERROR */

/* RVALUE REFERENCES (C++11) bind ONLY to rvalues: */
        int&& rr = 42;          /* OK */
        int&& bad2 = x;         /* ERROR - x is an lvalue */
        int&& ok = std::move(x); /* OK - move() casts to
                                    rvalue                   */

/* WHEN TO USE WHICH, in a function parameter:

     void f(T v)           by VALUE - for cheap types, or when
                           you need a copy anyway
     void f(const T& v)    by CONST REF - the default for
                           anything non-trivial you only read
     void f(T& v)          by REF - when you modify the
                           caller's object
     void f(T&& v)         by RVALUE REF - when you will STEAL
                           from it (chapter 05)
     void f(const T&& v)   almost never useful

/* THE THRESHOLD: pass by value for types up to about two
   registers (16 bytes on AArch64 - chapter 10's ABI), by
   const reference above that. int, float, pointers, small
   structs, string_view, span: by value. Everything else: by
   const reference.                                          */

/* THE DANGLING REFERENCE, and it is easy to write: */
        const std::string& f() {
                std::string s = "hello";
                return s;               /* DANGLING - s is
                                           destroyed         */
        }
        const int& bad = std::vector<int>{1,2,3}[0];
                                        /* the vector dies at
                                           the end of the
                                           statement         */
/* -Wreturn-local-addr and -Wdangling-gsl catch some of these;
   ASan catches the rest at run time.                       */
```

The five value categories

```
C++11 split C's lvalue/rvalue into a lattice, because move
semantics needed a third case.

                  expression
                 /          \
            glvalue          rvalue
           /       \        /     \
      lvalue        xvalue         prvalue

THE TWO PROPERTIES that define them:

  has IDENTITY?   can you take its address, does it name a
                  specific object?
  is MOVABLE?     may its resources be stolen?

  lvalue    identity, NOT movable      a named variable
  xvalue    identity, MOVABLE          std::move(x), a
                                       function returning T&&
  prvalue   NO identity, movable       42, f() returning T,
                                       a temporary

  glvalue = lvalue + xvalue     "has identity"
  rvalue  = xvalue + prvalue    "movable"

EXAMPLES:
     int x = 1;
     x                       lvalue
     42                      prvalue
     x + 1                   prvalue
     std::move(x)            xvalue
     f()   returning int     prvalue
     f()   returning int&    lvalue
     f()   returning int&&   xvalue
     arr[0]                  lvalue
     "hello"                 lvalue  (a string literal is
                                      an array object)

THE PRACTICAL RULE, which covers almost every case:
  IF IT HAS A NAME, IT IS AN LVALUE.
Even a parameter declared `T&& x` is an lvalue INSIDE the
function, because it has a name. That is precisely why
std::move is needed to pass it on (chapter 05).
```

Overload resolution

```
/* Given several candidates, C++ picks one by a defined
   procedure. Knowing it removes most surprise.            */

   1. NAME LOOKUP: gather candidates. Ordinary scope lookup,
      plus ARGUMENT-DEPENDENT LOOKUP (below).

   2. Discard candidates that cannot be called with these
      arguments (wrong arity, or no conversion exists).

   3. RANK the conversions for each argument:

        EXACT MATCH               identity, lvalue-to-rvalue,
                                  array-to-pointer,
                                  qualification (T* -> const T*)
        PROMOTION                 char -> int, float -> double
        STANDARD CONVERSION       int -> double, D* -> B*,
                                  anything -> bool
        USER-DEFINED CONVERSION   a converting constructor or
                                  a conversion operator
                                  (AT MOST ONE per argument)
        ELLIPSIS                  ...

   4. The BEST candidate is the one that is no worse for every
      argument and better for at least one. If none is, the
      call is AMBIGUOUS - an error.

   5. Templates lose to equally-good non-templates.

/* WORKED: */
        void f(int);            /* 1 */
        void f(double);         /* 2 */
        void f(const char*);    /* 3 */

        f(42);                  /* 1: exact */
        f(42.0);                /* 2: exact */
        f('a');                 /* 1: PROMOTION beats
                                   conversion             */
        f(42.0f);               /* 2: promotion */
        f("s");                 /* 3: array-to-pointer is
                                   exact                  */
        f(nullptr);             /* 3 */
        f(0);                   /* 1 - and this is why
                                   nullptr exists         */

/* AMBIGUITY: */
        void g(long);
        void g(float);
        g(42);                  /* ERROR: int -> long and
                                   int -> float are both
                                   standard conversions,
                                   neither better          */

/* THE LVALUE/RVALUE OVERLOAD, which is what move semantics
   is built on: */
        void h(const T&);       /* binds lvalues AND rvalues */
        void h(T&&);            /* binds ONLY rvalues, and
                                   PREFERRED for them       */

        T a;
        h(a);                   /* const T& */
```

```
        h(T{});                 /* T&& - better match */
        h(std::move(a));        /* T&& */
```

Argument-dependent lookup

```
/* For an unqualified call, C++ ALSO searches the namespaces
   of the argument types. Without this, operator overloading
   would not work across namespaces.                        */

        namespace lib {
                struct Widget {};
                void process(const Widget&);
                std::ostream& operator<<(std::ostream&,
                                         const Widget&);
        }

        lib::Widget w;
        process(w);             /* FOUND via ADL, without
                                   `lib::`                  */
        std::cout << w;         /* likewise - and this is why
                                   operator<< can be defined
                                   in the type's own
                                   namespace                */

/* THE IMPORTANT IDIOM it enables - customisation points: */
        template<typename T>
        void algorithm(T& a, T& b)
        {
                using std::swap;        /* the fallback */
                swap(a, b);             /* UNQUALIFIED: ADL
                                           finds a
                                           type-specific swap
                                           if one exists,
                                           otherwise
                                           std::swap        */
        }
/* Writing `std::swap(a, b)` instead would ALWAYS use the
   generic one, missing an optimised overload. The
   `using` + unqualified call pattern is the standard
   solution, and you will see it throughout the STL.

/* THE HAZARD: ADL can find candidates you did not intend,
   particularly with templates and with types from large
   namespaces. If an overload is chosen that surprises you,
   ADL is usually why - and the fix is to qualify the call.  */
```

THE TOOLS FOR "WHICH OVERLOAD WAS CHOSEN?"

```
clang++ -Xclang -ast-dump -fsyntax-only file.cpp
```

The AST names the exact function selected and every implicit conversion applied (compilers chapter 04). On an ambiguity error, Clang lists every candidate with the reason it was rejected — read that list rather than guessing. These two habits resolve almost every overload question in under a minute.

const and its propagation

```
        const int  ci = 1;
        int const  ci2 = 1;             /* the SAME thing */

        const int *p1;          /* pointer to const int -
                                   *p1 is const            */
        int const *p2;          /* identical to p1 */
        int * const p3 = &x;    /* CONST POINTER to int -
                                   p3 cannot be reseated   */
        const int * const p4 = &ci;     /* both */

/* READ RIGHT TO LEFT: `int * const` is "const pointer to
   int". Consistently declaring `int const *` rather than
   `const int *` makes the rule uniform - some codebases
   require it for that reason.

/* CONST MEMBER FUNCTIONS: */
        class Buffer {
                uint8_t *data_;
        public:
                uint8_t& at(size_t i)       { return data_[i]; }
                const uint8_t& at(size_t i) const
                                             { return data_[i]; }
        };
/* Two overloads differing only in constness - a const object
   gets the const one. Standard, and slightly tedious;
   C++23's "deducing this" collapses it into one.

/* CONSTNESS IS SHALLOW: a const member function may modify
   what a member pointer POINTS TO: */
        void Buffer::clear() const {
                data_[0] = 0;           /* LEGAL - data_ is
                                           const, *data_ is
                                           not               */
        }
/* Which is exactly the same rule as C, and a real source of
   false confidence. `std::experimental::propagate_const`
   exists for this, and is not widely used.

/* `mutable` - modifiable even in a const function: */
        class Cache {
                mutable bool valid_ = false;
                mutable int  cached_;
        public:
                int get() const {
                        if (!valid_) { cached_ = compute();
                                       valid_ = true; }
                        return cached_;
                }
        };
/* LEGITIMATE for caches, mutexes and lazily computed values -
   things that do not change the object's OBSERVABLE state.
   Anything else is a lie to the reader.                   */

/* AND THE EMBEDDED POINT: `const` on a namespace-scope object
   with a constant initialiser puts it in .rodata, which on a
   microcontroller means FLASH rather than RAM. On a part with
   32 KB of RAM that is not a stylistic matter.           */
```

Implicit conversions

```
/* C++ will convert types for you, and that is the source of
   several surprises. */

/* --- CONVERTING CONSTRUCTORS - block them --- */
        class Timeout {
                uint32_t ms_;
        public:
                Timeout(uint32_t ms) : ms_(ms) {}   /* implicit! */
        };
        void wait(Timeout t);
        wait(1000);             /* compiles - is 1000 ms, or
                                   seconds, or ticks?       */

        explicit Timeout(uint32_t ms);
        wait(1000);             /* now an ERROR */
        wait(Timeout{1000});    /* explicit at the call site */

/* --- CONVERSION OPERATORS - block those too --- */
        class Handle {
        public:
                operator int() const;   /* implicit - allows
                                           `handle + 1`, and
                                           every other
                                           nonsense           */
                explicit operator bool() const;  /* the useful
                                                    one       */
        };
        if (h) { }              /* explicit operator bool is
                                   still used HERE - a
                                   "contextual conversion" */

/* --- THE UNIFORM RULE that avoids all of it ---
     mark EVERY single-argument constructor and EVERY
     conversion operator `explicit`, except `operator bool`.
   Then conversions happen only where you wrote them.

/* --- ARITHMETIC CONVERSIONS still apply, exactly as in C
       (compilers chapter 04), including the signed/unsigned
       trap. Enable -Wconversion -Wsign-conversion.

/* --- AND enum class, which does NOT convert --- */
        enum        Old { A, B };       /* converts to int */
        enum class  New { A, B };       /* does NOT */

        int x = A;                      /* fine, and usually
                                           unwanted           */
        int y = New::A;                 /* ERROR */
        int z = static_cast<int>(New::A);   /* explicit */

        enum class Mode : uint8_t { Idle, Run, Fault };
/* An explicit underlying type is worth setting on embedded -
   it fixes the size and lets you use it in a packed
   structure.                                              */
```

How it shows up

Symptom	Cause
Garbage from a returned reference	Dangling — the referent was a local or a temporary
A move did not happen	The argument had a name, so it was an lvalue — needs `std::move`
"call of overloaded f(...) is ambiguous"	Two equally-good conversions — read Clang's candidate list
The wrong overload chosen	Promotion beat conversion, or ADL found something unexpected
An integer silently became an object	Non-`explicit` converting constructor
An object silently became an integer	Non-`explicit` conversion operator
A type-specific `swap` is never used	Called `std::swap` qualified instead of the ADL idiom
A const method modified the object	Constness is shallow — it went through a pointer member
A const array is in RAM, not flash	Non-constant initialiser, or it is not actually `const`
Comparison between enum and int compiles	Plain `enum` — use `enum class`
`f(0)` selects the pointer overload, or does not	Use `nullptr`, never `0` or `NULL`

Check yourself

- ✓ State the properties of lvalue, const-lvalue and rvalue references.
- ✓ Give the parameter-passing rule and its size threshold on AArch64.
- ✓ Name the five value categories and the two properties that define them.
- ✓ Classify eight expressions by value category.
- ✓ State the practical rule about names, and why it matters for moves.
- ✓ Walk the overload resolution procedure and rank the conversion categories.
- ✓ Explain why `f('a')` chooses the `int` overload.
- ✓ Explain ADL and write the `using std::swap` idiom correctly.
- ✓ Explain shallow constness and when `mutable` is legitimate.
- ✓ Say why every converting constructor should be `explicit`, with the one exception.

Move semantics and perfect forwarding

Transferring ownership instead of duplicating it. Move semantics is what makes `unique_ptr`, `vector` and every other resource-owning type efficient — and perfect forwarding is how a generic wrapper passes arguments on without losing information about them.

The problem it solves

```
/* Before C++11, returning a container copied it: */
        std::vector<int> make() {
                std::vector<int> v(1'000'000);
                fill(v);
                return v;               /* a COPY of a million
                                           ints, then the
                                           original is
                                           destroyed          */
        }

/* The copy is pure waste: the source is about to be
   destroyed. What we want is to STEAL its buffer.

/* WITH MOVE SEMANTICS: */
        vector(vector&& other) noexcept
                : data_(other.data_), size_(other.size_),
                  cap_(other.cap_)
        {
                other.data_ = nullptr;  /* the source no longer
                other.size_ = 0;           owns it - and is
                other.cap_  = 0;           still destructible */
        }

/* THREE POINTER ASSIGNMENTS instead of a million-element
   copy. That is the whole idea.

/* A MOVE IS NOT A SPECIAL OPERATION - it is just an OVERLOAD
   that takes an rvalue reference, and by convention steals
   rather than copies. The language provides the overload
   resolution; the stealing is yours to implement
   (chapter 03).                                          */
```

std::move

```
/* std::move does NOT move anything. It is a CAST to an rvalue
   reference, which changes which overload is selected.    */

        template<typename T>
        constexpr std::remove_reference_t<T>&&
        move(T&& t) noexcept
        {
                return static_cast<std::remove_reference_t<T>&&>(t);
        }

/* That is the entire implementation. It compiles to nothing.

/* USING IT: */
        std::vector<int> a = make();
        std::vector<int> b = a;                 /* COPY */
        std::vector<int> c = std::move(a);      /* MOVE - a is
                                                   now empty */

/* WHY IT IS NEEDED even inside a function taking T&&: */
        void sink(std::vector<int>&& v) {
                store(v);                       /* COPIES! v
                                                   HAS A NAME,
                                                   so it is an
                                                   LVALUE
                                                   (ch. 04)  */
                store(std::move(v));            /* moves */
        }
/* This is the single most common misunderstanding. An rvalue
   reference PARAMETER is an lvalue inside the function.

/* THE MOVED-FROM STATE: "valid but unspecified". You may
   destroy it and assign to it; you may not assume its value.
   For the standard containers it is in fact empty, but do not
   rely on that.                                            */
        std::string s = "hello";
        std::string t = std::move(s);
        /* s.size() is unspecified - do not read it */
        s = "new value";        /* fine - assignment is
                                   allowed */

/* WHEN NOT TO USE IT: */
        return std::move(local);        /* WRONG - defeats
                                           NRVO (chapter 03) */
        void f(const T& x) { g(std::move(x)); }
                                        /* USELESS - a const
                                           rvalue still binds
                                           to const T&, so it
                                           COPIES            */
        std::move(trivially_copyable)   /* pointless - no
                                           resources to steal */
```

Forwarding references

```
/* `T&&` in a DEDUCED context is not an rvalue reference. It
   is a FORWARDING (or "universal") reference, and it binds to
   anything.                                                  */

        template<typename T>
        void f(T&& x);          /* FORWARDING reference */

        void g(Widget&& x);     /* rvalue reference - T is not
                                   deduced                   */

        template<typename T>
        void h(std::vector<T>&& v);   /* rvalue reference -
                                         the type is not
                                         exactly T          */

/* THE RULE: `T&&` is a forwarding reference ONLY when T is a
   template parameter of that function being deduced. Also
   `auto&&`.

/* HOW IT BINDS - REFERENCE COLLAPSING: */
        T&  &   -> T&
        T&  &&  -> T&
        T&& &   -> T&
        T&& &&  -> T&&
/* "an lvalue reference wins".

        Widget w;
        f(w);                   /* T = Widget&, so
                                   T&& = Widget& && = Widget& */
        f(Widget{});            /* T = Widget, so
                                   T&& = Widget&&           */

/* SO T ENCODES WHETHER THE ARGUMENT WAS AN LVALUE OR AN
   RVALUE - and std::forward decodes it again.            */
```

Perfect forwarding

```
/* THE PROBLEM: a wrapper must pass its arguments on with
   their value category intact.                          */

/* NAIVE - always copies: */
        template<typename T>
        void wrapper(T x) { target(x); }

/* BETTER, still wrong - x has a name, so it is an lvalue: */
        template<typename T>
        void wrapper(T&& x) { target(x); }   /* always copies */

/* CORRECT: */
        template<typename T>
        void wrapper(T&& x) { target(std::forward<T>(x)); }

/* std::forward<T> casts to T&&, which after reference
   collapsing is:
        T = Widget&  -> Widget&   (stays an lvalue)
        T = Widget   -> Widget&&  (becomes an rvalue)
   Exactly preserving what was passed.

/* THE VARIADIC FORM, which is what every factory looks like:
*/
        template<typename T, typename... Args>
        std::unique_ptr<T> make_unique(Args&&... args)
        {
                return std::unique_ptr<T>(
                        new T(std::forward<Args>(args)...));
        }

        auto p = make_unique<Widget>(x, std::move(y), 42);
        /* x is copied into the constructor, y is moved, 42 is
           passed as an rvalue - each correctly               */

/* THE RULE, memorised as a pair:
     std::move     on an rvalue reference - you are done with
                   it
     std::forward  on a forwarding reference - pass on what
                   you were given
   Using move where forward belongs steals from the caller's
   lvalue, which is a real and nasty bug.                 */

/* AND THE PLACE IT MATTERS MOST - emplace: */
        std::vector<Widget> v;
        v.push_back(Widget{1, 2});      /* construct, then MOVE
                                           into the vector    */
        v.emplace_back(1, 2);           /* construct IN PLACE -
                                           no move at all     */
/* emplace_back forwards its arguments to the element's
   constructor. For a type where move is cheap the difference
   is small; for one where it is not, it is the whole cost. */
```

THE FORWARDING REFERENCE TRAP

```
template<typename T>
void f(T&& x);          // matches EVERYTHING
void f(int);            // rarely selected

f(42);                  // T&& wins: an exact match with
                        // T = int, versus a non-template
                        // that also needs no conversion –
                        // and the template's specialisation
                        // is exact for every argument type
```

A forwarding-reference overload is greedier than almost anything else, and it will silently hijack calls you intended for other overloads — including copy constructors, producing baffling errors. Constrain it with a concept (C++20) or `enable_if`, or avoid overloading on it at all.

Implementing move correctly

```
class Buffer {
        uint8_t *data_ = nullptr;
        size_t   size_ = 0;

public:
        Buffer(Buffer&& o) noexcept
                : data_(std::exchange(o.data_, nullptr)),
                  size_(std::exchange(o.size_, 0))
        {}
        /* std::exchange(obj, newval) sets obj and returns the
           OLD value - exactly the move idiom, in one call. */

        Buffer& operator=(Buffer&& o) noexcept
        {
                if (this != &o) {
                        delete[] data_;         /* release ours */
                        data_ = std::exchange(o.data_, nullptr);
                        size_ = std::exchange(o.size_, 0);
                }
                return *this;
        }
};

/* --- OR THE COPY-AND-SWAP IDIOM, which gives you both
       assignment operators from one function and is
       automatically self-assignment safe: --- */

        Buffer& operator=(Buffer o) noexcept   /* BY VALUE */
        {
                swap(*this, o);
                return *this;
        }                       /* o's destructor releases what
                                   we used to own            */

        friend void swap(Buffer& a, Buffer& b) noexcept
        {
                using std::swap;
                swap(a.data_, b.data_);
                swap(a.size_, b.size_);
        }

/* The by-value parameter is copy-constructed from an lvalue
   argument and move-constructed from an rvalue, so ONE
   operator handles both. Elegant, and slightly less efficient
   than separate operators for the copy case - which is why
   the standard library writes both.

/* --- THE noexcept REQUIREMENT, restated because it matters
       (chapter 03): --- */
        static_assert(std::is_nothrow_move_constructible_v<Buffer>);
/* Put that assertion in your test file. A move constructor
   that silently is not noexcept makes vector reallocation
   copy instead of move.

/* --- AND THE `= default` CASE --- */
        class Widget {
                std::unique_ptr<Impl> p_;
                std::string name_;
        public:
                Widget(Widget&&) noexcept = default;
```

```
                Widget& operator=(Widget&&) noexcept = default;
        };
/* Member-wise move, generated correctly. Prefer this to
   writing it by hand whenever every member is itself
   movable - which is the rule of zero again (chapter 03). */
```

Does it matter on embedded?

```
/* HONESTLY: less than in application code, because the types
   that benefit most - vector, string, shared_ptr - are often
   banned anyway (chapter 01). But it still matters in three
   places:

/* 1. MOVE-ONLY RESOURCE TYPES. This is the big one, and it
      is independent of the heap:                          */
        class DmaChannel {
                int ch_ = -1;
        public:
                explicit DmaChannel(int ch) : ch_(ch)
                        { dma_claim(ch_); }
                ~DmaChannel() { if (ch_ >= 0) dma_release(ch_); }

                DmaChannel(const DmaChannel&) = delete;
                DmaChannel(DmaChannel&& o) noexcept
                        : ch_(std::exchange(o.ch_, -1)) {}
                ...
        };

        DmaChannel acquire_channel();   /* RETURN BY VALUE,
                                           moved out, no
                                           allocation
                                           anywhere         */
        std::optional<DmaChannel> try_acquire();

/* THE OWNERSHIP IS IN THE TYPE. A DmaChannel cannot be
   accidentally copied, cannot be leaked, and can be returned
   from a factory - none of which is expressible in C without
   convention.

/* 2. FIXED-CAPACITY CONTAINERS still benefit: */
        etl::vector<Message, 16> queue;
        queue.push_back(std::move(msg));    /* moves the
                                               element's
                                               members       */

/* 3. std::optional and std::variant use moves internally, and
      both are extremely useful on embedded (chapter 15).

/* WHERE IT DOES NOT MATTER: a trivially copyable struct -
   a Point, a register value, a POD message - has no
   resources, so a move IS a copy. std::move on one is
   harmless and pointless.                                 */
```

Verifying it happens

```
/* Instrument a type and watch: */
struct Tracer {
        Tracer()                    { puts("ctor"); }
        Tracer(const Tracer&)       { puts("COPY"); }
        Tracer(Tracer&&) noexcept   { puts("move"); }
        Tracer& operator=(const Tracer&)
                { puts("COPY="); return *this; }
        Tracer& operator=(Tracer&&) noexcept
                { puts("move="); return *this; }
        ~Tracer()                   { puts("dtor"); }
};

        std::vector<Tracer> v;
        v.reserve(4);
        Tracer t;
        v.push_back(t);                 /* COPY */
        v.push_back(std::move(t));      /* move */
        v.emplace_back();               /* ctor - no copy or
                                           move at all      */

/* Drop the reserve() and watch reallocation move (or copy!)
   every element. Remove `noexcept` from the move constructor
   and watch it switch to COPY - that experiment makes the
   rule stick better than any explanation.

/* AND IN REAL CODE: */
        -Wpessimizing-move
        -Wredundant-move
        clang-tidy: performance-move-const-arg,
                    performance-unnecessary-value-param,
                    modernize-pass-by-value
        static_assert(std::is_nothrow_move_constructible_v<T>);
```

How it shows up

Symptom	Cause
A copy happens where you expected a move	The argument had a name — needs `std::move`
Same, in a template wrapper	Needs `std::forward`, not plain passing
Caller's object was emptied unexpectedly	Used `std::move` where `std::forward` belonged
`vector` growth copies elements	Move constructor not `noexcept`
Reading a moved-from object gives odd values	Its state is valid but unspecified — do not read it
Return value copied despite `std::move`	`std::move` on return defeats NRVO
`std::move` on a const object does nothing	A const rvalue binds to `const T&` — it copies
A template overload hijacks every call	Forwarding reference is too greedy — constrain it
Bizarre error mentioning the copy constructor	A forwarding-reference constructor competing with it
Move leaves the source unusable, then it is used	The moved-from object must remain valid — check your implementation

Check yourself

✓ Explain what problem move semantics solves and why a move is just an overload.

- ✓ Say what `std::move` actually does, and give three places not to use it.
- ✓ Explain why a `T&&` parameter is an lvalue inside the function.
- ✓ State when `T&&` is a forwarding reference and give the collapsing rules.
- ✓ Explain `std::forward` and the move-versus-forward rule.
- ✓ Write a correct move constructor and assignment using `std::exchange`.
- ✓ Write copy-and-swap and say what it costs.
- ✓ Explain why `noexcept` on moves changes `vector`'s behaviour.
- ✓ Give three places move semantics matters on embedded despite no heap.
- ✓ Use a tracer type to observe copies and moves, and to demonstrate the `noexcept` effect.

Templates and generic programming

Write one implementation, get a specialised copy for each type — with no runtime dispatch and no cost. Templates are how C++ achieves zero-overhead abstraction, and on embedded they are the mechanism for compile-time configuration.

Function and class templates

```
template<typename T>
constexpr const T& max(const T& a, const T& b)
{
        return a > b ? a : b;
}

        max(1, 2);              /* T = int, deduced */
        max(1.0, 2.0);          /* T = double */
        max<long>(1, 2);        /* T explicit */
        max(1, 2.0);            /* ERROR - T cannot be both */

/* EACH INSTANTIATION IS A SEPARATE FUNCTION, generated at
   compile time, and inlined like any other. `max(1,2)`
   compiles to a single `csel` - identical to the macro,
   with type checking and no double-evaluation bug.       */

template<typename T, size_t N>
class RingBuffer {
        std::array<T, N> data_{};
        size_t head_ = 0, tail_ = 0;

public:
        static constexpr size_t capacity = N;

        bool push(const T& v)
        {
                size_t next = (head_ + 1) % N;
                if (next == tail_) return false;    /* full */
                data_[head_] = v;
                head_ = next;
                return true;
        }

        bool pop(T& out)
        {
                if (head_ == tail_) return false;   /* empty */
                out = data_[tail_];
                tail_ = (tail_ + 1) % N;
                return true;
        }

        size_t size() const { return (head_ - tail_ + N) % N; }
};

        RingBuffer<uint8_t, 64>   rx;
        RingBuffer<Message, 16>   queue;

/* N IS A COMPILE-TIME CONSTANT, so:
     · the storage is a fixed array - NO HEAP
     · `% N` with N a power of two becomes an AND
     · the size is known, so bounds are checkable at compile
       time
   This is the embedded container pattern: capacity as a
   template parameter, storage inline.                    */

/* NON-TYPE TEMPLATE PARAMETERS can be integers, enums,
   pointers, and since C++20 floating point and literal class
   types:                                                  */
        template<uint32_t BaseAddr>
        class Uart {
```

```
                static constexpr auto *regs =
                        reinterpret_cast<volatile UartRegs *>(
                                BaseAddr);
        public:
                static void put(char c) { regs->DR = c; }
        };
        using Uart0 = Uart<0x09000000>;
/* The address is a constant folded into every access — no
   pointer is stored, and no register is used to hold it. */
```

Specialisation

```
/* Provide a different implementation for particular types. */

/* --- FULL SPECIALISATION --- */
template<typename T>
struct Serializer {
        static size_t write(uint8_t *buf, const T& v)
        {
                memcpy(buf, &v, sizeof(T));
                return sizeof(T);
        }
};

template<>
struct Serializer<std::string_view> {
        static size_t write(uint8_t *buf, std::string_view v)
        {
                buf[0] = static_cast<uint8_t>(v.size());
                memcpy(buf + 1, v.data(), v.size());
                return v.size() + 1;
        }
};

/* --- PARTIAL SPECIALISATION - CLASSES ONLY --- */
template<typename T>
struct Serializer<T*> {          /* any pointer */
        static size_t write(uint8_t *buf, T *p)
        {
                return Serializer<T>::write(buf, *p);
        }
};

/* FUNCTIONS CANNOT BE PARTIALLY SPECIALISED. Use overloading,
   or a class template with a static function - which is why
   the standard library's type traits are all classes.    */

/* --- TAG DISPATCH, the pre-concepts way to select an
       implementation --- */
        template<typename It>
        void advance_impl(It& it, int n,
                          std::random_access_iterator_tag)
                { it += n; }

        template<typename It>
        void advance_impl(It& it, int n,
                          std::forward_iterator_tag)
                { while (n--) ++it; }

        template<typename It>
        void advance(It& it, int n)
        {
                advance_impl(it, n,
                    typename std::iterator_traits<It>::
                        iterator_category{});
        }
/* Still worth recognising - the STL is full of it - but
   `if constexpr` and concepts have largely replaced it
   (below).                                               */
```

if constexpr

```
/* C++17's most useful template feature: a branch that is
   DISCARDED at compile time, so the untaken side need not
   even be valid for that type.                              */

template<typename T>
size_t serialise(uint8_t *buf, const T& v)
{
        if constexpr (std::is_trivially_copyable_v<T>) {
                memcpy(buf, &v, sizeof(T));
                return sizeof(T);
        } else if constexpr (has_serialise_method_v<T>) {
                return v.serialise(buf);
        } else {
                static_assert(always_false_v<T>,
                              "type is not serialisable");
        }
}

/* WITH A PLAIN `if`, every branch must COMPILE for every T,
   even the ones that never run. With `if constexpr` only the
   taken branch is instantiated - which is what makes it
   usable for dispatching on type properties.

/* AND IN EMBEDDED CONFIGURATION CODE: */
template<bool UseDma>
class Transfer {
public:
        void run(const uint8_t *data, size_t n)
        {
                if constexpr (UseDma) {
                        dma_setup(data, n);
                        dma_start();
                } else {
                        for (size_t i = 0; i < n; i++)
                                poll_write(data[i]);
                }
        }
};
/* Transfer<false> contains NO dma code at all - it is not
   compiled, so it does not exist in the binary. That is how
   you build a configurable driver with no runtime cost and
   no #ifdef.                                                */
```

`IF CONSTEXPR` REPLACES MOST `#IFDEF`

An `#ifdef` hides code from the compiler entirely, so the disabled path is never type-checked and rots silently. `if constexpr` on a `constexpr bool` is fully parsed and type-checked in every configuration, discarded only at instantiation. Same generated code, far better maintenance — and it is one of the strongest arguments for C++ over C in configurable firmware.

Concepts

```
/* C++20. Constrain a template, and get an error message that
   names the problem rather than a hundred lines of
   instantiation backtrace.                                  */

template<typename T>
concept Serialisable = requires(const T& t, uint8_t *buf) {
        { t.serialise(buf) } -> std::convertible_to<size_t>;
        { T::size } -> std::convertible_to<size_t>;
};

template<Serialisable T>
void send(const T& msg) { ... }

        send(42);
/* ERROR: constraints not satisfied
     because '42' (of type int) does not satisfy
     'Serialisable': the required expression
     't.serialise(buf)' is invalid

   Compare the pre-concepts version, which reported a failure
   deep inside send()'s body across eight levels of
   instantiation.

/* THE STANDARD CONCEPTS worth knowing: */
        std::integral, std::floating_point
        std::same_as, std::convertible_to, std::derived_from
        std::copyable, std::movable, std::default_initializable
        std::invocable, std::predicate
        std::ranges::range, std::ranges::sized_range

/* THREE WAYS TO WRITE A CONSTRAINT, all equivalent: */
        template<std::integral T> void f(T);
        template<typename T> requires std::integral<T> void f(T);
        void f(std::integral auto x);           /* terse */

/* AND CONCEPTS PARTICIPATE IN OVERLOAD RESOLUTION, with the
   MORE CONSTRAINED overload preferred: */
        template<std::integral T>       void g(T);   /* 1 */
        template<typename T>            void g(T);   /* 2 */
        g(42);                  /* 1 - more constrained */
/* Which replaces the enable_if SFINAE machinery entirely, and
   is the main reason to move to C++20 where the toolchain
   allows.                                                   */

/* THE PRE-C++20 EQUIVALENT, which you will still meet: */
        template<typename T,
                 typename = std::enable_if_t<
                        std::is_integral_v<T>>>
        void f(T x);
/* "Substitution Failure Is Not An Error" - if the enable_if
   fails to substitute, the candidate is silently removed
   rather than causing a compile error. Powerful, and the
   source of C++'s worst error messages.                  */
```

Variadic templates

```
/* Any number of arguments, type-safe, with no varargs. */

template<typename... Args>
void log(const char *fmt, Args&&... args)
{
        format_to(buffer, fmt, std::forward<Args>(args)...);
}

/* FOLD EXPRESSIONS (C++17) - the readable way to process a
   pack: */
        template<typename... Args>
        auto sum(Args... args) { return (args + ...); }
                                       /* unary right fold */

        template<typename... Args>
        bool all_valid(Args... args) { return (args.valid() && ...); }

        template<typename... Args>
        void print_all(Args&&... args)
        {
                ((std::cout << args << ' '), ...);
                                       /* comma fold */
        }

        sizeof...(Args)         /* the number of arguments */

/* A PRACTICAL EMBEDDED USE - a compile-time register field
   builder: */
        template<typename... Fields>
        constexpr uint32_t make_reg(Fields... f)
        {
                return (f.value | ...);
        }
        constexpr auto ctrl = make_reg(Enable{1}, Mode{2},
                                       Prescale{7});
/* Computed entirely at compile time; the result is one
   immediate in the instruction stream.                    */

/* PRE-C++17 RECURSION, which you will still see: */
        void print() {}                         /* base case */
        template<typename T, typename... Rest>
        void print(T first, Rest... rest)
        {
                std::cout << first;
                print(rest...);                 /* recurse */
        }
/* Fold expressions are shorter and compile faster. Use them
   where available.                                        */
```

The costs

```
/* Templates are not free in every dimension. */

/* --- CODE BLOAT --- */
        RingBuffer<uint8_t, 16>
        RingBuffer<uint8_t, 32>
        RingBuffer<uint16_t, 16>
/* THREE COMPLETE COPIES of every member function. On a
   flash-constrained part this adds up quickly.

   MITIGATIONS:
     · factor the type-independent parts into a non-template
       base:                                                */
        class RingBufferBase {          /* no template */
        protected:
                size_t head_, tail_, cap_;
                bool advance(size_t& idx);   /* shared code */
        };
        template<typename T, size_t N>
        class RingBuffer : RingBufferBase { ... };

     /* · use fewer distinct instantiations - prefer one
          capacity where you can
        · -Wl,--icf=all folds byte-identical functions
          (compilers ch. 12)
        · MEASURE: nm --size-sort -S, or bloaty            */

/* --- COMPILE TIME --- */
/* Templates are instantiated in every translation unit that
   uses them, then deduplicated by the linker. Heavy template
   use is the main cause of slow C++ builds.

   MITIGATIONS:
     extern template class RingBuffer<uint8_t, 64>;
     /* in a header - suppress instantiation here */
     template class RingBuffer<uint8_t, 64>;
     /* in ONE .cpp - instantiate it once */
     · -ftime-trace (clang) + speedscope to see where the time
       goes
     · precompiled headers, or C++20 modules if available    */

/* --- ERROR MESSAGES --- */
/* Without concepts, an error inside a template reports at the
   point of failure, not the point of misuse - hundreds of
   lines deep. Use concepts, or static_assert early: */
        template<typename T>
        void f(T x) {
                static_assert(std::is_integral_v<T>,
                              "f requires an integral type");
                ...
        }
/* One clear message instead of a wall.                    */

/* --- DEBUGGING --- */
/* Template names in a debugger and in a backtrace are
   enormous. c++filt and `set print asm-demangle` help;
   type aliases help more:                                 */
        using RxBuffer = RingBuffer<uint8_t, 64>;
```

CRTP: static polymorphism

```
/* Polymorphism with no vtable and no indirect call - the
   embedded alternative to virtual functions (chapter 11). */

template<typename Derived>
class SensorBase {
public:
        int read() {
                auto raw = self().read_raw();   /* dispatched
                                                   STATICALLY */
                return self().convert(raw);
        }

        void init() {
                self().configure();
                self().calibrate();
        }

private:
        Derived& self() { return static_cast<Derived&>(*this); }
};

class Thermistor : public SensorBase<Thermistor> {
public:
        uint16_t read_raw()          { return adc_read(CH0); }
        int      convert(uint16_t r) { return lookup(r); }
        void     configure()         { adc_init(CH0); }
        void     calibrate()         { }
};

        Thermistor t;
        int temp = t.read();

/* THE GENERATED CODE is fully inlined - read_raw and convert
   are called directly and usually vanish into the caller.
   NO vtable pointer in the object, NO indirect call, and the
   whole chain is optimisable.

/* THE COST: no runtime polymorphism. You cannot have a
   `std::vector<SensorBase*>` of mixed sensor types, because
   SensorBase<Thermistor> and SensorBase<Photodiode> are
   unrelated types.

/* WHEN TO USE WHICH:
     the set of types is KNOWN AT COMPILE TIME  -> CRTP
     the set varies at run time, or you need a
     heterogeneous container                    -> virtual
     you need both                              -> std::variant
                                                   (chapter 15)
*/
```

How it shows up

Symptom	Cause
200-line error inside the standard library	A constraint violated deep in instantiation — add concepts or a `static_assert`
"no matching function" with an obvious call	Deduction failed — often a mismatch like `max(1, 2.0)`

Symptom	Cause
Binary much larger than expected	Many instantiations — check with `nm --size-sort`
Build times growing rapidly	Template instantiation — try `extern template`, `-ftime-trace`
Template code not type-checked in some configs	You used `#ifdef` instead of `if constexpr`
Cannot partially specialise a function	Only classes can be — use overloading or a class template
An overload is never selected	A less-constrained template is winning — constrain it
SFINAE silently removes what you wanted	Substitution failure — concepts report it properly
Debugger shows unreadable type names	Introduce type aliases
CRTP object cannot go in a container with siblings	By design — different base types

Check yourself

- ✓ Write a function template and a class template with a non-type parameter.
- ✓ Explain why a template capacity parameter suits embedded containers.
- ✓ Distinguish full and partial specialisation, and say what functions cannot do.
- ✓ Explain `if constexpr` and why it beats `#ifdef`.
- ✓ Write a concept and show the error message it produces.
- ✓ Explain how concepts affect overload resolution.
- ✓ Use a fold expression to process a parameter pack.
- ✓ Name three costs of templates and a mitigation for each.
- ✓ Implement CRTP and say what it gives up compared with virtual functions.
- ✓ Measure the code size of several instantiations of one template.

`constexpr` and compile-time computation

Moving work from run time to compile time. On embedded this is not a micro-optimisation — a lookup table computed by the compiler costs zero cycles and lives in flash, and a configuration validated at compile time cannot be wrong in the field.

The keywords

```
/* --- const: "I will not modify this" ------------------- */
        const int a = 42;               /* compile-time
                                           constant here    */
        const int b = read_sensor();    /* runtime value that
                                           does not change  */

/* --- constexpr: "usable in a constant expression" ------ */
        constexpr int c = 42;
        constexpr int d = read_sensor();        /* ERROR */

        constexpr int square(int x) { return x * x; }
        constexpr int e = square(5);    /* computed at COMPILE
                                           time              */
        int n = get_n();
        int f = square(n);              /* the SAME function,
                                           called at RUN time */

/* A constexpr FUNCTION may be evaluated at compile time; it
   is not required to be. Called with runtime arguments it is
   an ordinary function.

/* --- consteval (C++20): "MUST be compile time" --------- */
        consteval int must_be_static(int x) { return x * x; }
        constexpr int g = must_be_static(5);    /* OK */
        int h = must_be_static(n);              /* ERROR */

/* Use it for anything whose whole point is compile-time
   evaluation - a hash of a string literal, a validated
   configuration, a register encoding.

/* --- constinit (C++20): "initialised at compile time" -- */
        constinit int counter = 0;      /* guaranteed static
                                           initialisation - no
                                           constructor runs
                                           before main
                                           (chapter 01)     */
/* It does NOT make the variable const; it only guarantees
   the initialisation is not dynamic. Exactly what you want
   for a mutable global on a bare-metal target.           */
```

Compile-time tables

```
/* THE HIGHEST-VALUE USE ON EMBEDDED. A table computed by the
   compiler costs nothing at run time and lives in flash.  */

/* --- CRC-32 table --- */
constexpr std::array<uint32_t, 256> make_crc_table()
{
        std::array<uint32_t, 256> table{};

        for (uint32_t i = 0; i < 256; i++) {
                uint32_t c = i;
                for (int k = 0; k < 8; k++)
                        c = (c & 1) ? (0xEDB88320u ^ (c >> 1))
                                    : (c >> 1);
                table[i] = c;
        }
        return table;
}

inline constexpr auto crc_table = make_crc_table();

uint32_t crc32(std::span<const uint8_t> data)
{
        uint32_t c = 0xFFFFFFFFu;

        for (uint8_t b : data)
                c = crc_table[(c ^ b) & 0xFF] ^ (c >> 8);

        return c ^ 0xFFFFFFFFu;
}

/* THE TABLE IS IN .rodata - flash, not RAM - fully computed.
   No initialisation code, no startup cost, and the source
   documents how it was derived rather than being 256
   inscrutable hex constants.

/* --- a sine table --- */
constexpr std::array<int16_t, 256> make_sine()
{
        std::array<int16_t, 256> t{};
        for (size_t i = 0; i < 256; i++) {
                /* a constexpr-friendly sine - std::sin is not
                   constexpr until C++26, so use a Taylor
                   series or CORDIC */
                t[i] = static_cast<int16_t>(
                        32767.0 * const_sin(2.0 * PI * i / 256));
        }
        return t;
}

/* --- a gamma correction table, from a formula --- */
template<size_t N, int GammaTimes100>
constexpr std::array<uint8_t, N> make_gamma()
{
        std::array<uint8_t, N> t{};
        for (size_t i = 0; i < N; i++)
                t[i] = static_cast<uint8_t>(
                        255.0 * const_pow(i / double(N - 1),
                                          GammaTimes100 / 100.0));
        return t;
}
```

```
        constexpr auto gamma22 = make_gamma<256, 220>();

/* CHANGE THE PARAMETER, GET A NEW TABLE. No script, no
   generated file to keep in sync, no build step. That is the
   argument.

/* CHECK IT LANDED IN FLASH: */
        nm -S prog.elf | grep crc_table
        readelf -S prog.elf         /* which section? */
/* If it is in .data rather than .rodata, something is not
   const and it is costing you RAM.                       */
```

THE EMBEDDED CASE, IN ONE SENTENCE

A `constexpr` table trades flash for RAM and cycles, is generated from readable source rather than a checked-in blob, and cannot drift out of sync with the formula that produced it. On a part with 32 KB of RAM and 512 KB of flash, that is nearly always the right trade.

What is allowed

```
/* The rules have relaxed substantially with each standard. */

/* C++11: essentially one return statement.
   C++14: loops, local variables, multiple statements, if.
   C++17: if constexpr, lambdas.
   C++20: try/catch (may not throw), dynamic allocation IF it
          is freed within the same evaluation, virtual calls,
          std::vector and std::string.
   C++23: goto, static/thread_local, more of the library.  */

/* WHAT IS STILL FORBIDDEN in a constant evaluation:
     · undefined behaviour of ANY kind - which is a feature:
       UB in a constexpr context is a COMPILE ERROR
     · reading a non-constexpr variable
     · reinterpret_cast
     · calling a non-constexpr function
     · anything touching hardware
     · allocation that escapes the evaluation

/* THE UB POINT IS WORTH DWELLING ON: */
        constexpr int f(int x) { return x + 1; }
        constexpr int bad = f(INT_MAX);
/* ERROR: overflow in constant expression
   The same expression at run time is silent UB
   (compilers chapter 15). Constant evaluation is the only
   place C++ is guaranteed to catch it.

/* DETECTING WHICH CONTEXT YOU ARE IN (C++20): */
        constexpr int fast_sqrt(int x)
        {
                if (std::is_constant_evaluated())
                        return exact_slow_sqrt(x);   /* compile
                                                        time  */
                else
                        return hardware_sqrt(x);     /* run
                                                        time  */
        }
/* C++23 spells the same thing `if consteval`.

/* AND static_assert, which is the point of much of this: */
        static_assert(crc32("hello") == 0x3610A686);
        static_assert(sizeof(Message) == 16,
                      "wire format changed");
        static_assert(TIMER_HZ % SAMPLE_RATE == 0,
                      "sample rate must divide the timer clock");
/* A configuration error that fails the BUILD is a
   configuration error that never ships.                  */
```

Compile-time configuration

```
/* Validate an entire board configuration at compile time. */

struct ClockConfig {
        uint32_t xtal_hz;
        uint32_t pll_mult;
        uint32_t pll_div;
        uint32_t ahb_div;

        constexpr uint32_t pll_hz() const
                { return xtal_hz * pll_mult / pll_div; }
        constexpr uint32_t ahb_hz() const
                { return pll_hz() / ahb_div; }

        constexpr bool valid() const
        {
                return xtal_hz >= 4'000'000
                    && xtal_hz <= 26'000'000
                    && pll_mult >= 2 && pll_mult <= 64
                    && pll_hz() <= 480'000'000
                    && ahb_hz() <= 200'000'000;
        }
};

inline constexpr ClockConfig board_clock{
        .xtal_hz  = 25'000'000,
        .pll_mult = 32,
        .pll_div  = 2,
        .ahb_div  = 2,
};
static_assert(board_clock.valid(), "invalid clock configuration");
static_assert(board_clock.ahb_hz() == 200'000'000);

/* AND DERIVED VALUES computed once, at compile time: */
        constexpr uint32_t uart_divisor(uint32_t clk,
                                        uint32_t baud)
        {
                return (clk + baud / 2) / (16 * baud);
        }
        constexpr auto UART_DIV =
                uart_divisor(board_clock.ahb_hz(), 115200);
        static_assert(UART_DIV > 0 && UART_DIV < 65536);

/* WHAT THIS REPLACES: a spreadsheet, a comment saying "if you
   change the crystal, recompute the divisors", and the bug
   where someone did not.

/* A COMPILE-TIME STRING HASH, for command dispatch with no
   strcmp at run time: */
        consteval uint32_t fnv1a(std::string_view s)
        {
                uint32_t h = 2166136261u;
                for (char c : s) {
                        h ^= static_cast<uint8_t>(c);
                        h *= 16777619u;
                }
                return h;
        }

        switch (fnv1a_runtime(input)) {
        case fnv1a("start"): do_start(); break;
```

```
        case fnv1a("stop"):  do_stop();  break;
        }
/* The case labels are integer constants; the switch is a
   jump table. And `consteval` guarantees the hashes are not
   computed at run time.                                    */
```

Type-safe units

```
/* Strong types with constexpr arithmetic: correctness with
   literally zero runtime cost.                             */

class Milliseconds {
        uint32_t v_;
public:
        explicit constexpr Milliseconds(uint32_t v) : v_(v) {}
        constexpr uint32_t count() const { return v_; }

        constexpr Milliseconds operator+(Milliseconds o) const
                { return Milliseconds{v_ + o.v_}; }
        constexpr auto operator<=>(const Milliseconds&) const
                = default;                       /* C++20 */
};

constexpr Milliseconds operator""_ms(unsigned long long v)
{
        return Milliseconds{static_cast<uint32_t>(v)};
}

        void delay(Milliseconds t);

        delay(100_ms);          /* clear */
        delay(100);             /* ERROR - explicit ctor */
        delay(1_s);             /* if you define _s too */

/* THE GENERATED CODE is identical to passing a bare uint32_t.
   The class is entirely compiled away - check on godbolt
   (chapter 14).

/* AND THE STANDARD LIBRARY ALREADY HAS THIS: */
        #include <chrono>
        using namespace std::chrono_literals;

        void delay(std::chrono::milliseconds t);
        delay(100ms);
        delay(2s);              /* converted automatically */
        delay(1500us);          /* and this */

/* std::chrono::duration is constexpr throughout, converts
   between units correctly at compile time, and refuses
   lossy conversions unless you ask with duration_cast. On
   embedded it is worth using even if you use nothing else
   from the standard library - it prevents an entire class of
   unit-confusion bug for free.                             */
```

Verifying it happened

```
/* THE RISK: you wrote constexpr, and it is being evaluated at
   run time anyway. Check.                                    */

/* 1. FORCE IT with a constexpr variable: */
        constexpr auto table = make_table();
/* If make_table() cannot be evaluated at compile time, this
   is a COMPILE ERROR - which is exactly the feedback you
   want. Assigning to `auto table = make_table();` would
   silently run it at startup.

/* 2. USE consteval where it must be compile time. */

/* 3. LOOK AT THE BINARY: */
        nm -S prog.elf | grep table
        readelf -x .rodata prog.elf | head
        objdump -s -j .rodata prog.elf
/* The table's bytes should be visible in .rodata. If the
   symbol is in .bss and there is code in .init_array, it is
   being computed at startup.

/* 4. CHECK .init_array IS EMPTY: */
        readelf -x .init_array prog.elf
/* For a well-configured firmware image it should be, or
   nearly so (chapter 01).

/* 5. AND THE COMPILE-TIME COST, which is real: */
        clang -ftime-trace ...
        /* then load the .json in speedscope or
           chrome://tracing */
/* Heavy constexpr evaluation - a large table with a complex
   formula - can add seconds to a build. Usually worth it;
   occasionally not.

/* THE LIMITS THE COMPILER IMPOSES: */
        -fconstexpr-depth=512           /* recursion */
        -fconstexpr-steps=1048576       /* clang: total
                                           operations */
        -fconstexpr-ops-limit=...       /* gcc */
/* Hitting these produces "constexpr evaluation exceeded
   maximum steps" - raise the limit, or simplify.        */
```

How it shows up

Symptom	Cause
Table is in RAM, not flash	Not `constexpr`, or not `const` — check the section
Startup code initialises a table	Computed at run time — force it with a `constexpr` variable
"call to non-constexpr function"	Something in the chain is not marked
"not a constant expression"	Reading a runtime value, or UB in the evaluation
Overflow error only in a `constexpr` context	Correct — the same code is silent UB at run time
"constexpr evaluation exceeded maximum steps"	Raise `-fconstexpr-steps`, or simplify
Build slowed by seconds	Heavy compile-time evaluation — measure with `-ftime-trace`
A configuration error reached the field	It was not `static_assert`ed

Symptom	Cause
Units confused (ms versus µs)	Bare integers — use `chrono` or a strong type
Strong-typed units cost performance	They should not — check the assembly; something is not inlining

Check yourself

- ✓ Distinguish `const`, `constexpr`, `consteval` and `constinit`.
- ✓ Write a `constexpr` function that generates a lookup table.
- ✓ Verify the table is in `.rodata` and that nothing runs at startup.
- ✓ Say what is forbidden in a constant evaluation, and why the UB rule is valuable.
- ✓ Use `static_assert` to validate a board configuration.
- ✓ Compute a derived hardware constant at compile time and assert its range.
- ✓ Write a compile-time string hash and use it in a `switch`.
- ✓ Build a strong unit type and prove it costs nothing.
- ✓ Use `std::chrono` for durations and explain what it prevents.
- ✓ Detect and fix a case where `constexpr` silently became runtime evaluation.

The standard library: containers

What each container costs in memory, allocation and cache behaviour — and which of them belong in embedded code. The right answer is usually `std::array`, and knowing why the others are wrong is more useful than knowing their interfaces.

The containers, and their real costs

Container	Layout	Allocates	Embedded verdict
`std::array<T,N>`	Contiguous, inline	**Never**	**Use freely**
`std::span<T>`	ptr + size, non-owning	Never	**Use freely**
`std::string_view`	ptr + size, non-owning	Never	**Use freely**
`std::vector<T>`	Contiguous, heap	On growth	Only with `reserve`, or not at all
`std::string`	Heap, with SSO	Above ~15 chars	Avoid; use `string_view` or a fixed buffer
`std::deque<T>`	Chunked	Per chunk	Avoid
`std::list<T>`	Nodes	**Per element**	**Avoid** — terrible cache behaviour
`std::map<K,V>`	Red-black tree	Per element	Avoid; sorted array + `binary_search`
`std::unordered_map`	Buckets + nodes	Per element	Avoid; a fixed hash table
`std::bitset<N>`	Inline bits	Never	Use freely
`std::optional<T>`	T + a bool, inline	Never	**Use freely**
`std::variant<...>`	Largest + a tag, inline	Never	**Use freely**
`std::pair`, `std::tuple`	Inline	Never	Use freely

THE PATTERN

Everything that stores its data *inline* is free and belongs in embedded code. Everything that owns heap memory is a decision. That single distinction covers the whole table, and it is why `std::array`, `span`, `optional` and `variant` are the four standard-library types worth adopting even in tightly constrained firmware.

std::array

```
#include <array>

        std::array<uint8_t, 64> buf{};          /* zeroed */
        std::array<int, 3> a{1, 2, 3};

        buf.size();             /* a compile-time constant */
        buf.data();             /* uint8_t* */
        buf[0];                 /* unchecked - same as C */
        buf.at(0);              /* THROWS if out of range -
                                   unusable with
                                   -fno-exceptions          */
        buf.front(); buf.back();
        for (auto& b : buf) { }
        std::fill(buf.begin(), buf.end(), 0);

/* IDENTICAL LAYOUT AND CODE to `uint8_t buf[64]`, plus:
     · it knows its size, so no separate length parameter
     · it does not decay to a pointer when passed
     · it can be returned by value, copied and compared
     · begin()/end() work with the algorithms

/* THE PASSING RULE: */
        void f(std::array<uint8_t, 64>& a);    /* one size
                                                  only     */
        void g(std::span<uint8_t> s);          /* ANY size -
                                                  prefer this */

/* CLASS TEMPLATE ARGUMENT DEDUCTION (C++17): */
        std::array a{1, 2, 3};          /* std::array<int,3> */

/* AND THE 2-D CASE: */
        std::array<std::array<float, 4>, 4> matrix{};
        matrix[1][2] = 3.0f;
/* Contiguous, no indirection - unlike float**.           */
```

std::span and string_view

```
#include <span>          /* C++20 */

/* A NON-OWNING view of contiguous memory: a pointer and a
   size. Replaces every (T *ptr, size_t len) pair.        */

        void process(std::span<const uint8_t> data)
        {
                for (auto b : data) { ... }
                if (data.size() < 4) return;
                auto header = data.first(4);
                auto body   = data.subspan(4);
        }

        std::array<uint8_t, 64> a;
        std::vector<uint8_t>    v;
        uint8_t                 c[32];

        process(a);             /* all three convert */
        process(v);             /* implicitly */
        process({c, 32});

/* WHY THIS MATTERS: it removes the commonest C bug shape -
   a pointer and a length passed separately, and one of them
   updated without the other.

/* FIXED-EXTENT SPANS carry the size in the type: */
        void f(std::span<uint8_t, 16> exactly16);
/* size() is then a compile-time constant, and passing the
   wrong size is a compile error.

/* string_view is the same idea for text: */
        void log(std::string_view msg);
        log("literal");                 /* no allocation, no
                                           strlen at run time -
                                           the size is known
                                           from the literal  */
        log(std::string{...});          /* also works */

/* THE LIFETIME HAZARD, and it is real: */
        std::string_view bad()
        {
                std::string s = build();
                return s;               /* DANGLING - s is
                                           destroyed         */
        }
        std::string_view sv = get_string();  /* if that returns
                                                by value,
                                                DANGLING     */
/* A view does not own. -Wdangling-gsl catches some cases;
   ASan catches the rest. Treat span and string_view as
   PARAMETERS, not as members or return values, unless you
   can see the owner's lifetime.                          */
```

std::vector, when you must

```
        std::vector<int> v;
        v.reserve(100);         /* ONE allocation, up front */
        for (int i = 0; i < 100; i++)
                v.push_back(i); /* no reallocation */

/* GROWTH: capacity doubles (or ×1.5), which means:
     · amortised O(1) push_back
     · reallocation COPIES OR MOVES every element
     · ALL ITERATORS AND POINTERS ARE INVALIDATED
     · unpredictable timing - the reallocation is a latency
       spike exactly where you cannot afford one

        v.size()        elements
        v.capacity()    allocated space
        v.shrink_to_fit()   a non-binding REQUEST
        v.clear()       size 0, capacity UNCHANGED

/* THE ITERATOR INVALIDATION TRAP: */
        for (auto it = v.begin(); it != v.end(); ++it)
                if (*it == x)
                        v.erase(it);    /* it is now INVALID */
        /* correct: */
                it = v.erase(it);       /* erase returns the
                                           next valid one    */
        /* or, better: */
        std::erase(v, x);               /* C++20 */

/* WITH A CUSTOM ALLOCATOR, vector can use a fixed pool: */
        std::pmr::monotonic_buffer_resource pool{buffer,
                                                 sizeof buffer};
        std::pmr::vector<int> v{&pool};
/* Bounded, deterministic, no global heap. Worth knowing, and
   in practice a fixed-capacity container is simpler.

/* THE EMBEDDED ALTERNATIVE - a fixed-capacity vector: */
        etl::vector<Message, 32> queue;   /* ETL */
        /* or roll your own: */
template<typename T, size_t N>
class StaticVector {
        alignas(T) std::byte storage_[N * sizeof(T)];
        size_t size_ = 0;
public:
        bool push_back(const T& v)
        {
                if (size_ >= N) return false;   /* FAILS
                                                   rather than
                                                   allocating */
                new (&data()[size_]) T(v);
                size_++;
                return true;
        }
        T *data() { return reinterpret_cast<T *>(storage_); }
        size_t size() const { return size_; }
        ...
};
/* The interface of vector, the memory behaviour of an array,
   and a bounded failure mode instead of an allocation.  */
```

Maps, and what to use instead

```
/* std::map is a red-black tree: one heap node per element,
   pointers everywhere, and a cache miss per level of the
   tree. std::unordered_map is buckets of nodes - the same
   problem plus a hash.

/* FOR A SMALL, FIXED SET, a sorted array beats both,
   dramatically: */

struct Entry { uint32_t key; Handler fn; };

inline constexpr std::array<Entry, 5> table{{
        {0x100, handle_status},
        {0x200, handle_config},
        {0x300, handle_data},
        {0x400, handle_reset},
        {0x500, handle_debug},
}};
static_assert(std::is_sorted(table.begin(), table.end(),
                [](auto& a, auto& b){ return a.key < b.key; }),
              "table must be sorted");

const Entry *lookup(uint32_t key)
{
        auto it = std::lower_bound(table.begin(), table.end(),
                        key,
                        [](const Entry& e, uint32_t k)
                                { return e.key < k; });
        return (it != table.end() && it->key == key)
                ? &*it : nullptr;
}

/* IN FLASH, no allocation, one cache line for the whole
   table, and the static_assert guarantees the sort order the
   binary search depends on.

/* FOR UP TO ABOUT 16 ENTRIES, a LINEAR SCAN is usually
   FASTER than a binary search - fewer branches, perfectly
   predictable, one cache line. Measure rather than assuming
   the asymptotically better algorithm wins at small N; on
   embedded it very often does not (CA chapter 14).

/* A FIXED HASH TABLE, when you need O(1) and have the space:
*/
template<typename K, typename V, size_t N>
class FlatMap {
        std::array<K, N> keys_{};
        std::array<V, N> vals_{};
        std::array<bool, N> used_{};
        /* open addressing, linear probing - no nodes, no
           allocation, contiguous                          */
};

/* AND FOR COMPILE-TIME LOOKUP, a perfect hash or simply a
   switch on a constexpr string hash (chapter 07) beats every
   container.                                              */
```

optional and variant

```
#include <optional>

/* "a T, or nothing" - without a sentinel value or an
   out-parameter.                                          */

        std::optional<uint32_t> read_sensor()
        {
                if (!ready()) return std::nullopt;
                return raw_value();
        }

        if (auto v = read_sensor()) {
                use(*v);
        }
        uint32_t x = read_sensor().value_or(0);

/* LAYOUT: sizeof(T) + one bool + padding. INLINE, no
   allocation. Replaces:
     · a magic sentinel (0xFFFFFFFF meaning "no reading")
     · a bool out-parameter
     · a pointer that might be null
   all of which are error-prone in ways optional is not.

#include <variant>

/* "exactly one of these types" - a tagged union with the
   tagging done correctly.                                 */

        using Event = std::variant<ButtonPress, SensorReading,
                                   Timeout>;

        void handle(const Event& e)
        {
                std::visit([](const auto& ev) {
                        using T = std::decay_t<decltype(ev)>;
                        if constexpr (std::is_same_v<T,
                                                     ButtonPress>)
                                on_button(ev);
                        else if constexpr (std::is_same_v<T,
                                                     SensorReading>)
                                on_sensor(ev);
                        else
                                on_timeout(ev);
                }, e);
        }

/* LAYOUT: as large as the largest alternative, plus a small
   index. Inline, no allocation.

   VERSUS A RAW UNION: the variant knows which member is
   active, destroys the right one, and std::visit is
   EXHAUSTIVE - add an alternative and the code that does not
   handle it fails to compile. That last property is the
   whole value.

/* THE EXCEPTIONS CAVEAT: std::get and std::visit can throw
   std::bad_variant_access. With -fno-exceptions, use
   std::get_if, which returns a pointer or null:          */
        if (auto *p = std::get_if<SensorReading>(&e))
                on_sensor(*p);
```

```
/* AND std::expected (C++23) - a value or an error, which is
   what you actually want for a fallible operation
   (chapter 12):                                          */
        std::expected<Reading, Error> read();
        if (auto r = read())  use(*r);
        else                  log(r.error());
```

Measuring the cost

```
/* Do not guess. Measure the three things that matter. */

/* --- 1. SIZE, at compile time --- */
        static_assert(sizeof(std::array<uint8_t, 64>) == 64);
        static_assert(sizeof(std::span<int>) == 16);
        static_assert(sizeof(std::optional<uint32_t>) == 8);
        static_assert(sizeof(std::string_view) == 16);
        /* and on your target: */
        static_assert(sizeof(std::vector<int>) == 24);
        static_assert(sizeof(std::string) == 32);

/* --- 2. ALLOCATIONS, at run time --- */
        static size_t g_allocs = 0;
        void *operator new(size_t n) {
                g_allocs++;
                return malloc(n);
        }
        void operator delete(void *p) noexcept { free(p); }
/* Then assert the count is zero over your hot path. On bare
   metal, simply do not link an operator new - any
   accidental allocation becomes a LINK ERROR, which is the
   strongest guarantee available.

/* --- 3. CODE SIZE --- */
        nm --size-sort -S prog.elf | tail -20
        bloaty prog.elf -d symbols
/* Watch for std::__cxx11::basic_string and the iostream
   machinery appearing - each is tens of kilobytes.

/* --- AND THE STRUCTURAL CHECK --- */
        grep -rn 'std::string\|std::vector\|std::map\|iostream' src/
/* In a codebase with a documented subset (chapter 01), this
   grep should return nothing outside the places you decided
   to allow it. Automate it in CI.                        */
```

How it shows up

Symptom	Cause
Unexpected heap allocation	`vector` growth, `string` above SSO, or a node container
Latency spike in a loop	`vector` reallocation — `reserve` up front
Crash after inserting into a container	Iterator or pointer invalidated by reallocation
Crash after erasing during iteration	Use the iterator `erase` returns, or `std::erase`
Garbage from a `string_view`	Dangling — the owner was destroyed
Poor performance despite a good algorithm	Node containers — cache misses dominate (CA ch. 14)

Symptom	Cause
Binary grew 40 KB	`std::string` or iostreams pulled in
`.at()` causes a link error	It throws; incompatible with `-fno-exceptions`
`std::get` on a variant throws	Use `std::get_if` with exceptions disabled
Binary search returns wrong results	The table is not sorted — assert it
Linear scan beats your binary search	Small N — expected; measure rather than assume

Check yourself

- ✓ Classify every standard container by whether it allocates, and state the pattern.
- ✓ Explain what `std::array` adds over a C array at zero cost.
- ✓ Use `span` to replace a pointer-and-length pair, and state its lifetime hazard.
- ✓ Explain `vector` growth, its three consequences, and how to avoid them.
- ✓ Write a fixed-capacity vector with a bounded failure mode.
- ✓ Replace a `std::map` with a sorted array plus a sortedness assertion.
- ✓ Say when a linear scan beats a binary search, and why.
- ✓ Use `optional` to replace a sentinel, and `variant` to replace a union.
- ✓ Explain why `std::visit` exhaustiveness is valuable.
- ✓ Verify container sizes with `static_assert` and prove your hot path allocates nothing.

Iterators, algorithms and ranges

The standard algorithms are templates that compile to the same loop you would write by hand — but named, correct, and hard to get wrong. Almost all of them allocate nothing, which makes this the part of the standard library that transfers straight into embedded work.

Iterators

```
An iterator generalises a pointer. The categories form a
hierarchy, and each algorithm requires a minimum category:

   input          read once, advance forward
      |           (an input stream)
   forward        read repeatedly, advance forward
      |           (forward_list, unordered_map)
   bidirectional  ...and backwards
      |           (list, map, set)
   random access  ...and jump: it += n, it2 - it1, it[n]
      |           (array, vector, deque, RAW POINTERS)
   contiguous     ...and the elements are adjacent in memory
                  (array, vector, span, pointers)  [C++20]

  A RAW POINTER IS A CONTIGUOUS ITERATOR. Every algorithm
  works on plain arrays:

        int a[10];
        std::sort(a, a + 10);
        std::sort(std::begin(a), std::end(a));

  WHY THE CATEGORY MATTERS: std::sort needs random access, so
  it cannot sort a std::list - which is why list has its own
  sort() member. std::advance is O(1) on random access and
  O(n) otherwise, which is why a loop calling it on a list is
  accidentally quadratic.

  THE RANGE CONVENTION is HALF-OPEN: [begin, end). end() is
  one past the last element and must not be dereferenced.
  This makes size = end - begin, an empty range is
  begin == end, and loops terminate naturally.
```

The algorithms worth knowing

```
#include <algorithm>
#include <numeric>

/* --- SEARCHING --- */
        std::find(b, e, value);
        std::find_if(b, e, pred);
        std::count(b, e, value);
        std::count_if(b, e, pred);
        std::all_of(b, e, pred);  any_of  none_of
        std::binary_search(b, e, value);        /* SORTED */
        std::lower_bound(b, e, value);          /* SORTED */
        std::upper_bound(b, e, value);
        std::equal_range(b, e, value);
        std::search(b, e, sb, se);              /* subsequence */
        std::min_element(b, e);  max_element  minmax_element

/* --- MODIFYING --- */
        std::copy(b, e, out);
        std::copy_if(b, e, out, pred);
        std::copy_n(b, n, out);
        std::move(b, e, out);           /* moves elements */
        std::fill(b, e, value);
        std::iota(b, e, 0);             /* 0,1,2,3,... */
        std::generate(b, e, fn);
        std::transform(b, e, out, fn);
        std::transform(b1, e1, b2, out, binary_fn);
        std::replace(b, e, old, new);
        std::reverse(b, e);
        std::rotate(b, mid, e);
        std::swap_ranges(b1, e1, b2);

/* --- REMOVING: the erase-remove idiom --- */
        v.erase(std::remove(v.begin(), v.end(), value),
                v.end());
/* std::remove does NOT remove - it SHIFTS the kept elements
   forward and returns the new logical end. The container
   still holds the old size until erase() is called. This
   surprises everyone once.
   C++20 has the sane spelling:                          */
        std::erase(v, value);
        std::erase_if(v, pred);

/* --- SORTING --- */
        std::sort(b, e);                /* introsort, O(n log n),
                                           NOT stable      */
        std::stable_sort(b, e);         /* may ALLOCATE */
        std::partial_sort(b, mid, e);   /* top-k only */
        std::nth_element(b, nth, e);    /* O(n) selection */
        std::is_sorted(b, e);
        std::partition(b, e, pred);
        std::stable_partition(b, e, pred);   /* may allocate */

/* --- NUMERIC --- */
        std::accumulate(b, e, init);
        std::accumulate(b, e, init, binary_op);
        std::reduce(b, e);              /* C++17, may be
                                           parallel/reordered */
        std::inner_product(b1, e1, b2, init);
        std::partial_sum(b, e, out);
        std::adjacent_difference(b, e, out);
```

```
        std::clamp(v, lo, hi);          /* <algorithm> */
        std::gcd(a, b);  std::lcm(a, b);  /* <numeric> */

/* --- COMPARING --- */
        std::equal(b1, e1, b2);
        std::lexicographical_compare(b1, e1, b2, e2);
        std::mismatch(b1, e1, b2);

/* WHICH ONES ALLOCATE - the only three that matter for
   embedded:
        std::stable_sort
        std::stable_partition
        std::inplace_merge
   Every other algorithm in this list allocates nothing.  */
```

WHY USE THEM RATHER THAN A HAND-WRITTEN LOOP

They compile to the same instructions — `std::find` on a `span<int>` is byte-identical to the loop you would write, and often better because the implementation is specialised for contiguous ranges and vectorises. What you gain is a *name* at the call site, no off-by-one, no inverted comparison, and correct behaviour on empty ranges. That last one is where hand-written loops actually fail.

Lambdas

```
        auto is_even = [](int x) { return x % 2 == 0; };

        int threshold = 10;
        auto above = [threshold](int x) { return x > threshold; };
                                        /* capture BY VALUE */
        auto count_it = [&count](int x) { if (x) count++; };
                                        /* capture BY REFERENCE */

/* CAPTURE FORMS: */
        [ ]             nothing
        [x]             x by value
        [&x]            x by reference
        [=]             everything used, by value    (avoid)
        [&]             everything used, by reference (avoid)
        [this]          the enclosing object's members
        [*this]         a COPY of the enclosing object (C++17)
        [x = expr]      init capture: a new variable
        [p = std::move(ptr)]    move into the lambda

/* PREFER EXPLICIT CAPTURES. `[&]` in a lambda that outlives
   the scope is a dangling reference, and the capture list is
   the only place a reader can see what the lambda depends
   on.

/* WHAT A LAMBDA IS: a compiler-generated class with an
   operator(), and one member per capture. */
        auto f = [a, b](int x) { return a * x + b; };
/* becomes, in effect: */
        struct __lambda {
                int a, b;
                int operator()(int x) const { return a*x + b; }
        };
/* A CAPTURELESS lambda is an empty class, converts to a plain
   function pointer, and costs nothing at all:            */
        void (*fp)(int) = [](int x) { handle(x); };
/* which is how you pass one as a C callback (chapter 16).

/* GENERIC LAMBDAS (C++14): */
        auto print = [](const auto& x) { log(x); };
/* `auto` parameters make operator() a template.

/* THE COST QUESTION: a lambda passed to an algorithm as a
   template parameter is INLINED COMPLETELY - zero cost.
   Stored in a std::function it is type-erased: possibly a
   heap allocation and an indirect call. That difference is
   the whole story (chapter 01).                          */

        template<typename F> void each(F f);   /* free */
        void each(std::function<void(int)> f); /* not free */
```

Ranges

```
#include <ranges>       /* C++20 */
#include <algorithm>

/* 1. ALGORITHMS TAKE A RANGE, not two iterators: */
        std::ranges::sort(v);
        std::ranges::find(v, 42);
        std::ranges::copy(v, out);

/* Shorter, and it cannot mismatch begin and end from
   different containers - a real bug the iterator form
   permits.

/* 2. PROJECTIONS - apply a function before comparing: */
        struct Reading { uint32_t time; int16_t value; };
        std::vector<Reading> readings;

        std::ranges::sort(readings, {}, &Reading::time);
                                /* sort by .time, with the
                                   default comparator      */
        auto it = std::ranges::find(readings, 100,
                                    &Reading::value);
        auto m = std::ranges::max_element(readings, {},
                                          &Reading::value);

/* This replaces a lambda per call, and reads better.

/* 3. VIEWS - lazy, composable, non-owning: */
        namespace v = std::views;

        for (int x : v | v::filter([](int i){ return i > 0; })
                       | v::transform([](int i){ return i * 2; })
                       | v::take(10))
                use(x);

/* LAZY means no intermediate container is created - the
   pipeline is fused into one loop, and generates the same
   code as the hand-written version.

        v::iota(0, 10)          /* 0..9 without a container */
        v::reverse
        v::drop(n)  v::take(n)
        v::take_while(pred)  v::drop_while(pred)
        v::split(delim)
        v::join
        v::keys  v::values      /* for pairs */
        v::enumerate            /* C++23: index and value */
        v::chunk(n)  v::slide(n)    /* C++23 */
        v::zip                  /* C++23 */

/* AN EMBEDDED-RELEVANT EXAMPLE: */
        for (auto [i, sample] : v::enumerate(buffer
                                | v::filter(is_valid)
                                | v::take(MAX_SAMPLES)))
                process(i, sample);

/* THE CAVEATS FOR EMBEDDED:
     · ranges support in older toolchains is patchy; check
       before committing to it
     · compile times increase noticeably
     · error messages, without concepts support, are poor
```

```
    · debugging a pipeline is harder than debugging a loop
    · SOME views allocate (ranges::to, split on some
      implementations) — check what you use

  THE VERDICT: ranges are excellent, and worth adopting on
  embedded Linux with a modern toolchain. On a
  microcontroller with a vendor GCC 8, they are not
  available anyway.                                    */
```

Algorithms on embedded

```
/* Almost all of them are directly usable. Some examples that
   earn their place: */

/* --- on a fixed buffer --- */
        std::array<int16_t, 256> samples;

        auto peak = *std::max_element(samples.begin(),
                                      samples.end());
        auto sum  = std::accumulate(samples.begin(),
                                    samples.end(), 0);
        std::transform(samples.begin(), samples.end(),
                       output.begin(),
                       [](int16_t s) { return s * gain >> 8; });

/* --- on a span, so it works with any buffer --- */
        int16_t rms(std::span<const int16_t> s)
        {
                auto sq = std::inner_product(
                        s.begin(), s.end(), s.begin(), 0LL);
                return isqrt(sq / s.size());
        }

/* --- searching a constexpr table (chapter 08) --- */
        auto it = std::lower_bound(table.begin(), table.end(),
                                   key, by_key);

/* --- and the compile-time versions --- */
        static_assert(std::is_sorted(table.begin(),
                                     table.end(), by_key));
/* Most algorithms became constexpr in C++20, so you can run
   them on constexpr data and assert the result.

/* WHAT TO WATCH:

   1. THE THREE ALLOCATING ALGORITHMS - stable_sort,
      stable_partition, inplace_merge. Use sort and partition
      instead unless stability matters.

   2. std::sort IS INTROSORT: quicksort, falling back to
      heapsort, with insertion sort for small ranges. Its
      WORST CASE is O(n log n), so it is real-time-safe in
      complexity - but its constant factor and code size are
      substantial. For fewer than about 32 elements, an
      insertion sort you write yourself is smaller and
      faster.

   3. CODE SIZE: each instantiation of sort for a distinct
      type and comparator is a separate copy of a fairly large
      function. Check with nm --size-sort.

   4. std::reduce and the parallel algorithms (std::execution)
      have no place on a microcontroller - and on embedded
      Linux they need a threading runtime.               */
```

Writing your own

```
/* Follow the same conventions and your code composes with
   the standard library. */

template<typename It, typename T>
constexpr It find_last(It first, It last, const T& value)
{
        It result = last;
        for (; first != last; ++first)
                if (*first == value)
                        result = first;
        return result;
}

/* THE CONVENTIONS:
     · take [first, last), return an iterator
     · return `last` to mean "not found"
     · take the predicate or comparator as a template
       parameter, never std::function
     · mark it constexpr if it can be
     · require the WEAKEST iterator category that works

/* A RANGE-BASED VERSION, and a concept to constrain it: */
template<std::ranges::forward_range R, typename T>
constexpr auto find_last(R&& r, const T& value)
{
        return find_last(std::ranges::begin(r),
                         std::ranges::end(r), value);
}

/* AND A CUSTOM ITERATOR, when you need to present something
   as a range - a hardware FIFO, for example: */
class FifoIterator {
        Fifo *f_;
        bool  at_end_;
public:
        using iterator_category = std::input_iterator_tag;
        using value_type        = uint8_t;
        using difference_type   = std::ptrdiff_t;
        using pointer           = const uint8_t *;
        using reference         = uint8_t;

        uint8_t operator*() const  { return f_->peek(); }
        FifoIterator& operator++() { f_->pop();
                                     at_end_ = f_->empty();
                                     return *this; }
        bool operator==(const FifoIterator& o) const
                { return at_end_ == o.at_end_; }
};
/* Now std::copy, std::find and the rest work on your FIFO,
   with no allocation and no intermediate buffer.        */
```

How it shows up

Symptom	Cause
`std::remove` did not change the size	It never does — pair it with `erase`, or use `std::erase`
`binary_search` gives wrong answers	The range is not sorted by the same comparator

Symptom	Cause
Quadratic performance with a list	`std::advance` or indexing on a non-random-access iterator
"no matching function" for `std::sort`	The iterator is not random access
Unexpected allocation	`stable_sort`, `stable_partition` or `inplace_merge`
Lambda captured a dangling reference	`[&]` on a lambda that outlived the scope
Lambda in `std::function` allocates	Type erasure — pass it as a template parameter instead
Algorithm crashes on an empty range	`max_element` and friends return `end()` — check before dereferencing
Binary grew after using `std::sort`	Introsort is large; for small N write an insertion sort
Ranges pipeline will not compile	Toolchain support, or a view requiring a stronger range
Mismatched `begin` / `end` from two containers	Use the ranges overloads, which make it impossible

Check yourself

- ✓ Name the iterator categories and say which algorithms each supports.
- ✓ Explain the half-open range convention and what it buys.
- ✓ List twenty algorithms and what each does.
- ✓ Explain the erase-remove idiom and why `remove` does not remove.
- ✓ Name the three allocating algorithms.
- ✓ Explain lambda capture forms and why `[&]` is risky.
- ✓ Say what a lambda compiles to, and when it is free versus not.
- ✓ Use ranges with projections and a view pipeline.
- ✓ State the embedded caveats for ranges.
- ✓ Write an algorithm and a custom iterator that follow the standard conventions.

Smart pointers and ownership

Making ownership visible in the type system. `unique_ptr` costs nothing and prevents leaks; `shared_ptr` costs atomics and is usually the wrong answer. On embedded, the most valuable use is not the heap at all — it is wrapping hardware handles.

Expressing ownership

```
A raw pointer says nothing about ownership. These do:

  T*                  a NON-OWNING observer. Someone else
                      frees it. May be null.
  T&                  a non-owning observer that cannot be
                      null and cannot be reseated.
  std::unique_ptr<T>  EXCLUSIVE ownership. Freed when it
                      goes out of scope. Move-only.
  std::shared_ptr<T>  SHARED ownership. Freed when the last
                      owner goes. Atomic refcount.
  std::weak_ptr<T>    a non-owning reference to a shared
                      object, which knows whether it is
                      still alive.
  std::optional<T>    a value that may be absent, stored
                      INLINE - not a pointer at all.
  std::span<T>        a non-owning view of a contiguous
                      range.

THE CONVENTION THIS ENABLES, and it is worth adopting
wholesale:

  · a function taking `unique_ptr<T>` by value TAKES
    OWNERSHIP
  · a function taking `T*` or `T&` BORROWS - the caller
    keeps ownership and must outlive the call
  · a function returning `unique_ptr<T>` TRANSFERS
    ownership
  · a raw pointer stored as a member means "someone else
    owns this, and I depend on their lifetime"

Once a codebase follows this, ownership is READABLE FROM
THE SIGNATURE, which is most of what documentation used to
have to carry.
```

unique_ptr

```
#include <memory>

        auto p = std::make_unique<Widget>(arg1, arg2);
        p->method();
        Widget& w = *p;
        Widget *raw = p.get();          /* observe, do not own */

        auto q = std::move(p);          /* transfer - p is now
                                           null              */
        p.reset();                      /* delete and null */
        Widget *released = p.release(); /* give up ownership;
                                           YOU must delete    */

        std::unique_ptr<Widget[]> arr =
                std::make_unique<Widget[]>(10);   /* uses
                                                     delete[] */

/* SIZE: exactly sizeof(T*). No overhead at all, provided the
   deleter is stateless. Verify: */
        static_assert(sizeof(std::unique_ptr<int>)
                      == sizeof(int *));

/* THE GENERATED CODE is identical to a raw pointer plus a
   manual delete on every exit path - including the ones you
   would have forgotten (chapter 01).

/* MOVE-ONLY BY DESIGN: */
        auto a = std::make_unique<int>(1);
        auto b = a;                     /* COMPILE ERROR */
        auto c = std::move(a);          /* fine */

/* IN A FACTORY, which is its most natural use: */
        std::unique_ptr<Driver> create_driver(DeviceType t)
        {
                switch (t) {
                case SPI: return std::make_unique<SpiDriver>();
                case I2C: return std::make_unique<I2cDriver>();
                }
                return nullptr;
        }
/* The caller owns the result and cannot forget to delete it.
   Note the return type is the BASE class - which requires a
   virtual destructor (chapter 11).                        */
```

Custom deleters — the embedded use

```
/* THE MOST VALUABLE PATTERN IN THIS CHAPTER FOR EMBEDDED
   WORK: unique_ptr does not have to own heap memory. It can
   own ANY resource with a release function.              */

/* --- a file descriptor --- */
        struct FdDeleter {
                using pointer = int;    /* the "pointer" type
                                           is an int!        */
                void operator()(int fd) const
                        { if (fd >= 0) ::close(fd); }
        };
        using UniqueFd = std::unique_ptr<int, FdDeleter>;

        UniqueFd fd{::open("/dev/thing", O_RDWR)};
        if (fd.get() < 0) return -1;
        ioctl(fd.get(), ...);
        /* closed automatically, on every path */

/* THE `using pointer = int;` IS THE TRICK: unique_ptr uses
   Deleter::pointer if it exists, so the "pointer" can be any
   handle type - an int, a HANDLE, a DMA channel number.

/* --- a C library handle --- */
        struct FileCloser {
                void operator()(FILE *f) const { fclose(f); }
        };
        std::unique_ptr<FILE, FileCloser> f{fopen(path, "r")};

        /* or, more briefly, with a function pointer type: */
        std::unique_ptr<FILE, decltype(&fclose)>
                f{fopen(path, "r"), &fclose};
/* NOTE: this second form makes the unique_ptr TWO pointers
   wide, because the deleter has state. Prefer the stateless
   functor.                                                 */

/* --- a hardware resource --- */
        struct DmaRereleaser {
                using pointer = DmaChannel;
                void operator()(DmaChannel c) const
                        { dma_release(c); }
        };
        using UniqueDma = std::unique_ptr<DmaChannel,
                                          DmaReleaser>;

        UniqueDma claim_dma()
        {
                return UniqueDma{dma_claim()};
        }
        /* move-only, released automatically, no heap involved
           anywhere */

/* --- and a placement-new object in a static pool --- */
        struct PoolDeleter {
                Pool *pool;
                void operator()(Widget *w) const
                {
                        w->~Widget();
                        pool->free(w);
                }
        };
```

```
        std::unique_ptr<Widget, PoolDeleter>
                make_pooled(Pool& p)
        {
                void *mem = p.alloc(sizeof(Widget));
                return {new (mem) Widget{}, PoolDeleter{&p}};
        }
/* RAII, ownership transfer, exception safety - with a fixed
   pool and no global heap. This is unique_ptr earning its
   place on a microcontroller.                          */
```

THE POINT FOR EMBEDDED

`unique_ptr` is not a heap tool. It is an *ownership* tool that happens to default to the heap. With a custom deleter it wraps file descriptors, DMA channels, hardware locks, pool allocations and vendor SDK handles — giving move-only semantics, automatic release and a signature that documents who owns what, at exactly zero runtime cost.

shared_ptr, and why to hesitate

```
        auto p = std::make_shared<Widget>(args);
        auto q = p;                     /* refcount 2 */
        p.use_count();

/* WHAT IT COSTS:
     · TWO pointers: the object, and the CONTROL BLOCK
     · the control block holds a strong count, a weak count,
       and a deleter
     · every copy and destruction is an ATOMIC increment or
       decrement - a full memory barrier on ARM
       (ARM chapter 22)
     · make_shared does ONE allocation for both; constructing
       from a raw pointer does TWO

/* WHY IT IS USUALLY THE WRONG ANSWER:

   1. THE ATOMICS ARE NOT FREE. Copying a shared_ptr in a hot
      path is a measurable cost, and on a multi-core system
      the cache line containing the refcount ping-pongs
      between cores (CA chapter 15).

   2. IT HIDES THE OWNERSHIP GRAPH. "Who frees this?" becomes
      unanswerable, and destruction happens at an
      unpredictable point, possibly on an unexpected thread.

   3. CYCLES LEAK. Two objects holding shared_ptr to each
      other never reach zero.

   4. IT IS OFTEN CHOSEN TO AVOID THINKING about lifetimes,
      which is exactly when it goes wrong.

/* WHEN IT IS GENUINELY RIGHT: several independent owners,
   with no clear "last one", and a lifetime that really is
   dynamic - a cache of shared resources, a plugin registry.
   That is rarer than its usage suggests.

/* BREAKING A CYCLE with weak_ptr: */
        struct Node {
                std::shared_ptr<Node> child;
                std::weak_ptr<Node>   parent;   /* NOT shared */
        };

        if (auto p = node->parent.lock()) {  /* promote to
                                                shared, or get
                                                null           */
                use(*p);
        }

/* ON EMBEDDED: shared_ptr is rarely appropriate. If you find
   yourself reaching for it, ask whether the real answer is a
   fixed pool of objects with indices, or a single owner and
   borrowed references.                                    */
```

Using them correctly

```
/* --- 1. ALWAYS make_unique / make_shared --- */
        auto p = std::make_unique<Widget>(args);   /* yes */
        std::unique_ptr<Widget> q{new Widget(args)}; /* avoid */
/* make_shared is also ONE allocation instead of two. And in
   C++14 and earlier, the make_ forms avoided a real exception
   -safety hole in expressions like f(unique_ptr(new A),
   unique_ptr(new B)).

/* --- 2. NEVER two owners from one raw pointer --- */
        Widget *raw = new Widget;
        std::unique_ptr<Widget> a{raw};
        std::unique_ptr<Widget> b{raw};   /* DOUBLE DELETE */

/* --- 3. PASS BY REFERENCE unless transferring ownership --- */
        void use(const Widget& w);              /* borrows */
        void use(Widget *w);                    /* borrows,
                                                   nullable  */
        void take(std::unique_ptr<Widget> w);   /* TAKES */
        void reseat(std::unique_ptr<Widget>& w);/* may replace */

        void bad(const std::unique_ptr<Widget>& w);
/* That last one is a common mistake: it borrows, but forces
   the caller to have a unique_ptr specifically. Take
   `const Widget&` instead - then any owner works.

/* --- 4. DO NOT store a raw pointer to something you do not
       control --- */
        class Bad {
                Widget *w_;             /* who owns this?
                                           will it outlive
                                           me?               */
        };
/* If the answer is "the caller guarantees it", say so in a
   comment and take it as a reference in the constructor. If
   it is not guaranteed, the design is wrong.

/* --- 5. FOR A POLYMORPHIC BASE, virtual destructor --- */
        class Base { public: virtual ~Base() = default; };
        std::unique_ptr<Base> p = std::make_unique<Derived>();
/* Without the virtual destructor, ~Derived never runs.
   (shared_ptr is the exception - it captures the deleter at
   construction, so it destroys correctly even without one.
   Do not rely on that.)                                  */
```

Ownership without a heap

```
/* On a target with no dynamic allocation, ownership still
   matters. The patterns: */

/* --- 1. A STATIC POOL WITH INDICES --- */
template<typename T, size_t N>
class Pool {
        std::array<std::optional<T>, N> slots_{};
public:
        struct Handle {
                uint8_t index = 0xFF;
                bool valid() const { return index < N; }
        };

        Handle acquire()
        {
                for (size_t i = 0; i < N; i++)
                        if (!slots_[i]) {
                                slots_[i].emplace();
                                return {static_cast<uint8_t>(i)};
                        }
                return {};      /* exhausted - a BOUNDED
                                   failure                  */
        }

        void release(Handle h)
                { if (h.valid()) slots_[h.index].reset(); }

        T *get(Handle h)
                { return h.valid() && slots_[h.index]
                         ? &*slots_[h.index] : nullptr; }
};
/* A HANDLE IS SMALLER THAN A POINTER, survives the pool
   moving, and can be validated. A generation counter added to
   the handle catches use-after-release:                   */
        struct Handle { uint8_t index; uint8_t generation; };
/* which is the standard "generational index" pattern, and it
   turns a dangling reference into a detectable error.

/* --- 2. SINGLE OWNER, BORROWED REFERENCES --- */
        class System {
                Uart   uart_{UART0_BASE};   /* System OWNS
                Sensor sensor_{&uart_};        these  */
                Logger logger_{&uart_};
        };
/* Members are constructed in declaration order and destroyed
   in reverse (chapter 03), so `uart_` outlives its users by
   construction. No allocation, no smart pointers, and the
   lifetimes are provable by reading the class.

/* --- 3. STATIC STORAGE WITH PLACEMENT NEW --- */
        alignas(Driver) static std::byte storage[sizeof(Driver)];
        Driver *drv = nullptr;

        void init() { drv = new (storage) Driver{cfg}; }
        void deinit() { drv->~Driver(); drv = nullptr; }
/* You control exactly when construction happens - useful when
   it must be after clock setup (chapter 01).            */
```

How it shows up

Symptom	Cause
Double free	Two smart pointers constructed from one raw pointer
Derived destructor never runs	Base destructor not `virtual`
Memory grows steadily	`shared_ptr` cycle — break it with `weak_ptr`
Hot path slower than expected	Copying `shared_ptr` — atomic refcounts
Cache line contention across cores	Shared refcount being modified by several threads
Destructor runs on an unexpected thread	`shared_ptr` — the last owner destroys it, wherever that is
`unique_ptr` is 16 bytes	A stateful deleter — use a stateless functor
"use of deleted function" copying a `unique_ptr`	Correct — it is move-only
Caller must have a `unique_ptr` to call your function	Take `const T&` instead
Use-after-free with a pool	No generation counter in the handle
Object outlives what it points to	Raw member pointer with no lifetime guarantee

Check yourself

- ✓ Say what each pointer type communicates about ownership.
- ✓ State the parameter conventions for taking versus borrowing.
- ✓ Prove `unique_ptr` has no size or code overhead.
- ✓ Write a custom deleter for a file descriptor and for a hardware channel.
- ✓ Explain the `using pointer =` trick.
- ✓ List four costs of `shared_ptr` and say when it is genuinely right.
- ✓ Break a reference cycle with `weak_ptr`.
- ✓ Give five rules for using smart pointers correctly.
- ✓ Design a static pool with generational handles and say what it detects.
- ✓ Express ownership in a heap-free system three different ways.

Inheritance, virtual functions and the vtable

How runtime polymorphism is implemented, exactly what it costs, and the four alternatives that give you the same flexibility without an indirect call. On embedded the answer is often "not virtual" — but you need to know the mechanism to make that judgement.

The vtable

```
class Shape {
public:
        virtual ~Shape() = default;
        virtual int area() const = 0;
        virtual void draw() const = 0;
};

class Circle : public Shape {
        int r_;
public:
        int area() const override { return 3 * r_ * r_; }
        void draw() const override { ... }
};

OBJECT LAYOUT of a Circle on AArch64:

   +0   __vptr    -----------+   8 bytes, ALWAYS FIRST
   +8   r_                   |   4 bytes (+ 4 padding)
   = 16 bytes total          |
                             v
   Circle's VTABLE (one per CLASS, in .rodata):
      [0]  offset-to-top   0
      [1]  typeinfo ptr    -> Circle's type_info (RTTI)
      [2]  &Circle::~Circle          (complete)
      [3]  &Circle::~Circle          (deleting)
      [4]  &Circle::area
      [5]  &Circle::draw

A CALL:
     shape->area();
compiles to:
     ldr  x8, [x0]           ; load the vptr
     ldr  x8, [x8, #32]      ; load the slot
     blr  x8                 ; indirect call

THREE INSTRUCTIONS AND TWO DEPENDENT LOADS, versus one
`bl` for a direct call.

THE COSTS, precisely:
  · 8 bytes per OBJECT for the vptr
  · one vtable per CLASS in .rodata
  · two dependent loads before the call - a potential
    cache miss each
  · an INDIRECT branch, which the predictor must learn
    (CA chapter 12)
  · NO INLINING, unless the compiler can prove the dynamic
    type - which blocks every downstream optimisation

THAT LAST POINT IS USUALLY THE LARGEST COST. The call
itself is a few cycles; the lost inlining can be a factor
of two on small functions.
```

The rules that matter

```
/* --- 1. A POLYMORPHIC BASE NEEDS A VIRTUAL DESTRUCTOR --- */
        class Base { public: ~Base(); };        /* NOT virtual */
        Base *p = new Derived;
        delete p;               /* ~Derived NEVER RUNS -
                                   UNDEFINED BEHAVIOUR       */

        class Base { public: virtual ~Base() = default; };
/* -Wnon-virtual-dtor / -Wdelete-non-virtual-dtor catch this.
   Enable them.

   THE EXCEPTION: if a base is never deleted through a base
   pointer, a PROTECTED non-virtual destructor is correct and
   cheaper:                                                  */
        class Interface {
        protected:
                ~Interface() = default;         /* cannot
                                                   delete
                                                   through
                                                   this      */
        public:
                virtual void run() = 0;
        };

/* --- 2. ALWAYS WRITE `override` --- */
        class Derived : public Base {
                void draw() const override;     /* checked */
                void draw();                    /* silently a
                                                   NEW
                                                   function -
                                                   const
                                                   mismatch  */
        };
/* -Wsuggest-override, -Winconsistent-missing-override.
   `override` turns a silent bug into a compile error, and
   costs one word.

/* --- 3. `final` enables DEVIRTUALISATION --- */
        class Circle final : public Shape { ... };
        void f(Circle& c) { c.area(); }   /* the compiler KNOWS
                                             the type -> a
                                             DIRECT, INLINABLE
                                             call            */
/* Mark leaf classes and non-overridden virtuals `final`. It
   is free and it recovers the inlining.

/* --- 4. NEVER CALL A VIRTUAL FROM A CONSTRUCTOR --- */
/* During Base's constructor the vptr points at BASE's vtable
   (chapter 03). The override is not called. Use two-phase
   init.

/* --- 5. SLICING --- */
        void f(Shape s);        /* BY VALUE - only the Shape
                                   part is copied           */
        Circle c;
        f(c);                   /* SLICED - r_ is lost, and
                                   the vptr is Shape's      */
/* Always pass polymorphic types by reference or pointer.
   Making the base abstract prevents it entirely, because
   `Shape s` will not compile.                              */
```

```
/* --- 6. DEFAULT ARGUMENTS ARE STATICALLY BOUND --- */
        class Base    { virtual void f(int x = 1); };
        class Derived { void f(int x = 2) override; };
        Base *p = new Derived;
        p->f();                 /* calls Derived::f(1) - the
                                   DEFAULT came from Base   */
/* Do not use default arguments on virtual functions.      */
```

Multiple and virtual inheritance

```
/* MULTIPLE INHERITANCE from interfaces is fine and cheap: */
        class Readable  { public: virtual int read() = 0; };
        class Writable  { public: virtual int write(int) = 0; };
        class Port : public Readable, public Writable { ... };

/* LAYOUT: TWO vptrs, one per base. And a `Writable*` obtained
   from a `Port*` is at a NON-ZERO OFFSET, so:            */
        Port p;
        Writable *w = &p;       /* w != (void*)&p ! */
/* The compiler adjusts the pointer. Casting back and forth
   with reinterpret_cast rather than static_cast breaks
   silently - which is one reason C-style casts are dangerous
   in C++.

/* AND THE THUNK: calling through Writable* needs `this`
   adjusted before entering Port's function, so the vtable
   entry points at a small thunk that does the subtraction.
   You will see these in disassembly as tiny functions named
   `non-virtual thunk to Port::write`.

/* VIRTUAL INHERITANCE - the diamond: */
        class Base { int x; };
        class A : virtual public Base {};
        class B : virtual public Base {};
        class D : public A, public B {};    /* ONE Base */

/* THE COST is substantial: a virtual base pointer per
   subobject, an extra indirection to reach Base's members,
   and complicated construction ordering (the most-derived
   class constructs the virtual base).

   ON EMBEDDED: avoid virtual inheritance entirely. If you
   need the diamond, you almost certainly want composition or
   pure interfaces with no data.                          */

/* THE INTERFACE RULE that avoids all of this:
     a class with virtual functions has NO DATA MEMBERS
     a class with data members has NO VIRTUAL FUNCTIONS and is
     not inherited from
   Then multiple inheritance is only ever from interfaces, and
   the diamond cannot arise.                              */
```

> **PREFER COMPOSITION TO INHERITANCE**
> Inheritance couples the derived class to the base's implementation, its layout, and its future changes. Composition — holding a member and forwarding — couples only to the interface. The C++ Core Guidelines put it as: use inheritance for *substitutability* (an interface), and composition for *reuse*. Almost every "share this code between classes" problem is composition, not inheritance.

The four alternatives

```
/* --- 1. TEMPLATES: static polymorphism (chapter 06) --- */
template<typename Sensor>
void sample_loop(Sensor& s)
{
        while (running)
                log(s.read());          /* resolved at COMPILE
                                           time, INLINED     */
}
/* ZERO cost, full inlining. The type set must be known at
   compile time, and each instantiation is a separate copy of
   the code.

/* --- 2. CRTP (chapter 06) --- */
template<typename D>
class SensorBase {
        D& self() { return static_cast<D&>(*this); }
public:
        int read() { return self().convert(self().read_raw()); }
};
/* An interface with shared implementation, statically
   dispatched.

/* --- 3. std::variant + std::visit (chapter 08) --- */
        using AnySensor = std::variant<Thermistor, Photodiode,
                                       Hall>;

        std::array<AnySensor, 4> sensors;

        for (auto& s : sensors)
                std::visit([](auto& sensor)
                        { log(sensor.read()); }, s);

/* A HETEROGENEOUS CONTAINER with no heap and no vtable. The
   dispatch is a jump table on the variant's index - one
   indirect branch, but the target is a known small set and
   the functions CAN be inlined into the visitor.

   THE TRADE: the type list is closed. Adding a sensor type
   means recompiling, which for firmware is fine and for a
   plugin system is not.

/* --- 4. A FUNCTION POINTER TABLE: the C way, still good --- */
        struct DriverOps {
                int  (*read)(void *ctx);
                int  (*write)(void *ctx, int v);
                void (*close)(void *ctx);
        };
        struct Driver {
                const DriverOps *ops;
                void *ctx;
        };
        d.ops->read(d.ctx);
/* Exactly a hand-rolled vtable - and this is precisely what
   the Linux kernel's file_operations is (Linux chapter 20).
   It is explicit, has no language machinery behind it, and
   costs the same indirect call.

/* CHOOSING:

     types known at compile time, one type per call site
```

```
          -> TEMPLATES
     interface with shared implementation, static
          -> CRTP
     small closed set, heterogeneous container, no heap
          -> VARIANT
     open set, runtime plugins, ABI boundary
          -> VIRTUAL (or an ops table)

   AND THE HONEST NOTE: virtual functions are not expensive
   in absolute terms. If the function does meaningful work,
   the indirect call is noise. The cost that matters is lost
   inlining on SMALL functions called in a loop - and that is
   the case where an alternative pays.                    */
```

Measuring the cost

```
/* --- SIZE --- */
        static_assert(sizeof(NonPolymorphic) == 4);
        static_assert(sizeof(Polymorphic) == 16);
                        /* 8 for the vptr + 4 + padding */

/* On an object you allocate a thousand of, 8 bytes each is
   8 KB. On a microcontroller that is a real consideration.

/* --- SEE THE VTABLES --- */
        clang++ -Xclang -fdump-vtable-layouts -c file.cpp
        nm -C prog.elf | grep vtable
        objdump -s -j .rodata prog.elf     /* they live here */

/* --- CODE SIZE --- */
        bloaty prog.elf -d symbols
/* Look for: vtables, typeinfo objects, thunks, and the
   __cxa_pure_virtual handler. With -fno-rtti the typeinfo
   disappears; with -fno-exceptions much of the rest does.

/* --- WHETHER A CALL WAS DEVIRTUALISED --- */
        gcc -fdump-ipa-devirt
        clang -Rpass=devirt
/* Or simply read the assembly (compilers chapter 16): a `bl`
   to a named function was devirtualised; `ldr`+`blr` was not.

/* --- WHAT HELPS DEVIRTUALISATION --- */
        final on classes and on individual virtual functions
        -fwhole-program or LTO
        anonymous namespaces, which prove no external
                overrides exist
        passing concrete types rather than base references
        where the call site knows

/* --- AND THE FLAGS THAT REMOVE THE MACHINERY --- */
        -fno-rtti               /* no typeinfo, no
                                   dynamic_cast            */
        -fno-exceptions
        -fno-threadsafe-statics
/* All three are standard for embedded C++ (chapter 01), and
   together they typically remove tens of kilobytes.      */
```

RTTI

```
#include <typeinfo>

        Shape *s = get_shape();

        if (Circle *c = dynamic_cast<Circle *>(s)) {
                use(*c);                /* it was a Circle */
        }
        Circle& r = dynamic_cast<Circle&>(*s);   /* THROWS
                                                    on failure */

        if (typeid(*s) == typeid(Circle)) { ... }
        const char *name = typeid(*s).name();   /* MANGLED */

/* THE COST: a typeinfo object per polymorphic class, plus a
   runtime walk of the inheritance graph for dynamic_cast -
   which is not constant time with multiple inheritance.

/* AND -fno-rtti REMOVES IT ENTIRELY, which is what embedded
   builds do. Then dynamic_cast and typeid are compile
   errors.

/* THE ALTERNATIVE when you need to recover the concrete type:
   put a tag in the base and use static_cast:              */
        class Shape {
        public:
                enum class Kind { Circle, Square };
                Kind kind() const { return kind_; }
                virtual ~Shape() = default;
        protected:
                explicit Shape(Kind k) : kind_(k) {}
        private:
                Kind kind_;
        };

        if (s->kind() == Shape::Kind::Circle)
                auto *c = static_cast<Circle *>(s);

/* This is LLVM's own idiom - its `isa<>` and `dyn_cast<>`
   are exactly this, built on a kind field, and LLVM is
   compiled with -fno-rtti for the reason above.

/* AND THE BETTER ANSWER, usually: if you are asking what
   concrete type something is, the interface is probably
   missing a virtual function that would let you avoid
   asking.                                                 */
```

How it shows up

Symptom	Cause
Derived destructor never runs; memory leaks	Base destructor not `virtual`
An override is silently not called	Signature mismatch — `override` would have caught it
Object loses its derived data	Slicing — passed by value
Wrong default argument used	Defaults are statically bound on virtual functions
Virtual call in constructor calls the base version	The vptr is not yet the derived one

Symptom	Cause
Pointer comparison fails after a cast	Multiple inheritance — a base pointer is at an offset
Crash after `reinterpret_cast` between base and derived	Same — use `static_cast`
Objects 8 bytes larger than expected	The vptr
Small virtual function is a bottleneck	Lost inlining — mark `final`, or use a template
`dynamic_cast` is a compile error	`-fno-rtti` — use a kind tag
Link error: `__cxa_pure_virtual`	A pure virtual called during construction, or missing runtime support
Tens of kilobytes of typeinfo in the binary	RTTI enabled — turn it off

Check yourself

- ✓ Draw an object's layout and its vtable, and write out the three instructions of a virtual call.
- ✓ List the five costs of a virtual call and say which usually dominates.
- ✓ Explain why a polymorphic base needs a virtual destructor, and the protected exception.
- ✓ Explain what `override` and `final` each buy.
- ✓ Explain slicing and how to make it impossible.
- ✓ Explain why a base pointer under multiple inheritance is at an offset.
- ✓ State the interface rule that prevents the diamond.
- ✓ Give four alternatives to virtual dispatch and say when each fits.
- ✓ Measure vtable and typeinfo cost in a real binary.
- ✓ Replace `dynamic_cast` with a kind tag and explain LLVM's use of it.

Exceptions and error-handling strategies

How C++ exceptions actually work, what they cost, and why most embedded projects disable them. Then the alternatives — and one of them, `std::expected`, is genuinely better than either exceptions or error codes.

How they work

```
throw MyError{42};
     |
1. ALLOCATE the exception object. __cxa_allocate_exception
   uses malloc, falling back to an emergency static buffer.
     |
2. __cxa_throw begins UNWINDING.
     |
3. PHASE 1 - SEARCH. Walk up the stack using the .eh_frame
   unwind tables (compilers chapter 14), asking each frame's
   "personality routine" whether it has a matching handler.
   NOTHING IS DESTROYED YET.
     |
4. If no handler is found -> std::terminate. This is why an
   uncaught exception can abort with the stack intact.
     |
5. PHASE 2 - CLEANUP. Walk up again, this time running each
   frame's destructors and landing pads, and transfer
   control to the handler.
     |
catch (const MyError& e) { ... }

THE TWO-PHASE DESIGN exists so that if no handler exists,
the program terminates with the throwing frame still on the
stack - which makes the core dump useful.

THE IMPLEMENTATION IS TABLE-DRIVEN ("zero-cost"):
  · NO code on the non-throwing path. No flag to set, no
    branch, no register saved. A function that never throws
    runs exactly as fast as the C equivalent.
  · The cost is entirely in DATA: .eh_frame and
    .gcc_except_table describe, for every address, what to
    destroy and where the handlers are.

SO THE HONEST COST is:
  RUNTIME (happy path)   zero
  RUNTIME (throwing)     microseconds - table lookup,
                         unwinding, allocation. NOT bounded.
  CODE SIZE              typically 10-20% larger binary
  RAM                    a heap allocation per throw
  DETERMINISM            none - the unwind time depends on
                         stack depth and table contents
```

Why embedded disables them

```
/* -fno-exceptions is the default choice in embedded C++, and
   the reasons are concrete rather than dogmatic:         */

   1. CODE SIZE. The tables are 10-20% of the binary, and the
      unwinder itself (libgcc_eh or libunwind) is tens of
      kilobytes. On a 256 KB part that is decisive.

   2. NON-DETERMINISM. Throw time depends on stack depth, the
      number of frames with destructors, and table lookups.
      A hard real-time deadline cannot accommodate an
      unbounded operation on any path.

   3. THE ALLOCATION. __cxa_allocate_exception calls malloc.
      On a system with no heap that is a link error; on one
      with a heap it is an allocation on the error path, which
      is exactly where you least want one.

   4. WRITING EXCEPTION-SAFE CODE IS HARD, and the
      consequences of getting it wrong are subtle - a
      half-updated data structure after an unwind is worse
      than an error code that was ignored.

   5. THE ECOSYSTEM. Vendor SDKs, RTOS APIs and HALs are C.
      An exception cannot propagate through a C stack frame
      (there are no unwind tables), so it terminates.

   BUILD WITH:
        -fno-exceptions -fno-unwind-tables
        -fno-asynchronous-unwind-tables

   WHAT CHANGES:
     · `throw` and `try`/`catch` are compile errors
     · std::terminate is called where the library would throw
     · new returns nullptr if you use std::nothrow, otherwise
       it terminates - so use the nothrow form
     · vector::at, optional::value, variant::get become
       unusable - use operator[], *opt, get_if
     · noexcept is implied everywhere

   MEASURE IT ON YOUR OWN CODE before deciding. On embedded
   Linux with megabytes of flash, exceptions may be entirely
   affordable, and the argument is then only about
   determinism.                                           */
```

> **THE ONE THING EXCEPTIONS GENUINELY DO BETTER**
>
> They cannot be ignored. An error code returned and not checked is silent; an exception not caught terminates loudly. And they propagate through call chains that have no way to return a value — most importantly constructors, which is why a constructor that can fail either throws or requires a two-phase init. Every alternative below has to answer that second point.

std::expected

```
#include <expected>     /* C++23; std::optional plus an error */

/* THE BEST OF BOTH: a value or an error, in the return type,
   with no allocation, no unwinding, and no way to ignore it
   accidentally.                                              */

enum class Error { Timeout, Nack, BusBusy, BadArgument };

std::expected<uint16_t, Error> read_register(uint8_t addr)
{
        if (addr > MAX_REG)
                return std::unexpected(Error::BadArgument);

        if (!bus_acquire())
                return std::unexpected(Error::BusBusy);

        auto v = bus_read(addr);
        if (!v)
                return std::unexpected(Error::Timeout);

        return *v;              /* the success value */
}

        auto r = read_register(0x10);
        if (r) {
                use(*r);
        } else {
                log(r.error());
        }

        uint16_t v = read_register(0x10).value_or(0);

/* AND IT COMPOSES - monadic operations (C++23): */
        auto result = read_register(0x10)
                .and_then([](uint16_t v)
                        { return validate(v); })
                .transform([](uint16_t v)
                        { return v * 2; })
                .or_else([](Error e)
                        { return fallback(e); });

/* LAYOUT: a union of the value and the error, plus a
   discriminant. INLINE, no allocation - typically
   max(sizeof(T), sizeof(E)) + alignment.

   static_assert(sizeof(std::expected<uint16_t, Error>) == 4);

/* MARK IT [[nodiscard]] and ignoring it becomes a warning: */
        [[nodiscard]] std::expected<uint16_t, Error>
                read_register(uint8_t addr);

/* IF YOUR TOOLCHAIN LACKS C++23, tl::expected is a
   header-only implementation with the same interface, and
   it is widely used in embedded projects for exactly this
   reason.                                                 */
```

The other strategies

```
/* --- 1. ERROR CODES, the C way ------------------------- */
        Status read(uint8_t addr, uint16_t *out);
        if (read(0x10, &v) != Status::Ok) { ... }
/* PROS: universal, no machinery, works with C.
   CONS: out-parameters, ignorable, no composition, and the
   value cannot be const.
   FIX THE IGNORABILITY: */
        [[nodiscard]] Status read(...);

/* --- 2. optional, when there is only one failure mode --- */
        std::optional<uint16_t> read(uint8_t addr);
/* Simpler than expected when the caller does not need to
   know WHY.

/* --- 3. AN ERROR STATE ON THE OBJECT, sticky ------------ */
class Bus {
        Error last_ = Error::None;
public:
        uint16_t read(uint8_t a)
        {
                if (last_ != Error::None) return 0;   /* already
                                                         failed */
                ...
        }
        Error error() const { return last_; }
        void clear_error() { last_ = Error::None; }
        explicit operator bool() const
                { return last_ == Error::None; }
};
        bus.write(0x10, 1);
        bus.write(0x11, 2);
        bus.write(0x12, 3);
        if (!bus) handle(bus.error());   /* CHECK ONCE, after
                                            a sequence       */
/* THE STICKY-ERROR PATTERN is genuinely good for a sequence
   of hardware operations: no per-call checking, and the
   first failure suppresses the rest so nothing operates on
   garbage. It is how iostreams work, and how many HAL
   layers should.

/* --- 4. ASSERT AND ABORT, for programmer errors ---------- */
        void set_channel(uint8_t ch)
        {
                assert(ch < NUM_CHANNELS);   /* a BUG, not a
                                                runtime error */
                ...
        }
/* DISTINGUISH THE TWO CASES, and this is the important
   distinction in the whole chapter:

     A PROGRAMMER ERROR - a precondition violated, an invalid
     index, a null where one is impossible - is a BUG. Assert,
     and fail fast. Returning an error code invites the caller
     to continue with a broken invariant.

     A RUNTIME ERROR - the hardware timed out, the input was
     malformed, the resource is busy - is an EXPECTED
     CONDITION. Return it.

   Conflating them produces either code full of unreachable
```

```
   error handling, or bugs papered over as failures.      */

/* --- 5. CONSTRUCTORS THAT CANNOT FAIL ------------------- */
/* The problem exceptions solve. Without them: */

        /* (a) two-phase init */
        class Device {
                bool ok_ = false;
        public:
                Device() = default;
                bool init(uintptr_t base);   /* returns success */
                explicit operator bool() const { return ok_; }
        };

        /* (b) a static factory returning expected */
        class Device {
                explicit Device(uintptr_t base);   /* private,
                                                      cannot
                                                      fail    */
        public:
                static std::expected<Device, Error>
                create(uintptr_t base)
                {
                        if (!probe(base))
                                return std::unexpected(
                                        Error::NotPresent);
                        return Device{base};
                }
        };
        auto d = Device::create(0x40000000);

/* (b) IS THE BETTER PATTERN: there is no "constructed but
   invalid" state to check for, and the type system enforces
   that you handled the failure before you have a Device.  */
```

Exception safety, if you do use them

```
/* FOUR GUARANTEES a function can offer: */

   NOTHROW      it never throws. Mark it `noexcept`.
   STRONG       if it throws, the program state is UNCHANGED -
                the operation is transactional.
   BASIC        if it throws, everything is still VALID and
                destructible, but possibly modified. No leaks,
                no broken invariants.
   NONE         all bets are off. Unacceptable.

/* THE BASIC GUARANTEE IS THE MINIMUM. Achieve it with RAII
   (chapter 02): if every resource is owned by an object,
   unwinding releases everything automatically.

/* THE STRONG GUARANTEE, via copy-and-swap: */
        void Container::insert(const T& v)
        {
                Container tmp = *this;  /* may throw - harmless */
                tmp.do_insert(v);       /* may throw - harmless */
                swap(*this, tmp);       /* noexcept - COMMITS */
        }
/* Do all the throwing work on a copy, then commit with an
   operation that cannot fail. Expensive, and the only
   general way to be transactional.

/* noexcept, and why it matters: */
        void f() noexcept;
/* If f throws anyway, std::terminate is called IMMEDIATELY -
   no unwinding. So `noexcept` is a promise, not a filter.

   MARK noexcept:
     · move constructors and move assignment (chapter 03 -
       vector depends on it)
     · destructors (implicitly noexcept already)
     · swap
     · anything genuinely trivial
   DO NOT mark it speculatively: removing it later is an ABI
   break.

/* DESTRUCTORS MUST NOT THROW. They are implicitly noexcept,
   and a throwing destructor during unwinding terminates the
   program. If a destructor performs an operation that can
   fail - closing a file, flushing a buffer - either swallow
   the error or provide an explicit close() the user calls
   first.                                                  */
```

Interoperating with C

```
/* An exception must NEVER propagate through a C stack frame.
   There are no unwind tables for it, and the behaviour is
   undefined - in practice, terminate.                    */

/* SO EVERY C CALLBACK NEEDS A BARRIER: */
extern "C" int my_callback(void *ctx, int arg) noexcept
{
        try {
                auto *self = static_cast<Handler *>(ctx);
                return self->handle(arg);
        } catch (const std::exception& e) {
                log_error(e.what());
                return -1;
        } catch (...) {
                return -1;
        }
}

/* THE `noexcept` ON AN extern "C" FUNCTION is the belt and
   braces: even if a catch is missed, terminate happens HERE,
   at a diagnosable point, rather than corrupting the C
   caller's stack.

/* AND THE SAME AT EVERY BOUNDARY:
     · a signal handler
     · a thread entry function
     · an interrupt handler (in the rare case C++ is used
       there)
     · anything registered with a C library
     · a DLL/shared-library export

   RULE: `extern "C"` and `noexcept` go together, with a
   catch-all inside.                                      */
```

Choosing

Context	Strategy
Bare metal, hard real-time	`-fno-exceptions`; `expected` or error codes; assert for bugs
Bare metal, soft real-time	Same — the code size argument usually decides it
Embedded Linux application	Either. `expected` for recoverable errors, exceptions for genuinely exceptional ones
A library with a C API	No exceptions across the boundary; translate at the edge
Kernel or driver code	Never — no runtime support exists
Constructor that can fail	A static factory returning `expected`
Programmer error	`assert`, always — never an error return
Existing codebase	Match it. Mixing two strategies is worse than either

How it shows up

Symptom	Cause
Link error: `__gxx_personality_v0`	Exceptions enabled but no unwinder linked — use `-fno-exceptions`

Symptom	Cause
Link error: `__cxa_throw`, `_Unwind_Resume`	Same
Binary 20% larger than expected	Unwind tables — check with `size -A`
Terminate with no message	An exception escaped a `noexcept` function or a C boundary
Terminate during stack unwinding	A destructor threw
Crash on the error path only	Allocation failure inside `__cxa_allocate_exception`
`vector::at` causes a link error	It throws — use `operator[]`
`new` terminates instead of returning null	Use `new (std::nothrow)`
Data structure half-updated after an error	Only the basic guarantee was provided where strong was needed
`vector` copies instead of moving	Move constructor not `noexcept` (ch. 03)
An error was silently ignored	No `[[nodiscard]]` on the return type
Latency spike on an error path	Unwinding — the reason real-time systems disable it

Check yourself

- ✓ Explain the two-phase unwinding process and why it is two phases.
- ✓ State the four costs of exceptions precisely, including the zero one.
- ✓ Give five reasons embedded projects disable them, and what changes when you do.
- ✓ Say the one thing exceptions do that alternatives must answer for.
- ✓ Use `std::expected` including its monadic operations, and state its layout.
- ✓ Distinguish a programmer error from a runtime error, and handle each correctly.
- ✓ Give two ways to handle a constructor that can fail, and say which is better.
- ✓ Name the four exception-safety guarantees and achieve the strong one.
- ✓ Say when to mark `noexcept` and why it is an ABI commitment.
- ✓ Write a correct C callback barrier.

The C++ memory model, threads and atomics

C++11 gave the language a formal memory model — the first time C or C++ said anything precise about what threads may observe. It maps directly onto the ARM barriers from ARM chapter 21, and it is what makes portable lock-free code possible at all.

The memory model

```
THE CENTRAL RULE:

  A DATA RACE IS UNDEFINED BEHAVIOUR.

A data race exists when two threads access the same memory
location, at least one writes, and the accesses are not
ordered by a happens-before relationship.

NOT "you get one value or the other". Undefined - the
compiler may cache the value in a register forever, split a
store into two, invent a store, or fold the branch away
(compilers chapter 15).

SO EVERY SHARED MUTABLE LOCATION must be either:
  · protected by a mutex, or
  · declared std::atomic

`volatile` IS NOT THE ANSWER. volatile means "this access
is observable, do not elide or reorder it relative to other
volatile accesses". It says NOTHING about atomicity or
about ordering relative to non-volatile accesses. It is for
MMIO (chapter 02), not for threads. This is the single most
common misconception in C++ concurrency.

HAPPENS-BEFORE is established by:
  · sequenced-before, within one thread
  · a mutex unlock, then a lock of the same mutex
  · a release store, then an acquire load that reads it
  · thread creation, and join
  · and transitively through all of the above
```

Atomics

```
#include <atomic>

        std::atomic<int> counter{0};

        counter++;                      /* atomic RMW */
        counter.fetch_add(1);
        counter.store(5);
        int v = counter.load();
        int old = counter.exchange(10);

        int expected = 5;
        if (counter.compare_exchange_strong(expected, 10)) {
                /* it WAS 5, now it is 10 */
        } else {
                /* it was not; `expected` now holds the actual
                   value - note the IN-OUT parameter        */
        }

/* THE WEAK FORM may fail SPURIOUSLY, and is cheaper on
   LL/SC architectures like ARM - so always use it in a
   loop: */
        int old = counter.load();
        int next;
        do {
                next = compute(old);
        } while (!counter.compare_exchange_weak(old, next));

/* IS IT LOCK-FREE? */
        static_assert(std::atomic<int>::is_always_lock_free);
        std::atomic<BigStruct> x;
        assert(x.is_lock_free());       /* probably FALSE -
                                           it uses a hidden
                                           MUTEX             */
/* An atomic larger than the machine's widest atomic
   instruction is implemented with a lock, which on embedded
   is almost never acceptable. Assert lock-freedom on
   anything you rely on.

   ON AARCH64: 1, 2, 4, 8 bytes are lock-free natively, and
   16 bytes are with LSE (ARMv8.1) via CASP.

/* std::atomic_flag is the only type GUARANTEED lock-free
   everywhere: */
        std::atomic_flag lock = ATOMIC_FLAG_INIT;
        while (lock.test_and_set(std::memory_order_acquire))
                ;                       /* a spinlock */
        ...
        lock.clear(std::memory_order_release);
```

Memory orderings

```
/* Six orderings, from strongest to weakest. Each maps to
   specific ARM instructions.                              */

   memory_order_seq_cst      the DEFAULT. Sequential
                             consistency: a single total order
                             of all seq_cst operations, seen
                             identically by every thread.
        ARM: ldar / stlr, plus a dmb ish for stores on some
        implementations.

   memory_order_acquire      a load. Nothing after it in
                             program order may move before it.
        ARM: ldar

   memory_order_release      a store. Nothing before it may
                             move after it.
        ARM: stlr

   memory_order_acq_rel      for read-modify-write: both.
        ARM: ldaxr / stlxr

   memory_order_relaxed      atomicity only. NO ordering
                             guarantees at all.
        ARM: a plain ldr / str

   memory_order_consume      deprecated in practice - every
                             implementation promotes it to
                             acquire.

/* THE RELEASE/ACQUIRE PAIR is the workhorse, and it is
   exactly the ARM pattern from chapter 21: */

        /* producer */
        data = 42;                              /* plain */
        ready.store(true, std::memory_order_release);

        /* consumer */
        if (ready.load(std::memory_order_acquire))
                use(data);      /* GUARANTEED to see 42 */

/* THE RELEASE STORE publishes everything written before it;
   the ACQUIRE LOAD that observes it sees all of that. This is
   RCU's rcu_assign_pointer/rcu_dereference (Linux chapter 12)
   expressed in the language.

/* RELAXED, and when it is correct: */
        std::atomic<uint64_t> packet_count{0};
        packet_count.fetch_add(1, std::memory_order_relaxed);
/* A statistic that nothing else depends on: you need the
   increment to be atomic, and you do not care when other
   threads see it. Relaxed is a plain `ldxr/stxr` (or an LSE
   `ldadd`) with no barrier - meaningfully cheaper.

/* THE COST ON ARM, roughly:
     relaxed     ~ the same as a plain access
     acquire     ldar - a few cycles
     release     stlr - a few cycles
     seq_cst     as above, plus possibly a dmb - tens of
                 cycles under contention
```

```
   USE THE DEFAULT (seq_cst) unless you have measured a
   problem AND can prove the weaker ordering is correct.
   Reasoning about relaxed orderings is genuinely difficult,
   and the failures are unreproducible.                  */
```

THE `VOLATILE` TRAP, STATED ONCE MORE

```
volatile bool ready = false;    // WRONG for threads
ready = true;                   // not atomic, no ordering
```

`volatile` prevents the compiler eliding the access. It does **not** make it atomic, and it emits no barrier — so on ARM the CPU may still reorder it relative to the data it was meant to publish. Java and C# gave `volatile` acquire/release semantics; C and C++ did not. Use `std::atomic` for threads and `volatile` for MMIO, and never confuse them.

Threads and mutexes

```
#include <thread>
#include <mutex>
#include <condition_variable>

        std::thread t{[]{ work(); }};
        std::thread t2{worker_fn, arg1, arg2};

        t.join();               /* wait for it */
        t.detach();             /* let it run independently */
/* A std::thread that is neither joined nor detached calls
   std::terminate in its destructor. That is deliberate:
   silently abandoning a thread is worse.

        std::jthread jt{[](std::stop_token st) {
                while (!st.stop_requested()) work();
        }};                     /* C++20 - joins automatically
                                   in its destructor, and
                                   carries a stop token     */

/* MUTEXES, always via a guard (RAII, chapter 02): */
        std::mutex m;

        {
                std::lock_guard lk{m};          /* C++17 CTAD */
                shared_data++;
        }                                       /* unlocked */

        std::unique_lock lk{m};         /* movable, can unlock
                                           and relock        */
        lk.unlock();
        lk.lock();

        std::scoped_lock lk{m1, m2};    /* SEVERAL mutexes,
                                           deadlock-free
                                           ordering          */

        std::shared_mutex sm;
        { std::shared_lock r{sm}; }     /* many readers */
        { std::unique_lock w{sm}; }     /* one writer */

/* NEVER lock and unlock by hand. An early return or an
   exception between them leaves it locked forever.

/* CONDITION VARIABLES: */
        std::mutex m;
        std::condition_variable cv;
        bool ready = false;

        /* waiter */
        {
                std::unique_lock lk{m};
                cv.wait(lk, []{ return ready; });   /* the
                                                       PREDICATE
                                                       form   */
                consume();
        }

        /* notifier */
        {
                std::lock_guard lk{m};
```

```
                ready = true;
        }
        cv.notify_one();

/* THE PREDICATE FORM IS MANDATORY. Without it a SPURIOUS
   WAKEUP - which is permitted and does happen - returns from
   wait() with the condition false. The predicate overload
   loops for you.

/* AND THE LOST-WAKEUP RULE: set the condition WHILE HOLDING
   the mutex, then notify. Notifying without the lock is
   allowed and sometimes faster, but setting the flag without
   it is a race.                                            */
```

Patterns

```
/* --- SINGLE-PRODUCER SINGLE-CONSUMER RING, lock-free ---- */
template<typename T, size_t N>
class SpscQueue {
        static_assert((N & (N - 1)) == 0, "N must be a power
                                           of two");
        std::array<T, N> buf_;
        alignas(64) std::atomic<size_t> head_{0};   /* producer */
        alignas(64) std::atomic<size_t> tail_{0};   /* consumer */

public:
        bool push(const T& v)
        {
                size_t h = head_.load(std::memory_order_relaxed);
                size_t t = tail_.load(std::memory_order_acquire);

                if (h - t >= N) return false;   /* full */

                buf_[h & (N - 1)] = v;
                head_.store(h + 1, std::memory_order_release);
                return true;
        }

        bool pop(T& out)
        {
                size_t t = tail_.load(std::memory_order_relaxed);
                size_t h = head_.load(std::memory_order_acquire);

                if (h == t) return false;       /* empty */

                out = buf_[t & (N - 1)];
                tail_.store(t + 1, std::memory_order_release);
                return true;
        }
};

/* THE THREE THINGS THAT MAKE IT CORRECT:
     1. each index is written by ONE thread only, so no CAS is
        needed
     2. the release store publishes the DATA written before
        it; the acquire load on the other side sees it
     3. alignas(64) puts head_ and tail_ on SEPARATE CACHE
        LINES - without it, the producer's store to head_
        invalidates the consumer's cached tail_ on every
        operation. FALSE SHARING (CA chapter 15), and it can
        cost an order of magnitude.

/* --- A SPINLOCK, when a mutex is too heavy --------------- */
class Spinlock {
        std::atomic_flag flag_ = ATOMIC_FLAG_INIT;
public:
        void lock()
        {
                while (flag_.test_and_set(
                                std::memory_order_acquire)) {
                        while (flag_.test(
                                std::memory_order_relaxed))
                                __builtin_arm_yield();
                                /* the ARM `yield` hint -
                                   relaxes the pipeline and
                                   helps SMT/cluster peers  */
```

```
                }
        }
        void unlock()
                { flag_.clear(std::memory_order_release); }
};
/* THE TEST-AND-TEST-AND-SET SHAPE matters: spinning on
   test_and_set writes the cache line every iteration,
   bouncing it between cores. Spinning on a relaxed `test`
   only reads, so the line stays shared until it is actually
   free.

/* --- CALL ONCE --- */
        std::once_flag flag;
        std::call_once(flag, []{ expensive_init(); });

/* --- AND THE SIMPLEST CORRECT SINGLETON --- */
        Device& device() {
                static Device instance;  /* thread-safe
                                            initialisation is
                                            GUARANTEED since
                                            C++11            */
                return instance;
        }
/* -fno-threadsafe-statics removes the guard variable, which
   is correct only if you know initialisation is
   single-threaded (chapter 01).                          */
```

On embedded

```
/* std::thread needs an OS. On bare metal you have interrupts
   and possibly an RTOS instead - but the MEMORY MODEL still
   applies, and atomics are still the right tool.        */

/* --- SHARING WITH AN INTERRUPT HANDLER --- */
        std::atomic<uint32_t> sample_count{0};
        std::atomic<bool>     data_ready{false};
        Sample buffer[N];               /* plain */

        extern "C" void ADC_IRQHandler(void)
        {
                buffer[idx] = read_adc();       /* plain
                                                   stores    */
                data_ready.store(true,
                        std::memory_order_release);
        }

        void main_loop(void)
        {
                if (data_ready.load(std::memory_order_acquire)) {
                        process(buffer);        /* sees the
                                                   stores    */
                        data_ready.store(false,
                                std::memory_order_relaxed);
                }
        }

/* ON A SINGLE CORE, an interrupt cannot interleave with
   itself, so the ordering concern is only the COMPILER's -
   and atomic gives you that for free, portably, instead of a
   `volatile` plus a hand-written barrier.

   ON A MULTI-CORE MCU or an AMP system, the full memory model
   applies exactly as on a big system.

/* --- WHAT std::atomic COMPILES TO on an ARMv7-M --- */
        std::atomic<uint32_t> x;
        x.fetch_add(1);
   ->   a LDREX/STREX loop - no lock, no library call.
        std::atomic<uint64_t> y;        /* on 32-bit ARM */
        y.fetch_add(1);
   ->   possibly a LIBRARY CALL with a lock. Check with
        is_always_lock_free before relying on it.

/* --- AND THE CRITICAL-SECTION ALTERNATIVE --- */
        class InterruptLock { ... };    /* chapter 02 */
        {
                InterruptLock guard;
                shared_struct.field_a = 1;      /* a MULTI-WORD
                shared_struct.field_b = 2;         update      */
        }
/* For anything larger than one atomic word on a single-core
   part, disabling interrupts briefly is simpler and cheaper
   than a lock-free algorithm. Use atomics for single values
   and interrupt masking for compound updates.           */
```

Finding races

```
# ThreadSanitizer - the only tool that reliably finds these:
    g++ -fsanitize=thread -g -O1 prog.cpp
    ./prog

    WARNING: ThreadSanitizer: data race
      Write of size 4 at 0x... by thread T2:
        #0 worker() prog.cpp:15
      Previous read of size 4 at 0x... by thread T1:
        #0 main prog.cpp:22
      Location is global 'counter' of size 4

# ~10x slower, ~5x memory. Run your test suite under it
# nightly; it finds races that will never reproduce under
# ordinary testing.

# HELGRIND, for lock-order problems:
    valgrind --tool=helgrind ./prog

# AND THE STATIC CHECKS:
    clang -Wthread-safety, with annotations:
        class Cache {
                std::mutex m_;
                int data_ GUARDED_BY(m_);
                void update() REQUIRES(m_);
        };
# The compiler then verifies at BUILD TIME that data_ is only
# touched with m_ held. This is genuinely excellent and badly
# underused - it turns a class of race into a compile error.

# ON EMBEDDED, where sanitizers are unavailable:
#   · reason explicitly about every shared variable and write
#     the reasoning down
#   · make everything shared either atomic or interrupt-masked
#   · use static analysis and code review
#   · stress test with an interrupt rate far above the
#     expected one
#   · and prefer designs with a single owner per datum, so
#     the question does not arise
```

How it shows up

Symptom	Cause
Works in debug, fails in release	A race the optimiser exposed — `volatile` instead of `atomic`
Works on one core, fails on many	Missing barriers; the ordering was accidental
A flag is never observed as set	The compiler cached it in a register — needs `atomic`
Data visible after the flag, but stale	Missing release/acquire pairing
Spurious wakeup processes garbage	Condition variable wait without a predicate
Deadlock acquiring two mutexes	Inconsistent order — use `std::scoped_lock`
Terminate on thread destruction	Neither joined nor detached — use `jthread`
Atomic operations are surprisingly slow	`seq_cst` under contention, or not lock-free
Queue throughput collapses with two cores	False sharing — `alignas(64)` the indices

Symptom	Cause
A 64-bit atomic calls into the library	Not lock-free on that target — assert it
Race found by TSan that never reproduces	Real. Fix it — reproducibility is not the test

Check yourself

- ✓ State what a data race is and what the standard says happens.
- ✓ Explain precisely why `volatile` is not a threading tool.
- ✓ Name the ways happens-before is established.
- ✓ Use `compare_exchange` correctly, and say why the weak form needs a loop.
- ✓ Name the six memory orderings and their ARM instructions.
- ✓ Write a release/acquire pair and say exactly what it guarantees.
- ✓ Say when `relaxed` is correct.
- ✓ Explain why a condition variable wait needs a predicate.
- ✓ Write an SPSC ring and justify each ordering and the `alignas`.
- ✓ Explain test-and-test-and-set and the cache-line reason for it.
- ✓ Use atomics to share data with an interrupt handler, and say when to mask instead.
- ✓ Run TSan and use `-Wthread-safety` annotations.

Zero-cost abstraction: reading the generated assembly

C++'s central claim is that its abstractions cost nothing you would not have paid by hand. That claim is checkable in about thirty seconds per case, and this chapter is a series of those checks — the ones that hold, and the ones that do not.

The claim, stated precisely

```
Stroustrup's formulation:

  "What you don't use, you don't pay for. And what you do
   use, you couldn't hand-code any better."

THE FIRST HALF IS ABOUT ABSENCE: a program that uses no
virtual functions carries no vtables; one that throws no
exceptions pays nothing on the happy path.

THE SECOND HALF IS ABOUT PRESENCE: an abstraction whose
types are known at compile time is compiled away entirely.

WHAT MAKES AN ABSTRACTION FREE:
  · the type is known at compile time
  · the function is visible for inlining
  · no indirection the compiler cannot see through
  · no allocation

WHAT MAKES ONE COST:
  · TYPE ERASURE — virtual, std::function, dynamic_cast.
    The compiler cannot know the target, so it cannot
    inline.
  · ALLOCATION — vector, string, shared_ptr, exceptions
  · ATOMIC OPERATIONS — shared_ptr's refcount
  · CODE the abstraction adds that you would not have
    written: bounds checks, refcounts, unwind tables

THE METHOD FOR THE REST OF THIS CHAPTER: write both
versions, compile both at -O2 for aarch64, and diff the
assembly (compilers chapter 16).
```

The ones that are free

```
/* --- std::array versus a C array ------------------------ */
        int sum_c(const int *a, size_t n) {
                int s = 0;
                for (size_t i = 0; i < n; i++) s += a[i];
                return s;
        }
        int sum_cpp(const std::array<int, 4>& a) {
                return std::accumulate(a.begin(), a.end(), 0);
        }
/* -O2: sum_cpp is BETTER - the size is known, so it fully
   unrolls:
        ldp  w1, w2, [x0]
        ldp  w3, w4, [x0, #8]
        add  w1, w1, w2
        add  w3, w3, w4
        add  w0, w1, w3
        ret
   Five instructions, no loop. The C version cannot do this
   because n is a runtime value.

/* --- unique_ptr versus new/delete ----------------------- */
        void f_c()   { Widget *p = new Widget; use(p);
                       delete p; }
        void f_cpp() { auto p = std::make_unique<Widget>();
                       use(p.get()); }
/* IDENTICAL assembly. Byte for byte.

/* --- a class wrapper around a register ------------------ */
        class Reg {
                volatile uint32_t *p_;
        public:
                explicit Reg(uintptr_t a)
                        : p_(reinterpret_cast<volatile uint32_t *>(a)) {}
                uint32_t read() const  { return *p_; }
                void write(uint32_t v) { *p_ = v; }
        };
        void f(Reg r) { r.write(r.read() | 1); }
/* ->  ldr  w1, [x0]
        orr  w1, w1, #1
        str  w1, [x0]
        ret
   Identical to the C version. The class does not exist at run
   time.

/* --- a strong type (chapter 07) ------------------------- */
        void delay_c(uint32_t ms);
        void delay_cpp(Milliseconds ms);
        delay_cpp(100_ms);
/* ->  mov  w0, #100
        b    delay
   The literal suffix, the class, the constructor - all gone.

/* --- a lambda in an algorithm --------------------------- */
        auto n = std::count_if(v.begin(), v.end(),
                               [](int x){ return x > 10; });
/* Compiles to the same loop as a hand-written one, and often
   vectorises where a function pointer would not - because
   the predicate is INLINED and therefore visible to the
   vectoriser (compilers chapter 07).
```

```
/* --- CRTP versus virtual (chapter 06) ------------------- */
        struct Base { virtual int f() = 0; };
        struct D : Base { int f() override { return 42; } };
        int use_virt(Base& b) { return b.f() + 1; }
/* ->  ldr  x8, [x0]        ; vptr
        ldr  x8, [x8]        ; slot
        blr  x8              ; INDIRECT CALL
        add  w0, w0, #1

        template<typename D> struct CBase {
                int f() { return static_cast<D&>(*this).impl(); }
        };
        struct CD : CBase<CD> { int impl() { return 42; } };
        int use_crtp(CD& d) { return d.f() + 1; }
/* ->  mov  w0, #43
        ret
   The entire call chain constant-folded away.           */
```

CHECK IT YOURSELF, IN THIRTY SECONDS

Open godbolt.org, set the compiler to *armv8-a clang* or *ARM64 gcc*, flags to `-O2`, and paste both versions side by side. Every claim in this chapter is verifiable that way, and the habit of verifying rather than believing is the actual skill being taught.

The ones that are not

```
/* --- std::function ---------------------------------------- */
        void apply_fn(std::function<int(int)> f, int x)
                { use(f(x)); }
/* ->  a call through a type-erased vtable, plus possibly a
        heap allocation when the std::function was
        constructed. NOT inlinable.

        template<typename F>
        void apply_tmpl(F f, int x) { use(f(x)); }
        apply_tmpl([](int y){ return y * 2; }, 5);
/* ->  mov  w0, #10
        b    use
   Fully inlined and folded. The SAME lambda, two orders of
   magnitude apart, purely because of type erasure.

   THE EMBEDDED-FRIENDLY MIDDLE GROUND - a fixed-capacity
   inplace_function, or simply a function pointer plus a
   context pointer (the C ops-table idiom, chapter 11).

/* --- shared_ptr ------------------------------------------- */
        void f(std::shared_ptr<Widget> p) { use(*p); }
/* Passing by value: an ATOMIC increment on entry and an
   atomic decrement on exit, each a full barrier on ARM. Pass
   `const shared_ptr&` or, better, `Widget&`.

/* --- std::string ------------------------------------------ */
        void log_cpp(const std::string& s);
        log_cpp("literal");
/* Constructs a temporary std::string: possibly an allocation,
   a copy, and a destruction. Use string_view (chapter 08):
        void log_sv(std::string_view s);
        log_sv("literal");
   ->  two immediates - a pointer and a length. No
        allocation, no strlen at run time.

/* --- .at() versus operator[] ------------------------------ */
        int a(std::vector<int>& v, size_t i) { return v.at(i); }
/* ->  a comparison, a branch, and a call to
        __throw_out_of_range - plus the unwind machinery.
        int b(std::vector<int>& v, size_t i) { return v[i]; }
/* ->  one `ldr`.
   Both are correct choices; know which you are paying for.

/* --- iostreams -------------------------------------------- */
        std::cout << "value: " << x << '\n';
/* Pulls in locale, facets, the whole formatting machinery -
   commonly 100 KB+ on a bare-metal target. std::format
   (C++20) is smaller but still substantial; a hand-rolled
   printf-style function or std::to_chars is what embedded
   code should use.
        std::to_chars(buf, buf + n, x);   /* no allocation, no
                                             locale, fast     */
```

Measuring properly

```
# --- CODE SIZE, per symbol ---
    nm --size-sort -S -C prog.elf | tail -20
    bloaty prog.elf -d symbols,compileunits
    size -A prog.elf

# --- DIFF TWO VERSIONS ---
    g++ -O2 -S -o a.s a.cpp
    g++ -O2 -S -o b.s b.cpp
    diff -u a.s b.s

# --- COUNT INSTRUCTIONS IN A FUNCTION ---
    objdump -d prog.elf | awk '/<myfunc>:/,/^$/' | wc -l

# --- PROVE NO ALLOCATION HAPPENS ---
    /* on bare metal, simply do not provide operator new:
       any accidental allocation becomes a LINK ERROR - the
       strongest guarantee available */

    /* on a hosted system, count them: */
    static std::atomic<size_t> g_allocs{0};
    void *operator new(size_t n) { g_allocs++; return malloc(n); }
    void operator delete(void *p) noexcept { free(p); }

    size_t before = g_allocs;
    hot_path();
    assert(g_allocs == before);         /* in a test */

# --- PROVE A TYPE IS WHAT YOU THINK ---
    static_assert(sizeof(Wrapper) == sizeof(uint32_t));
    static_assert(std::is_trivially_copyable_v<Message>);
    static_assert(std::is_standard_layout_v<RegBlock>);
    static_assert(alignof(Buffer) == 64);

# --- AND ACTUAL TIME, which is the only thing that
#     ultimately matters ---
    perf stat -r 10 ./prog
    /* cycles, instructions, IPC, cache-misses,
       branch-misses (compilers chapter 16) */
```

When the abstraction is not free

```
/* Usually because inlining did not happen. The causes, in
   order of frequency: */

   1. THE DEFINITION IS NOT VISIBLE.
        A member function defined in a .cpp cannot be inlined
        into another translation unit without LTO
        (compilers chapter 12). Define small functions in the
        HEADER.

   2. IT IS TOO LARGE for the inliner's threshold.
        Split it: a small inlinable wrapper around a large
        out-of-line body.
                inline int fast_path(int x) {
                        if (likely(x < 16)) return table[x];
                        return slow_path(x);   /* not inlined,
                                                  and that is
                                                  fine       */
                }

   3. IT IS VIRTUAL and the type is not provable.
        Mark the class or the function `final` (chapter 11),
        or use a template.

   4. IT IS CALLED THROUGH A FUNCTION POINTER or
      std::function.

   5. THE ADDRESS OF A LOCAL ESCAPED, so the variable cannot
      be promoted to a register (compilers chapter 05).

   6. -O0. Nothing is inlined; measuring there tells you
      nothing.

/* FORCE IT, when you have measured a reason: */
        __attribute__((always_inline)) inline void f();
        [[gnu::always_inline]] inline void f();
/* AND FORBID IT, for cold paths that would pollute the
   I-cache: */
        __attribute__((noinline)) void error_path();

/* ASK WHY IT DID NOT HAPPEN: */
        clang -Rpass-missed=inline -Rpass-analysis=inline
        gcc -fopt-info-inline-missed
/* which prints the reason per call site - "cost exceeds
   threshold", "function not inlinable", "recursive". That
   output is the answer far more often than guessing.    */
```

A worked comparison

```
/* A realistic embedded case: a GPIO abstraction. */

/* --- C --- */
        #define GPIO_BASE 0x40020000
        #define GPIO_ODR  (*(volatile uint32_t *)(GPIO_BASE + 0x14))
        static inline void gpio_set(int pin)
                { GPIO_ODR |= (1u << pin); }

/* --- C++ --- */
template<uintptr_t Base>
class GpioPort {
        struct Regs {
                volatile uint32_t MODER, OTYPER, OSPEEDR,
                                  PUPDR, IDR, ODR;
        };
        static Regs *regs()
                { return reinterpret_cast<Regs *>(Base); }
public:
        template<uint8_t Pin>
        class Pin_t {
                static_assert(Pin < 16, "invalid pin");
        public:
                static void set()    { regs()->ODR |=  (1u << Pin); }
                static void clear()  { regs()->ODR &= ~(1u << Pin); }
                static bool read()   { return regs()->IDR &
                                              (1u << Pin); }
        };
};
        using PortA = GpioPort<0x40020000>;
        using LedPin = PortA::Pin_t<5>;

        LedPin::set();

/* BOTH COMPILE TO: */
        movz w8, #0x2000, lsl #16       ; the base
        movk w8, #0x14                  ; + ODR offset
        ldr  w9, [x8]
        orr  w9, w9, #0x20              ; bit 5
        str  w9, [x8]

/* IDENTICAL. And the C++ version additionally gives you:
     · a static_assert on the pin number - an invalid pin is
       a BUILD error
     · named, typed registers instead of offsets
     · LedPin as a TYPE, passable to templates
     · no macros, so no namespace pollution and no
       double-evaluation hazard
     · the port and pin cannot be mismatched, because they
       are one type

   THAT IS THE ARGUMENT for C++ in firmware, in one example:
   the same instructions, with errors moved from run time to
   compile time.                                          */
```

A verification checklist

Claim	How to check
"This wrapper is free"	Diff the assembly against the raw version
"No allocation in this path"	Instrument `operator new`, or omit it entirely
"This type is one word"	`static_assert(sizeof(T) == ...)`
"This is inlined"	Look for the `bl`; or `-Rpass=inline`
"This call is devirtualised"	A named `bl` rather than `ldr` + `blr`
"This is computed at compile time"	It is in `.rodata`; `readelf -x`
"This loop vectorises"	`v` registers in the output; `-fopt-info-vec`
"Exceptions cost nothing here"	`size -A` with and without `-fno-exceptions`
"This is faster"	`perf stat -r 10` — the only claim that needs timing

How it shows up

Symptom	Cause
An abstraction that should be free is not	Inlining did not happen — ask the compiler why
A wrapper adds instructions	Definition not visible; needs to be in the header or LTO
Unexpected `bl` to `operator new`	A hidden allocation — `string`, `function`, `vector`
Indirect call where you expected direct	Virtual and not devirtualised — mark `final`
A lambda is not inlined	Stored in `std::function` — pass as a template parameter
Binary grew after adding one header	iostreams, or a heavy template instantiation
Measured at `-O0` and concluded C++ is slow	Measure at the level you ship
A benchmark shows zero time	The whole thing was optimised away — the result is unused
Assembly identical but the program is slower	Memory bound, not code bound — check `perf stat`

Check yourself

- ✓ State the zero-cost claim precisely and say what makes an abstraction free.
- ✓ Verify on godbolt that `unique_ptr`, `array` and a register wrapper are free.
- ✓ Show that a lambda as a template parameter is free and in `std::function` is not.
- ✓ Name five abstractions that cost, and what each costs.
- ✓ Prove a code path performs no allocation.
- ✓ List six reasons inlining fails, and ask the compiler which applies.
- ✓ Write a templated GPIO abstraction and prove it matches the C version.
- ✓ Say what that abstraction buys beyond the identical instructions.
- ✓ Work the verification checklist against a claim in your own code.

Modern C++ for embedded

A practical assembly of everything in this track: the features worth adopting, the patterns that recur in real firmware, and a coding standard you could hand to a team on Monday.

The adoption list

Feature	Since	Why it earns its place
`enum class`	C++11	No implicit int conversion; explicit underlying type
`nullptr`	C++11	Overload resolution works correctly
`constexpr`	C++11/14	Tables and configuration in flash (ch. 07)
`static_assert`	C++11	Build-time validation of layouts and configuration
`std::array`	C++11	An array that knows its size, at zero cost
`std::unique_ptr`	C++11	Ownership in the type, with custom deleters for handles
`override`, `final`	C++11	Catch signature mistakes; enable devirtualisation
`= delete`	C++11	Make copying a compile error
`<atomic>`	C++11	A real memory model (ch. 13)
`<chrono>`	C++11	Unit-safe durations, entirely `constexpr`
`std::string_view`	C++17	Strings with no allocation
`std::optional`	C++17	Absence without a sentinel
`std::variant`	C++17	A tagged union, exhaustively checked
`if constexpr`	C++17	Replaces most `#ifdef` (ch. 06)
Structured bindings	C++17	Readable destructuring
`[[nodiscard]]`	C++17	Error returns cannot be silently dropped
Guaranteed copy elision	C++17	Return by value is free
`std::span`	C++20	Replaces every pointer-plus-length pair
Concepts	C++20	Comprehensible template errors
Designated initialisers	C++20	Readable configuration structs
`consteval`, `constinit`	C++20	Guarantees about when initialisation happens
`std::bit_cast`	C++20	Type punning without UB (compilers ch. 15)
`std::expected`	C++23	The best error-handling primitive available

Patterns that recur

```
/* --- 1. STRUCTURED BINDINGS + designated initialisers --- */
        struct Config { uint32_t rate; uint8_t gain;
                        bool enabled; };

        constexpr Config cfg{
                .rate    = 48000,       /* C++20 - order must
                .gain    = 3,              match declaration */
                .enabled = true,
        };

        auto [rate, gain, enabled] = cfg;   /* C++17 */

        for (auto& [key, value] : map) { ... }

        if (auto [it, ok] = set.insert(x); ok) { ... }
                                        /* init-statement in
                                           an if - C++17     */

/* --- 2. A TYPED REGISTER, with compile-time field
       checking --- */
template<uint32_t Addr>
struct Register {
        static uint32_t read()
                { return *reinterpret_cast<volatile uint32_t *>(Addr); }
        static void write(uint32_t v)
                { *reinterpret_cast<volatile uint32_t *>(Addr) = v; }

        template<uint8_t Hi, uint8_t Lo>
        struct Field {
                static_assert(Hi < 32 && Lo <= Hi);
                static constexpr uint32_t mask =
                        ((1u << (Hi - Lo + 1)) - 1) << Lo;

                static uint32_t get()
                        { return (read() & mask) >> Lo; }

                static void set(uint32_t v)
                {
                        write((read() & ~mask)
                              | ((v << Lo) & mask));
                }
        };
};
        using CTRL   = Register<0x40000000>;
        using Enable = CTRL::Field<0, 0>;
        using Mode   = CTRL::Field<5, 4>;

        Enable::set(1);
        auto m = Mode::get();
/* Shifts and masks computed at compile time; an out-of-range
   field is a build error (chapter 14 proves the cost).

/* --- 3. A STATE MACHINE with variant ---------------------- */
        struct Idle {};
        struct Connecting { uint32_t started; };
        struct Connected  { uint8_t session; };
        struct Error      { ErrorCode code; };

        using State = std::variant<Idle, Connecting,
                                   Connected, Error>;
```

```
        State next(const State& s, Event e)
        {
                return std::visit([&](const auto& st) -> State {
                        using T = std::decay_t<decltype(st)>;

                        if constexpr (std::is_same_v<T, Idle>) {
                                if (e == Event::Connect)
                                        return Connecting{now()};
                        } else if constexpr (
                                std::is_same_v<T, Connecting>) {
                                if (e == Event::Ack)
                                        return Connected{alloc()};
                                if (now() - st.started > TIMEOUT)
                                        return Error{
                                             ErrorCode::Timeout};
                        }
                        return st;      /* unchanged */
                }, s);
        }
/* EACH STATE CARRIES ITS OWN DATA, the compiler checks that
   every state is handled, and there is no heap. Adding a
   state without handling it fails to compile.

/* --- 4. SPAN EVERYWHERE at interfaces ------------------- */
        size_t encode(std::span<uint8_t> out,
                      std::span<const Sample> in);
/* No length parameters to get out of sync, works with arrays,
   vectors and raw buffers alike.

/* --- 5. CHRONO for every duration ----------------------- */
        using namespace std::chrono_literals;

        void set_timeout(std::chrono::milliseconds t);
        set_timeout(500ms);
        set_timeout(2s);        /* converted correctly */
        set_timeout(500);       /* COMPILE ERROR - good */

        constexpr auto PERIOD = 10ms;
        constexpr auto TICKS  = PERIOD / 1ms;   /* = 10 */

/* --- 6. [[nodiscard]] on every fallible operation -------- */
        [[nodiscard]] std::expected<Reading, Error> read();
        [[nodiscard]] bool try_lock();
        read();                 /* WARNING */

/* --- 7. A COMPILE-TIME DISPATCH TABLE ------------------- */
        constexpr std::array handlers{
                &handle_status, &handle_config, &handle_data,
        };
        static_assert(handlers.size() == NUM_COMMANDS);
        if (cmd < handlers.size())
                handlers[cmd]();
/* In flash, bounds-checked at build time, one indirect
   call.                                                    */
```

Freestanding C++

```
/* On bare metal, much of the standard library is unavailable -
   but the LANGUAGE is entirely available, and the
   header-only parts of the library mostly are too.       */

/* AVAILABLE without a hosted implementation: */
        <type_traits>   <limits>      <cstddef>
        <cstdint>       <utility>     <initializer_list>
        <atomic>        <bit>         <concepts>
        <compare>       <ratio>       <array> (mostly)
        <span>          <string_view> (mostly)
        <algorithm>     (the non-allocating parts)
        <chrono>        (the duration parts)
        <optional>      <variant>     (with -fno-exceptions
                                       caveats)

/* WHAT YOU MUST PROVIDE YOURSELF: */
        /* the runtime support the compiler assumes exists */
        extern "C" void __cxa_pure_virtual() { for (;;) ; }
        extern "C" int  __cxa_atexit(void (*)(void *), void *,
                                     void *) { return 0; }
        extern "C" void __cxa_guard_acquire() { }
        /* or build with -fno-use-cxa-atexit
           -fno-threadsafe-statics and avoid needing them */

        /* operator new, if anything uses it - or DELIBERATELY
           OMIT IT so any use is a link error (chapter 14) */
        void *operator new(size_t) = delete;
        void  operator delete(void *) noexcept = delete;

        /* memcpy, memset - the compiler emits calls to these
           even in freestanding mode (compilers chapter 07) */
        extern "C" void *memcpy(void *d, const void *s, size_t n);

/* THE STARTUP SEQUENCE that must run before main: */
        extern void (*__init_array_start[])(void);
        extern void (*__init_array_end[])(void);

        static void call_constructors(void)
        {
                for (auto **p = __init_array_start;
                     p < __init_array_end; p++)
                   (*p)();
        }
/* Called from the reset handler after copying .data and
   zeroing .bss (compilers chapter 12). If .init_array is
   empty - the goal (chapter 01) - this loop does nothing and
   costs nothing.

/* THE FLAGS: */

        -fno-unwind-tables -fno-asynchronous-unwind-tables
        -ffunction-sections -fdata-sections
        -Wl,--gc-sections -nostdlib
        -Os -std=c++17
```

FIXED-CAPACITY LIBRARY CHOICES

ETL (Embedded Template Library) gives you the STL's interfaces with fixed capacity and no heap: `etl::vector<T, N>`, `etl::map`, `etl::string`, `etl::optional`, state machines and message routing. **Boost.SML** for state machines. **fmt** or `std::to_chars` instead of iostreams. **tl::expected** if you are pre-C++23. Each is header-only and designed for exactly this environment.

A coding standard

```
# Embedded C++ Coding Standard
# ============================

## Build flags (mandatory)
  -std=c++17            (or c++20 where the toolchain allows)
  -fno-exceptions -fno-rtti
  -fno-threadsafe-statics -fno-use-cxa-atexit
  -Wall -Wextra -Wpedantic -Werror
  -Wshadow -Wconversion -Wsign-conversion
  -Wnon-virtual-dtor -Wold-style-cast -Wcast-align
  -Wuseless-cast -Wdouble-promotion -Wformat=2
  -Wsuggest-override
  -ffunction-sections -fdata-sections -Wl,--gc-sections

## Forbidden
  - dynamic allocation after initialisation
  - std::string, std::vector, std::map, std::function
  - iostreams
  - exceptions, dynamic_cast, typeid
  - virtual inheritance
  - C-style casts
  - macros where constexpr, inline or a template works
  - `using namespace` at file scope in a header
  - raw owning pointers

## Required
  - every resource wrapped in RAII
  - every single-argument constructor `explicit`
  - `override` on every override
  - `final` on every leaf class
  - `[[nodiscard]]` on every fallible function
  - `const` on every member function that does not mutate
  - `constexpr` wherever it compiles
  - `static_assert` on every struct whose layout matters
  - fixed-width types (uint32_t), never `int` for hardware
  - std::span or std::array at every buffer interface
  - std::chrono for every duration

## Preferred
  - the rule of zero (chapter 03)
  - composition over inheritance
  - templates or variant over virtual, where the type set is
    closed
  - std::expected or an error enum over error codes
  - free functions over member functions where possible
  - anonymous namespaces over `static` at file scope

## Review checklist
  - does it allocate?          (grep for new, make_unique)
  - can it fail silently?      ([[nodiscard]]?)
  - is every path bounded?     (no unbounded loops or waits)
  - is shared state atomic or masked?  (chapter 13)
  - does the binary grow?      (size -A, before and after)

# ONE PAGE. Enforceable by the compiler for most of it, and by
# grep in CI for the rest. That is the point - a standard
# nobody can check is a standard nobody follows.
```

Migrating a C codebase

```
/* Incremental, in this order - each step is independently
   valuable and independently revertible.                  */

   1. COMPILE THE EXISTING C AS C++. Fix what breaks:
        · implicit void* conversions need casts
        · `class`, `new`, `template` etc. as identifiers
        · stricter enum rules
        · missing casts on malloc
      This alone finds real bugs, and it is the whole step -
      do not change anything else yet.

   2. REPLACE MACROS with constexpr and inline functions.
      Typed, scoped, debuggable.

   3. WRAP RESOURCES IN RAII, one at a time. Each conversion
      removes a class of leak. Start with the ones whose
      cleanup is most often forgotten.

   4. REPLACE ARRAYS AND POINTER PAIRS with std::array and
      std::span at interfaces.

   5. INTRODUCE enum class for state and mode values.

   6. ADD [[nodiscard]] to fallible functions and fix the
      warnings.

   7. REPLACE FUNCTION-POINTER TABLES with templates or
      variant WHERE THE TYPE SET IS CLOSED - and leave them
      alone where it is not.

   8. ONLY THEN consider classes with virtual functions, and
      only where runtime polymorphism is genuinely needed.

/* WHAT NOT TO DO:
     · rewrite everything at once
     · introduce exceptions into a codebase that does not
       expect them
     · use inheritance to share implementation
     · adopt the whole standard library because it is there

/* AND MEASURE AT EVERY STEP:
        size -A before.elf after.elf
        perf stat, or a cycle counter on the target
   A migration that grows the binary by 40% has gone wrong,
   and you want to know which step did it.               */
```

How it shows up

Symptom	Cause
Link error: `__cxa_pure_virtual`	Missing freestanding runtime support
Link error: `operator new`	Something allocates — find it, that is the point
Link error: `__cxa_guard_acquire`	A function-local static — add `-fno-threadsafe-statics`
Code runs before `main` unexpectedly	A static constructor — use `constexpr` or `constinit`
Binary grew after migration	Measure per step; usually one specific feature

Symptom	Cause
`std::optional::value()` is a link error	It throws — use `*opt`
Designated initialisers rejected	C++20, and the order must match declaration order
Concepts unavailable	Toolchain predates C++20 — use `static_assert`
Team disagrees about C++ features	No written standard — that is the actual problem
Warnings ignored across the codebase	No `-Werror` in CI

Check yourself

- ✓ Name twenty modern features worth adopting and what each buys.
- ✓ Write a typed register abstraction with compile-time field checking.
- ✓ Implement a state machine with `variant` and explain the exhaustiveness guarantee.
- ✓ List what is available in freestanding C++ and what you must supply.
- ✓ Write the reset-handler sequence including `.init_array`.
- ✓ Produce a one-page coding standard with mandatory flags and a review checklist.
- ✓ Explain why omitting `operator new` is a strong guarantee.
- ✓ Give the eight migration steps in order and say what each is worth alone.
- ✓ Name three fixed-capacity libraries and what each replaces.
- ✓ Measure a migration step's effect on binary size.

Interoperating with C

Every embedded C++ project sits on top of C: a vendor HAL, an RTOS, a driver, libc. Mixing them safely is a small set of rules about linkage, layout and lifetimes — and getting them wrong produces link errors at best and silent corruption at worst.

extern "C"

```
/* C++ MANGLES function names to encode types, so overloads
   get distinct symbols. C does not. `extern "C"` says "use C
   linkage for this".                                        */

        void foo(int);          /* C++: _Z3fooi */
        extern "C" void foo(int);   /* C: foo */

        nm prog.o
          0000000000000000 T _Z3fooi
          0000000000000000 T foo
        c++filt _Z3fooi
          foo(int)

/* THE HEADER PATTERN, so one header works for both
   languages: */

        /* driver.h */
        #ifndef DRIVER_H
        #define DRIVER_H

        #include <stdint.h>

        #ifdef __cplusplus
        extern "C" {
        #endif

        int  driver_init(uintptr_t base);
        int  driver_read(uint8_t *buf, size_t n);
        void driver_close(void);

        #ifdef __cplusplus
        }
        #endif

        #endif

/* WHAT extern "C" DOES:
     · disables name mangling
     · uses the C calling convention (identical on AArch64,
       but not on every platform)
   WHAT IT DOES NOT DO:
     · it does NOT change the language rules inside the
       function - you may still use C++ features
     · it does NOT allow OVERLOADING, because there is only
       one symbol name available:                          */
        extern "C" void f(int);
        extern "C" void f(double);      /* ERROR */

/* CALLING C++ FROM C: expose a C-linkage wrapper. */
        /* wrapper.hpp */
        class Driver { ... };

        /* wrapper.cpp */
        extern "C" void *driver_create(uintptr_t base)
        {
                return new (std::nothrow) Driver{base};
        }
        extern "C" int driver_read(void *h, uint8_t *b, size_t n)
        {
                return static_cast<Driver *>(h)->read(b, n);
```

```
        }
        extern "C" void driver_destroy(void *h)
        {
                delete static_cast<Driver *>(h);
        }
/* An OPAQUE HANDLE plus C-linkage functions is the standard
   shape, and it is exactly what a C library with a struct
   pointer looks like from the outside.                   */
```

Layout compatibility

```
/* For C and C++ to agree on a struct, it must be STANDARD
   LAYOUT: no virtual functions, no virtual bases, all
   non-static data members with the same access control, no
   base class with data members.                          */

        struct Message {               /* shareable */
                uint32_t id;
                uint16_t length;
                uint8_t  payload[64];
        };
        static_assert(std::is_standard_layout_v<Message>);
        static_assert(std::is_trivially_copyable_v<Message>);
        static_assert(sizeof(Message) == 72);
        static_assert(offsetof(Message, payload) == 8);

/* THOSE FOUR ASSERTIONS are what makes it safe to pass this
   struct to C, memcpy it, or DMA it. Put them next to every
   type that crosses the boundary.

/* WHAT BREAKS LAYOUT COMPATIBILITY: */
        struct Bad {
                uint32_t id;
                virtual void f();      /* adds a VPTR at
                                          offset 0       */
        };
        struct Bad2 {
        public:  uint32_t a;
        private: uint32_t b;           /* mixed access -
                                          order is
                                          unspecified    */
        };

/* WHAT IS SAFE to add to a standard-layout struct:
     · member FUNCTIONS (non-virtual) - they are not stored
     · static members
     · constructors and destructors - though adding them
       makes it non-TRIVIAL, so it can no longer be memcpy'd
       or DMA'd

        struct Message {
                uint32_t id;
                uint16_t length;
                uint8_t  payload[64];

                /* these cost NOTHING and change no layout: */
                std::span<const uint8_t> data() const
                        { return {payload, length}; }
                bool valid() const { return length <= 64; }
        };
/* SAME BYTES, better interface. This is a genuinely
   underused technique: take the C struct exactly as it is
   and add methods.                                       */

/* AND THE ENUM QUESTION: */
        enum class Mode : uint8_t { Idle, Run };
/* An enum class with an explicit underlying type has exactly
   that representation, so it is safe in a shared struct - C
   sees a uint8_t.                                        */
```

STANDARD LAYOUT VERSUS TRIVIALLY COPYABLE

Two different guarantees. **Standard layout** means C and C++ agree on where the members are, so the struct can cross the boundary. **Trivially copyable** means it can be `memcpy`'d, DMA'd or stored in a union — no user-provided copy, move or destructor. A struct with a constructor is standard layout but not trivially copyable, and DMA into it is undefined. Assert both where both matter.

Callbacks

```
/* C libraries take function pointers, usually with a `void
   *context`. C++ has three ways to supply one.           */

        typedef void (*event_cb)(void *ctx, int event);
        void register_handler(event_cb cb, void *ctx);

/* --- 1. A CAPTURELESS LAMBDA converts to a function
       pointer --- */
        register_handler([](void *ctx, int ev) {
                static_cast<Handler *>(ctx)->on_event(ev);
        }, &my_handler);
/* Clean, and the lambda has C++ linkage - which is
   technically not the same as `extern "C"` and is accepted
   by every real compiler. For strict correctness on unusual
   platforms, use form 2.

/* --- 2. A STATIC MEMBER, or a free extern "C" function --- */
        class Handler {
                void on_event(int ev);
        public:
                static void trampoline(void *ctx, int ev)
                {
                        static_cast<Handler *>(ctx)->on_event(ev);
                }
                void install() { register_handler(trampoline,
                                                  this); }
        };

/* --- 3. A TEMPLATE TRAMPOLINE, generated per type --- */
        template<typename T, void (T::*M)(int)>
        void trampoline(void *ctx, int ev)
        {
                (static_cast<T *>(ctx)->*M)(ev);
        }
        register_handler(trampoline<Handler,
                                    &Handler::on_event>,
                         &h);
/* Fully inlined, no runtime indirection beyond the C call
   itself.

/* --- THE THREE RULES for every C callback --- */

/* (a) NO EXCEPTIONS MAY ESCAPE (chapter 12): */
        extern "C" void cb(void *ctx, int ev) noexcept
        {
                try   { handler(ctx, ev); }
                catch (...) { log("callback threw"); }
        }

/* (b) THE CONTEXT MUST OUTLIVE THE REGISTRATION. A callback
       registered with `this` and never unregistered before
       the object is destroyed is a dangling pointer waiting
       for an event. Unregister in the destructor:        */
        ~Handler() { unregister_handler(trampoline, this); }

/* (c) A NON-CAPTURELESS LAMBDA CANNOT CONVERT. */
        int x = 5;
        register_handler([x](void*, int){ use(x); }, nullptr);
        /* ERROR - it has state, so it is not a plain
```

```
            function. Put the state in the context pointer,
            which is what the context pointer is FOR.     */
```

Wrapping an RTOS or HAL

```
/* The most valuable thing C++ does to a C API: wrap it in
   RAII once, and every user gets correct cleanup.        */

/* --- a FreeRTOS mutex --- */
class Mutex {
        SemaphoreHandle_t h_;
public:
        Mutex() : h_(xSemaphoreCreateMutex()) {
                configASSERT(h_ != nullptr);
        }
        ~Mutex() { vSemaphoreDelete(h_); }

        Mutex(const Mutex&) = delete;
        Mutex& operator=(const Mutex&) = delete;

        void lock()   { xSemaphoreTake(h_, portMAX_DELAY); }
        void unlock() { xSemaphoreGive(h_); }
        bool try_lock_for(TickType_t t)
                { return xSemaphoreTake(h_, t) == pdTRUE; }
};
/* NOW std::lock_guard WORKS ON IT - the standard library's
   locking types only require lock() and unlock():       */
        Mutex m;
        {
                std::lock_guard lk{m};
                shared++;
        }
        std::scoped_lock lk{m1, m2};    /* deadlock-free
                                           ordering, free   */

/* --- a task --- */
class Task {
        TaskHandle_t h_ = nullptr;

        template<typename F>
        static void entry(void *p)
        {
                (*static_cast<F *>(p))();
                vTaskDelete(nullptr);
        }
public:
        template<typename F>
        Task(F&& f, const char *name, uint16_t stack,
             UBaseType_t prio)
        {
                /* the functor must outlive the task - store
                   it, or require a captureless lambda    */
                xTaskCreate(entry<std::decay_t<F>>, name,
                            stack, &f, prio, &h_);
        }
        ~Task() { if (h_) vTaskDelete(h_); }
};

/* --- a vendor HAL handle --- */
class SpiBus {
        SPI_HandleTypeDef h_{};
public:
        explicit SpiBus(SPI_TypeDef *inst)
        {
                h_.Instance = inst;
```

```
                h_.Init = { ... };
                if (HAL_SPI_Init(&h_) != HAL_OK)
                        panic("SPI init failed");
        }
        ~SpiBus() { HAL_SPI_DeInit(&h_); }

        SpiBus(const SpiBus&) = delete;

        [[nodiscard]] std::expected<void, HAL_StatusTypeDef>
        transfer(std::span<const uint8_t> tx,
                 std::span<uint8_t> rx)
        {
                auto st = HAL_SPI_TransmitReceive(&h_,
                        const_cast<uint8_t *>(tx.data()),
                        rx.data(),
                        static_cast<uint16_t>(tx.size()),
                        HAL_MAX_DELAY);
                if (st != HAL_OK) return std::unexpected(st);
                return {};
        }
};

/* THE PATTERN IN ONE SENTENCE: keep the C API exactly as it
   is, and add a thin class that gives it a destructor, a
   span-based interface, and an error type that cannot be
   ignored. The generated code is the same; the failure
   modes are gone.                                          */
```

The pitfalls

```
/* --- 1. C++ IS NOT A SUPERSET OF C. These differ: --- */
        void *p = malloc(n);            /* C: fine.
                                           C++: ERROR, needs a
                                           cast              */
        int f();                        /* C: unspecified
                                           args. C++: no args */
        char c[] = "x";  sizeof('a');   /* C: 4. C++: 1 */
        enum E { A }; int x = A;        /* both fine, but
                                           enum class differs */
        struct S { };                   /* C: size may be 0.
                                           C++: size 1      */
        /* and C++ has more keywords: class, new, delete,
           template, typename, this, operator, ...          */

/* --- 2. INITIALISATION ORDER ACROSS THE BOUNDARY --- */
/* A C++ static constructor may run before the C library it
   depends on is initialised (chapter 01). Use constinit,
   lazy initialisation, or explicit init functions.

/* --- 3. `restrict` IS NOT IN C++ --- */
        void f(int * restrict p);       /* C only */
        void f(int * __restrict p);     /* the compiler
                                           extension both
                                           accept           */

/* --- 4. VARIABLE-LENGTH ARRAYS ARE NOT IN C++ --- */
        void f(int n) { int a[n]; }     /* C99; a GNU
                                           extension in C++ */
/* Use std::array with a fixed bound, or alloca, or a static
   buffer.

/* --- 5. COMPOUND LITERALS DIFFER --- */
        f((struct S){1, 2});            /* C99. In C++ use a
                                           temporary:       */
        f(S{1, 2});

/* --- 6. DESIGNATED INITIALISERS --- */
        struct S s = { .b = 2, .a = 1 };  /* C: ANY order.
                                             C++20: must
                                             match
                                             DECLARATION
                                             order         */

/* --- 7. const AT FILE SCOPE --- */
        const int x = 1;        /* C: EXTERNAL linkage.
                                   C++: INTERNAL linkage    */
/* So a `const int` in a header is one object per translation
   unit in C++ and a duplicate-definition error in C. Use
   `inline constexpr` in C++17.

/* --- 8. STRICTER TYPE RULES generally --- */
        int *p = (void *)q;             /* needs a cast */
        enum E e = 1;                   /* needs a cast */
        char *s = "literal";            /* C++: ERROR, use
                                           const char *     */
/* Every one of these is C++ catching something C permitted,
   which is why step 1 of a migration (chapter 15) is
   valuable on its own.                                     */
```

Building mixed projects

```
# --- CMake ---
    project(firmware C CXX ASM)

    set(CMAKE_C_STANDARD 11)
    set(CMAKE_CXX_STANDARD 17)
    set(CMAKE_CXX_STANDARD_REQUIRED ON)
    set(CMAKE_CXX_EXTENSIONS OFF)

    add_executable(fw
        main.cpp driver.cpp        # C++
        vendor_hal.c startup.c     # C
        vectors.S)                 # assembly

    target_compile_options(fw PRIVATE
        $<$<COMPILE_LANGUAGE:CXX>:-fno-exceptions -fno-rtti>
        $<$<COMPILE_LANGUAGE:C>:-std=c11>
        -Wall -Wextra -Os)

# --- THE LINKER MUST BE THE C++ ONE ---
#   g++, not gcc - it links libstdc++ and, crucially, the
#   static-constructor machinery. Linking with gcc gives
#   undefined references to __cxa_* and silently skips
#   .init_array.
#   CMake does this automatically when any source is C++.

# --- CHECK WHAT LANGUAGE A SYMBOL HAS ---
    nm -C prog.o | grep myfunc
    #   `myfunc`           C linkage
    #   `myfunc(int)`      C++ linkage (demangled)

# --- AND THE COMMONEST LINK ERROR ---
#   "undefined reference to `driver_init'"
#   where driver_init is defined in a .c file
#   -> the C++ caller saw a declaration WITHOUT extern "C",
#      so it looked for the mangled name. Add the
#      #ifdef __cplusplus guard to the header.
#
#   THE REVERSE: a C file calling a C++ function that was not
#   declared extern "C" - same error, same cause.
```

How it shows up

Symptom	Cause
"undefined reference" to a function that clearly exists	Missing `extern "C"` — check with `nm -C`
Link error only when the caller is C++	Same, in the header
Undefined `__cxa_*` symbols	Linked with `gcc` instead of `g++`
Static constructors never run	Same, or `.init_array` not walked in startup code
Struct fields wrong across the boundary	Not standard layout — assert it
DMA into a struct corrupts it	Not trivially copyable — it has a constructor
Terminate inside a C library	An exception escaped a callback
Crash in a callback after an object was destroyed	Not unregistered in the destructor
A capturing lambda will not convert to a function pointer	By design — use the context pointer

Symptom	Cause
Duplicate symbol for a `const` in a header	Different linkage rules — use `inline constexpr`
C code compiles, the same code as C++ does not	Stricter rules — each one is finding something

Check yourself

- ✓ Explain what `extern "C"` does and does not do.
- ✓ Write a header usable from both languages.
- ✓ Expose a C++ class through an opaque-handle C API.
- ✓ Distinguish standard layout from trivially copyable and say when each matters.
- ✓ Add methods to a C struct without changing its layout.
- ✓ Give three ways to supply a C callback from C++, and the three rules for all of them.
- ✓ Wrap an RTOS mutex so `std::lock_guard` works with it.
- ✓ Name eight ways C++ differs from C in existing code.
- ✓ Explain why the linker must be `g++`.
- ✓ Diagnose an `extern "C"` link error using `nm`.

> **END OF THE C++ TRACK**
>
> Sixteen chapters: what C++ buys, what it costs, how to verify both, and a subset you can defend in review. Next: Rust, which takes the same goal — zero-cost abstraction over hardware — and reaches it by making the compiler prove memory safety rather than trusting discipline.

TRACK

Rust

The memory-safety model that is now in the Linux kernel, explained as a systems programmer needs it rather than as a tutorial.

17 chapters

Why Rust for systems programming

Rust's claim is specific: memory safety and data-race freedom, proved at compile time, with no garbage collector and no runtime cost. This chapter is about what that claim actually covers, what it does not, and why the Linux kernel accepted it.

The claim, precisely

```
IN SAFE RUST, the following are IMPOSSIBLE:

  use after free            dangling pointers
  double free               buffer overflow
  null pointer dereference  uninitialised memory reads
  data races                iterator invalidation

Not "unlikely", not "caught by tools" - REJECTED BY THE
COMPILER. The program does not build.

WHAT IS STILL POSSIBLE, and this matters:
  · memory LEAKS (safe, just wasteful)
  · deadlocks
  · integer overflow (panics in debug, wraps in release -
    both defined)
  · logic errors
  · panics, which abort or unwind
  · resource exhaustion
  · anything inside an `unsafe` block

THE COST: none at run time. No GC, no runtime, no hidden
allocation. Rust compiles through LLVM to the same
instructions C would (chapter 06 of the compilers track),
and often better - because its aliasing rules are stronger
than C's, so LLVM can optimise more aggressively.

WHERE THE COST IS PAID: at COMPILE TIME, in your head. The
borrow checker rejects programs that are actually correct
but that it cannot prove correct, and learning to write in
a shape it accepts takes weeks.
```

Why the industry moved

```
/* THE DATA, which is what changed minds:

   · MICROSOFT: ~70% of CVEs assigned each year are memory
     safety issues. Consistent across a decade.
   · GOOGLE (Chrome): ~70% of serious security bugs are
     memory safety.
   · GOOGLE (Android): memory-safety vulnerabilities fell
     from 76% of the total to 24% as the proportion of new
     code written in Rust and Java grew - WITHOUT rewriting
     the old code.
   · THE US GOVERNMENT (ONCD, 2024) recommended memory-safe
     languages for new critical software.

   THE ANDROID RESULT IS THE IMPORTANT ONE: the drop came
   from NEW code being memory-safe. Vulnerability density is
   highest in new code, so replacing the growth edge rather
   than rewriting the base is the effective strategy - which
   is exactly the position an existing C codebase is in.

/* AND THE COUNTER-ARGUMENTS, stated fairly:
      · the learning curve is real, and steeper than any
        mainstream language
      · compile times are slow
      · the embedded ecosystem is younger than C's by three
        decades
      · vendor SDKs, HALs and certified toolchains are C
      · safety-certification stories (ISO 26262, DO-178C) are
        emerging but not yet routine
      · `unsafe` is required for hardware access, so the
        guarantee is only as good as the audit of those
        blocks                                              */
```

Against C and C++

	C	C++	Rust
Memory safety	None	Opt-in, by discipline	**Guaranteed in safe code**
Data-race freedom	None	None	**Guaranteed in safe code**
Resource cleanup	Manual	RAII	RAII, and *enforced* — no copy of an owner
Null	Any pointer	Any pointer	`Option<&T>` — the check is the type
Error handling	Return codes	Exceptions or codes	`Result`, `#[must_use]`
Undefined behaviour	Extensive	Extensive	Only inside `unsafe`
Generics	Macros	Templates (duck-typed)	Traits — *constrained*, so errors are local
Build system	Make, CMake, …	Same	**Cargo**, uniform
Dependencies	System packages	Same, or vendored	crates.io, versioned
Testing	Third-party	Third-party	Built in: `#[test]`, doctests
Toolchain maturity	50 years	40 years	10 years
Compile speed	Fast	Slow	Slow
Embedded vendor support	Universal	Common	Growing

The mechanism, in one page

```
/* Three rules do almost all the work. Chapters 02-04 cover
   each properly; this is the shape.                        */

/* --- 1. OWNERSHIP: every value has exactly one owner --- */
        let s = String::from("hello");
        let t = s;              // MOVED. `s` is no longer
                                // usable.
        println!("{}", s);      // COMPILE ERROR

/* When the owner goes out of scope, the value is dropped.
   Exactly once, automatically, on every path. This is C++'s
   RAII with the copy-that-double-frees made impossible
   (C++ chapter 03).

/* --- 2. BORROWING: many readers XOR one writer --- */
        let mut v = vec![1, 2, 3];

        let a = &v;             // shared borrow
        let b = &v;             // another - fine
        println!("{:?} {:?}", a, b);

        let m = &mut v;         // exclusive borrow
        let n = &v;             // ERROR - cannot borrow while
                                // mutably borrowed

/* THIS ONE RULE eliminates data races AND iterator
   invalidation AND aliasing bugs, because all three are the
   same underlying problem: two references to one thing, one
   of them writing.

/* --- 3. LIFETIMES: a reference cannot outlive its
       referent --- */
        let r;
        {
                let x = 5;
                r = &x;
        }                       // x dropped
        println!("{}", r);      // ERROR - r outlives x

/* THE COMPILER TRACKS THIS ACROSS FUNCTION BOUNDARIES, which
   is what makes returning a reference safe.

/* AND THE PAYOFF, in one example - this C bug: */
        char *f(void) {
                char buf[64];
                sprintf(buf, "hi");
                return buf;             /* DANGLING */
        }
/* is, in Rust, not a bug you have to find. It does not
   compile.                                                 */
```

> **THE TRADE, STATED HONESTLY**
>
> The borrow checker rejects some programs that are correct. Learning Rust is largely learning which program *shapes* it can prove correct, and restructuring toward them. That is a real cost, paid up front, in exchange for a class of bug that never reaches production. Whether that trade is worth it depends on how expensive your bugs are — which for firmware, kernels and anything network-facing is usually "very".

Rust on embedded

```
/* THE PARTS THAT FIT EMBEDDED WELL:

   · no_std - the core language and `core` with no OS, no
     allocator, no runtime (chapter 15). Rust was designed for
     this from the start.
   · ZERO-COST ABSTRACTIONS, verified the same way as C++'s
     (C++ chapter 14) - and the compiler is LLVM, so the
     optimiser is the same one.
   · TYPE-STATE: encode hardware state in the type system, so
     "configure the pin before using it" is checked at
     compile time rather than documented.
   · No hidden allocation. If it allocates, you can see it.
   · Cargo, which after CMake and vendor IDEs is a relief.
   · Excellent cross-compilation: rustup target add
     thumbv7em-none-eabihf, and it works.

/* THE PARTS THAT DO NOT FIT YET:
   · vendor HALs and SDKs are C - so every project has an FFI
     layer (chapter 12), and that layer is `unsafe`
   · certified toolchains (Ferrocene exists; the ecosystem
     around it is young)
   · debugging and trace tooling is thinner than for C
   · binary size can be larger without care - though
     opt-level="z", LTO and panic=abort close most of the gap
   · the async story on bare metal is excellent but recent
     (Embassy - chapter 16)

/* WHERE IT IS ALREADY IN PRODUCTION:
     Android (Binder, Keystore, the Bluetooth stack, parts of
       the kernel)
     Windows (parts of the kernel and font parsing)
     the LINUX KERNEL (chapter 17)
     AWS Firecracker, Cloudflare's proxy, Discord, Dropbox
     Oxide Computer's firmware (Hubris - an entire embedded OS)
     Espressif, Nordic and STM32 HALs

/* THE HONEST RECOMMENDATION for a 2026 embedded team:
      · a NEW project on a well-supported chip: seriously
        consider it
      · an EXISTING C codebase: consider Rust for new
        components with a clean interface, not a rewrite
      · a project constrained by a vendor SDK or certification:
        C or C++, and revisit in two years
      · and LEARN IT REGARDLESS - the ideas improve how you
        write C++, and the kernel now accepts it            */
```

Getting started

```
# --- INSTALL ---
    curl --proto '=https' --tlsv1.2 -sSf https://sh.rustup.rs | sh
    rustup update
    rustup component add rust-src rustfmt clippy
    rustup target add aarch64-unknown-linux-gnu
    rustup target add thumbv7em-none-eabihf   # Cortex-M4F

# --- A HOSTED PROJECT ---
    cargo new hello
    cd hello
    cargo run
    cargo build --release
    cargo test
    cargo clippy -- -D warnings         # the linter. Use it.
    cargo fmt                           # one formatting
                                        # standard, no debate

# --- CROSS-COMPILE ---
    cargo build --target aarch64-unknown-linux-gnu --release

# --- THE FILES ---
    Cargo.toml          dependencies, metadata, profiles
    Cargo.lock          exact versions - COMMIT this for a
                        binary, not for a library
    src/main.rs         the binary crate root
    src/lib.rs          the library crate root

# --- A FIRST PROGRAM, showing the shape ---
fn main() {
    let data = vec![3, 1, 4, 1, 5, 9, 2, 6];

    let sum: i32 = data.iter().sum();
    let max = data.iter().max().expect("non-empty");

    let mut sorted = data.clone();
    sorted.sort();

    println!("sum={sum} max={max} sorted={sorted:?}");

    match find_first_even(&data) {
        Some(x) => println!("first even: {x}"),
        None    => println!("no even numbers"),
    }
}

fn find_first_even(v: &[i32]) -> Option<&i32> {
    v.iter().find(|&&x| x % 2 == 0)
}

/* THINGS TO NOTICE ALREADY:
     `&[i32]`      a SLICE - a pointer and a length, like
                   std::span (C++ chapter 08)
     Option<&i32>  "a reference or nothing" - and the compiler
                   forces you to handle both cases
     `match`       exhaustive: forget a case and it does not
                   compile
     no semicolon  on the last expression of a function - it
                   is the return value
     `{sum}`       inline format arguments                */
```

Reading Rust as a C programmer

```
    fn name(arg: Type) -> Ret { }       // function
    let x = 5;                          // immutable BY
                                        // DEFAULT
    let mut y = 5;                      // mutable
    const MAX: u32 = 100;               // compile-time
    static GLOBAL: u32 = 0;             // a static

    &T          a shared reference       (const T* that cannot
                                         be null)
    &mut T      an exclusive reference   (T* that cannot be
                                         null, and is the ONLY
                                         one)
    *const T    a raw pointer           (needs unsafe to
                                         deref)
    Box<T>      an owned heap value      (unique_ptr)
    Vec<T>      a growable array        (vector)
    &[T]        a slice                 (span)
    &str        a string slice          (string_view)
    String      an owned string
    Option<T>   Some(T) or None         (optional)
    Result<T,E> Ok(T) or Err(E)         (expected)

    struct S { a: u32 }                 // a struct
    enum E { A, B(u32), C { x: u8 } }   // a TAGGED UNION -
                                        // variants carry data
    impl S { fn method(&self) {} }      // methods, defined
                                        // separately
    trait T { fn f(&self); }            // an interface
    impl T for S { fn f(&self) {} }     // implementing it

    match x {                           // exhaustive
        0 => a(),
        1..=9 => b(),
        _ => c(),
    }

    if let Some(v) = opt { }            // match one pattern
    while let Some(v) = it.next() { }

    v.iter().map(f).filter(g).sum()     // iterator chains -
                                        // lazy, fused, zero
                                        // cost

/* THE TWO THINGS THAT LOOK STRANGEST AT FIRST:
     1. `impl` blocks separate from the struct - which means a
        type can have methods added by anyone who imports the
        trait
     2. no `return` on the last expression - the value of the
        final expression IS the return value. `return` exists
        for early exits.                                    */
```

How it shows up

Symptom	Meaning
"borrow of moved value"	Ownership transferred — clone, borrow, or restructure (ch. 02)
"cannot borrow as mutable more than once"	The aliasing rule (ch. 03)

Symptom	Meaning
"does not live long enough"	A reference outliving its referent (ch. 04)
"missing lifetime specifier"	The compiler cannot infer which input a returned reference came from
"non-exhaustive patterns"	A `match` arm is missing — the feature working
"cannot find function" for a trait method	The trait is not in scope — `use` it
Fighting the borrow checker constantly	Normal for the first weeks; usually the design wants restructuring
Binary much larger than the C equivalent	Panic machinery and formatting — see chapter 15
Slow compile times	Real. Use `cargo check` while iterating
Everything requires `unsafe`	You are writing C in Rust — find the safe abstraction

Check yourself

- ✓ State exactly what safe Rust guarantees, and five things it does not.
- ✓ Explain why the Android result is the important data point.
- ✓ Compare Rust with C and C++ across ten dimensions.
- ✓ State the three rules — ownership, borrowing, lifetimes — and what each eliminates.
- ✓ Explain the trade the borrow checker imposes.
- ✓ Name five things that fit embedded well and four that do not yet.
- ✓ Give a defensible recommendation for three different project situations.
- ✓ Install the toolchain and cross-compile for an ARM target.
- ✓ Read a page of Rust and map each construct to its C or C++ equivalent.
- ✓ Explain what `Option<&T>` replaces and why it is safer.

Ownership

One value, one owner, dropped exactly once. This is C++'s RAII with the loopholes closed — and it is the rule from which use-after-free, double-free and leaks all become impossible rather than merely unlikely.

The three rules

```
1. Every value has exactly ONE OWNER.
2. There can be only one owner at a time.
3. When the owner goes out of scope, the value is DROPPED.

{
     let s = String::from("hello");  // s owns the heap
                                     // buffer
     use(&s);
}                                    // s dropped here.
                                     // The buffer is
                                     // freed. Exactly
                                     // once, on every
                                     // path.

COMPARE C++ (chapter 03 of that track):
     std::string s = "hello";        // same
     std::string t = s;              // a COPY - two
                                     // buffers
COMPARE RUST:
     let s = String::from("hello");
     let t = s;                      // a MOVE - one
                                     // buffer, and `s` is
                                     // dead

THE DIFFERENCE IS THE DEFAULT. C++ copies unless you say
move; Rust moves unless the type opts into Copy. So the
accidental deep copy and the accidental shallow copy - the
two classic C++ bugs - are both eliminated by the same
choice.
```

Moves

```
    let s1 = String::from("hello");
    let s2 = s1;                        // MOVE
    println!("{s1}");                   // ERROR:
                                        // borrow of moved value

/* THE ERROR MESSAGE, which is genuinely helpful:

     error[E0382]: borrow of moved value: `s1`
       --> src/main.rs:3:20
        |
      1 |     let s1 = String::from("hello");
        |         -- move occurs because `s1` has type
        |            `String`, which does not implement the
        |            `Copy` trait
      2 |     let s2 = s1;
        |              -- value moved here
      3 |     println!("{s1}");
        |                ^^^^ value borrowed here after move
        |
      help: consider cloning the value
        |
      2 |     let s2 = s1.clone();

/* MOVES HAPPEN ON:
     assignment            let b = a;
     passing by value      f(a);
     returning             return a;
     pushing into a
       collection          v.push(a);
     pattern matching by
       value               match a { ... }

/* WHAT A MOVE COSTS: a memcpy of the value itself - for a
   String that is three words (pointer, length, capacity).
   THE HEAP BUFFER IS NOT COPIED. And the compiler usually
   elides even the memcpy.

/* THE MOVED-FROM VALUE IS GONE, not "valid but unspecified"
   as in C++ - the compiler prevents you from touching it at
   all. That is strictly stronger.                          */

/* PASSING TO A FUNCTION MOVES: */
    fn consume(s: String) { }           // takes OWNERSHIP

    let s = String::from("hi");
    consume(s);
    println!("{s}");                    // ERROR

/* SO IF THE CALLER NEEDS IT AFTERWARDS, borrow instead
   (chapter 03): */
    fn inspect(s: &String) { }          // BORROWS
    inspect(&s);
    println!("{s}");                    // fine

/* OR RETURN IT BACK - the pattern before borrowing existed,
   and still occasionally useful: */
    fn transform(mut s: String) -> String { s.push('!'); s }
    let s = transform(s);
```

Copy types

```
    let x = 5;
    let y = x;                          // COPIED, not moved
    println!("{x}");                    // fine - x is still
                                        // valid

/* TYPES THAT IMPLEMENT `Copy` are duplicated bitwise instead
   of moved. The rule: a type may be Copy only if every part
   of it is Copy and it has no Drop implementation.

   COPY TYPES:
     all integers, floats, bool, char
     &T (shared references)
     raw pointers
     arrays and tuples of Copy types
     any struct you derive Copy on

   NOT COPY:
     String, Vec<T>, Box<T>      - they own a resource
     &mut T                      - copying it would create
                                   two exclusive references
     anything with a Drop impl   - copying would double-drop

/* DERIVING IT: */
    #[derive(Copy, Clone, Debug, PartialEq)]
    struct Point { x: i32, y: i32 }

    let p = Point { x: 1, y: 2 };
    let q = p;                          // copied
    println!("{p:?} {q:?}");            // both usable

/* Copy REQUIRES Clone - Copy is "Clone, and it is a bitwise
   memcpy". You always derive both together.

/* WHEN TO DERIVE Copy: for small, plain-data types - a
   register value, a coordinate, an enum of states, a message
   header. It makes them behave like C values, which is what
   you want.
   WHEN NOT TO: anything large (a copy becomes implicit and
   invisible), or anything that owns a resource.

/* AND `Clone` FOR EXPLICIT DEEP COPIES: */
    let s2 = s1.clone();                // explicit,
                                        // potentially
                                        // expensive, VISIBLE
/* The visibility is the point: in C++ a deep copy can happen
   in a function call you did not look at. In Rust it says
   `.clone()`.                                              */
```

THE `.CLONE()` ESCAPE HATCH

When the borrow checker refuses, cloning usually makes it compile. That is fine while learning — but treat a `.clone()` you added to silence an error as a note to revisit. Frequently the real fix is to borrow instead of own, or to restructure so one function owns the data and the others take references. Reaching for `clone` reflexively produces Rust that works and performs like a garbage-collected language.

Drop

```
    struct Uart { base: usize }

    impl Drop for Uart {
        fn drop(&mut self) {
            // called automatically when the owner goes out of
            // scope
            unsafe { write_reg(self.base + CTRL, 0); }
        }
    }

    {
        let uart = Uart { base: 0x4000_0000 };
        uart.write(b"hello");
    }   // drop() runs HERE, on every path

/* DROP ORDER:
     · local variables in REVERSE declaration order
     · struct fields in DECLARATION order
     · the outer value's drop() runs BEFORE its fields are
       dropped

    struct Device {
        clock: ClockGate,       // dropped SECOND
        uart:  Uart,            // dropped FIRST
    }
/* Wait - fields drop in declaration order, so `clock` drops
   first. If the UART needs the clock enabled to be shut down
   cleanly, declare it the other way round:              */
    struct Device {
        uart:  Uart,            // dropped first - good
        clock: ClockGate,       // dropped second
    }

/* YOU CANNOT CALL drop() DIRECTLY: */
    uart.drop();                          // ERROR
    drop(uart);                           // this instead - it
                                          // MOVES the value
                                          // into a function
                                          // that does nothing,
                                          // so it drops there

/* AND `std::mem::forget` LEAKS DELIBERATELY: */
    std::mem::forget(uart);               // drop is NOT called
/* Which is SAFE Rust - leaking is not a memory-safety
   violation. It matters for FFI: when you hand ownership to
   C, you forget the Rust value so it is not dropped twice
   (chapter 12).

/* A TYPE WITH Drop CANNOT BE Copy - which the compiler
   enforces, because a bitwise copy followed by two drops is
   exactly the C++ double-free (C++ chapter 03).        */
```

Ownership of hardware

```
/* THE EMBEDDED APPLICATION: make a peripheral a value that
   can only be owned once. Then "two drivers configured the
   same UART" is a compile error.                          */

    pub struct Uart0 { _private: () }   // cannot be
                                        // constructed outside
                                        // this module

    pub struct Peripherals {
        pub uart0: Uart0,
        pub spi1:  Spi1,
        pub gpio:  Gpio,
    }

    static TAKEN: AtomicBool = AtomicBool::new(false);

    impl Peripherals {
        pub fn take() -> Option<Self> {
            if TAKEN.swap(true, Ordering::SeqCst) {
                None                    // ALREADY TAKEN
            } else {
                Some(unsafe { Self::steal() })
            }
        }
    }

    fn main() -> ! {
        let p = Peripherals::take().unwrap();

        let uart = UartDriver::new(p.uart0);   // MOVES the
                                               // token in
        // p.uart0 is now gone - nobody else can construct a
        // second UartDriver for it, at all.
        loop { }
    }

/* THIS IS THE SINGLETON PATTERN the whole embedded Rust
   ecosystem is built on (chapter 16). The peripheral token
   is a zero-sized type - it occupies no memory and generates
   no code - and moving it expresses exclusive access in a way
   the compiler checks.

/* AND TYPE-STATE, taking it further: encode the CONFIGURATION
   in the type, so an unconfigured pin cannot be used.    */

    struct Pin<MODE> { pin: u8, _mode: PhantomData<MODE> }
    struct Input;
    struct Output;

    impl Pin<Input> {
        fn into_output(self) -> Pin<Output> {
            configure_as_output(self.pin);
            Pin { pin: self.pin, _mode: PhantomData }
        }
        fn read(&self) -> bool { read_pin(self.pin) }
    }

    impl Pin<Output> {
        fn set_high(&mut self) { write_pin(self.pin, true); }
        // NO read() - an output pin cannot be read
```

```
    }

    let pin: Pin<Input> = ...;
    pin.set_high();             // COMPILE ERROR
    let mut pin = pin.into_output();
    pin.set_high();             // fine

/* PhantomData IS ZERO-SIZED, so Pin<Input> and Pin<Output>
   are both one byte and generate identical code. The
   distinction exists only at compile time - which is the
   definition of a zero-cost abstraction (C++ chapter 14, the
   same idea).                                              */
```

Scopes and shadowing

```
    let x = 5;
    let x = x + 1;              // SHADOWING - a new variable,
    let x = x * 2;              // same name. Not mutation.
    println!("{x}");            // 12

/* SHADOWING lets you change the TYPE, which mutation cannot:
*/
    let input = "42";                   // &str
    let input: u32 = input.parse()?;    // now u32

/* IDIOMATIC AND USEFUL - it avoids `input_str` and
   `input_num`. Distinct from `mut`, which keeps one variable
   and changes its value.

/* BLOCKS ARE EXPRESSIONS: */
    let y = {
        let a = compute();
        a * 2                   // no semicolon = the block's
                                // value
    };

/* WHICH IS WHY: */
    let max = if a > b { a } else { b };
    let msg = match code {
        0 => "ok",
        _ => "error",
    };
/* `if` and `match` are expressions, so there is no ternary
   operator and no need for one.

/* AND THE SEMICOLON RULE, which trips everyone once: */
    fn f() -> i32 { 5 }         // returns 5
    fn g() -> i32 { 5; }        // ERROR - `5;` is a
                                // STATEMENT, and the block's
                                // value is () - the unit
                                // type
```

A mental model

```
WHEN THE BORROW CHECKER REJECTS SOMETHING, ask in order:

1. Does this function need to OWN the value, or only READ
   it?
      -> if only read, take &T (chapter 03)

2. Does it need to MODIFY it in place?
      -> take &mut T

3. Does it need to KEEP it beyond the call?
      -> take T by value; the caller gives it up

4. Do TWO parts of the program genuinely need to own it?
      -> they cannot. Either
           · one owns and the other borrows, or
           · restructure so there is a clear owner, or
           · use Rc/Arc for genuinely shared ownership
             (chapter 09) - which is the C++ shared_ptr
             answer, with the same caveats

5. Am I fighting a design problem rather than the
   compiler?
      -> frequently yes. "Who owns this?" is a question C
         lets you avoid answering and Rust does not, and
         answering it usually improves the design.

THE COMMONEST BEGINNER SHAPE that fights the checker:
a struct holding references to other parts of the same
structure. Rust makes self-referential structures hard on
purpose, because they are exactly what goes wrong when
something moves. Use indices into an arena instead - which
is the same advice as the generational-handle pattern in
C++ chapter 10.
```

How it shows up

Error	Meaning and fix
"use of moved value"	You gave it away. Borrow, clone, or return it back
"cannot move out of borrowed content"	You have `&T` and tried to take ownership — clone, or take `T`
"cannot move out of index"	Moving one element out of a `Vec` — use `swap_remove`, `take`, or clone
"cannot move out of `self`"	The method takes `&self`; it needs `self`
"the trait `Copy` is not implemented"	The type owns a resource — that is why it moves
"cannot implement Copy for a type with Drop"	Correct — that combination is a double free
Value dropped earlier than expected	Field or variable declaration order
Resource not released	`mem::forget`, an `Rc` cycle, or an early `drop` you did not intend
Peripheral `take()` returns `None`	Something already took it — working as designed
A function returns `()` unexpectedly	A stray semicolon on the last expression

Check yourself

- ✓ State the three ownership rules and what each prevents.
- ✓ Explain why move-by-default eliminates two distinct C++ bugs.
- ✓ List the operations that move a value.
- ✓ Say which types are `Copy` and which cannot be, with reasons.
- ✓ Explain when to derive `Copy` and when not to.
- ✓ Implement `Drop` and state the drop order rules.
- ✓ Explain why `Drop` and `Copy` are mutually exclusive.
- ✓ Write a peripheral singleton with a `take()` and explain what it guarantees.
- ✓ Write a type-state pin and explain why it costs nothing.
- ✓ Work the five-question mental model on a borrow-checker error.

Borrowing and references

Access without ownership, governed by one rule: many readers *or* one writer, never both. That single constraint eliminates data races, iterator invalidation and aliasing bugs simultaneously — because all three are the same problem.

The rule

```
AT ANY GIVEN TIME, for any given value, you may have
EITHER:

  · any number of SHARED references    &T
  · exactly one EXCLUSIVE reference    &mut T

but never both, and never two exclusive ones.

AND every reference must be VALID for its whole lifetime -
it cannot outlive what it points to (chapter 04).

     let mut v = vec![1, 2, 3];

     let a = &v;             // shared
     let b = &v;             // another shared - FINE
     println!("{a:?} {b:?}");

     let m = &mut v;         // exclusive - fine, because
                             // a and b are no longer USED
     m.push(4);

     println!("{a:?}");      // ERROR if this came after
                             // the &mut

NON-LEXICAL LIFETIMES: a borrow ends at its LAST USE, not
at the end of the scope. So this compiles:

     let a = &v;
     println!("{a:?}");      // a's last use
     let m = &mut v;         // fine - a is dead
     m.push(4);

which is why modern Rust is far less irritating than the
2015-era descriptions suggest.

THE NAMES: `&T` is often called "immutable" and `&mut T`
"mutable", but SHARED and EXCLUSIVE are the accurate
words - the real distinction is aliasing, not mutation.
Cell and Mutex allow mutation through &T (chapter 09),
which is only confusing if you learned the wrong names.
```

What it eliminates

```
/* --- 1. ITERATOR INVALIDATION --- */
    let mut v = vec![1, 2, 3];
    for x in &v {               // v is borrowed SHARED here
        v.push(*x);             // ERROR - push needs &mut
    }
/* THE C++ EQUIVALENT compiles, runs, and corrupts memory
   when the vector reallocates (C++ chapter 08). Here it is a
   compile error, and the error message says exactly why.

/* --- 2. USE AFTER FREE --- */
    let r;
    {
        let x = 5;
        r = &x;
    }
    println!("{r}");            // ERROR: `x` does not live
                                // long enough

/* --- 3. DATA RACES --- */
    let mut data = vec![1, 2, 3];
    thread::spawn(|| data.push(4));     // ERROR - the closure
    data.push(5);                       // would need &mut
                                        // while main also
                                        // has it
/* The SAME RULE that prevents iterator invalidation prevents
   data races, because they are the same shape: two paths to
   one value, one of them writing.

/* --- 4. ALIASING BUGS --- */
    fn f(a: &mut i32, b: &mut i32) { *a = 1; *b = 2; }
    let mut x = 0;
    f(&mut x, &mut x);          // ERROR - two exclusive
                                // borrows
/* In C this is legal, and the compiler must assume a and b
   may alias - which prevents optimisation. Rust's guarantee
   is why rustc emits LLVM's `noalias` on &mut parameters,
   and why Rust sometimes optimises BETTER than the
   equivalent C.                                          */
```

Borrowing in functions

```
    fn read(v: &Vec<i32>) -> i32 { v[0] }       // shared
    fn modify(v: &mut Vec<i32>) { v.push(4); }  // exclusive
    fn consume(v: Vec<i32>) { }                 // takes
                                                // ownership

    let mut v = vec![1, 2, 3];
    read(&v);
    modify(&mut v);
    println!("{v:?}");          // still usable
    consume(v);
    println!("{v:?}");          // ERROR - moved

/* THE PARAMETER RULE, and it is the whole design decision:
     need to READ it              -> &T
     need to MODIFY it in place   -> &mut T
     need to KEEP it              -> T
   Exactly the C++ const-ref / ref / value decision
   (C++ chapter 04), but enforced.

/* PREFER SLICES TO CONCRETE TYPES: */
    fn sum(v: &Vec<i32>) -> i32 { ... }         // narrow
    fn sum(v: &[i32])    -> i32 { ... }         // BETTER

    sum(&vec);                  // Vec derefs to a slice
    sum(&array);                // arrays too
    sum(&vec[1..3]);            // and sub-slices

    fn greet(s: &String) { }    // narrow
    fn greet(s: &str)    { }    // BETTER - accepts String,
                                // &str and literals
/* This is exactly the std::span / std::string_view advice
   from C++ chapter 08, and for the same reason.

/* METHODS take self in one of four ways: */
    impl Buffer {
        fn len(&self) -> usize { ... }          // read
        fn push(&mut self, b: u8) { ... }       // modify
        fn into_vec(self) -> Vec<u8> { ... }    // CONSUMES
        fn new() -> Self { ... }                // no self -
                                                // an
                                                // associated
                                                // function
    }
/* `into_*` by convention means "consumes self". `as_*` means
   a cheap borrowed view. `to_*` means an expensive
   conversion producing an owned value. Following those
   conventions makes an API readable at a glance.        */
```

THE MUTABILITY IS ON THE BINDING, NOT THE TYPE

```
let v = vec![1];        // immutable binding
v.push(2);              // ERROR
let mut v = vec![1];    // mutable binding
v.push(2);              // fine

fn f(v: &mut Vec<i32>)  // an exclusive reference
let mut r = &v;         // a MUTABLE BINDING holding a
                        // SHARED reference - r can be
                        // reassigned, *r cannot be written
```

`mut` in a `let` and `mut` in `&mut` are different things, and reading them as one is a common early confusion.

Working with the checker

```
/* --- 1. TWO FIELDS OF ONE STRUCT: fine --- */
    struct S { a: Vec<i32>, b: Vec<i32> }
    let ra = &mut s.a;
    let rb = &mut s.b;          // FINE - disjoint fields
/* The compiler tracks fields separately. But NOT through a
   method: */
    let ra = s.get_a_mut();     // borrows ALL of s
    let rb = s.get_b_mut();     // ERROR
/* Fix by having one method return both, or by borrowing the
   fields directly.

/* --- 2. SPLITTING A SLICE --- */
    let (left, right) = v.split_at_mut(mid);
    // two &mut into DISJOINT halves - the standard library
    // provides this because it needs unsafe internally, and
    // it is proved correct once so you never need to.

    for chunk in v.chunks_mut(64) { ... }
    let [a, b] = v.get_disjoint_mut([0, 5]).unwrap();  // 1.86

/* --- 3. A LOOP THAT MODIFIES WHAT IT ITERATES --- */
    // WRONG:
    for x in &v { if bad(x) { v.remove(...); } }
    // RIGHT:
    v.retain(|x| !bad(x));
    // or collect the indices first, or iterate mutably:
    for x in &mut v { *x += 1; }
    // or drain:
    let removed: Vec<_> = v.drain(..).filter(keep).collect();

/* --- 4. RETURNING A REFERENCE INTO A LOCAL: impossible --- */
    fn f() -> &str {
        let s = String::from("hi");
        &s                      // ERROR
    }
    fn f() -> String { String::from("hi") }     // return the
                                                // value

/* --- 5. THE SELF-REFERENTIAL STRUCT: do not --- */
    struct Bad<'a> { data: Vec<u8>, slice: &'a [u8] }
/* If `slice` points into `data`, moving the struct
   invalidates it. Rust makes this hard on purpose. Use
   INDICES instead:                                    */
    struct Good { data: Vec<u8>, range: Range<usize> }
/* which is the arena/handle pattern again.

/* --- 6. WHEN YOU GENUINELY NEED SHARED MUTATION --- */
    RefCell<T>      runtime-checked borrows, single-threaded
    Cell<T>         get/set of Copy values, no borrows at all
    Mutex<T>        across threads
    RwLock<T>       many readers or one writer, across
                    threads
/* All four are "interior mutability" - mutation through &T,
   with the aliasing rule enforced at RUN TIME instead of
   compile time (chapter 09).                          */
```

Reborrowing

```
/* A `&mut` can be temporarily lent out. The compiler does
   this implicitly, and knowing it explains several
   otherwise-confusing errors.                              */

    fn f(v: &mut Vec<i32>) {
        g(v);                   // implicitly REBORROWS:
                                // g(&mut *v)
        v.push(1);              // v is usable again after g
                                // returns
    }
    fn g(v: &mut Vec<i32>) { }

/* WITHOUT reborrowing this would MOVE the &mut into g and v
   would be unusable afterwards - which is what happens when
   the type is not obviously a reference:                */

    fn h<T>(x: T) { }
    fn f(v: &mut Vec<i32>) {
        h(v);                   // MOVES - T is inferred as
                                // &mut Vec, no reborrow
        v.push(1);              // ERROR
    }
    // fix: h(&mut *v);         // explicit reborrow

/* AND IN A LOOP, the classic: */
    let mut current = &mut head;
    loop {
        current = &mut current.next;     // moves out of
                                         // current
    }
/* Linked-list traversal with &mut is genuinely awkward, and
   is one of the shapes where an index-based arena is simply
   better in Rust.                                          */
```

The optimisation payoff

```
/* Rust's aliasing guarantee is stronger than C's, and LLVM
   uses it.                                                  */

    // C: the compiler CANNOT assume a and b are distinct
    void add(int *a, const int *b, int n) {
            for (int i = 0; i < n; i++)
                    a[i] += b[i];   // must reload b[i] in
                                    // case a[i] aliased it
    }
    // which is why `restrict` exists (compilers chapter 07).

    // Rust: &mut is UNIQUE by construction
    fn add(a: &mut [i32], b: &[i32]) {
        for i in 0..a.len().min(b.len()) {
            a[i] += b[i];
        }
    }
/* rustc emits `noalias` on the &mut parameter, so LLVM knows
   they are disjoint and vectorises without a runtime alias
   check - the same code C gets only with `restrict`, and
   without the risk of the promise being false.

/* CHECK IT: */
    cargo asm --rust my_crate::add
    # or paste into godbolt with the Rust compiler selected

/* THE BOUNDS CHECK QUESTION, which everyone asks:
     a[i] IS bounds-checked. But:
       · the check is a compare and a branch, predicted
         perfectly
       · LLVM removes it whenever it can prove the index is in
         range - which iterators always can
       · so idiomatic Rust (iterators, chapter 08) usually has
         NO bounds checks at all:                          */
    for (x, y) in a.iter_mut().zip(b.iter()) { *x += *y; }
/* -> no bounds checks, vectorised, identical to the C with
   restrict.

   THE RULE: write iterator chains, not index loops, and the
   bounds-check cost disappears along with the aliasing
   question.                                                 */
```

How it shows up

Error	Meaning and fix
"cannot borrow as mutable because it is also borrowed as immutable"	A shared borrow is still live — shorten it, or restructure
"cannot borrow as mutable more than once"	Two `&mut` — split the data, or use `split_at_mut`
"cannot borrow as mutable, not declared as mutable"	Missing `mut` on the `let`
"cannot assign to `*x` which is behind a `&` reference"	You have a shared reference; you need `&mut`
"cannot move out of borrowed content"	Clone, or take ownership instead of borrowing
"does not live long enough"	The reference outlives its referent (ch. 04)

Error	Meaning and fix
Two disjoint fields refuse to borrow	A method borrowed all of `self` — borrow the fields directly
A `&mut` becomes unusable after a call	It was moved, not reborrowed — write `&mut *x`
Linked-list traversal will not compile	Expected — use indices into an arena
Index loop is slower than expected	Bounds checks — use iterators

Check yourself

- ✓ State the borrowing rule using the words shared and exclusive.
- ✓ Explain non-lexical lifetimes and why they matter in practice.
- ✓ Show how one rule prevents iterator invalidation, use-after-free and data races.
- ✓ Give the parameter-passing rule for the three reference kinds.
- ✓ Explain why `&[T]` and `&str` are better parameters than `&Vec<T>` and `&String`.
- ✓ Distinguish `mut` on a binding from `&mut`.
- ✓ Give six techniques for restructuring code the checker rejects.
- ✓ Explain reborrowing and when it does not happen implicitly.
- ✓ Explain why `&mut` lets LLVM optimise better than C.
- ✓ Explain when bounds checks cost nothing, and how to write code that way.

Lifetimes

Lifetimes are how the compiler proves a reference never outlives what it points to. Most of the time they are inferred and invisible; when you must write them, they are describing a relationship you already understood implicitly.

What a lifetime is

```
A lifetime is a REGION OF CODE for which a reference is
valid. It is not a runtime value - it exists only during
type checking, and generates no code whatsoever.

     {
         let r;                       // ---------+-- 'a
         {                            //          |
             let x = 5;               // -+-- 'b  |
             r = &x;                  //  |       |
         }                            // -+       |
         println!("{r}");             //          |
     }                                // ---------+

`r` has lifetime 'a; `x` has lifetime 'b. The reference
`&x` cannot outlive 'b, but it is used within 'a. Since
'b is SHORTER than 'a, this is rejected:

     error[E0597]: `x` does not live long enough

THE COMPILER IS ANSWERING ONE QUESTION: for every
reference, is the thing it points to still alive at every
point where the reference is used? That is the whole
feature.

AND THE SYNTAX, when you must write it:
     &'a T           a shared reference living at least 'a
     &'a mut T       an exclusive one
     'static         lives for the whole program
```

Elision — why you rarely write them

```
/* Three rules let the compiler infer lifetimes in almost
   every function signature.                                */

   1. Each elided lifetime in a PARAMETER gets its own
      distinct lifetime.
   2. If there is EXACTLY ONE input lifetime, it is assigned
      to all elided output lifetimes.
   3. If one of the parameters is `&self` or `&mut self`, ITS
      lifetime is assigned to all elided output lifetimes.

/* SO THESE ARE ALL FINE without annotation: */

    fn first(s: &str) -> &str { &s[..1] }
    // rule 2: one input, so the output borrows from it

    fn len(s: &str) -> usize { s.len() }
    // no output reference - nothing to infer

    impl Buffer {
        fn as_slice(&self) -> &[u8] { &self.data }
        // rule 3: the output borrows from self
    }

/* AND THIS ONE IS NOT, which is the case you will meet: */

    fn longest(a: &str, b: &str) -> &str {      // ERROR
        if a.len() > b.len() { a } else { b }
    }
    // error[E0106]: missing lifetime specifier
    //   this function's return type contains a borrowed
    //   value, but the signature does not say whether it is
    //   borrowed from `a` or `b`

/* Rule 1 gives a and b DIFFERENT lifetimes, and rule 2 does
   not apply because there are two. So you must say: */

    fn longest<'a>(a: &'a str, b: &'a str) -> &'a str {
        if a.len() > b.len() { a } else { b }
    }

/* WHAT THAT SIGNATURE MEANS: the returned reference is valid
   for as long as BOTH inputs are - i.e. for the shorter of
   the two. It is not choosing a lifetime; it is stating a
   CONSTRAINT the caller must satisfy.

/* AND IF ONLY ONE INPUT IS ACTUALLY BORROWED FROM, say so -
   it is less restrictive for the caller: */
    fn prefix<'a>(s: &'a str, sep: &str) -> &'a str {
        s.split(sep).next().unwrap_or(s)
    }
    // `sep` can now be a shorter-lived temporary          */
```

> **A LIFETIME ANNOTATION DOES NOT CHANGE ANYTHING AT RUN TIME**
>
> It does not extend a value's life, allocate anything, or emit code. It is a *claim about a relationship* that the compiler then verifies. Writing `<'a>` never fixes a problem by itself — it either states a relationship that is true, and the code compiles, or one that is false, and the error moves to the call site.

Lifetimes in structs

```
/* A struct holding a reference must declare the lifetime,
   because the struct cannot outlive what it borrows.     */

    struct Parser<'a> {
        input: &'a str,
        pos: usize,
    }

    impl<'a> Parser<'a> {
        fn new(input: &'a str) -> Self {
            Parser { input, pos: 0 }
        }

        fn next_token(&mut self) -> Option<&'a str> {
            // returns a slice of the ORIGINAL input, not of
            // self - so it lives as long as 'a, and the
            // caller may hold it after calling next_token
            // again
            ...
        }
    }

    let text = String::from("a b c");
    let mut p = Parser::new(&text);
    let t = p.next_token();
    // drop(text);              // ERROR - p and t borrow it

/* NOTE THE DIFFERENCE between these two: */
    fn next_a(&mut self) -> Option<&'a str>    // borrows the
                                               // INPUT
    fn next_b(&mut self) -> Option<&str>       // elision
                                               // rule 3:
                                               // borrows SELF
/* The second one keeps `self` borrowed for as long as the
   result is held, so you cannot call it twice and keep both
   results. The first can. Choosing correctly is the main
   reason to write lifetimes explicitly on methods.

/* AND THE GENERAL ADVICE FOR EMBEDDED: a struct holding
   references is often better as a struct holding INDICES or
   owning its data. Borrowing structs are excellent for
   parsers and views over a buffer; they are awkward for
   long-lived state.                                       */
```

'static

```
/* 'static means "valid for the entire program". Two distinct
   things use it, and confusing them causes real trouble. */

/* --- 1. &'static T - a reference that lives forever --- */
    let s: &'static str = "hello";      // string literals are
                                        // in .rodata
    static TABLE: [u8; 256] = [0; 256];
    let t: &'static [u8] = &TABLE;

/* On embedded this is common and useful: */
    static mut BUFFER: [u8; 1024] = [0; 1024];
    // `static mut` requires unsafe to access - use a
    // StaticCell or a Mutex<RefCell<..>> instead
    // (chapter 15)

/* --- 2. T: 'static - a TYPE BOUND --- */
    fn spawn<F: FnOnce() + Send + 'static>(f: F);

/* This does NOT mean "lives forever". It means "contains no
   references with a lifetime shorter than 'static" - i.e. it
   either owns all its data, or only holds &'static
   references.

   String is 'static. i32 is 'static. Vec<String> is 'static.
   &'a str is NOT 'static unless 'a is.

   THAT IS WHY thread::spawn requires it: the thread may
   outlive the spawning scope, so its closure must not borrow
   anything local. Scoped threads (chapter 13) lift the
   requirement by guaranteeing the join happens first.

/* THE ANTI-PATTERN: adding `+ 'static` to silence an error.
   It usually pushes the problem to the caller, who then has
   to clone or leak. Work out what the real lifetime
   relationship is instead.                              */
```

Bounds and subtyping

```
/* --- LIFETIME BOUNDS --- */
    fn f<'a, 'b: 'a>(x: &'a str, y: &'b str) -> &'a str
/* `'b: 'a` reads "'b OUTLIVES 'a" - 'b is at least as long.
   So a &'b can be used where a &'a is expected.

    struct Wrapper<'a, T: 'a> { r: &'a T }
/* `T: 'a` means T contains no references shorter than 'a.
   Since Rust 2018 this is inferred in most positions and you
   rarely write it.

/* --- SUBTYPING: a longer lifetime coerces to a shorter --- */
    let long = String::from("x");
    {
        let r: &str = &long;    // &'long coerces to a shorter
                                // lifetime here
    }
/* This is why passing a &'static where &'a is wanted always
   works.

/* --- VARIANCE, which you will meet in error messages --- */
    &'a T           COVARIANT in 'a and in T
                    (a longer 'a works where a shorter is
                     wanted)
    &'a mut T       covariant in 'a, INVARIANT in T
    Cell<T>         invariant in T
    fn(T) -> U      CONTRAVARIANT in T, covariant in U

/* WHY &mut T IS INVARIANT IN T: if it were covariant you
   could write a shorter-lived reference through a
   &mut &'static T, creating a dangling &'static. The
   compiler forbids it, and the resulting error mentions
   "lifetime may not live long enough" in a way that only
   makes sense once you know variance exists.

/* YOU DO NOT NEED TO MEMORISE THIS. You need to recognise
   that an error about a &mut of a reference type is probably
   variance, and that the fix is usually to restructure
   rather than to add annotations.                       */
```

Practical patterns

```
/* --- 1. A ZERO-COPY PARSER, the best use of lifetimes --- */
    struct Packet<'a> {
        header: &'a [u8; 8],
        payload: &'a [u8],
    }

    fn parse(buf: &[u8]) -> Option<Packet<'_>> {
        if buf.len() < 8 { return None; }
        let (h, rest) = buf.split_at(8);
        Some(Packet {
            header: h.try_into().ok()?,
            payload: rest,
        })
    }
/* NO ALLOCATION, no copying - the packet is a VIEW into the
   receive buffer, and the compiler guarantees the buffer
   outlives it. That is a genuinely better answer than either
   copying (C++ safe version) or a raw pointer (C version).

   `'_` is the ANONYMOUS lifetime - "infer it, but I
   acknowledge one exists". Prefer it to omitting the
   parameter entirely; `-> Option<Packet>` is deprecated
   style for exactly this reason.

/* --- 2. A BUILDER THAT BORROWS --- */
    struct Config<'a> { name: &'a str, retries: u32 }

    impl<'a> Config<'a> {
        fn name(mut self, n: &'a str) -> Self {
            self.name = n; self
        }
        fn retries(mut self, r: u32) -> Self {
            self.retries = r; self
        }
    }
    let c = Config::default().name("dev").retries(3);
/* Taking `self` by value and returning it makes the chain
   work without any borrowing at all.

/* --- 3. AVOIDING LIFETIMES: own it, or index it --- */
    struct Owned { data: Vec<u8> }              // no
                                                // lifetimes
    struct Indexed { range: Range<usize> }      // no
                                                // lifetimes
/* When a struct with a lifetime becomes awkward - which
   happens when it needs to be stored, sent between threads,
   or held in a collection - one of these two is the answer.

/* --- 4. WHEN A REFERENCE MUST OUTLIVE ITS SCOPE --- */
    let leaked: &'static mut [u8] =
        Box::leak(vec![0u8; 1024].into_boxed_slice());
/* Deliberately leaks a heap allocation to obtain a 'static
   reference. Legitimate for one-time initialisation at
   startup - a DMA buffer, a global table - and a red flag
   anywhere else.

   ON no_std, StaticCell does the same thing without a heap
   (chapter 15).                                          */
```

Reading the errors

```
error[E0597]: `x` does not live long enough
  --> src/main.rs:6:13
   |
 5 |         let x = 5;
   |             - binding `x` declared here
 6 |         r = &x;
   |             ^^ borrowed value does not live long enough
 7 |     }
   |     - `x` dropped here while still borrowed
 8 |     println!("{r}");
   |               --- borrow later used here

/* THE THREE SPANS tell you everything: where it was
   borrowed, where it was dropped, and where the borrow was
   still needed. Read them in that order and the fix is
   usually obvious - either move the value out, extend its
   scope, or stop holding the reference.

/* THE OTHER COMMON ONES:

   E0106  missing lifetime specifier
          -> the compiler cannot tell which input the output
             borrows from. Add <'a> and say.

   E0621  explicit lifetime required
          -> a returned reference needs a longer lifetime
             than the signature promises.

   E0716  temporary value dropped while borrowed
          -> you borrowed from something that dies at the end
             of the statement:
                 let r = &String::from("x");    // ERROR
                 let s = String::from("x");
                 let r = &s;                    // fine

   E0759  argument requires that it is borrowed for 'static
          -> usually thread::spawn or a trait object; own the
             data or use a scoped thread.

/* AND THE PRACTICAL ADVICE: when stuck, try in this order:
     1. does the function really need to return a reference,
        or can it return an owned value?
     2. can the caller keep ownership and pass &T in?
     3. can the struct own its data instead of borrowing?
     4. can indices replace the references?
     5. only then, write the lifetime annotations.
   Four out of five times one of the first four is the right
   answer, and the annotation was a symptom.             */
```

How it shows up

Error	Meaning and fix
E0106 missing lifetime specifier	Two inputs, one output reference — say which it comes from
E0597 does not live long enough	Read the three spans; usually restructure or own the data
E0716 temporary dropped while borrowed	Bind the temporary to a variable first

Error	Meaning and fix
E0759 requires 'static	A thread or trait object — own it, or use a scoped thread
"lifetime may not live long enough"	Often variance, through a `&mut` of a reference type
A method keeps `self` borrowed too long	Elision rule 3 — annotate the output to borrow the input instead
A struct with a lifetime cannot be stored	Make it own its data, or use indices
Adding `'static` moves the error to the caller	It was the wrong fix — find the real relationship
Everything needs `.clone()`	The ownership design wants revisiting, not more clones

Check yourself

- ✓ Explain what a lifetime is and that it generates no code.
- ✓ State the three elision rules and apply them to five signatures.
- ✓ Explain what `fn longest<'a>(a: &'a str, b: &'a str) -> &'a str` claims.
- ✓ Write a struct that borrows, and explain what it constrains.
- ✓ Distinguish `&'static T` from `T: 'static`.
- ✓ Explain why `thread::spawn` requires `'static`.
- ✓ Explain `'b: 'a` and why `&mut T` is invariant in T.
- ✓ Write a zero-copy parser using the anonymous lifetime.
- ✓ Give four ways to avoid needing lifetime annotations at all.
- ✓ Read an E0597 error and identify the three spans.

Structs, enums and pattern matching

Rust's enums carry data and its `match` is exhaustive. Together they let you make invalid states unrepresentable — which is a stronger guarantee than any amount of validation, and the single most useful design technique the language offers.

Structs

```
    struct Point { x: i32, y: i32 }             // named fields
    struct Wrapper(u32);                        // TUPLE struct
    struct Marker;                              // UNIT struct -
                                                // zero sized

    let p = Point { x: 1, y: 2 };
    let w = Wrapper(42);
    println!("{}", w.0);

    let x = 1; let y = 2;
    let p = Point { x, y };                     // field
                                                // shorthand

    let q = Point { x: 5, ..p };                // struct
                                                // update
                                                // syntax

/* METHODS live in an `impl` block, separate from the data: */
    impl Point {
        fn new(x: i32, y: i32) -> Self { Self { x, y } }
                                        // an ASSOCIATED
                                        // function - no self
        fn magnitude(&self) -> f64 { ... }      // borrows
        fn translate(&mut self, dx: i32) { ... }// mutates
        fn into_tuple(self) -> (i32, i32) { ... }// consumes
    }
    let p = Point::new(1, 2);           // :: for associated
    let m = p.magnitude();              // .  for methods

/* NEWTYPES - a tuple struct wrapping one value - are the
   idiomatic way to get a distinct type at zero cost: */
    struct Celsius(f32);
    struct Fahrenheit(f32);
    fn set_target(t: Celsius) { }
    set_target(Fahrenheit(98.6));       // COMPILE ERROR
/* Same representation, different type. This is the C++
   strong-typedef pattern (C++ chapter 07) with less
   ceremony, and it is used pervasively in embedded Rust for
   units, register values and hardware identifiers.

/* DERIVES do the boilerplate: */
    #[derive(Debug, Clone, Copy, PartialEq, Eq,
             PartialOrd, Ord, Hash, Default)]
    struct Config { rate: u32, gain: u8 }

    println!("{c:?}");          // Debug
    println!("{c:#?}");         // pretty-printed Debug
    let d = Config::default();  // Default - zeroes
    if a == b { }               // PartialEq
```

Enums that carry data

```
/* THE CENTRAL DIFFERENCE FROM C: a Rust enum is a TAGGED
   UNION, and each variant may carry different data.      */

    enum Message {
        Quit,                                   // no data
        Move { x: i32, y: i32 },                // named
                                                // fields
        Write(String),                          // one value
        Colour(u8, u8, u8),                     // a tuple
    }

/* IN C YOU WOULD WRITE: */
        struct Message {
                enum { QUIT, MOVE, WRITE, COLOUR } tag;
                union {
                        struct { int x, y; } move_;
                        char *write;
                        struct { uint8_t r,g,b; } colour;
                } data;
        };
/* ...and nothing stops you reading `data.write` when the tag
   says MOVE. Rust makes that impossible: you can only reach
   the payload through a `match` that has already checked the
   tag.

/* SIZE: as large as the biggest variant, plus a
   discriminant - and Rust applies NICHE OPTIMISATION: */
    assert_eq!(size_of::<Option<&u8>>(), size_of::<&u8>());
/* A reference can never be null, so `None` is represented by
   the null bit pattern - Option<&T> is EXACTLY the size of a
   pointer. Same for Option<Box<T>>, Option<NonZeroU32>, and
   any enum with an unused bit pattern available. So the
   safety costs nothing.

/* C-LIKE ENUMS with explicit values, for hardware: */
    #[derive(Clone, Copy, PartialEq)]
    #[repr(u8)]
    enum Mode { Idle = 0, Run = 1, Fault = 0xFF }

    let raw = Mode::Run as u8;          // enum -> integer:
                                        // free
    let m = Mode::try_from(raw)?;       // integer -> enum:
                                        // CHECKED
/* `#[repr(u8)]` fixes the representation, which matters for
   FFI and for register fields (chapter 12). Converting FROM
   an integer must be fallible, because not every value is
   valid - and that is exactly the check C omits.        */
```

Pattern matching

```
    match msg {
        Message::Quit => cleanup(),
        Message::Move { x, y } => move_to(x, y),
        Message::Write(text) => print(&text),
        Message::Colour(r, g, b) => set_colour(r, g, b),
    }
/* EXHAUSTIVE: omit a variant and it does not compile. Add a
   variant to the enum later, and every match that does not
   handle it fails to build - which is precisely the review
   you want.

/* PATTERN FORMS: */
    match x {
        0 => "zero",
        1 | 2 | 3 => "small",           // alternatives
        4..=9 => "medium",              // an inclusive RANGE
        n if n < 0 => "negative",       // a GUARD
        _ => "large",                   // the wildcard
    }

    match point {
        Point { x: 0, y: 0 } => "origin",
        Point { x: 0, y } => "on the y axis",
        Point { x, .. } => "elsewhere",         // .. ignores
                                                // the rest
    }

    match slice {
        [] => "empty",
        [one] => "one element",
        [first, .., last] => "several",         // slice
                                                // patterns
        [first, rest @ ..] => "head and tail",  // BINDING with
                                                // @
    }

    match opt {
        Some(n @ 1..=9) => println!("single digit {n}"),
        Some(n) => println!("{n}"),
        None => println!("nothing"),
    }

/* MATCH ERGONOMICS - matching on a reference binds
   references, so you rarely need to write & or *: */
    match &opt {
        Some(v) => use(v),      // v is &T automatically
        None => {}
    }

/* THE SHORTHANDS: */
    if let Some(v) = opt { use(v); }
    else { handle_none(); }

    let Some(v) = opt else { return; };  // LET-ELSE - the
                                         // else branch must
                                         // diverge

    while let Some(item) = queue.pop() { process(item); }

    // and matches! for a boolean test:
```

```
    if matches!(state, State::Running | State::Paused) { }

/* LET-ELSE IS THE ONE TO ADOPT: it replaces the pyramid of
   `if let` nesting with early returns, which reads exactly
   like the guard-clause style good C already uses.      */
```

MAKE INVALID STATES UNREPRESENTABLE

```
// BAD: four booleans = sixteen states, twelve invalid
struct Conn { connected: bool, authed: bool,
              error: bool, session: Option<u32> }

// GOOD: exactly the states that exist
enum Conn {
    Disconnected,
    Connecting { started: Instant },
    Authenticated { session: u32 },
    Failed(Error),
}
```

The second version cannot represent "authenticated but not connected", so no code needs to check for it and no test needs to cover it. This is the highest-leverage design technique in the language, and it transfers directly to C++ (`std::variant`) and even to C with discipline.

Modelling hardware

```
/* --- A REGISTER FIELD as an enum --- */
    #[repr(u8)]
    #[derive(Clone, Copy, PartialEq, Debug)]
    pub enum Prescaler { Div1 = 0, Div2 = 1, Div4 = 2,
                         Div8 = 3 }

    impl Prescaler {
        pub const fn divisor(self) -> u32 {
            1 << (self as u8)
        }
    }
/* An invalid prescaler value cannot exist, and the divisor
   is computed at compile time.

/* --- A COMMAND PROTOCOL --- */
    enum Command {
        Read  { addr: u16, len: u8 },
        Write { addr: u16, data: [u8; 4] },
        Reset,
        SetMode(Mode),
    }

    fn encode(cmd: &Command, out: &mut [u8]) -> usize {
        match cmd {
            Command::Read { addr, len } => {
                out[0] = 0x01;
                out[1..3].copy_from_slice(&addr.to_le_bytes());
                out[3] = *len;
                4
            }
            Command::Write { addr, data } => {
                out[0] = 0x02;
                out[1..3].copy_from_slice(&addr.to_le_bytes());
                out[3..7].copy_from_slice(data);
                7
            }
            Command::Reset => { out[0] = 0x03; 1 }
            Command::SetMode(m) => { out[0] = 0x04;
                                     out[1] = *m as u8; 2 }
        }
    }
/* Add a command and every encoder, decoder and handler that
   does not cover it fails to compile. In C that is a
   comment; here it is the build.

/* --- A STATE MACHINE, where the state OWNS its data --- */
    enum State {
        Idle,
        Sampling { buffer: [u16; 64], count: usize },
        Transmitting { remaining: usize },
        Error(ErrorKind),
    }

    fn step(state: State, ev: Event) -> State {
        match (state, ev) {
            (State::Idle, Event::Start) =>
                State::Sampling { buffer: [0; 64], count: 0 },

            (State::Sampling { mut buffer, count },
             Event::Sample(v)) if count < 64 => {
```

```
                buffer[count] = v;
                State::Sampling { buffer, count: count + 1 }
            }

            (State::Sampling { count: 64, .. },
             Event::Sample(_)) =>
                State::Transmitting { remaining: 64 },

            (s, Event::Reset) => { let _ = s; State::Idle }

            (s, _) => s,        // unchanged
        }
    }
/* MATCHING ON A TUPLE of (state, event) is the idiomatic
   transition table, and it is checked for exhaustiveness
   across BOTH dimensions.

   NOTE the buffer lives INSIDE the Sampling variant - so it
   does not exist while Idle, and cannot be touched from any
   other state. That is the same "invalid states
   unrepresentable" idea applied to memory.             */
```

Traits on your types, briefly

```
/* Full coverage is chapter 06; the ones you implement on
   almost every type: */

    use core::fmt;

    impl fmt::Display for Temperature {
        fn fmt(&self, f: &mut fmt::Formatter<'_>)
                -> fmt::Result {
            write!(f, "{:.1}°C", self.0)
        }
    }
    // Display is for USERS; Debug (usually derived) is for
    // PROGRAMMERS.

    impl From<u16> for Raw {
        fn from(v: u16) -> Self { Raw(v) }
    }
    // implementing From gives you Into for free:
    let r: Raw = 42u16.into();

    impl TryFrom<u8> for Mode {
        type Error = ();
        fn try_from(v: u8) -> Result<Self, ()> {
            match v {
                0 => Ok(Mode::Idle),
                1 => Ok(Mode::Run),
                0xFF => Ok(Mode::Fault),
                _ => Err(()),
            }
        }
    }
    // the CHECKED integer-to-enum conversion from above

    impl Default for Config {
        fn default() -> Self {
            Config { rate: 48_000, gain: 0 }
        }
    }

/* AND THE DERIVE LIST worth putting on most data types: */
    #[derive(Debug, Clone, Copy, PartialEq, Eq, Default)]
/* Debug for diagnostics, Clone/Copy if it is plain data,
   PartialEq for tests, Default if there is a sensible one. */
```

How it shows up

Error	Meaning and fix
"non-exhaustive patterns: `X` not covered"	Add the arm — the feature working as intended
"unreachable pattern"	An earlier arm already matches everything this one would
"cannot move out of ... which is behind a reference"	Matching by value on a `&T` — bind by reference or clone
"binding moves value" in a match arm	Use `ref`, or match on `&value`
`Option<T>` is larger than expected	No niche available — check with `size_of`
Enum discriminant differs from C	Missing `#[repr(u8)]` or `#[repr(C)]`

Error	Meaning and fix
A struct's layout differs from C	Rust reorders fields by default — use `#[repr(C)]`
Two units confused at a call site	Use newtypes
Many booleans, most combinations invalid	Replace with an enum
Adding a variant broke twenty files	Exactly right — those were the places that needed updating

Check yourself

- ✓ Write named, tuple and unit structs, and say when each fits.
- ✓ Explain newtypes and give an embedded use.
- ✓ Explain how a Rust enum differs from a C one, and what it makes impossible.
- ✓ Explain niche optimisation and demonstrate it with `size_of`.
- ✓ Use `#[repr(u8)]` and explain why integer-to-enum must be fallible.
- ✓ Write matches using ranges, guards, bindings, slice patterns and `..`.
- ✓ Use `let-else` to flatten nested `if let`.
- ✓ Redesign a struct of booleans as an enum and say what that removes.
- ✓ Write a state machine matching on `(state, event)`.
- ✓ Implement `Display`, `From`, `TryFrom` and `Default`.

Traits and generics

Rust's abstraction mechanism: interfaces that types opt into, and generics constrained by them. Unlike C++ templates, the constraints are checked when the generic is *defined*, so the errors appear where the mistake is.

Traits

```
    trait Sensor {
        fn read(&mut self) -> u16;              // required

        fn read_averaged(&mut self, n: u8) -> u16 {
            let mut sum = 0u32;                 // a DEFAULT
            for _ in 0..n {                     // method
                sum += self.read() as u32;
            }
            (sum / n as u32) as u16
        }

        const MAX_VALUE: u16 = 4095;            // associated
                                                // constant
        type Unit;                              // associated
                                                // TYPE
    }

    struct Thermistor { channel: u8 }

    impl Sensor for Thermistor {
        type Unit = Celsius;
        fn read(&mut self) -> u16 { adc_read(self.channel) }
        // read_averaged comes free from the default
    }

/* THE COHERENCE (ORPHAN) RULE: you may implement a trait for
   a type only if you own the TRAIT or you own the TYPE. So
   nobody can implement a foreign trait for a foreign type,
   which guarantees exactly one implementation exists
   anywhere in the program.

   THE WORKAROUND when you need to: a newtype (chapter 05).
        struct MyVec(Vec<u8>);
        impl SomeForeignTrait for MyVec { ... }

/* A TRAIT MUST BE IN SCOPE to call its methods: */
    use my_crate::Sensor;       // without this, `.read()` is
                                // "method not found"
/* Which is why the standard library has PRELUDES, and why
   embedded HAL crates tell you to `use embedded_hal::prelude
   ::*`.                                                  */
```

Generics

```
    fn largest<T: PartialOrd>(list: &[T]) -> &T {
        let mut max = &list[0];
        for x in list {
            if x > max { max = x; }
        }
        max
    }

/* THE BOUND `T: PartialOrd` IS CHECKED AT DEFINITION. If the
   body used `+` you would get an error HERE, not at some
   distant instantiation - which is the central difference
   from C++ templates (C++ chapter 06), and the reason Rust's
   generic errors are readable.

/* THREE SYNTAXES for the same thing: */
    fn f<T: Display + Clone>(x: T) { }
    fn f<T>(x: T) where T: Display + Clone { }
    fn f(x: impl Display + Clone) { }           // "impl
                                                // Trait" -
                                                // shortest,
                                                // but the
                                                // caller
                                                // cannot
                                                // turbofish it

/* GENERIC STRUCTS AND IMPLS: */
    struct RingBuffer<T, const N: usize> {
        data: [T; N],
        head: usize,
        tail: usize,
    }

    impl<T: Copy + Default, const N: usize> RingBuffer<T, N> {
        pub const fn capacity(&self) -> usize { N }

        pub fn push(&mut self, v: T) -> Result<(), T> {
            let next = (self.head + 1) % N;
            if next == self.tail { return Err(v); }
            self.data[self.head] = v;
            self.head = next;
            Ok(())
        }
    }

    let mut rb: RingBuffer<u8, 64> = RingBuffer::new();

/* CONST GENERICS (`const N: usize`) are the embedded feature:
   a fixed-capacity container with the size in the type, no
   heap, and `% N` folded to an AND when N is a power of two.
   Exactly the C++ template-parameter pattern (C++ ch. 06).

/* MONOMORPHISATION: the compiler generates a separate copy
   for each concrete type used - same as C++ templates, same
   code-size consideration, same zero runtime cost.       */
```

CONSTRAINED GENERICS VERSUS DUCK-TYPED TEMPLATES

A C++ template is checked when instantiated, so an error inside `std::sort` reports a hundred lines deep. A Rust generic is checked when *defined*: if the body calls a method the bound does not promise, the error is on that line, in your function. That is why C++20 added concepts (C++ chapter 06) — it is retrofitting the same property.

Static versus dynamic dispatch

```
/* --- STATIC: one copy per type, fully inlinable --- */
    fn sample<S: Sensor>(s: &mut S) -> u16 { s.read() }

    sample(&mut thermistor);    // generates sample::<Thermistor>
    sample(&mut photodiode);    // and sample::<Photodiode>

/* -> a direct call, usually inlined to nothing. Zero cost,
   more code.

/* --- DYNAMIC: one copy, a vtable --- */
    fn sample_dyn(s: &mut dyn Sensor) -> u16 { s.read() }

    let sensors: [&mut dyn Sensor; 3] = [&mut a, &mut b,
                                         &mut c];
    for s in sensors { sample_dyn(s); }

/* A `&dyn Trait` is a FAT POINTER - two words: the data
   pointer and a vtable pointer. Note the difference from
   C++ (C++ chapter 11), where the vptr is INSIDE the object:
     · a Rust object has no vtable pointer unless you make a
       trait object of it, so non-polymorphic use costs
       nothing
     · but &dyn T is 16 bytes rather than 8

    assert_eq!(size_of::<&u8>(), 8);
    assert_eq!(size_of::<&dyn Sensor>(), 16);

/* OBJECT SAFETY - a trait can only be a `dyn` object if:
     · no generic methods
     · no methods taking or returning `Self` by value
     · no associated constants (before Rust 1.79)
     · every method is dispatchable
   `Clone` is not object safe, for instance, because clone()
   returns Self.

/* CHOOSING - the same decision as C++ chapter 11:
     the type set is known at compile time  -> GENERICS
     a heterogeneous collection, or a plugin -> dyn
     code size matters more than speed       -> dyn
     it is in a hot path                     -> generics

   ON EMBEDDED, generics dominate: the peripheral set is
   known, and monomorphisation lets the optimiser fold the
   whole driver stack into a few instructions.

/* AND `impl Trait` IN RETURN POSITION, which is static
   dispatch with the type hidden: */
    fn make_sensor() -> impl Sensor { Thermistor::new(0) }
/* One concrete type, chosen by the function, opaque to the
   caller. No allocation, no vtable. For a heterogeneous
   return you need Box<dyn Sensor> instead.             */
```

The traits that matter

Trait	Meaning
`Copy`, `Clone`	Bitwise duplication; explicit duplication (ch. 02)

Trait	Meaning
`Drop`	Run code when the value dies
`Debug`, `Display`	Formatting for programmers; for users
`Default`	A sensible zero value
`PartialEq`, `Eq`	Equality; equality that is reflexive (so `f32` is only `PartialEq`)
`PartialOrd`, `Ord`	Ordering, total ordering
`Hash`	Usable as a map key
`From`, `Into`	Infallible conversion — implement `From`, get `Into` free
`TryFrom`, `TryInto`	Fallible conversion
`Deref`, `DerefMut`	Behave like a reference to something else
`Index`, `IndexMut`	`x[i]`
`Iterator`, `IntoIterator`	Iteration (ch. 08)
`Send`, `Sync`	Thread safety (ch. 13)
`Sized`	Known size — an implicit bound on every generic parameter
`Fn`, `FnMut`, `FnOnce`	Callables (ch. 08)
Operator traits	`Add`, `Sub`, `BitOr`, `Not`, ...

```
/* OPERATOR OVERLOADING is just implementing a trait: */
    use core::ops::{Add, BitOr};

    #[derive(Clone, Copy)]
    struct Flags(u32);

    impl BitOr for Flags {
        type Output = Flags;
        fn bitor(self, rhs: Flags) -> Flags {
                Flags(self.0 | rhs.0) }
    }
    let f = Flags(1) | Flags(2);

/* Deref, and its one legitimate use - smart pointers: */
    impl Deref for MyBox<T> {
        type Target = T;
        fn deref(&self) -> &T { &self.0 }
    }
/* DO NOT use Deref to fake inheritance. It is for types that
   ARE a pointer to something, and abusing it produces
   confusing method resolution.                          */
```

The embedded-hal traits

```
/* The embedded ecosystem is built on one set of traits, so a
   driver written once works on every chip (chapter 16).  */

    use embedded_hal::digital::{OutputPin, InputPin};
    use embedded_hal::spi::SpiDevice;
    use embedded_hal::delay::DelayNs;

    pub struct Display<SPI, DC, RST> {
        spi: SPI,
        dc:  DC,
        rst: RST,
    }

    impl<SPI, DC, RST, E> Display<SPI, DC, RST>
    where
        SPI: SpiDevice<Error = E>,
        DC:  OutputPin,
        RST: OutputPin,
    {
        pub fn init(&mut self, delay: &mut impl DelayNs)
                -> Result<(), E>
        {
            self.rst.set_low().ok();
            delay.delay_ms(10);
            self.rst.set_high().ok();
            delay.delay_ms(120);

            self.dc.set_low().ok();             // command mode
            self.spi.write(&[0x11])?;           // sleep out
            Ok(())
        }
    }

/* THIS DRIVER COMPILES FOR EVERY CHIP whose HAL implements
   the traits - STM32, nRF, ESP32, RP2040 - with no
   conditional compilation and no porting layer. That is the
   ecosystem's central achievement, and it has no equivalent
   in the C world, where every vendor HAL has its own
   incompatible API.

   AND IT IS ZERO COST: SPI, DC and RST are concrete types at
   the call site, so every trait call is direct and inlined.
   The generated code is identical to a chip-specific
   driver.                                                */
```

Patterns worth knowing

```
/* --- BLANKET IMPLEMENTATIONS --- */
    trait Loggable { fn log(&self); }

    impl<T: Display> Loggable for T {
        fn log(&self) { println!("{self}"); }
    }
/* EVERY type implementing Display now implements Loggable.
   The standard library uses this heavily - `impl<T> Into<U>
   for T where U: From<T>` is why implementing From gives you
   Into.

/* --- MARKER TRAITS: no methods, only a promise --- */
    unsafe trait Zeroable {}            // "all-zero bits is a
                                        // valid value"
    unsafe impl Zeroable for u32 {}
    fn zeroed<T: Zeroable>() -> T { unsafe { core::mem::zeroed() } }
/* `unsafe trait` means implementing it is a promise the
   compiler cannot check - which is how Send and Sync work
   (chapter 13).

/* --- EXTENSION TRAITS: add methods to a foreign type --- */
    trait BitExt { fn bit(self, n: u8) -> bool; }
    impl BitExt for u32 {
        fn bit(self, n: u8) -> bool { (self >> n) & 1 != 0 }
    }
    if reg.bit(5) { }
/* Legal because you own the trait. Extremely useful for
   register manipulation.

/* --- SEALED TRAITS: public to use, private to implement --- */
    mod private { pub trait Sealed {} }
    pub trait Register: private::Sealed { ... }
    impl private::Sealed for CTRL {}
    impl Register for CTRL { ... }
/* Nobody outside your crate can implement Register, because
   they cannot name Sealed. Used throughout the PAC crates
   (chapter 16) so the register set is closed.

/* --- ASSOCIATED TYPES versus GENERIC PARAMETERS --- */
    trait Container { type Item; fn get(&self)
                                      -> Option<&Self::Item>; }
    trait Convert<T> { fn convert(&self) -> T; }
/* USE AN ASSOCIATED TYPE when there is exactly one sensible
   choice per implementing type (Iterator::Item). Use a
   GENERIC PARAMETER when a type may implement it several
   ways (From<u8> and From<u16> for the same type). Getting
   this wrong makes an API either too rigid or ambiguous. */
```

How it shows up

Error	Meaning and fix
"no method named `x` found"	The trait is not in scope — `use` it
"the trait bound `T: Foo` is not satisfied"	Add the bound, or implement the trait
"only traits defined in the current crate can be implemented"	The orphan rule — use a newtype
"the trait cannot be made into an object"	Not object safe — use generics, or restructure the trait

Error	Meaning and fix
"type annotations needed"	Inference is ambiguous — turbofish it: `x.parse::<u32>()`
"conflicting implementations"	Two impls could apply — usually a blanket impl clashing
"the size for values of type `T` cannot be known"	Needs `?Sized`, or a reference
Binary larger than expected	Monomorphisation — consider `dyn` for cold paths
A generic function will not inline	Check it is not accidentally a trait object
An API is too rigid or too ambiguous	Associated type versus generic parameter chosen wrongly

Check yourself

- ✓ Define a trait with a required method, a default method and an associated type.
- ✓ State the orphan rule and its newtype workaround.
- ✓ Explain why a trait must be in scope to call its methods.
- ✓ Write the same bound three ways and say when each is preferable.
- ✓ Explain why Rust's generic errors appear at the definition and C++'s at instantiation.
- ✓ Use const generics for a fixed-capacity container.
- ✓ Compare `&dyn Trait` with C++'s vptr, including the size difference.
- ✓ State the object-safety rules and why `Clone` fails them.
- ✓ Write a driver generic over `embedded-hal` traits and say what it buys.
- ✓ Use a blanket impl, an extension trait and a sealed trait.

Error handling with `Option` and `Result`

No exceptions, no error codes to forget. Failure is in the return type, the compiler makes you handle it, and the `?` operator makes propagation as terse as ignoring it would be in C.

Two types

```
    enum Option<T> { Some(T), None }
    enum Result<T, E> { Ok(T), Err(E) }

/* THAT IS ALL THEY ARE - ordinary enums (chapter 05), with a
   great many convenience methods.

     Option    "a value, or nothing" - absence is not an error
     Result    "a value, or an error explaining why"

   USE Option WHEN: a lookup misses, a buffer is empty, a
   configuration field is unset, a conversion has one obvious
   failure mode.
   USE Result WHEN: the caller needs to know WHY, or wants to
   propagate.

/* THERE IS NO NULL. `Option<&T>` is the same size as `&T`
   (niche optimisation, chapter 05), so the safety is free -
   and the check is not optional:                          */

    fn find(&self, id: u32) -> Option<&Device>;

    let d = self.find(id);
    d.name();                   // COMPILE ERROR - it is an
                                // Option
    if let Some(d) = self.find(id) { d.name(); }

/* COMPARE C, where the null check is a convention nobody
   enforces, and C++, where std::optional is opt-in and the
   raw pointer remains available.

/* AND #[must_use]: Result is marked with it, so ignoring one
   is a warning: */
    write_register(0x10, 5);    // warning: unused
                                // `Result` that must be used
    let _ = write_register(0x10, 5);    // explicit "I am
                                        // ignoring this"  */
```

The `?` operator

```
/* WITHOUT it, propagation is verbose: */
    fn read_config() -> Result<Config, Error> {
        let raw = match read_flash(CONFIG_ADDR) {
            Ok(v) => v,
            Err(e) => return Err(e),
        };
        let parsed = match parse(&raw) {
            Ok(v) => v,
            Err(e) => return Err(e),
        };
        Ok(parsed)
    }

/* WITH it: */
    fn read_config() -> Result<Config, Error> {
        let raw = read_flash(CONFIG_ADDR)?;
        let parsed = parse(&raw)?;
        Ok(parsed)
    }

/* `expr?` means: if Ok(v), evaluate to v; if Err(e), RETURN
   Err(e.into()) from the enclosing function.

   THE `.into()` IS THE IMPORTANT PART: the error is converted
   via the From trait (chapter 06), so a function returning
   `Result<_, MyError>` can use `?` on anything whose error
   type converts into MyError.                              */

    #[derive(Debug)]
    enum Error {
        Flash(FlashError),
        Parse(ParseError),
        Timeout,
    }

    impl From<FlashError> for Error {
        fn from(e: FlashError) -> Self { Error::Flash(e) }
    }
    impl From<ParseError> for Error {
        fn from(e: ParseError) -> Self { Error::Parse(e) }
    }
/* Now `?` converts automatically at every call site, and
   adding a new error source is one From impl.

/* `?` ALSO WORKS ON Option, inside a function returning
   Option: */
    fn first_even(v: &[i32]) -> Option<i32> {
        let x = v.iter().find(|x| *x % 2 == 0)?;
        Some(*x * 2)
    }

/* AND THE CHAIN, which is where it earns its keep: */
    fn handle(&mut self, cmd: &[u8]) -> Result<Response, Error> {
        let parsed = Command::parse(cmd)?;
        let result = self.execute(parsed)?;
        let encoded = result.encode()?;
        self.transmit(&encoded)?;
        Ok(Response::Ok)
    }
```

```
/* Four fallible operations, four characters of error
   handling, and not one of them can be forgotten.       */
```

WHY THIS BEATS BOTH ALTERNATIVES

An error code can be ignored silently — and in C, routinely is. An exception cannot be ignored but is invisible in the signature and unwinds unpredictably (C++ chapter 12). `Result` is in the type, cannot be dropped without a warning, costs nothing at run time, and propagates in one character. It is the design C++23's `std::expected` is copying.

The methods worth knowing

```
/* --- EXTRACTING --- */
    opt.unwrap()                // PANICS on None
    opt.expect("msg")           // panics with your message
    opt.unwrap_or(default)
    opt.unwrap_or_else(|| compute())
    opt.unwrap_or_default()

    res.unwrap()                // panics, printing the Err
    res.expect("msg")
    res.unwrap_or(default)
    res.unwrap_err()            // panics if Ok

/* USE `expect` OVER `unwrap` - the message tells the next
   reader WHY you believed it could not fail:            */
    let p = Peripherals::take()
        .expect("peripherals taken twice");

/* --- TRANSFORMING --- */
    opt.map(|v| v * 2)                  // Option<T> ->
                                        // Option<U>
    opt.and_then(|v| lookup(v))         // flat_map - avoids
                                        // Option<Option<T>>
    opt.filter(|v| *v > 0)
    opt.or(other)
    opt.take()                          // leaves None behind
    opt.replace(v)
    opt.get_or_insert_with(|| make())

    res.map(|v| v * 2)
    res.map_err(|e| Error::Wrapped(e))  // convert the ERROR
    res.and_then(|v| next_step(v))
    res.ok()                            // Result -> Option,
                                        // discarding the
                                        // error
    opt.ok_or(Error::Missing)           // Option -> Result
    opt.ok_or_else(|| Error::Missing)

/* --- INSPECTING --- */
    opt.is_some()  opt.is_none()
    res.is_ok()    res.is_err()
    opt.as_ref()                        // Option<T> ->
                                        // Option<&T>
    opt.as_mut()
    res.as_ref()
    opt.iter()                          // 0 or 1 items

/* --- COLLECTING, which is a genuinely useful trick --- */
    let results: Vec<Result<u32, E>> = ...;
    let all: Result<Vec<u32>, E> = results.into_iter().collect();
/* Collects into Ok(vec) if EVERY element is Ok, or the FIRST
   Err. One line replaces a loop with an early return.

    let vals: Vec<u32> = results.into_iter()
                               .flatten()  // keep the Oks
                               .collect();

/* --- THE LAZY VARIANTS --- */
    opt.unwrap_or(expensive())          // ALWAYS evaluates
    opt.unwrap_or_else(|| expensive())  // only on None
/* The `_else` and `_with` suffixes always mean "lazy". On
```

```
    embedded, where the default might be a hardware read,
    this matters.                                          */
```

Designing an error type

```
/* --- FOR no_std / EMBEDDED: a small enum, Copy if
       possible --- */
    #[derive(Debug, Clone, Copy, PartialEq, Eq)]
    pub enum Error {
        Timeout,
        BusError,
        Nack,
        InvalidAddress(u8),
        BufferTooSmall { needed: usize, got: usize },
    }

    impl core::fmt::Display for Error {
        fn fmt(&self, f: &mut core::fmt::Formatter<'_>)
                -> core::fmt::Result {
            match self {
                Error::Timeout => write!(f, "timeout"),
                Error::Nack => write!(f, "not acknowledged"),
                Error::InvalidAddress(a) =>
                        write!(f, "invalid address {a:#x}"),
                Error::BufferTooSmall { needed, got } =>
                        write!(f, "buffer too small: need \
                                   {needed}, got {got}"),
                _ => write!(f, "bus error"),
            }
        }
    }

/* SIZE MATTERS on embedded: keep the variants small, and
   prefer Copy so the error can be returned without a move.
   `Result<(), Error>` with a Copy enum is typically one or
   two bytes.

/* --- THE thiserror CRATE removes the boilerplate (std or
       no_std with `core-error`): --- */
    #[derive(Debug, thiserror::Error)]
    pub enum Error {
        #[error("timeout after {0} ms")]
        Timeout(u32),

        #[error("SPI failure")]
        Spi(#[from] SpiError),           // generates the From
                                         // impl AND the
                                         // source chain
    }

/* --- FOR APPLICATIONS, anyhow: --- */
    fn main() -> anyhow::Result<()> {
        let cfg = read_config()
            .context("reading configuration")?;
        run(cfg).context("running")?;
        Ok(())
    }
/* anyhow::Error boxes any error and accumulates CONTEXT, so
   the final message is "running: reading configuration: file
   not found". Perfect for a binary; wrong for a library,
   because callers cannot match on the error.

/* THE RULE: LIBRARIES define a concrete enum so callers can
```

```
   match. APPLICATIONS use anyhow so they can report. Embedded
   firmware is a library in this sense - define the enum. */
```

Panics

```
/* A panic is for a BUG, not a runtime failure - the same
   distinction as assert versus error return (C++ chapter 12).
*/

    panic!("invariant violated: {state:?}");
    assert!(index < LEN, "index {index} out of range");
    assert_eq!(a, b);
    debug_assert!(expensive_check());   // debug builds only
    unreachable!("state machine reached an impossible state");
    todo!()  unimplemented!()

/* WHAT HAPPENS: by default the stack UNWINDS, running Drop
   for every live value, then the thread dies. With
   `panic = "abort"` it terminates immediately.

/* THESE PANIC, and knowing which is important on embedded:
     unwrap() / expect() on None or Err
     array or slice indexing out of range
     integer division by zero
     INTEGER OVERFLOW in debug builds (release wraps)
     .unwrap() on a poisoned Mutex

/* AVOIDING PANICS in code that must not: */
    v.get(i)                    // Option, not a panic
    v.get_mut(i)
    a.checked_add(b)            // Option
    a.saturating_add(b)         // clamps
    a.wrapping_add(b)           // explicit wrap
    a.overflowing_add(b)        // (value, did_overflow)
    a.checked_div(b)            // None on zero

/* ON EMBEDDED (chapter 15): */
    #[panic_handler]
    fn panic(info: &PanicInfo) -> ! {
        // log it somewhere persistent, then reset
        write_panic_log(info);
        cortex_m::peripheral::SCB::sys_reset();
    }

    // in Cargo.toml
    [profile.release]
    panic = "abort"             // no unwinder - smaller
    overflow-checks = false     // or true, if you prefer the
                                // panic

/* AND THE panic-never TRICK: if you can prove no panic is
   reachable, the `panic-never` crate makes any residual panic
   a LINK ERROR. Combined with careful use of `get` and
   `checked_*`, that gives a build-time guarantee of no
   panics - which for safety-critical firmware is a strong
   property.                                              */
```

Patterns

```
/* --- 1. FALLIBLE CONSTRUCTION --- */
    impl Uart {
        pub fn new(base: usize, baud: u32)
                -> Result<Self, Error>
        {
            if baud == 0 || baud > MAX_BAUD {
                return Err(Error::InvalidBaud);
            }
            let uart = Uart { base };
            uart.configure(baud)?;
            Ok(uart)
        }
    }
/* No "constructed but invalid" state - if you have a Uart, it
   works. Same argument as the C++ static-factory pattern.

/* --- 2. RETRY WITH A BOUND --- */
    fn read_with_retry(&mut self, n: u8)
            -> Result<u16, Error>
    {
        let mut last = Error::Timeout;
        for _ in 0..n {
            match self.read() {
                Ok(v) => return Ok(v),
                Err(e) => last = e,
            }
        }
        Err(last)
    }

/* --- 3. CLEANUP ON ERROR is automatic --- */
    fn transfer(&mut self) -> Result<(), Error> {
        let _cs = self.cs.assert();     // a Drop guard
        self.write(&[0x01])?;           // early return here
        self.write(&[0x02])?;           // or here
        Ok(())
    }                                   // _cs drops on EVERY
                                        // path, including the
                                        // ? returns
/* This is why RAII and `?` compose so well: the early return
   is exactly as safe as the normal one.

/* --- 4. MATCHING ON THE ERROR --- */
    match sensor.read() {
        Ok(v) => process(v),
        Err(Error::Timeout) => retry(),
        Err(Error::Nack) => reset_bus(),
        Err(e) => fatal(e),
    }
/* A concrete error enum makes this possible. anyhow does
   not - which is the reason libraries should not use it.

/* --- 5. TESTS --- */
    #[test]
    fn rejects_zero_baud() {
        assert!(matches!(Uart::new(0x4000, 0),
                         Err(Error::InvalidBaud)));
    }

    #[test]
```

```
    fn works() -> Result<(), Error> {
        let u = Uart::new(0x4000, 115200)?;   // `?` in a test
        assert_eq!(u.baud(), 115200);
        Ok(())
    }
```

How it shows up

Symptom	Cause and fix
"unused `Result` that must be used"	Handle it, or write `let _ =` deliberately
"the `?` operator can only be used in a function that returns Result"	Change the return type, or handle it explicitly
"`?` couldn't convert the error"	Missing `From` impl for that error type
"cannot use `?` on an Option in a Result function"	Use `.ok_or(...)?`
Panic: "called `unwrap()` on a `None`"	Handle the case, or use `expect` with a reason
Panic: "index out of bounds"	Use `.get()`
Panic in release but not debug, or vice versa	Integer overflow — checked in debug, wrapping in release
Binary large because of panic machinery	`panic = "abort"`, and avoid formatting in the handler
Cannot match on a library's errors	It used `anyhow` — a library design mistake
Error type is large and copied everywhere	Box the payload, or shrink the variants

Check yourself

- ✓ Say when to use `Option` and when `Result`.
- ✓ Explain why `Option<&T>` costs nothing.
- ✓ Explain exactly what `?` does, including the conversion.
- ✓ Write `From` impls so `?` works across three error types.
- ✓ Use ten combinator methods and say which are lazy.
- ✓ Collect a `Vec<Result>` into a `Result<Vec>`.
- ✓ Design an error enum suitable for `no_std`.
- ✓ Say why libraries define enums and applications use `anyhow`.
- ✓ List what panics, and the non-panicking alternative for each.
- ✓ Write a `#[panic_handler]` and explain `panic = "abort"`.
- ✓ Show why RAII and `?` compose safely.

Collections, iterators and closures

Rust's iterators are lazy, composable and compile to the same loop you would write by hand — usually without bounds checks. On embedded they are the main reason idiomatic Rust is fast, and the main reason it needs no heap.

The Iterator trait

```
    trait Iterator {
        type Item;
        fn next(&mut self) -> Option<Self::Item>;

        // ...and about seventy provided methods, all built
        // on next()
    }

/* THAT IS THE WHOLE INTERFACE. Implement `next` and you get
   map, filter, zip, take, fold, sum and everything else for
   free.                                                    */

    struct Countdown(u32);

    impl Iterator for Countdown {
        type Item = u32;
        fn next(&mut self) -> Option<u32> {
            if self.0 == 0 { None }
            else { self.0 -= 1; Some(self.0 + 1) }
        }
    }

    for x in Countdown(3) { print!("{x} "); }   // 3 2 1
    let v: Vec<u32> = Countdown(3).collect();
    let s: u32 = Countdown(100).filter(|x| x % 3 == 0).sum();

/* THREE WAYS TO ITERATE A COLLECTION, and choosing wrongly
   is the commonest early mistake:                          */

    for x in &v      { }        // x: &T        - borrows
    for x in &mut v  { }        // x: &mut T    - borrows
                                //                mutably
    for x in v       { }        // x: T         - CONSUMES v

    v.iter()                    // -> &T
    v.iter_mut()                // -> &mut T
    v.into_iter()               // -> T, consumes

/* `for x in v` MOVES v. If you use v afterwards, the error
   is "use of moved value" and the fix is `&v`.          */
```

Adapters and consumers

```
/* ADAPTERS are lazy - they build a new iterator and do
   nothing until consumed.                                  */

    .map(|x| x * 2)
    .filter(|x| *x > 0)
    .filter_map(|x| x.checked_mul(2))   // filter + map, on
                                        // Option
    .flat_map(|x| x.iter())
    .flatten()                          // Iterator<Iterator>
                                        // -> Iterator
    .take(5)  .skip(5)
    .take_while(|x| *x < 10)
    .skip_while(|x| *x < 10)
    .step_by(2)
    .chain(other)                       // concatenate
    .zip(other)                         // pairs; stops at the
                                        // shorter
    .enumerate()                        // (index, item)
    .rev()                              // needs
                                        // DoubleEndedIterator
    .peekable()                         // .peek() without
                                        // consuming
    .windows(3)   .chunks(4)            // on SLICES, not
                                        // iterators
    .scan(state, f)                     // stateful map
    .inspect(|x| println!("{x:?}"))     // debugging, no
                                        // effect

/* CONSUMERS drive the whole chain: */
    .collect::<Vec<_>>()
    .sum::<i32>()   .product()
    .count()  .last()  .nth(3)
    .min()  .max()  .min_by_key(|x| x.len())
    .fold(init, |acc, x| acc + x)
    .try_fold(init, |acc, x| acc.checked_add(x))
    .reduce(|a, b| a.max(b))            // fold with no init
    .any(|x| x > 0)   .all(|x| x > 0)   // SHORT-CIRCUIT
    .find(|x| pred(x))   .position(|x| pred(x))
    .for_each(|x| do_it(x))
    .partition(|x| pred(x))             // into two
                                        // collections
    .unzip()

/* THE LAZINESS MATTERS: */
    let it = v.iter().map(|x| expensive(x));    // NOTHING
                                                // happens
    let first = it.take(1).collect::<Vec<_>>(); // ONE call to
                                                // expensive
/* And short-circuiting consumers stop early:               */
    v.iter().any(|x| *x < 0)            // stops at the first
                                        // negative

/* COLLECT IS POLYMORPHIC in its target: */
    let v: Vec<i32>              = it.collect();
    let s: String                = chars.collect();
    let m: HashMap<K, V>         = pairs.collect();
    let r: Result<Vec<i32>, E>   = results.collect();  // ch. 07
    let (a, b): (Vec<_>, Vec<_>) = it.unzip();
```

WHY ITERATORS BEAT INDEX LOOPS

An index loop needs a bounds check per access, and the compiler can only remove it if it can prove the index is in range. An iterator *is* the proof — it never produces an out-of-range index — so there is nothing to check. The result is that `a.iter_mut().zip(b).for_each(|(x, y)| *x += y)` vectorises and `for i in 0..n { a[i] += b[i] }` may not. On embedded this is the difference between idiomatic and fast, and it is the same code.

Closures

```
    let add = |a, b| a + b;
    let double = |x: i32| -> i32 { x * 2 };

    let factor = 3;
    let scale = |x| x * factor;         // CAPTURES factor

/* THREE TRAITS, by what the closure does with its captures:

     FnOnce   consumes them - callable once
     FnMut    mutates them  - callable repeatedly, needs
              &mut
     Fn       only reads them - callable repeatedly, from &

   Every closure implements FnOnce; those that do not consume
   also implement FnMut; those that do not mutate also
   implement Fn. So `Fn: FnMut: FnOnce`.

    fn call_once<F: FnOnce()>(f: F) { f(); }
    fn call_many<F: FnMut()>(mut f: F) { f(); f(); }
    fn call_shared<F: Fn()>(f: &F) { f(); f(); }

/* CAPTURE MODE IS INFERRED - by reference if that suffices,
   by mutable reference if needed, by value if required.
   `move` forces capture by value:                        */

    let data = vec![1, 2, 3];
    let closure = move || println!("{data:?}");
    // data is MOVED into the closure - required for
    // thread::spawn (chapter 13), because the closure may
    // outlive this scope

/* A CLOSURE IS A STRUCT with one field per capture, plus an
   impl of the call trait - exactly like a C++ lambda
   (C++ chapter 09). A closure capturing nothing is
   zero-sized and coerces to a plain function pointer:    */

    let f: fn(i32) -> i32 = |x| x + 1;
    register_callback(f);       // usable as a C callback
                                // (chapter 12)

/* PASSING CLOSURES:
     fn f<F: Fn(u32)>(cb: F)            // generic - INLINED,
                                        // zero cost
     fn f(cb: &dyn Fn(u32))             // trait object - an
                                        // indirect call
     fn f(cb: Box<dyn Fn(u32)>)         // heap - avoid on
                                        // embedded

   The first is what you want. The same static-versus-dynamic
   trade as C++'s template parameter versus std::function
   (C++ chapter 14).                                       */
```

Collections

Type	Allocates	Embedded
`[T; N]`	No — inline	**Use freely**

Type	Allocates	Embedded
`&[T]`, `&mut [T]`	No — a view	**Use freely**
`&str`	No	**Use freely**
`Vec<T>`	Yes	Needs `alloc`
`String`	Yes	Needs `alloc`
`VecDeque`, `BTreeMap`, `HashMap`	Yes	Needs `alloc`; `HashMap` needs `std`
`heapless::Vec<T, N>`	**No**	**The embedded answer**
`heapless::String<N>`	No	Same
`heapless::spsc::Queue`	No	Lock-free, for ISR-to-main

```
/* THE heapless CRATE gives you the standard interfaces with
   the capacity in the type (chapter 06's const generics): */

    use heapless::Vec;

    let mut v: Vec<u8, 64> = Vec::new();
    v.push(1).unwrap();                 // Result - it can be
                                        // FULL
    v.extend_from_slice(&[2, 3])?;
    let s: &[u8] = &v;                  // derefs to a slice
    for x in &v { }                     // iterates like Vec

    use heapless::String;
    let mut s: String<32> = String::new();
    write!(s, "value: {}", x).ok();     // core::fmt::Write

    use heapless::spsc::Queue;
    static mut Q: Queue<Event, 16> = Queue::new();
    let (mut prod, mut cons) = unsafe { Q.split() };
    // prod goes to the ISR, cons to the main loop -
    // lock-free, no critical section (chapter 13)

/* THE KEY DIFFERENCE FROM std: push returns Result, because
   a fixed-capacity container can be full. That is the
   BOUNDED FAILURE you want on embedded, instead of an
   allocation that might fail or a reallocation that costs
   unpredictable time.                                    */
```

Slices

```
    let a = [1, 2, 3, 4, 5];
    let s: &[i32] = &a;
    let mid = &a[1..4];         // [2, 3, 4]
    let head = &a[..2];
    let tail = &a[2..];

/* A SLICE IS A FAT POINTER - a pointer and a length, 16
   bytes. Exactly std::span (C++ chapter 08), and the same
   advice: take &[T] in parameters, not &Vec<T>.

/* THE METHODS worth knowing: */
    s.len()  s.is_empty()  s.first()  s.last()
    s.get(i)                        // Option - NO PANIC
    s.split_at(mid)  s.split_at_mut(mid)
    s.chunks(n)  s.chunks_exact(n)  s.windows(n)
    s.iter().rev()
    s.contains(&x)  s.starts_with(&pre)
    s.binary_search(&x)             // Result<index,
                                    // insertion_point>
    s.sort()  s.sort_unstable()     // unstable does NOT
                                    // allocate - prefer it
    s.copy_from_slice(&other)       // lengths must MATCH
    s.fill(0)
    s.rotate_left(n)
    s.split_first()  s.split_last()

/* PARSING A BUFFER, zero-copy: */
    fn parse(buf: &[u8]) -> Option<(&[u8; 4], &[u8])> {
        let (h, rest) = buf.split_first_chunk::<4>()?;
        Some((h, rest))
    }
/* No allocation, no copying, and the lifetime ties the
   result to the buffer (chapter 04).

/* AND THE BYTE CONVERSIONS, which embedded code needs
   constantly: */
    u32::from_le_bytes(bytes.try_into().ok()?)
    u32::from_be_bytes(...)
    value.to_le_bytes()                 // -> [u8; 4]
    s.copy_from_slice(&value.to_be_bytes());
/* Explicit endianness, checked length. Compare the C
   memcpy-and-hope, or the pointer cast that is undefined
   behaviour (compilers chapter 15).                     */
```

The generated code

```
/* --- A CHAIN COMPILES TO ONE LOOP --- */
    fn sum_evens(v: &[i32]) -> i32 {
        v.iter().filter(|x| *x % 2 == 0).sum()
    }
/* -O2 aarch64: one loop, no closure objects, no
   intermediate collection - and it vectorises. The
   adapters are structs whose next() methods inline into
   one another completely.

/* --- BOUNDS CHECKS DISAPPEAR --- */
    fn add_indexed(a: &mut [i32], b: &[i32]) {
        for i in 0..a.len() { a[i] += b[i]; }
                               // b[i] IS bounds-checked -
                               // the compiler cannot prove
                               // b is long enough
    }
    fn add_iter(a: &mut [i32], b: &[i32]) {
        for (x, y) in a.iter_mut().zip(b) { *x += *y; }
                               // NO checks - zip stops at
                               // the shorter
    }
/* The second is shorter, safer AND faster. That combination
   is unusual and worth internalising.

/* --- VERIFY IT --- */
    cargo asm my_crate::sum_evens --rust
    cargo bloat --release -n 20
    # or godbolt with the Rust compiler

/* --- AND THE ONE THING TO WATCH --- */
    let v: Vec<i32> = it.collect();     // ALLOCATES
    let n = it.count();                 // does not
/* `collect` is where a chain stops being free. On embedded,
   collect into a heapless::Vec (which returns Result), or
   consume with fold/sum/for_each and never materialise the
   intermediate at all.                                    */
```

How it shows up

Symptom	Cause and fix
"use of moved value" after a `for` loop	`for x in v` consumed it — use `&v`
"cannot borrow as mutable" inside a loop over the same collection	Use `iter_mut`, `retain`, or collect indices first
An iterator chain does nothing	Adapters are lazy — it was never consumed
"type annotations needed" on `collect`	Say the target: `collect::<Vec<_>>()`
"expected closure, found a different closure"	Every closure has a unique type — use a generic parameter or `impl Fn`
"cannot move out of captured variable"	The closure needs `move`, or is `FnOnce` where `Fn` is required
Closure will not convert to a function pointer	It captures — put the state in a context parameter
Unexpected allocation	`collect`, `Box`, `String`, or `sort` (stable)
Index loop slower than expected	Bounds checks — use iterators

Symptom	Cause and fix
`heapless::Vec::push` returns `Err`	Full — the bounded failure, by design
`copy_from_slice` panics	Lengths differ — check first, or use `chunks`

Check yourself

- ✓ Implement `Iterator` for a custom type and say what you get free.
- ✓ Distinguish `iter`, `iter_mut` and `into_iter`.
- ✓ Name fifteen adapters and ten consumers.
- ✓ Explain laziness and short-circuiting with an example of each.
- ✓ Explain why iterators eliminate bounds checks and index loops may not.
- ✓ Name the three closure traits and their relationship.
- ✓ Say when `move` is required and what a captureless closure becomes.
- ✓ Use `heapless` containers and explain the `Result` from `push`.
- ✓ Parse a byte buffer zero-copy with slice methods and explicit endianness.
- ✓ Verify that an iterator chain compiles to one loop with no allocation.

`Box`, `Rc`, `RefCell` and interior mutability

When the ownership rules from chapters 02 and 03 are too rigid for the design, these types relax them — some at compile time, some by moving the check to run time. Knowing which is which is the whole chapter.

Box

```
    let b = Box::new(42);       // one value, on the heap
    let v = *b;                 // deref

/* THE SAME THING AS std::unique_ptr (C++ chapter 10): one
   owner, freed on drop, zero overhead beyond the allocation
   itself. sizeof(Box<T>) == sizeof(&T).

/* THE THREE REASONS TO USE IT:

/* 1. A RECURSIVE TYPE, which otherwise has infinite size: */
    enum List { Cons(i32, Box<List>), Nil }
    // without Box: "recursive type has infinite size"

/* 2. A TRAIT OBJECT that must be owned: */
    let sensors: Vec<Box<dyn Sensor>> = vec![
        Box::new(Thermistor::new(0)),
        Box::new(Photodiode::new(1)),
    ];

/* 3. MOVING A LARGE VALUE cheaply - moving a Box moves one
      pointer, not the payload.

/* AND THE CONVERSIONS that matter for FFI (chapter 12): */
    let raw: *mut T = Box::into_raw(b);  // give up ownership
    let b = unsafe { Box::from_raw(raw) };// take it back
/* into_raw LEAKS unless something later calls from_raw. That
   is exactly how you hand a Rust-allocated object to C and
   get it back.                                            */
```

Interior mutability

```
THE PROBLEM: sometimes you need to mutate through a shared
reference. A cache, a refcount, a peripheral behind a
global.

THE RULE (chapter 03) says &T means no mutation. Interior
mutability types are the sanctioned exception: they
provide `fn set(&self, ...)` and uphold the aliasing
guarantee some other way.

  UnsafeCell<T>   the PRIMITIVE. The only legal way to get
                  &mut from &. Everything below is built
                  on it.
  Cell<T>         get/set by VALUE for Copy types. No
                  references handed out, so no aliasing
                  question. Zero cost.
  RefCell<T>      hands out &T and &mut T, with the
                  borrow rule checked AT RUN TIME.
                  PANICS on violation.
  Mutex<T>        the same, across threads, by blocking.
  RwLock<T>       many readers or one writer, across
                  threads.
  Atomic*         lock-free single values.

THE PATTERN: the compile-time check is moved to run time,
or to a lock. You pay either a panic risk or a
synchronisation cost, and you get flexibility.

THE CHOICE, in one line:
  Copy value, single thread    -> Cell
  needs references, single
    thread                     -> RefCell
  across threads               -> Mutex, RwLock or Atomic
  performance-critical single
    value                      -> Atomic
```

```
/* --- Cell: no borrows, so no possible failure --- */
    use core::cell::Cell;

    struct Counter { count: Cell<u32> }

    impl Counter {
        fn increment(&self) {           // note: &self, not
                                        // &mut self
            self.count.set(self.count.get() + 1);
        }
    }
/* Cell::get COPIES the value out; set replaces it. No
   reference to the interior ever exists, so there is nothing
   to alias. Zero cost - it compiles to a plain load and
   store.

/* --- RefCell: borrows, checked at run time --- */
    use core::cell::RefCell;

    let c = RefCell::new(vec![1, 2, 3]);

    {
        let r = c.borrow();             // Ref<Vec<i32>>
        println!("{}", r.len());
    }                                   // released here

    c.borrow_mut().push(4);             // RefMut

    let a = c.borrow();
    let b = c.borrow_mut();             // PANIC: already
                                        // borrowed

    // the non-panicking forms:
    if let Ok(mut m) = c.try_borrow_mut() { m.push(5); }

/* RefCell KEEPS A COUNTER of active borrows and panics if
   the rule is violated. So the guarantee is preserved - you
   just find out at run time instead of compile time.

   COST: one usize per RefCell, and a check per borrow.

   ON EMBEDDED: a panic in a RefCell is a bug that reaches
   the field. Prefer designs where the compiler can check;
   use try_borrow when a runtime failure is genuinely
   possible.                                              */
```

`UNSAFECELL` IS THE ONLY LEGAL ROUTE

Obtaining `&mut T` from `&T` by any other means — a pointer cast, `transmute` — is undefined behaviour, because the compiler emits `noalias` on shared references and will optimise on that assumption. `UnsafeCell` is the marker that tells it not to. Every safe interior-mutability type wraps one, and any `unsafe` code of your own that mutates through a shared reference must too.

Rc and Arc

```
    use std::rc::Rc;            // single-threaded
    use std::sync::Arc;         // Atomic - across threads

    let a = Rc::new(vec![1, 2, 3]);
    let b = Rc::clone(&a);      // refcount 2 - NOT a deep
                                // copy
    println!("{}", Rc::strong_count(&a));   // 2

/* SHARED OWNERSHIP: the value lives until the last Rc drops.
   The same as std::shared_ptr (C++ chapter 10), with the
   same caveats:

     · Rc is NOT thread-safe (no atomics) - and the compiler
       enforces that, because Rc is not Send (chapter 13).
       Arc is, and pays for atomic refcounting.
     · CYCLES LEAK. Two Rcs pointing at each other never
       reach zero.
     · Rc gives you &T only. For mutation you need
       Rc<RefCell<T>> - which is the shape most "I need
       shared mutable state" designs end up in, and which
       should prompt you to reconsider the design.

/* BREAKING A CYCLE with Weak: */
    use std::rc::{Rc, Weak};

    struct Node {
        children: RefCell<Vec<Rc<Node>>>,
        parent: RefCell<Weak<Node>>,    // NOT Rc
    }

    if let Some(p) = node.parent.borrow().upgrade() {
        // Weak::upgrade returns Option<Rc<T>> - None if the
        // target is gone
    }

/* ON EMBEDDED: Rc and Arc need `alloc`, and the atomic
   refcounting in Arc is a real cost. Ask first whether:
     · one clear owner plus borrowed references works
     · a static arena with indices works (chapter 04)
     · the sharing is actually needed
   Reaching for Rc<RefCell<T>> is usually a sign the
   ownership design has not been decided.               */
```

Globals on embedded

```
/* THE PROBLEM: a peripheral is a global, and an interrupt
   handler needs to reach it. `static mut` is unsafe to
   touch, and as of Rust 2024 taking a reference to one is a
   hard error.                                              */

/* --- THE OLD WAY, now forbidden --- */
    static mut UART: Option<Uart> = None;
    unsafe { UART.as_mut().unwrap().write(b"x"); }
                                // undefined behaviour if an
                                // interrupt races

/* --- 1. Mutex<RefCell<T>> with a critical section --- */
    use cortex_m::interrupt::{self, Mutex};
    use core::cell::RefCell;

    static UART: Mutex<RefCell<Option<Uart>>> =
        Mutex::new(RefCell::new(None));

    fn init(uart: Uart) {
        interrupt::free(|cs| {
            UART.borrow(cs).replace(Some(uart));
        });
    }

    #[interrupt]
    fn USART1() {
        interrupt::free(|cs| {
            if let Some(u) = UART.borrow(cs).borrow_mut()
                                 .as_mut() {
                u.handle_irq();
            }
        });
    }

/* `cortex_m::interrupt::Mutex` is NOT a blocking mutex - it
   requires a CriticalSection token, proving interrupts are
   disabled. So access is sound by construction, and the
   token costs nothing at run time. This is the standard
   pattern in the embedded ecosystem.

/* --- 2. StaticCell: initialise once, get &'static mut --- */
    use static_cell::StaticCell;

    static BUFFER: StaticCell<[u8; 1024]> = StaticCell::new();

    let buf: &'static mut [u8; 1024] = BUFFER.init([0; 1024]);
/* Panics if called twice. Gives you a 'static mutable
   reference without a heap - which is exactly what a DMA
   buffer or a network stack needs (chapter 16).

/* --- 3. Atomics, for simple flags and counters --- */
    use core::sync::atomic::{AtomicU32, AtomicBool, Ordering};

    static COUNT: AtomicU32 = AtomicU32::new(0);
    static READY: AtomicBool = AtomicBool::new(false);

    #[interrupt]
    fn TIMER() {
        COUNT.fetch_add(1, Ordering::Relaxed);
        READY.store(true, Ordering::Release);
```

```
    }

    fn main_loop() {
        if READY.load(Ordering::Acquire) {
            // sees everything the ISR wrote before the store
            // (chapter 13)
        }
    }
/* No critical section, no panic risk, no allocation. For a
   flag or a counter this is strictly the best option.

/* --- 4. RTIC, which removes the question entirely --- */
    #[app(device = stm32f4xx_hal::pac)]
    mod app {
        #[shared] struct Shared { uart: Uart }
        #[task(binds = USART1, shared = [uart])]
        fn on_uart(mut cx: on_uart::Context) {
            cx.shared.uart.lock(|u| u.handle_irq());
        }
    }
/* RTIC computes the required critical sections at COMPILE
   time from the priority ceiling, so the lock is often free
   (chapter 16).                                          */
```

Deref and custom smart pointers

```
    use core::ops::{Deref, DerefMut};

    struct Guard<'a, T> { inner: &'a mut T }

    impl<T> Deref for Guard<'_, T> {
        type Target = T;
        fn deref(&self) -> &T { self.inner }
    }
    impl<T> DerefMut for Guard<'_, T> {
        fn deref_mut(&mut self) -> &mut T { self.inner }
    }

    impl<T> Drop for Guard<'_, T> {
        fn drop(&mut self) { release_hardware(); }
    }

    let g = acquire();          // returns a Guard
    g.method();                 // DEREF COERCION - calls
                                // T::method
                                // released when g drops

/* DEREF COERCION is why `&String` works where `&str` is
   wanted, and `&Vec<T>` where `&[T]` is - and why you should
   take the slice types in parameters (chapter 03).

/* THE RULE FOR IMPLEMENTING Deref: only for types that ARE a
   pointer or a guard. Using it to fake inheritance produces
   confusing method resolution, exactly as in C++
   (C++ chapter 06).

/* THE GUARD PATTERN IS THE USEFUL ONE, and it is how Mutex
   works: lock() returns a guard, the guard derefs to the
   data, and dropping it unlocks. RAII plus Deref gives you
   an API that cannot be used without holding the lock.  */
```

Choosing

Need	Use	Cost
One owner, heap	`Box<T>`	The allocation
Mutate a Copy value through `&`	`Cell<T>`	None
Mutate anything through `&`, one thread	`RefCell<T>`	A counter, and a panic risk
Shared ownership, one thread	`Rc<T>`	Refcount, cycles leak
Shared ownership, threads	`Arc<T>`	Atomic refcount
Shared mutable, threads	`Arc<Mutex<T>>`	Allocation + locking
A flag or counter, ISR-shared	`Atomic*`	Near zero
A peripheral, ISR-shared	`Mutex<RefCell<T>>` + critical section	Interrupt latency
A one-time `'static` buffer, no heap	`StaticCell`	None
All of the above, managed	RTIC or Embassy	None — computed at compile time

How it shows up

Symptom	Cause and fix
Panic: "already borrowed: BorrowMutError"	Two `RefCell` borrows overlap — use `try_borrow_mut`, or restructure
Panic: "already mutably borrowed"	Same, the other way round
"recursive type has infinite size"	Add a `Box`
Memory grows steadily with `Rc`	A cycle — make one direction `Weak`
"`Rc<T>` cannot be sent between threads"	Correct — use `Arc`
"cannot borrow as mutable behind a `&`"	You need interior mutability, or `&mut self`
"creating a mutable reference to a `static mut`"	Forbidden in Rust 2024 — use `Mutex<RefCell>` or an atomic
Data corruption between an ISR and main	No critical section, or the wrong ordering on an atomic
`StaticCell::init` panics	Called twice — by design
Everything is `Rc<RefCell<T>>`	The ownership design needs revisiting

Check yourself

- ✓ Give the three reasons to use `Box` and its FFI conversions.
- ✓ Explain interior mutability and name the five types that provide it.
- ✓ Explain why `Cell` cannot fail and `RefCell` can.
- ✓ Explain why `UnsafeCell` is the only legal route, in terms of `noalias`.
- ✓ Contrast `Rc` with `Arc` and say how the compiler enforces the difference.
- ✓ Break a reference cycle with `Weak`.
- ✓ Give four ways to share a peripheral with an interrupt handler on embedded.
- ✓ Explain what the `CriticalSection` token proves and why it is free.
- ✓ Explain `StaticCell` and what it replaces.
- ✓ Implement a guard with `Deref` and `Drop`, and say what it guarantees.

Modules, crates and Cargo

Rust's code organisation and build system. After CMake, vendor IDEs and hand-written Makefiles, Cargo is the single feature most likely to make an embedded engineer want to switch — and the module system is where privacy and API boundaries live.

Modules

```
/* A module is a namespace and a PRIVACY BOUNDARY. Everything
   is private by default.                                    */

    mod uart {
        pub struct Uart { base: usize }     // the TYPE is
                                            // public
                                            // `base` is not

        impl Uart {
            pub fn new(base: usize) -> Self { Uart { base } }
            pub fn write(&mut self, b: u8) { self.put(b); }
            fn put(&mut self, b: u8) { /* private */ }
        }

        pub(crate) fn debug_dump() { }      // visible in this
                                            // CRATE only
        pub(super) fn helper() { }          // visible to the
                                            // PARENT module
        pub(in crate::drivers) fn x() { }   // a specific path
    }

    use uart::Uart;
    let mut u = Uart::new(0x4000_0000);
    u.write(b'x');
    u.put(b'y');                // ERROR - private

/* PRIVACY IS PER-MODULE, not per-type: a child module can
   see its ancestors' private items. So `mod tests` inside a
   module can test private functions - which is why Rust's
   unit tests live in the file they test.

/* FILE LAYOUT: */
    src/
      main.rs           the binary crate root
      lib.rs            the library crate root
      uart.rs           -> `mod uart;`
      drivers/
        mod.rs          -> `mod drivers;` (older style)
        spi.rs          -> `mod spi;` inside drivers
      drivers.rs        -> the 2018+ style: a sibling file
                           instead of drivers/mod.rs

    // in lib.rs
    mod uart;                   // private module
    pub mod drivers;            // public module
    pub use uart::Uart;         // RE-EXPORT: users write
                                // my_crate::Uart, not
                                // my_crate::uart::Uart

/* THE RE-EXPORT IS THE API DESIGN TOOL: organise the source
   however you like, and present a flat, deliberate public
   surface with `pub use`.

/* PATHS: */
    use crate::drivers::spi::Spi;       // absolute, from the
                                        // crate root
    use super::helper;                  // the parent module
    use self::inner::thing;             // this module
    use core::fmt::Write;               // another crate
```

```
    use heapless::{Vec, String};        // grouped
    use embedded_hal::digital::*;       // glob - use
                                        // sparingly, except
                                        // for preludes
    use core::result::Result as R;      // rename
```

Crates and workspaces

```
# A CRATE is a compilation unit: one library or one binary.
# A PACKAGE is one Cargo.toml, containing up to one library
# and any number of binaries.

    my-project/
      Cargo.toml
      src/
        lib.rs            the library crate
        main.rs           a binary crate
        bin/
          tool.rs         another binary: cargo run --bin tool
      tests/              INTEGRATION tests - one crate each
      benches/
      examples/           cargo run --example blink

# A WORKSPACE shares one target directory and one lock file
# across several packages - which is how a real firmware
# project is laid out:

    # Cargo.toml at the root
    [workspace]
    resolver = "2"
    members = ["firmware", "protocol", "hal-ext"]

    [workspace.dependencies]
    heapless = "0.8"
    embedded-hal = "1.0"

    # firmware/Cargo.toml
    [dependencies]
    protocol = { path = "../protocol" }
    heapless.workspace = true

# WHY IT MATTERS ON EMBEDDED: the protocol crate can be
# `no_std` and tested on the HOST with `cargo test`, while
# the firmware crate cross-compiles. That split - testable
# logic in a portable crate, hardware in a target crate - is
# the single most valuable structural decision in an embedded
# Rust project.
```

Cargo.toml

```
[package]
name = "firmware"
version = "0.1.0"
edition = "2021"                # 2015/2018/2021/2024 - opt-in
                                # language changes
rust-version = "1.75"           # the MSRV

[dependencies]
cortex-m = "0.7"
cortex-m-rt = "0.7"
embedded-hal = "1.0"
heapless = { version = "0.8", default-features = false }
nb = "1.0"
defmt = "0.3"

[dependencies.stm32f4xx-hal]
version = "0.21"
features = ["stm32f411", "rtic"]

[dev-dependencies]                      # tests and examples
                                        # only
proptest = "1"

[build-dependencies]                    # for build.rs
cc = "1"

[features]
default = ["logging"]
logging = ["dep:defmt"]
debug-uart = []

[profile.release]
opt-level = "z"                 # optimise for SIZE
                                # ("s" is less aggressive)
lto = "fat"                     # link-time optimisation
codegen-units = 1               # one unit - better
                                # optimisation, slower build
panic = "abort"                 # no unwinder (chapter 07)
debug = true                    # KEEP symbols - they cost
                                # nothing in flash, and
                                # defmt/probe-rs need them
overflow-checks = false

[profile.dev]
opt-level = 1                   # -O0 firmware is often too
                                # slow to run at all

# VERSION REQUIREMENTS:
#   "1.0"     ^1.0  - any 1.x, compatible
#   "=1.0.3"  exactly
#   "~1.0.3"  >=1.0.3, <1.1.0
#   "*"       anything - never do this
#
# Cargo.lock records the EXACT resolved versions.
# COMMIT IT for a binary; do NOT for a library.
```

> **THE RELEASE PROFILE IS THE SIZE LEVER**
>
> `opt-level = "z"`, `lto = "fat"`, `codegen-units = 1` and `panic = "abort"` together typically halve a firmware binary compared with the defaults. Set them before concluding Rust produces large binaries — the default release profile is tuned for server workloads, not for a 256 KB part.

Features

```
    [features]
    default = ["std"]
    std = ["alloc", "serde/std"]
    alloc = []
    logging = ["dep:defmt"]
    hardware-crc = []

    [dependencies]
    defmt = { version = "0.3", optional = true }

/* IN CODE: */
    #[cfg(feature = "logging")]
    fn log(msg: &str) { defmt::info!("{}", msg); }

    #[cfg(not(feature = "logging"))]
    fn log(_: &str) { }

    #[cfg(all(feature = "std", not(feature = "no-alloc")))]
    use std::vec::Vec;

/* AND THE STANDARD no_std SHAPE: */
    #![cfg_attr(not(feature = "std"), no_std)]

/* FEATURES MUST BE ADDITIVE. If two crates depend on yours
   with different features, Cargo UNIFIES them - enabling the
   union. So a feature that REMOVES functionality breaks that
   crate for everyone else in the build. Never write
   `no-floats`; write `floats` and leave it off by default.

/* THE OTHER cfg CONDITIONS: */
    #[cfg(target_arch = "arm")]
    #[cfg(target_os = "none")]
    #[cfg(target_pointer_width = "32")]
    #[cfg(debug_assertions)]
    #[cfg(test)]

/* AND ON THE COMMAND LINE: */
    cargo build --features "logging,hardware-crc"
    cargo build --no-default-features
    cargo build --all-features
```

The commands

```
# --- DAILY ---
    cargo check                 # TYPE-CHECK only - 5x faster
                                # than build. Use this while
                                # iterating.
    cargo build
    cargo build --release
    cargo run
    cargo test
    cargo clippy -- -D warnings # the linter. Genuinely
                                # excellent - it finds real
                                # bugs, not just style.
    cargo fmt                   # one format, no arguments
    cargo doc --open            # generate and view docs

# --- CROSS-COMPILATION ---
    rustup target add thumbv7em-none-eabihf
    cargo build --target thumbv7em-none-eabihf --release

    # .cargo/config.toml, so you can omit --target:
    [build]
    target = "thumbv7em-none-eabihf"

    [target.thumbv7em-none-eabihf]
    runner = "probe-rs run --chip STM32F411RETx"
    rustflags = ["-C", "link-arg=-Tlink.x"]

    # then `cargo run` FLASHES AND RUNS ON THE TARGET, with
    # defmt output streaming back. That single line of
    # configuration replaces an IDE.

# --- EMBEDDED TOOLING ---
    cargo install probe-rs-tools cargo-binutils cargo-bloat \
                  flip-link cargo-embed
    rustup component add llvm-tools

    cargo size --release -- -A          # section sizes
    cargo bloat --release -n 20         # what is taking space
    cargo nm --release
    cargo objdump --release -- -d
    probe-rs run --chip STM32F411RETx target/.../firmware

# --- MAINTENANCE ---
    cargo update                # update within the
                                # constraints
    cargo tree                  # the dependency graph
    cargo tree -d               # DUPLICATE versions - a
                                # common cause of bloat
    cargo audit                 # known vulnerabilities
    cargo deny check            # licences, bans, advisories
    cargo outdated
    cargo expand                # show macro expansions -
                                # invaluable for debugging
                                # derive macros
```

Testing

```
/* UNIT TESTS live beside the code, and can see private
   items: */
    fn parse(s: &str) -> Option<u32> { ... }

    #[cfg(test)]
    mod tests {
        use super::*;

        #[test]
        fn parses_decimal() {
            assert_eq!(parse("42"), Some(42));
        }

        #[test]
        fn rejects_garbage() {
            assert!(parse("x").is_none());
        }

        #[test]
        #[should_panic(expected = "index out of range")]
        fn panics_on_bad_index() { lookup(999); }

        #[test]
        fn returns_result() -> Result<(), Error> {
            let v = fallible()?;         // `?` works in tests
            assert_eq!(v, 1);
            Ok(())
        }
    }

/* DOC TESTS - examples in documentation that are COMPILED
   AND RUN: */
    /// Converts a raw ADC reading to millivolts.
    ///
    /// # Examples
    /// ```
    /// use my_crate::to_mv;
    /// assert_eq!(to_mv(2048), 1650);
    /// ```
    pub fn to_mv(raw: u16) -> u16 { ... }

/* DOCUMENTATION THAT CANNOT GO STALE, because `cargo test`
   runs it. This is one of Rust's genuinely distinctive
   features and it is worth using everywhere.

/* THE EMBEDDED TESTING STRATEGY: */
    1. put the LOGIC in a no_std crate with no hardware
       dependencies - protocol parsing, state machines,
       filters, checksums
    2. `cargo test` it on the HOST, where you have a debugger
       and instant feedback
    3. keep the hardware layer thin, and test it on target
       with defmt-test or embedded-test
    4. use traits (chapter 06) so the logic can be tested
       against a MOCK implementation:

    #[cfg(test)]
    struct MockSpi { written: Vec<u8> }
    impl SpiDevice for MockSpi { ... }
```

```
    #[test]
    fn sends_init_sequence() {
        let mut spi = MockSpi::default();
        let mut d = Display::new(&mut spi);
        d.init().unwrap();
        assert_eq!(spi.written, &[0x11, 0x29]);
    }
/* THIS IS THE BIGGEST PRACTICAL WIN in embedded Rust: most
   of your firmware becomes testable on a laptop, in
   milliseconds, without hardware.                       */
```

build.rs and documentation

```
/* build.rs runs BEFORE compilation - for generated code,
   linker scripts, or compiling C.                          */

    // build.rs
    use std::{env, fs, path::PathBuf};

    fn main() {
        let out = PathBuf::from(env::var("OUT_DIR").unwrap());

        // put the linker script where the linker will find it
        fs::write(out.join("memory.x"),
                  include_bytes!("memory.x")).unwrap();
        println!("cargo:rustc-link-search={}", out.display());
        println!("cargo:rerun-if-changed=memory.x");

        // compile a C file from the vendor SDK (chapter 12)
        cc::Build::new()
            .file("vendor/hal.c")
            .include("vendor/include")
            .compile("vendorhal");
    }

/* THE `cargo:` DIRECTIVES it can emit:
     rustc-link-lib, rustc-link-search, rustc-cfg,
     rustc-env, rerun-if-changed, rerun-if-env-changed,
     warning

/* DOCUMENTATION: */
    //! Crate-level documentation, at the top of lib.rs.

    /// Documentation for the item that follows.
    ///
    /// # Errors
    /// Returns [`Error::Timeout`] if the device does not
    /// respond within 10 ms.
    ///
    /// # Safety
    /// (for unsafe fn) The caller must guarantee ...
    ///
    /// # Panics
    /// Panics if `len` exceeds the buffer capacity.
    pub fn read(&mut self, len: usize) -> Result<&[u8], Error>

    #![deny(missing_docs)]      // require docs on every
                                // public item

    cargo doc --open
/* The generated documentation links types, shows source, and
   runs the examples. `#[deny(missing_docs)]` on a library
   crate is worth adopting from the first commit.        */
```

How it shows up

Symptom	Cause and fix
"module not found"	Missing `mod x;` in the parent, or the file is misnamed
"function is private"	Add `pub`, or `pub(crate)` if it is internal

Symptom	Cause and fix
"unresolved import"	Wrong path — remember `crate::`, `super::`, `self::`
A trait method is "not found"	The trait is not in scope (ch. 06)
Two versions of the same crate linked	`cargo tree -d` — align the version requirements
A feature enabled unexpectedly	Feature unification — check `cargo tree -f`
Disabling a feature breaks another crate	The feature is subtractive — it should be additive
Release binary far larger than expected	Default profile — set `opt-level="z"`, LTO, `panic="abort"`
Builds are slow	Use `cargo check`; raise `codegen-units` in dev
`cargo test` fails to link on an embedded target	Tests need a host target — put logic in a portable crate
Linker script not found	`build.rs` must copy it to `OUT_DIR` and add a link-search path

Check yourself

- ✓ Explain module privacy, including what a child module can see.
- ✓ Use `pub use` to design a public API independent of the file layout.
- ✓ Distinguish a crate, a package and a workspace.
- ✓ Lay out a firmware project so the logic is host-testable.
- ✓ Write a release profile tuned for size and say what each setting does.
- ✓ Explain why features must be additive and what happens if they are not.
- ✓ Configure `.cargo/config.toml` so `cargo run` flashes the target.
- ✓ Write unit tests, a doc test, and a test using a mock trait implementation.
- ✓ Use `cargo size`, `cargo bloat` and `cargo tree -d`.
- ✓ Write a `build.rs` that installs a linker script and compiles a C file.

Unsafe Rust and the unsafe boundary

Hardware access requires operations the compiler cannot verify. `unsafe` is where you take responsibility for them — and the discipline that makes Rust worthwhile is confining it behind safe abstractions rather than spreading it through the codebase.

What unsafe actually permits

```
`unsafe` enables exactly FIVE things:

  1. dereference a RAW POINTER (*const T, *mut T)
  2. call an `unsafe fn` (including every extern "C"
     function)
  3. access or modify a `static mut`
  4. implement an `unsafe trait` (Send, Sync, and your own)
  5. access a union field

IT DOES NOT:
  · turn off the borrow checker
  · turn off lifetimes
  · turn off type checking
  · make anything faster
  · permit undefined behaviour

THAT LAST POINT IS THE ONE PEOPLE GET WRONG. `unsafe` does
not grant permission to break the rules; it moves
RESPONSIBILITY FOR UPHOLDING THEM from the compiler to you.
Breaking them inside `unsafe` is still undefined behaviour,
with all the consequences from compilers chapter 15 - and
worse, because the rest of the program was optimised on
the assumption that you did not.

THE PROPERTIES YOU MUST UPHOLD:
  · no dangling or misaligned pointer dereferences
  · no aliasing violations: never two &mut, never &mut
    alongside &
  · no data races
  · every value must be VALID for its type - no bool that
    is 2, no char that is not a scalar value, no
    uninitialised reads
  · no breaking of any safe abstraction's invariants
```

Raw pointers

```
    let x = 42;
    let p: *const i32 = &x;
    let mut y = 42;
    let q: *mut i32 = &mut y;

    // creating them is SAFE; dereferencing is not
    unsafe { println!("{}", *p); }
    unsafe { *q = 43; }

/* RAW POINTERS, unlike references:
     · may be null
     · may dangle
     · have no lifetime
     · may alias freely
     · are not automatically dereferenced

/* THE OPERATIONS worth knowing: */
    core::ptr::null::<u8>()
    core::ptr::null_mut::<u8>()
    p.is_null()
    p.offset(3)                // in ELEMENTS, and it is UB
                               // to go out of bounds
    p.add(3)  p.sub(3)
    p.wrapping_add(3)          // no UB, but the result may
                               // not be dereferenceable

    unsafe { core::ptr::read(p) }
    unsafe { core::ptr::write(q, 5) }
    unsafe { core::ptr::read_volatile(p) }      // for MMIO
    unsafe { core::ptr::write_volatile(q, 5) }
    unsafe { core::ptr::copy(src, dst, n) }     // memmove
    unsafe { core::ptr::copy_nonoverlapping(src, dst, n) }
                                                // memcpy
    unsafe { core::ptr::swap(a, b) }

/* ALIGNMENT MATTERS AND IS CHECKED IN DEBUG BUILDS: */
    let buf: [u8; 8] = [0; 8];
    let p = buf.as_ptr() as *const u32;
    unsafe { *p }              // UB if buf is not 4-aligned
    // correct:
    unsafe { p.read_unaligned() }
    // or, better, no unsafe at all:
    u32::from_le_bytes(buf[0..4].try_into().unwrap())

/* AND `addr_of!` FOR UNALIGNED OR PACKED FIELDS - creating
   a reference to a misaligned field is UB even without
   dereferencing it: */
    use core::ptr::addr_of;
    let p = unsafe { addr_of!((*packed_ptr).field) };
    let v = unsafe { p.read_unaligned() };
```

The unsafe boundary

```
THE CENTRAL DISCIPLINE:

  unsafe code should be SMALL, LOCAL, and WRAPPED IN A SAFE
  API whose invariants you can state and check.

The goal is not to eliminate unsafe — hardware access
requires it. The goal is that the REST of the program
never needs it, so that a memory-safety bug can only be in
the few hundred lines you audited.

BAD:                          GOOD:
┌──────────────────────┐      ┌──────────────────────┐
│ unsafe everywhere    │      │   safe application   │
│ every driver, every  │      ├──────────────────────┤
│ access, no           │      │   safe driver API    │
│ invariants written   │      ├──────────────────────┤
│ down                 │      │ unsafe: 20 lines,    │
│                      │      │ documented, tested   │
└──────────────────────┘      └──────────────────────┘

THE TEST: can you state, in one sentence, what the caller
must guarantee? If yes, that sentence is the safety
comment, and the wrapper can be safe. If no, the
abstraction is wrong.
```

```
/* --- A SAFE MMIO WRAPPER, the canonical example --- */

pub struct Uart {
    base: *mut u32,
}

// SAFETY: the caller of `new` guarantees exclusive access to
// this peripheral, so sending it between contexts is sound.
unsafe impl Send for Uart {}

impl Uart {
    /// # Safety
    /// `base` must be the address of a UART peripheral of
    /// this type, correctly clocked, and no other Uart must
    /// exist for the same address.
    pub const unsafe fn new(base: usize) -> Self {
        Uart { base: base as *mut u32 }
    }

    // SAFE from here on - the constructor took the promise
    pub fn write_byte(&mut self, b: u8) {
        while self.flags() & FR_TXFF != 0 {}
        // SAFETY: base is valid by the constructor's
        // contract; DR is within the peripheral's register
        // block
        unsafe { self.base.add(REG_DR)
                          .write_volatile(b as u32) };
    }

    fn flags(&self) -> u32 {
        // SAFETY: as above
        unsafe { self.base.add(REG_FR).read_volatile() }
    }
}

/* TWO UNSAFE BLOCKS, each one line, each with a SAFETY
   comment. Everything above is safe, and a user of this
   driver writes no unsafe at all.

/* THE CONVENTIONS the ecosystem follows, and clippy enforces:
     · `# Safety` doc section on every `unsafe fn`, stating
       what the CALLER must guarantee
     · `// SAFETY:` comment on every `unsafe` BLOCK, stating
       why the requirements hold HERE
     · #![deny(unsafe_op_in_unsafe_fn)] - so an unsafe fn
       still needs explicit blocks inside, rather than being
       unsafe throughout
     · #![warn(clippy::undocumented_unsafe_blocks)]        */
```

THE TWO COMMENT KINDS, AND WHY BOTH

`# Safety` on a function is a *precondition*: what the caller must ensure. `// SAFETY:` on a block is a *proof*: why the preconditions are met at this site. A codebase with both can be audited by reading only the unsafe blocks and checking each proof — which is exactly the property that makes the guarantee worth anything.

Hardware access patterns

```
/* --- 1. VOLATILE, always, for MMIO --- */
    unsafe { ptr.write_volatile(v) }
    unsafe { ptr.read_volatile() }
/* A plain `*p = v` may be elided, reordered or merged - the
   same rule as C's volatile (C++ chapter 02). Rust has no
   `volatile` type qualifier; it has volatile OPERATIONS,
   which is the more honest design.

/* --- 2. USE A PAC, and write no unsafe at all --- */
    let p = pac::Peripherals::take().unwrap();
    p.gpioa.moder.modify(|_, w| w.moder5().output());
    p.gpioa.odr.write(|w| w.odr5().set_bit());
/* The svd2rust-generated PAC (chapter 16) contains the
   unsafe; you get a typed, field-named, safe API. This is
   what "confine unsafe to a small audited layer" looks like
   when the layer is generated from the vendor's own SVD
   file.

/* --- 3. A CRITICAL SECTION for shared state --- */
    critical_section::with(|cs| {
        SHARED.borrow(cs).borrow_mut().update();
    });
/* The `cs` token proves interrupts are disabled
   (chapter 09). No unsafe needed at the use site.

/* --- 4. A STATIC BUFFER without `static mut` --- */
    use static_cell::StaticCell;
    static BUF: StaticCell<[u8; 1024]> = StaticCell::new();
    let buf: &'static mut [u8; 1024] = BUF.init([0; 1024]);
/* Safe, panics on double init, no heap.

/* --- 5. TRANSMUTE: almost always the wrong answer --- */
    let f: f32 = unsafe { core::mem::transmute(bits) };  // no
    let f = f32::from_bits(bits);                        // yes
    let bytes = unsafe { core::mem::transmute::<u32,
                                    [u8;4]>(x) };        // no
    let bytes = x.to_le_bytes();                         // yes
    let s = unsafe { core::str::from_utf8_unchecked(b) }; // no
    let s = core::str::from_utf8(b)?;                    // yes
/* transmute is the most dangerous function in Rust: it
   reinterprets bits with NO checking of size, validity or
   alignment. There is nearly always a safe alternative, and
   where there is not, `bytemuck` or `zerocopy` provide
   audited, trait-gated versions.

/* --- 6. slice::from_raw_parts, for a DMA buffer --- */
    // SAFETY: the DMA engine has finished (we checked the
    // completion flag), `ptr` points to `len` initialised
    // bytes within BUFFER, and no other reference to that
    // region exists.
    let data = unsafe {
        core::slice::from_raw_parts(ptr, len)
    };
/* One of the legitimate uses. Note the safety comment covers
   validity, initialisation, length AND aliasing - all four
   are required.                                          */
```

Unions and uninitialised memory

```
/* --- UNIONS, for FFI compatibility --- */
    #[repr(C)]
    union Register {
        word: u32,
        bytes: [u8; 4],
    }
    let r = Register { word: 0x1234_5678 };
    let b = unsafe { r.bytes };         // reading ANY field
                                        // is unsafe
/* Prefer an enum (chapter 05) unless you are matching a C
   layout. For bit reinterpretation, to_le_bytes is safe and
   clearer.

/* --- MaybeUninit, for genuinely uninitialised memory --- */
    use core::mem::MaybeUninit;

    let mut buf: [MaybeUninit<u8>; 1024] =
        unsafe { MaybeUninit::uninit().assume_init() };
        // ^ sound ONLY because MaybeUninit<u8> has no
        //   validity requirement

    let n = read_into(&mut buf);

    // SAFETY: read_into initialised the first `n` elements
    let data = unsafe {
        core::slice::from_raw_parts(buf.as_ptr() as *const u8,
                                    n)
    };

/* NEVER `mem::uninitialized()` - it is deprecated and always
   UB for types with validity requirements. And note that
   reading uninitialised memory is UB even for u8: the value
   is "poison" (compilers chapter 15), not a random number.

/* THE SAFE ALTERNATIVE, and usually the right one: */
    let mut buf = [0u8; 1024];          // zeroing 1 KB costs
                                        // ~100 cycles
/* Measure before deciding the initialisation is too
   expensive. It usually is not.                          */
```

Verifying unsafe code

```
# --- MIRI: an interpreter that detects UB ---
    rustup +nightly component add miri
    cargo +nightly miri test

# It catches:
#   out-of-bounds accesses
#   use-after-free
#   invalid values (a bool that is 2)
#   misaligned accesses
#   ALIASING VIOLATIONS, under Stacked Borrows / Tree Borrows
#   data races
#   uninitialised reads
#   memory leaks
#
# MIRI IS THE MOST IMPORTANT TOOL IN THIS CHAPTER. It finds
# aliasing bugs that no amount of testing would, because the
# consequence of an aliasing violation is a wrong
# optimisation, not a crash.
#
# LIMITATION: it cannot run code that touches real hardware or
# calls into C. So structure the unsafe helpers so they can be
# tested against a mock on the host - the same argument as
# chapter 10's testing strategy.

# --- THE SANITIZERS ---
    RUSTFLAGS="-Zsanitizer=address" cargo +nightly test
    RUSTFLAGS="-Zsanitizer=thread"  cargo +nightly test

# --- CLIPPY LINTS worth denying ---
    #![deny(unsafe_op_in_unsafe_fn)]
    #![warn(clippy::undocumented_unsafe_blocks)]
    #![warn(clippy::multiple_unsafe_ops_per_block)]
    #![warn(clippy::missing_safety_doc)]
    #![warn(clippy::ptr_as_ptr, clippy::cast_ptr_alignment)]

# --- AND THE STRUCTURAL CHECK ---
    cargo geiger                # counts unsafe per dependency
    grep -rn 'unsafe' src/ | wc -l
# Track that number. In a well-structured embedded crate it
# should be in the tens and concentrated in a few files, not
# spread across every driver.
```

A review checklist

Check	Why
Is there a `# Safety` section on every `unsafe fn`?	The caller cannot uphold an unstated contract
Is there a `// SAFETY:` on every block?	It is the proof that makes the audit possible
Is the block as small as it can be?	Large blocks hide the operation that matters
Is every pointer non-null, aligned and in-bounds?	All three are separate UB conditions
Could two `&mut` to the same data exist?	The commonest and most damaging violation
Is the memory initialised before being read?	Uninitialised reads are UB even for `u8`
Are all values valid for their type?	A `bool` that is 2 is UB immediately
Does an interrupt or another core race here?	Data races are UB regardless of the outcome

Check	Why
Is `write_volatile` used for MMIO?	A plain write may be elided or reordered
Is there a safe alternative?	Usually yes — `from_bits`, `to_le_bytes`, a PAC
Does Miri pass?	It finds what testing cannot
Is the safe wrapper's invariant actually upheld?	A safe API over unsound unsafe is worse than no wrapper

How it shows up

Symptom	Cause and fix
"this operation is unsafe"	Wrap it in a block — and write the SAFETY comment
Works in debug, wrong in release	Aliasing violation the optimiser exploited — run Miri
Miri: "attempting a read access ... tag does not exist"	A pointer derived from a reference that has since been invalidated
Miri: "constructing invalid value"	A value outside its type's valid range
Misaligned access fault on ARM	Cast a `u8` pointer to a wider type — use `read_unaligned`
Register write has no effect	Not `volatile` — the compiler removed it
Corruption only with interrupts enabled	Missing critical section or atomic
Undefined behaviour after `transmute`	Sizes, validity or alignment mismatched — use a safe conversion
Safe API turns out to be unsound	The invariant was not actually enforced — the worst failure mode
`unsafe` appearing throughout the codebase	The abstraction boundary is missing

Check yourself

- ✓ Name the five things `unsafe` permits, and four it does not.
- ✓ List the properties you must uphold inside an unsafe block.
- ✓ Explain the unsafe boundary and the one-sentence test for a correct wrapper.
- ✓ Write a safe MMIO wrapper with correct `# Safety` and `// SAFETY:` comments.
- ✓ Explain why volatile operations rather than a volatile type.
- ✓ Give safe alternatives to `transmute` for four common cases.
- ✓ Explain `MaybeUninit` and why reading uninitialised memory is UB.
- ✓ Run Miri and say what it catches that testing cannot.
- ✓ Enable the four lints that enforce unsafe discipline.
- ✓ Work the twelve-point review checklist on a real unsafe block.

FFI: calling C and being called by C

Every real embedded Rust project sits on a C vendor SDK. This chapter is the boundary: how to call C safely, how to be called from C, and the layout, ownership and panic rules that make the seam sound rather than merely working.

Calling C

```
    // declare what the C side provides
    extern "C" {
        fn HAL_GPIO_WritePin(port: *mut GPIO_TypeDef,
                             pin: u16, state: u32);
        fn HAL_Delay(ms: u32);
        fn malloc(size: usize) -> *mut core::ffi::c_void;
    }

    // every call is unsafe - the compiler cannot check
    // anything about C
    unsafe { HAL_Delay(100); }

    // Rust 2024: `unsafe extern` makes the declaration itself
    // an unsafe act, which is more honest
    unsafe extern "C" {
        safe fn abs(x: i32) -> i32;     // and individual
                                        // functions may be
                                        // marked safe
        unsafe fn free(p: *mut c_void);
    }

/* THE C TYPES, from core::ffi: */
    c_char  c_schar  c_uchar
    c_short c_ushort c_int  c_uint
    c_long  c_ulong  c_longlong c_ulonglong
    c_float c_double
    c_void
    CStr    CString  (CString needs alloc)

/* USE THESE, not u8/i32 - c_char is i8 on x86 and u8 on ARM,
   and c_long is 32 bits on Windows and 64 on Linux
   (compilers chapter 10). Getting it wrong compiles and then
   misbehaves.

/* LINKING: */
    #[link(name = "vendorhal")]         // -lvendorhal
    extern "C" { ... }

    #[link(name = "m")]
    #[link(name = "static_thing", kind = "static")]

    // or from build.rs (chapter 10):
    println!("cargo:rustc-link-lib=static=vendorhal");
    println!("cargo:rustc-link-search=native=vendor/lib");
```

Layout

```
/* RUST REORDERS STRUCT FIELDS BY DEFAULT to minimise
   padding. For anything crossing the boundary, say
   #[repr(C)].                                          */

    #[repr(C)]
    pub struct Message {
        pub id: u32,
        pub length: u16,
        pub flags: u8,
        pub _pad: u8,               // explicit, so both sides
                                    // agree
        pub payload: [u8; 64],
    }
    const _: () = assert!(core::mem::size_of::<Message>() == 72);
    const _: () = assert!(core::mem::offset_of!(Message,
                                            payload) == 8);

/* THE `const _: () = assert!(...)` IDIOM is a compile-time
   check in a const context - the Rust equivalent of
   static_assert, and it should be on every FFI struct
   (C++ chapter 16 makes the same argument).

/* THE repr ATTRIBUTES: */
    #[repr(C)]              C-compatible layout
    #[repr(transparent)]    exactly like the single field -
                            for newtypes crossing FFI
    #[repr(packed)]         no padding. DANGEROUS - taking a
                            reference to a misaligned field is
                            UB (chapter 11)
    #[repr(align(64))]      minimum alignment
    #[repr(u8)] / #[repr(i32)]      a fixed enum
                                    discriminant
    #[repr(C, packed)]      combined

/* ENUMS ACROSS FFI: */
    #[repr(C)]
    #[derive(Clone, Copy, PartialEq)]
    pub enum Status { Ok = 0, Error = 1, Timeout = 2 }

/* BUT RECEIVING one from C is unsound if C can send a value
   outside the set - a Rust enum with an invalid discriminant
   is immediate UB. So take an integer and convert: */
    #[no_mangle]
    pub extern "C" fn handle(raw: u32) -> i32 {
        match Status::try_from(raw) {
            Ok(s) => process(s),
            Err(_) => -1,
        }
    }

/* AND NEWTYPES with repr(transparent), which cost nothing: */
    #[repr(transparent)]
    pub struct Handle(*mut c_void);
/* Passed in a register exactly like the raw pointer, but a
   distinct type on the Rust side.

/* AUTOMATE IT: bindgen generates all of this from the C
   headers (below), and it gets the platform-dependent types
   right.                                               */
```

Strings and slices

```
/* RUST STRINGS ARE UTF-8 AND NOT NUL-TERMINATED. C strings
   are NUL-terminated and of no particular encoding. The
   conversion is not free and can fail.                    */

    use core::ffi::{CStr, c_char};

/* --- C -> Rust --- */
    // SAFETY: `p` points to a NUL-terminated string that
    // remains valid for the duration of this call
    let s: &CStr = unsafe { CStr::from_ptr(p) };
    let bytes: &[u8] = s.to_bytes();
    let text: &str = s.to_str()?;       // FAILS on invalid
                                        // UTF-8

/* --- Rust -> C --- */
    // a literal, NUL-terminated at compile time:
    let s = c"hello";                   // Rust 1.77 - &CStr
    unsafe { c_puts(s.as_ptr()); }

    // or, with alloc:
    let owned = CString::new("hello")?; // fails if it
                                        // contains a NUL
    unsafe { c_puts(owned.as_ptr()); }
    // `owned` MUST outlive the call - this is wrong:
    unsafe { c_puts(CString::new("x")?.as_ptr()); }
                                // the CString is dropped at
                                // the end of the statement,
                                // leaving a dangling pointer

/* --- SLICES --- */
    // C -> Rust
    #[no_mangle]
    pub extern "C" fn process(data: *const u8, len: usize)
            -> i32
    {
        if data.is_null() { return -1; }
        // SAFETY: the caller guarantees `data` points to
        // `len` initialised bytes that are not mutated for
        // the duration of this call
        let s = unsafe { core::slice::from_raw_parts(data,
                                                     len) };
        do_work(s)
    }

    // Rust -> C
    let v = [1u8, 2, 3];
    unsafe { c_send(v.as_ptr(), v.len()); }

/* THE THREE THINGS TO CHECK on every incoming pointer:
     1. is it null?
     2. is the length plausible? (a bound, not just non-zero)
     3. is the alignment right for the element type?
   And then state in the SAFETY comment what you are trusting
   the caller for - because you cannot check the rest.    */
```

THE FFI BOUNDARY IS A TRUST BOUNDARY

Everything arriving from C is unvalidated: pointers may be null or dangling, lengths may be wrong, enum values may be out of range, strings may not be NUL-terminated. This is exactly the position a kernel driver is in with respect to userspace (Linux chapter 21), and it deserves the same discipline: check what you can, document what you cannot, and keep the unchecked surface small.

Being called from C

```
    #[no_mangle]
    pub extern "C" fn rust_process(data: *const u8,
                                   len: usize) -> i32
    {
        // 1. VALIDATE
        if data.is_null() || len == 0 || len > MAX_LEN {
            return -1;
        }

        // 2. CONVERT
        // SAFETY: checked non-null; the caller guarantees
        // `len` valid bytes
        let s = unsafe { core::slice::from_raw_parts(data,
                                                     len) };

        // 3. CATCH PANICS - unwinding into C is UB
        let result = core::panic::catch_unwind(|| {
            do_work(s)
        });

        match result {
            Ok(Ok(v))  => v as i32,
            Ok(Err(_)) => -2,
            Err(_)     => -3,       // it panicked
        }
    }

/* `#[no_mangle]` gives it a plain symbol name.
   `extern "C"` gives it the C calling convention.
   BOTH are required.

/* THE PANIC RULE: a panic that unwinds across an FFI boundary
   is UNDEFINED BEHAVIOUR, exactly like a C++ exception
   escaping into C (C++ chapter 16). Three ways to prevent
   it:
     1. panic = "abort" in the profile - the embedded answer
     2. catch_unwind at every entry point - needs std
     3. extern "C-unwind" if you WANT unwinding to propagate,
        and the C side is built to handle it

/* --- HANDING OWNERSHIP TO C, and getting it back --- */
    #[no_mangle]
    pub extern "C" fn device_create(base: usize)
            -> *mut Device
    {
        match Device::new(base) {
            Ok(d) => Box::into_raw(Box::new(d)),    // LEAKS,
                                                    // deliberately
            Err(_) => core::ptr::null_mut(),
        }
    }

    #[no_mangle]
    pub unsafe extern "C" fn device_destroy(d: *mut Device) {
        if !d.is_null() {
            // SAFETY: `d` came from device_create and has not
            // been destroyed
            drop(unsafe { Box::from_raw(d) });
        }
    }
```

```
    #[no_mangle]
    pub unsafe extern "C" fn device_read(d: *mut Device,
                                         out: *mut u16) -> i32
    {
        if d.is_null() || out.is_null() { return -1; }
        // SAFETY: as above
        let dev = unsafe { &mut *d };
        match dev.read() {
            Ok(v) => { unsafe { out.write(v) }; 0 }
            Err(_) => -1,
        }
    }

/* THE OPAQUE-HANDLE PATTERN, identical to the C++ one
   (C++ chapter 16): create returns a pointer, operations
   take it, destroy frees it. `Box::into_raw` and
   `from_raw` are the ownership transfer, and forgetting the
   destroy is a leak while calling it twice is a
   double-free.

/* GENERATE THE C HEADER automatically: */
    # cbindgen.toml + build.rs
    cbindgen --config cbindgen.toml --crate my_crate \
             --output include/my_crate.h
/* So the header cannot drift from the Rust definitions.  */
```

Callbacks

```
/* --- REGISTERING A RUST FUNCTION AS A C CALLBACK --- */

    type Callback = unsafe extern "C" fn(ctx: *mut c_void,
                                         event: u32);

    extern "C" {
        fn register_handler(cb: Callback, ctx: *mut c_void);
    }

    struct Handler { count: u32 }

    unsafe extern "C" fn trampoline(ctx: *mut c_void,
                                    event: u32)
    {
        if ctx.is_null() { return; }
        // SAFETY: `ctx` is the Handler pointer we registered,
        // it is still alive (we unregister in Drop), and this
        // callback is not re-entrant
        let h = unsafe { &mut *(ctx as *mut Handler) };
        h.count += 1;
        h.on_event(event);
    }

    impl Handler {
        fn install(&mut self) {
            unsafe {
                register_handler(trampoline,
                                 self as *mut _ as *mut c_void);
            }
        }
    }
    impl Drop for Handler {
        fn drop(&mut self) {
            unsafe { unregister_handler(trampoline); }
        }
    }

/* THE THREE RULES, the same as C++ chapter 16's:
     1. no panic may escape
     2. the context must outlive the registration - hence the
        Drop impl
     3. a capturing closure cannot be a C function pointer;
        put the state in the context

/* A CAPTURELESS CLOSURE does coerce: */
    let f: extern "C" fn(u32) = |x| handle(x);

/* AND THE PINNING PROBLEM: `self as *mut _` is only valid
   while the Handler does not MOVE. If it might, use
   Box::into_raw so the address is stable, or Pin.       */
```

bindgen and cc

```
# --- bindgen: generate Rust declarations from C headers ---
    # build.rs
    let bindings = bindgen::Builder::default()
        .header("vendor/hal.h")
        .clang_arg("-Ivendor/include")
        .clang_arg("--target=thumbv7em-none-eabihf")
        .use_core()                     // no_std
        .ctypes_prefix("core::ffi")
        .derive_default(true)
        .derive_debug(true)
        .allowlist_function("HAL_.*")   // do not import the
        .allowlist_type("GPIO_.*")      // whole SDK
        .blocklist_type("__va_list")
        .parse_callbacks(Box::new(
            bindgen::CargoCallbacks::new()))
        .generate()?;

    bindings.write_to_file(out.join("bindings.rs"))?;

    // in lib.rs
    #[allow(non_upper_case_globals, non_camel_case_types,
            non_snake_case, dead_code)]
    mod bindings {
        include!(concat!(env!("OUT_DIR"), "/bindings.rs"));
    }

# ALLOWLISTING MATTERS: without it, bindgen imports the
# entire transitive header closure - thousands of items,
# a slow build, and name collisions.

# --- cc: compile C sources into the crate ---
    cc::Build::new()
        .file("vendor/hal.c")
        .include("vendor/include")
        .define("STM32F411xE", None)
        .flag("-mcpu=cortex-m4")
        .compile("vendorhal");

# --- THE RESULTING PROJECT SHAPE, which is what a real
#     embedded Rust project on a vendor SDK looks like:

    my-hal-sys/         raw bindgen output. unsafe, ugly,
                        generated. Nobody reads it.
      build.rs
      vendor/           the C SDK
    my-hal/             a SAFE wrapper. Hand-written, small,
                        every unsafe documented (chapter 11).
    firmware/           the application. NO unsafe at all.

/* THE `-sys` CRATE CONVENTION is universal in the Rust
   ecosystem: `foo-sys` is the raw bindings, `foo` is the
   safe wrapper. Following it makes your crate legible to
   everyone else.                                        */
```

The pitfalls

```
/* --- 1. UNWINDING ACROSS FFI: UB. panic = "abort", or
       catch_unwind at every entry.

/* --- 2. LAYOUT MISMATCH: silent corruption. Always
       #[repr(C)], and assert sizes and offsets.

/* --- 3. INVALID VALUES FROM C: */
    #[no_mangle] pub extern "C" fn f(b: bool) { }
/* If C passes 2, that is instant UB - a bool must be 0 or 1.
   Take u8 and convert. Same for char, enums, references and
   NonNull.

/* --- 4. NULL WHERE A REFERENCE IS EXPECTED: */
    #[no_mangle] pub extern "C" fn f(p: &Device) { }   // UB if
                                                       // C
                                                       // passes
                                                       // NULL
    #[no_mangle] pub extern "C" fn f(p: *const Device) { }
/* Take a raw pointer and check. Or Option<&Device>, which is
   FFI-safe and represents null as None (chapter 05's niche
   optimisation) - that is the elegant answer.

/* --- 5. LIFETIME ASSUMPTIONS: C gives you a pointer with no
       lifetime. Copy the data, or document precisely how long
       the caller must keep it valid.

/* --- 6. THREAD SAFETY: C code may call your function from
       any thread or interrupt. Nothing in the type system
       tells you. Assume the worst.

/* --- 7. `static mut` IN GENERATED BINDINGS: bindgen emits
       these for C globals. Wrap access, or use an atomic.

/* --- 8. ALIGNMENT: a *const u8 from C may not be aligned for
       a wider type. read_unaligned, or from_le_bytes.

/* --- 9. VARIADIC FUNCTIONS: printf-style functions can be
       declared but are awkward and easy to misuse. Prefer a
       fixed-argument wrapper on the C side.

/* --- 10. THE ONE THAT COSTS MOST TIME: a C header that
       differs from the compiled library. bindgen reads the
       header; the linker uses the binary. If they disagree,
       everything compiles and the layout is wrong. Rebuild
       both from the same source.                        */
```

How it shows up

Symptom	Cause and fix
"undefined reference" at link time	Missing `#[no_mangle]`, or the library is not linked
Struct fields wrong across the boundary	Missing `#[repr(C)]` — Rust reordered them
Works on x86, wrong on ARM	`c_char` signedness, or `c_long` width
Crash in `CStr::from_ptr`	Not NUL-terminated, or the pointer is dangling
Dangling pointer from a `CString`	The temporary was dropped at the end of the statement

Symptom	Cause and fix
UB with no obvious cause	An invalid `bool`, `char` or enum from C
Abort inside a C caller	A panic unwound across FFI
Double free	`Box::from_raw` called twice, or on a pointer not from `into_raw`
Memory grows	`into_raw` with no matching destroy
Callback crashes after the object moved	The context pointer was to a stack value — box it
bindgen output is enormous	No allowlist
Everything compiles, layout is silently wrong	Header and library built from different sources

Check yourself

- ✓ Declare and call a C function, using the correct `core::ffi` types.
- ✓ Explain why `c_char` and `c_long` matter.
- ✓ Write an FFI struct with `#[repr(C)]` and compile-time size assertions.
- ✓ Convert strings and slices in both directions, and name the three checks on an incoming pointer.
- ✓ Export a Rust function with validation, conversion and panic handling.
- ✓ Implement the opaque-handle ownership pattern with `into_raw` / `from_raw`.
- ✓ Register a Rust callback with a C library and state the three rules.
- ✓ Configure bindgen with an allowlist and explain the `-sys` crate convention.
- ✓ List ten FFI pitfalls and the fix for each.
- ✓ Explain why `Option<&T>` is the elegant answer to nullable parameters.

Fearless concurrency: `Send`, `Sync`, threads and channels

Rust's data-race guarantee comes from two marker traits and the borrow checker. That is the whole mechanism — and it means a program that compiles cannot have a data race, which is a guarantee no other systems language offers.

Send and Sync

```
Send    it is safe to MOVE this type to another thread
Sync    it is safe to SHARE &T with another thread
        (equivalently: &T is Send)

BOTH ARE AUTO TRAITS: the compiler implements them
automatically for any type whose components all implement
them. You almost never write them.

WHAT IS NOT Send:
  Rc<T>           - a non-atomic refcount
  *const T, *mut T - raw pointers, conservatively
  MutexGuard      - some platforms require unlock on the
                    locking thread

WHAT IS NOT Sync:
  Cell<T>, RefCell<T>  - unsynchronised interior
                         mutability
  Rc<T>
  raw pointers

WHAT IS BOTH: almost everything else. i32, String,
Vec<T> (if T is), Arc<T> (if T is Send+Sync), Mutex<T>
(if T is Send), atomics.

AND THE COMBINATION THAT MATTERS:
     Mutex<T>   is Sync if T: Send
because the mutex provides the synchronisation, so sharing
a reference to it is safe as long as the contents can move
between threads.

THE ENFORCEMENT IS AUTOMATIC:

     let rc = Rc::new(5);
     thread::spawn(move || { println!("{rc}"); });
     // error: `Rc<i32>` cannot be sent between threads
     //        safely
     //        required because it appears within the type
     //        of the closure

You did not annotate anything. The compiler worked out
that the closure captures an Rc, that Rc is not Send, and
that spawn requires Send. THAT is the whole data-race
guarantee.
```

Threads

```
    use std::thread;

    let h = thread::spawn(|| {
        expensive_work()
    });
    let result = h.join().unwrap();     // Result - Err if it
                                        // panicked

/* THE SIGNATURE explains the constraints: */
    pub fn spawn<F, T>(f: F) -> JoinHandle<T>
    where
        F: FnOnce() -> T + Send + 'static,
        T: Send + 'static;

/*   Send      the closure moves to another thread
     'static   the thread may outlive this scope, so the
               closure must not borrow anything local
               (chapter 04)

/* WHICH IS WHY `move` IS USUALLY REQUIRED: */
    let data = vec![1, 2, 3];
    thread::spawn(move || println!("{data:?}"));   // data
                                                   // MOVED in

/* SCOPED THREADS lift the 'static requirement, because the
   scope guarantees they are joined before it ends: */
    let data = vec![1, 2, 3];
    thread::scope(|s| {
        s.spawn(|| println!("{data:?}"));   // BORROWS - no
                                            // move, no clone
        s.spawn(|| println!("{}", data.len()));
    });                                     // both joined
                                            // here
    println!("{data:?}");                   // still usable

/* Two shared borrows in two threads - allowed, because
   neither mutates. The borrow checker's rule extends across
   threads with no extra machinery.                      */
```

Sharing data

```
    use std::sync::{Arc, Mutex, RwLock};

/* --- Arc<Mutex<T>>: the standard shape --- */
    let counter = Arc::new(Mutex::new(0));

    let mut handles = vec![];
    for _ in 0..10 {
        let c = Arc::clone(&counter);
        handles.push(thread::spawn(move || {
            let mut n = c.lock().unwrap();
            *n += 1;
        }));                    // the GUARD drops here,
                                // unlocking
    }
    for h in handles { h.join().unwrap(); }
    println!("{}", *counter.lock().unwrap());   // 10

/* THE GUARD IS THE POINT: `lock()` returns a
   MutexGuard<T> which Derefs to T and unlocks on Drop
   (chapter 09). YOU CANNOT ACCESS THE DATA WITHOUT HOLDING
   THE LOCK - the API makes it impossible, rather than
   documenting it.

   Compare C++ (C++ chapter 13), where std::mutex and the
   data it protects are separate objects and nothing connects
   them. Rust's Mutex<T> CONTAINS the data.

/* POISONING: if a thread panics while holding the lock, the
   mutex is poisoned and later lock() calls return Err -
   because the data may be in a half-updated state.       */
    match m.lock() {
        Ok(g) => use(g),
        Err(poisoned) => {
            let g = poisoned.into_inner();  // use it anyway
            recover(g);
        }
    }

/* RwLock, for read-heavy data: */
    let cfg = Arc::new(RwLock::new(Config::default()));
    { let r = cfg.read().unwrap(); use(&r); }   // many
    { let mut w = cfg.write().unwrap(); w.rate = 48000; }
                                               // one

/* ATOMICS, for single values (C++ chapter 13 covers the
   memory model, which is the SAME model): */
    use std::sync::atomic::{AtomicU32, AtomicBool, Ordering};

    static COUNT: AtomicU32 = AtomicU32::new(0);
    COUNT.fetch_add(1, Ordering::Relaxed);

    READY.store(true, Ordering::Release);
    if READY.load(Ordering::Acquire) { /* sees prior writes */ }

    let ok = FLAG.compare_exchange(false, true,
                                   Ordering::AcqRel,
                                   Ordering::Acquire).is_ok();

/* THE ORDERINGS AND THEIR ARM INSTRUCTIONS are identical to
   C++'s (C++ chapter 13, ARM chapter 21): Relaxed is a plain
```

```
   access, Acquire is ldar, Release is stlr, SeqCst adds a
   barrier. Use SeqCst unless you have measured a reason.  */
```

> **WHY "FEARLESS" IS NOT MARKETING**
> In C or C++, a data race is undefined behaviour you discover through corruption months later, and ThreadSanitizer finds only races your tests happen to execute. In Rust, the same mistake is a compile error with a message naming the type that is not `Send`. The class of bug does not become easier to debug — it becomes impossible to write outside `unsafe`.

Channels

```
    use std::sync::mpsc;

    let (tx, rx) = mpsc::channel();     // unbounded, multi-
                                        // producer,
                                        // single-consumer

    for i in 0..3 {
        let tx = tx.clone();
        thread::spawn(move || {
            tx.send(format!("from {i}")).unwrap();
        });
    }
    drop(tx);                   // drop the ORIGINAL, or rx
                                // never sees a disconnect

    for msg in rx {             // iterates until every sender
        println!("{msg}");      // is dropped
    }

    let (tx, rx) = mpsc::sync_channel(4);   // BOUNDED - send
                                            // blocks when
                                            // full

    rx.recv()                   // blocks; Err when all
                                // senders drop
    rx.try_recv()               // non-blocking
    rx.recv_timeout(dur)

/* CHANNELS TRANSFER OWNERSHIP. `send(v)` moves v; the
   receiver owns it afterwards. No sharing, therefore no
   locking, therefore no race - which is why "share memory by
   communicating" works so cleanly here.

/* AND THE BETTER CRATE: */
    use crossbeam_channel as chan;
    let (tx, rx) = chan::bounded(16);
    chan::select! {                     // wait on several
        recv(rx1) -> msg => handle(msg),
        recv(rx2) -> msg => handle(msg),
        default(Duration::from_millis(10)) => timeout(),
    }
/* crossbeam adds multi-CONSUMER, select, and better
   performance. It is what most production code uses.    */
```

Concurrency without an OS

```
/* On bare metal there are no threads - there are interrupts,
   and possibly several cores. Send and Sync still apply, and
   the ecosystem uses them.                                  */

/* --- 1. ATOMICS, for flags and counters --- */
    use core::sync::atomic::{AtomicU32, Ordering};

    static TICKS: AtomicU32 = AtomicU32::new(0);

    #[interrupt]
    fn SysTick() { TICKS.fetch_add(1, Ordering::Relaxed); }

    fn now() -> u32 { TICKS.load(Ordering::Relaxed) }

/* NOTE: not every target has atomics. Cortex-M0 lacks
   LDREX/STREX, so `portable-atomic` provides them via
   critical sections:                                        */
    use portable_atomic::AtomicU64;     // works everywhere

/* --- 2. CRITICAL SECTIONS, for compound state --- */
    use critical_section::Mutex;
    use core::cell::RefCell;

    static SHARED: Mutex<RefCell<State>> =
        Mutex::new(RefCell::new(State::new()));

    #[interrupt]
    fn TIM2() {
        critical_section::with(|cs| {
            SHARED.borrow(cs).borrow_mut().tick();
        });
    }
/* `critical_section::Mutex` is not a blocking lock - it
   requires a token proving interrupts are disabled
   (chapter 09). Zero cost, and sound by construction.

/* --- 3. A LOCK-FREE SPSC QUEUE, ISR to main --- */
    use heapless::spsc::{Queue, Producer, Consumer};

    static mut Q: Queue<Event, 16> = Queue::new();

    // in init, once:
    let (mut prod, mut cons) = unsafe { Q.split() };
    // `prod` goes to the ISR, `cons` to the main loop -
    // and the TYPES enforce that only one end does each

    #[interrupt]
    fn EXTI0() {
        PRODUCER.enqueue(Event::Button).ok();   // never
                                                // blocks
    }
    fn main_loop() {
        while let Some(ev) = CONSUMER.dequeue() { handle(ev); }
    }
/* Single-producer single-consumer needs no lock at all - the
   same design as the C++ ring in C++ chapter 13, with the
   producer and consumer halves as distinct TYPES so the
   invariant cannot be violated.

/* --- 4. RTIC: priorities and resources, checked at compile
```

```
       time --- */
    #[app(device = pac, peripherals = true)]
    mod app {
        #[shared] struct Shared { counter: u32 }
        #[local]  struct Local  { led: Led }

        #[task(binds = TIM2, shared = [counter], priority = 2)]
        fn timer(mut cx: timer::Context) {
            cx.shared.counter.lock(|c| *c += 1);
        }

        #[idle(shared = [counter])]
        fn idle(mut cx: idle::Context) -> ! {
            loop {
                let n = cx.shared.counter.lock(|c| *c);
                ...
            }
        }
    }
/* RTIC applies the STACK RESOURCE POLICY: it computes each
   resource's priority ceiling at compile time and raises
   BASEPRI only as far as needed - so a resource shared only
   between equal-priority tasks needs NO critical section at
   all. Deadlock is impossible by construction, and the
   analysis is done by the macro, not at run time
   (chapter 16).                                          */
```

Implementing Send and Sync

```
/* Occasionally you must assert it yourself - almost always
   because a raw pointer made the type conservatively
   non-Send.                                              */

    pub struct Uart { base: *mut u32 }

    // SAFETY: `base` points to a memory-mapped peripheral.
    // The Uart is created once via a token that guarantees
    // exclusive ownership, so moving it between contexts
    // cannot create aliasing.
    unsafe impl Send for Uart {}

    // NOT Sync: two &Uart in two contexts could interleave
    // register writes. Callers must wrap it in a Mutex.

/* THE DISCIPLINE: `unsafe impl Send` and `unsafe impl Sync`
   are promises the compiler cannot check (chapter 11).
   Write the SAFETY comment, and state which of the two you
   are NOT implementing and why - that second half is what
   readers need.

/* AND THE OPPOSITE - explicitly opting OUT: */
    use core::marker::PhantomData;
    pub struct NotSync {
        data: u32,
        _marker: PhantomData<*const ()>,    // raw pointer:
                                            // not Send, not
                                            // Sync
    }
/* PhantomData with a chosen type is how you control auto
   traits without any runtime cost. `PhantomData<&'a T>`
   also expresses a lifetime relationship for a type that
   holds no reference - which is what type-state patterns
   need (chapter 02).                                     */
```

How it shows up

Error	Meaning and fix
"`Rc<T>` cannot be sent between threads safely"	Use `Arc`
"`RefCell<T>` cannot be shared between threads"	Use `Mutex` or `RwLock`
"`*mut T` cannot be sent"	Wrap it and `unsafe impl Send`, with a justification
"closure may outlive the current function"	Add `move`, or use a scoped thread
"borrowed data escapes outside of function"	The `'static` bound — own the data or scope the thread
`lock()` returns `Err`	Poisoned — a previous holder panicked
Deadlock	Rust does **not** prevent this — establish a lock order
Receiver never terminates	A sender clone was not dropped
`fetch_add` unavailable on Cortex-M0	No LDREX — use `portable-atomic`
Corruption between an ISR and main	No critical section, or the wrong atomic ordering
RTIC reports a priority error	The analysis found a real ceiling violation at compile time

Check yourself

- ✓ Define `Send` and `Sync` and say which common types lack each.
- ✓ Explain how the compiler derives them and why you rarely write them.
- ✓ Explain why `thread::spawn` requires `Send + 'static`.
- ✓ Use scoped threads to borrow local data, and say why it is sound.
- ✓ Explain why `Mutex<T>` containing the data beats a separate mutex.
- ✓ Explain lock poisoning and how to recover.
- ✓ Use a channel and explain why ownership transfer removes the need for locking.
- ✓ Give four concurrency mechanisms for bare metal and when each fits.
- ✓ Explain what RTIC computes at compile time and what it eliminates.
- ✓ Write a justified `unsafe impl Send` and say what you deliberately did not implement.

Async Rust

Concurrency without threads: a state machine the compiler writes for you. On embedded this is transformative — Embassy gives you cooperative multitasking with no RTOS, no per-task stacks, and code that reads like blocking code.

The model

```
An `async fn` does not run when called. It returns a
FUTURE - a value representing work not yet done.

     async fn read_sensor() -> u16 { ... }

     let fut = read_sensor();        // NOTHING HAS
                                     // HAPPENED
     let v = fut.await;              // now it runs, and
                                     // may yield

THE FUTURE TRAIT, which is the whole mechanism:

     trait Future {
         type Output;
         fn poll(self: Pin<&mut Self>, cx: &mut Context<'_>)
                 -> Poll<Self::Output>;
     }
     enum Poll<T> { Ready(T), Pending }

The EXECUTOR calls poll(). If the future returns Pending,
it has arranged - via the Waker in the Context - to be
woken when progress is possible, and the executor runs
something else. When woken, poll() is called again.

THE COMPILER TRANSFORMS an async fn into a STATE MACHINE:

     async fn f() {
         let a = step1().await;      // state 0
         let b = step2(a).await;     // state 1
         finish(b);                  // state 2
     }

becomes, in effect:

     enum F { S0, S1 { a: A }, S2 { b: B }, Done }
     impl Future for F {
         fn poll(...) -> Poll<()> {
             loop { match self.state {
                 S0 => match step1().poll() {
                     Pending => return Pending,
                     Ready(a) => self.state = S1 { a },
                 },
                 ...
             }}
         }
     }

THE SIZE OF THAT ENUM is the size of the future - it holds
every local that is live across an await point. That is
why async needs no per-task stack: the state that would
have lived on a stack lives in the future instead, sized
exactly, at compile time.

AND WHY THAT MATTERS ON EMBEDDED: an RTOS gives every task
a stack, sized by guesswork and usually over-provisioned.
Embassy's tasks are futures - typically tens or a few
hundred bytes, exactly measured by the compiler.
```

Writing async code

```
    async fn fetch(id: u32) -> Result<Data, Error> {
        let conn = connect().await?;            // `?` works
        let raw = conn.request(id).await?;
        Ok(parse(raw)?)
    }

/* IT READS LIKE BLOCKING CODE. That is the point - the
   alternative is a hand-written state machine or a chain of
   callbacks, both of which obscure the control flow.

/* CONCURRENCY WITHIN ONE TASK: */
    use futures::future::join;

    let (a, b) = join(read_temp(), read_pressure()).await;
    // both progress; completes when BOTH do

    use futures::future::select;
    match select(read_sensor(), timer(Duration::from_ms(100)))
              .await {
        Either::Left((v, _))  => got_value(v),
        Either::Right((_, _)) => timed_out(),
    }
    // whichever finishes first; the other is DROPPED

/* IN EMBASSY the same things read better: */
    use embassy_futures::{join::join, select::{select,
                                               Either}};

    match select(uart.read(&mut buf),
                 Timer::after_millis(100)).await {
        Either::First(r) => handle(r?),
        Either::Second(_) => return Err(Error::Timeout),
    }
/* A TIMEOUT ON ANY OPERATION, in three lines, with no timer
   callbacks and no state to unwind. This single pattern is
   worth the whole model on embedded.

/* CANCELLATION IS DROPPING THE FUTURE: */
    let fut = long_operation();
    drop(fut);                  // it simply stops - its Drop
                                // runs, releasing whatever it
                                // held
/* WHICH IS WHY `select` can abandon the loser safely, and
   why every async operation must be CANCEL SAFE: it must be
   correct to stop at any await point. A future that has
   started a DMA transfer must stop it in Drop, or the
   hardware writes into a buffer that no longer exists.
   THIS IS THE MAIN CORRECTNESS HAZARD in embedded async, and
   it is the one to think about when writing a driver.   */
```

> **ASYNC IS CONCURRENCY, NOT PARALLELISM**
>
> On a single core, an executor interleaves tasks at await points — one runs at a time, and a task that never awaits blocks everything. That is cooperative multitasking, and it means no preemption, no data races between tasks on one executor, and no locking needed for data shared between them. It also means a compute-bound loop must yield explicitly.

Embassy

```
#![no_std]
#![no_main]

use embassy_executor::Spawner;
use embassy_stm32::gpio::{Level, Output, Speed};
use embassy_time::{Duration, Timer};

#[embassy_executor::task]
async fn blink(mut led: Output<'static>) {
    loop {
        led.set_high();
        Timer::after_millis(500).await;      // YIELDS - the
        led.set_low();                       // executor runs
        Timer::after_millis(500).await;      // other tasks
    }
}

#[embassy_executor::task]
async fn sensor(mut i2c: I2c<'static, Async>) {
    let mut buf = [0u8; 2];
    loop {
        i2c.write_read(ADDR, &[REG_TEMP], &mut buf)
           .await
           .unwrap();                         // an actual DMA
                                              // transfer,
                                              // awaited
        let temp = i16::from_be_bytes(buf);
        CHANNEL.send(Reading::Temp(temp)).await;
        Timer::after_secs(1).await;
    }
}

#[embassy_executor::main]
async fn main(spawner: Spawner) {
    let p = embassy_stm32::init(Default::default());

    let led = Output::new(p.PC13, Level::Low, Speed::Low);
    spawner.spawn(blink(led)).unwrap();
    spawner.spawn(sensor(i2c)).unwrap();

    loop {
        match CHANNEL.receive().await {
            Reading::Temp(t) => log(t),
        }
    }
}

/* WHAT IS HAPPENING UNDERNEATH:

   · `Timer::after_millis(500).await` registers with a
     hardware timer and returns Pending. The executor finds
     nothing else runnable and executes WFI - the core sleeps
     until an interrupt. Power consumption drops to
     microamps.

   · `i2c.write_read(...).await` starts a DMA transfer and
     returns Pending. The DMA-complete interrupt wakes the
     task. NO POLLING, NO BUSY-WAIT, and the core sleeps
     during the transfer.
```

```
   · Each task is a future stored in a statically allocated
     slot sized by the compiler. NO HEAP, NO PER-TASK STACK.

   THE COMPARISON WITH AN RTOS:
     FreeRTOS: 8 tasks x 1 KB stack = 8 KB of RAM, guessed,
               plus context-switch cost, plus a scheduler
     Embassy:  8 futures x ~100 bytes = under 1 KB, exact,
               with switches that are ordinary function
               returns

/* THE SYNCHRONISATION PRIMITIVES, all no-alloc: */
    use embassy_sync::{channel::Channel, mutex::Mutex,
                       signal::Signal, pubsub::PubSubChannel};
    use embassy_sync::blocking_mutex::raw::ThreadModeRawMutex;

    static CHANNEL: Channel<ThreadModeRawMutex, Reading, 8>
                = Channel::new();
    static SIGNAL: Signal<ThreadModeRawMutex, ()>
                = Signal::new();

    // an ASYNC mutex - awaiting the lock yields rather than
    // blocking
    static SHARED: Mutex<ThreadModeRawMutex, State>
                = Mutex::new(State::new());
    { let mut s = SHARED.lock().await; s.update(); }
```

Pin, briefly

```
/* A future that holds a reference into itself - which the
   state machine transformation produces whenever a local
   reference lives across an await - must not MOVE, or the
   reference dangles.

   `Pin<P>` is the type-level promise that the pointee will
   not move.                                                */

    async fn f() {
        let data = [0u8; 64];
        let slice = &data[..];          // a reference INTO
                                        // the future
        io.read(slice).await;           // live across an
                                        // await ->
                                        // self-referential
    }

/* IN PRACTICE YOU RARELY TOUCH Pin:
     · `.await` handles pinning for you
     · pin_mut! or Box::pin when you must hold a future
     · implementing Future by hand is where you meet it

    use futures::pin_mut;
    let fut = do_thing();
    pin_mut!(fut);              // pins it to the stack
    poll_fn(|cx| fut.as_mut().poll(cx)).await;

/* `Unpin` MEANS "moving me is fine" - most types are Unpin,
   and only self-referential ones are not. If an error
   mentions Unpin, you are holding a future that needs
   pinning; pin_mut! or Box::pin is the fix.             */
```

Async on Linux

```
/* For embedded LINUX rather than bare metal, tokio is the
   standard runtime. */

    #[tokio::main]
    async fn main() -> Result<()> {
        let listener = TcpListener::bind("0.0.0.0:8080")
                           .await?;
        loop {
            let (socket, _) = listener.accept().await?;
            tokio::spawn(async move { handle(socket).await });
        }
    }

/* TOKIO gives you: a multi-threaded work-stealing executor,
   async file and socket I/O, timers, channels, and
   synchronisation primitives. It is what a network service
   on an embedded Linux gateway should use.

/* THE CATCH - BLOCKING IN AN ASYNC CONTEXT: */
    async fn bad() {
        std::thread::sleep(Duration::from_secs(1));  // BLOCKS
                                                     // THE
                                                     // EXECUTOR
        let data = std::fs::read("file")?;           // ditto
    }
    async fn good() {
        tokio::time::sleep(Duration::from_secs(1)).await;
        let data = tokio::fs::read("file").await?;
        // and for genuinely blocking work:
        let r = tokio::task::spawn_blocking(|| heavy_cpu())
                    .await?;
    }
/* A blocking call in an async task stalls every other task
   on that executor thread. This is the commonest async bug,
   in every language that has it.

/* AND THE RUNTIME QUESTION: async code is tied to its
   runtime's primitives, so a library written against tokio
   does not work under async-std or Embassy. Libraries should
   be runtime-agnostic where possible - which in practice
   means depending only on `futures` traits.            */
```

When to use it

Situation	Approach
Many I/O-bound tasks, bare metal	**Embassy** — this is its case
Hard real-time, priority-driven	**RTIC** — preemptive, with compile-time analysis
A simple superloop with two or three activities	A plain loop with state; async adds nothing
Network service on embedded Linux	**tokio**
CPU-bound work	Threads, or `spawn_blocking` — async does not help
Existing RTOS codebase	Keep the RTOS; async is not a drop-in replacement
Very tight flash budget	Measure — Embassy is small but not free

```
/* THE HONEST TRADE-OFFS:

   IN FAVOUR:
     · code that reads sequentially for logic that is
       concurrent
     · no per-task stacks - typically a large RAM saving
     · automatic power management: the executor sleeps when
       nothing is ready
     · timeouts and cancellation are three lines
     · no priority inversion, no preemption races between
       tasks on one executor

   AGAINST:
     · the state machine transformation makes debugging
       harder - a backtrace shows the executor, not your
       logic
     · CANCEL SAFETY is a real hazard: every await point is a
       possible cancellation point
     · a future's size can surprise you - a large array
       across an await lives in the future
     · no preemption, so a long computation starves
       everything; you must yield explicitly
     · error messages involving Pin and generic futures are
       poor
     · it is newer than the alternatives

   MEASURE THE FUTURE SIZES, which is the one number that
   catches people out:                                    */
        const _: () = assert!(
            core::mem::size_of_val(&my_task()) < 512);
/* A future holding a 4 KB buffer across an await is 4 KB of
   static RAM. Box it, or restructure so the buffer is not
   live across the await.                                 */
```

How it shows up

Symptom	Cause and fix
The async function never runs	The future was created and not awaited
Everything stalls	A blocking call, or a compute loop with no await
"future cannot be sent between threads"	It holds a non-`Send` value across an await
"`X` is not `Unpin`"	Pin it: `pin_mut!` or `Box::pin`
DMA writes into a freed buffer	The future was cancelled without stopping the transfer — cancel safety
Data lost on a timeout	The abandoned future had consumed input — restructure to be cancel safe
Static RAM much larger than expected	A large local live across an await
Backtrace shows only the executor	Expected — instrument with `defmt` instead
Deadlock on an async mutex	Held across an await that waits on the holder
Power consumption never drops	A task is polling rather than awaiting a real interrupt

Check yourself

- ✓ Explain what an `async fn` returns and when the work happens.
- ✓ Describe the state machine transformation and where the state lives.

- ✓ Explain why async needs no per-task stack, and compare with an RTOS.
- ✓ Use `join` and `select`, and implement a timeout.
- ✓ Explain cancel safety and give a hardware example where it matters.
- ✓ Write an Embassy task and explain what happens at each await.
- ✓ Explain why the core can sleep during an awaited DMA transfer.
- ✓ Say what `Pin` is for and when you actually meet it.
- ✓ Name the commonest async bug on a hosted runtime and its fix.
- ✓ Decide between Embassy, RTIC, an RTOS and a superloop for four situations.
- ✓ Measure a future's size and say what makes it large.

`no_std` and bare-metal Rust

Rust without an operating system: what you lose, what you keep, and the boilerplate that turns a crate into a firmware image. Unlike C++, Rust was designed for this case from the start, and the result is genuinely comfortable.

The three layers

```
core          ALWAYS AVAILABLE. No OS, no allocator.
              Option, Result, Iterator, slices, str,
              integers and floats, core::fmt, atomics,
              mem, ptr, marker traits, panic machinery.
              Most of the LANGUAGE lives here.

alloc         needs a GLOBAL ALLOCATOR, nothing more.
              Box, Vec, String, BTreeMap, Rc, Arc.
              Opt in with `extern crate alloc;`.

std           needs an OS. Files, sockets, threads,
              processes, time, environment, HashMap
              (because of random seeding).

`#![no_std]` OPTS OUT OF std, keeping core. Add `alloc`
back if you want heap collections and can supply an
allocator.

THE PRACTICAL POINT: `core` is not a cut-down subset -
it contains iterators, the whole Option/Result API,
formatting, atomics and the numeric traits. Idiomatic
Rust works almost unchanged; what you lose is I/O,
threads and heap collections.

COMPARE C++ FREESTANDING (C++ chapter 15), where you must
check header by header what is available and supply
several runtime functions yourself.
```

A minimal firmware crate

```
#![no_std]
#![no_main]

use panic_halt as _;            // supplies #[panic_handler]
use cortex_m_rt::entry;         // supplies the reset vector
use cortex_m::asm;

#[entry]
fn main() -> ! {                // NEVER returns
    let p = pac::Peripherals::take().unwrap();

    p.RCC.ahb1enr.modify(|_, w| w.gpiocen().set_bit());
    p.GPIOC.moder.modify(|_, w| w.moder13().output());

    loop {
        p.GPIOC.bsrr.write(|w| w.bs13().set_bit());
        asm::delay(8_000_000);
        p.GPIOC.bsrr.write(|w| w.br13().set_bit());
        asm::delay(8_000_000);
    }
}

/* `#![no_main]` because the C `main` signature and the
   pre-main runtime do not exist. `#[entry]` from
   cortex-m-rt provides the reset handler, which zeroes .bss,
   copies .data from flash, initialises the FPU, and calls
   your function (compilers chapter 12).

/* THE PANIC HANDLER is mandatory - core cannot provide one
   because the right behaviour is application-specific: */
    use panic_halt as _;        // spin forever
    use panic_reset as _;       // system reset
    use panic_probe as _;       // print over RTT, then halt
    use panic_persist as _;     // save the message to RAM
                                // across a reset

/* OR WRITE ONE, which is what a product does: */
    #[panic_handler]
    fn panic(info: &core::panic::PanicInfo) -> ! {
        // save the location for the next boot to report
        cortex_m::interrupt::disable();
        write_panic_record(info.location());
        cortex_m::peripheral::SCB::sys_reset();
    }

/* AND THE INTERRUPT HANDLERS: */
    use cortex_m_rt::exception;
    use stm32f4xx_hal::pac::interrupt;

    #[exception]
    fn SysTick() { TICKS.fetch_add(1, Ordering::Relaxed); }

    #[interrupt]
    fn USART1() { critical_section::with(|cs| { ... }); }

    #[exception]
    unsafe fn HardFault(ef: &ExceptionFrame) -> ! {
        // ef holds the stacked registers - log them
        log_fault(ef);
        loop {}
```

```
    }
/* The names are checked against the device's vector table by
   the PAC, so a typo is a compile error rather than an
   interrupt that never fires.                          */
```

Project layout

```
# Cargo.toml
    [dependencies]
    cortex-m = "0.7"
    cortex-m-rt = "0.7"
    embedded-hal = "1.0"
    stm32f4xx-hal = { version = "0.21",
                      features = ["stm32f411"] }
    heapless = "0.8"
    defmt = "0.3"
    defmt-rtt = "0.4"
    panic-probe = { version = "0.3", features = ["print-defmt"] }
    critical-section = "1.1"

    [profile.release]
    opt-level = "z"
    lto = "fat"
    codegen-units = 1
    panic = "abort"
    debug = 2                   # symbols cost nothing in
                                # flash and defmt needs them
    overflow-checks = false

    [profile.dev]
    opt-level = 1               # -O0 firmware is often too
                                # slow to run

# .cargo/config.toml
    [build]
    target = "thumbv7em-none-eabihf"

    [target.thumbv7em-none-eabihf]
    runner = "probe-rs run --chip STM32F411RETx"
    rustflags = [
      "-C", "link-arg=-Tlink.x",        # from cortex-m-rt
      "-C", "link-arg=-Tdefmt.x",       # for defmt
      "-C", "linker=flip-link",         # STACK OVERFLOW
                                        # PROTECTION
    ]

# memory.x - the memory map, read by cortex-m-rt's link.x
    MEMORY
    {
      FLASH : ORIGIN = 0x08000000, LENGTH = 512K
      RAM   : ORIGIN = 0x20000000, LENGTH = 128K
    }

# build.rs copies memory.x into OUT_DIR (chapter 10).

# THEN:
    cargo run --release
# builds, flashes and runs on the target, streaming defmt
# logs back. One command.

/* flip-link IS WORTH SPECIAL MENTION: it moves the stack
   BELOW static memory, so a stack overflow hits an unmapped
   region and faults immediately instead of silently
   corrupting .bss. That is a free fix for the single worst
   embedded failure mode (Linux chapter 02 describes the same
   problem), and it costs nothing.                          */
```

> **THE THREE TOOLS THAT CHANGE THE EXPERIENCE**
>
> **probe-rs** — flash, run, debug and stream logs with one command, no vendor IDE. **defmt** — deferred formatting: the format string stays in the ELF and only the arguments go over the wire, so a log line costs a few bytes and a handful of cycles. **flip-link** — stack overflow becomes a fault instead of corruption. Together they are why embedded Rust tooling is frequently better than the C equivalent, not merely comparable.

What you lose, and the replacement

Absent	Use instead
`Vec<T>`, `String`	`heapless::Vec<T, N>`, `heapless::String<N>`
`HashMap`	`heapless::FnvIndexMap`, or a sorted array
`println!`	`defmt::info!`, or `write!` to a UART
`std::error::Error`	Your own enum (ch. 07)
`std::time::Instant`	`embassy_time::Instant`, or a tick counter
`std::thread`	Interrupts, RTIC tasks, or Embassy tasks
`std::sync::Mutex`	`critical_section::Mutex`, `embassy_sync::Mutex`
Floating-point `f64::sin` etc.	`libm`, or fixed-point
`rand`	The hardware RNG, or a PRNG crate with `default-features=false`
`std::io`	`embedded-io`, `core::fmt::Write`

```
/* MAKING A LIBRARY WORK BOTH WAYS - the convention every
   good crate follows: */

    #![cfg_attr(not(feature = "std"), no_std)]

    #[cfg(feature = "alloc")]
    extern crate alloc;

    #[cfg(feature = "alloc")]
    use alloc::vec::Vec;

    // Cargo.toml
    [features]
    default = ["std"]
    std = ["alloc"]
    alloc = []

/* AND THE CHECK: `cargo build --no-default-features` in CI,
   so a std-only dependency cannot creep in unnoticed.

/* USING A DEPENDENCY IN no_std: */
    serde = { version = "1", default-features = false,
              features = ["derive"] }
/* `default-features = false` is the crucial part - most
   crates enable std by default. If a crate does not support
   no_std, that is usually a hard blocker.               */
```

Adding a heap, if you must

```
    #![no_std]
    extern crate alloc;

    use embedded_alloc::LlffHeap as Heap;
    use alloc::{vec::Vec, string::String};

    #[global_allocator]
    static HEAP: Heap = Heap::empty();

    #[entry]
    fn main() -> ! {
        {
            use core::mem::MaybeUninit;
            const HEAP_SIZE: usize = 8 * 1024;
            static mut MEM: [MaybeUninit<u8>; HEAP_SIZE] =
                [MaybeUninit::uninit(); HEAP_SIZE];
            unsafe {
                HEAP.init(core::ptr::addr_of_mut!(MEM) as usize,
                          HEAP_SIZE)
            }
        }

        let mut v = Vec::new();
        v.push(42);
        ...
    }

/* HANDLING EXHAUSTION: */
    let mut v = Vec::new();
    v.try_reserve(100)?;                // Result, not a panic
    // otherwise allocation failure calls the OOM handler,
    // which by default panics

/* SHOULD YOU? Usually not.
     · fragmentation is unbounded over a long uptime
     · allocation time is not deterministic
     · failure handling is awkward
     · heapless gives you the same interfaces with a bounded
       failure mode (chapter 08)

   WHEN IT IS REASONABLE: a device with megabytes of RAM
   running a network stack or a filesystem, where the working
   set genuinely varies. On a 64 KB microcontroller, use
   heapless and static allocation.                          */
```

Controlling size

```
# --- MEASURE FIRST ---
    cargo size --release -- -A
       .vector_table  1024
       .text         18432
       .rodata        2048
       .data           128
       .bss           4096

    cargo bloat --release -n 30
    cargo bloat --release --crates       # by dependency

# --- THE BIGGEST WINS, in order ---

# 1. THE PROFILE (chapter 10) - typically halves the binary:
    opt-level = "z", lto = "fat", codegen-units = 1,
    panic = "abort"

# 2. AVOID CORE::FMT. The formatting machinery is often the
#    single largest item in a small firmware:
    panic!("bad value: {}", x);         // pulls in fmt
    panic!("bad value");                // does not
    defmt::info!("value {=u32}", x);    // FORMATS ON THE
                                        // HOST - the string
                                        // never enters the
                                        // binary

# 3. defmt INSTEAD OF ANY OTHER LOGGING. It is the difference
#    between a few hundred bytes and several kilobytes.

# 4. PANICS. Every `unwrap`, every index, every slice
#    operation can panic, and each panic site carries a
#    location string. Use `get()`, `checked_*` and explicit
#    handling (chapter 07). Then:
    panic-never = "0.1"
#    makes any REACHABLE panic a LINK ERROR - which is a
#    build-time proof that no panic can occur.

# 5. build-std, to rebuild core with your profile:
    cargo +nightly build -Z build-std=core \
        -Z build-std-features=panic_immediate_abort \
        --target thumbv7em-none-eabihf --release
#    `panic_immediate_abort` removes the panic formatting
#    from core itself. Often several kilobytes.

# 6. --gc-sections is on by default via link.x, but check:
    cargo nm --release | sort -k1

# A REALISTIC RESULT: a blinky is around 2 KB; a firmware
# with a HAL, defmt logging and a USB stack is 30-60 KB.
# Comparable with C once the profile is right, and the
# difference is usually formatting rather than the language.
```

Testing and debugging

```
/* --- HOST TESTS for the portable logic (chapter 10) --- */
    #[cfg(test)]
    mod tests {
        use super::*;
        #[test]
        fn crc_matches_reference() {
            assert_eq!(crc32(b"hello"), 0x3610A686);
        }
    }
    // cargo test --target x86_64-unknown-linux-gnu
    // put the logic in a portable crate so this works

/* --- ON-TARGET TESTS --- */
    #[defmt_test::tests]
    mod tests {
        #[test]
        fn uart_loopback() {
            let mut u = setup_uart();
            u.write(b'x').unwrap();
            assert_eq!(u.read().unwrap(), b'x');
        }
    }
    // cargo test --target thumbv7em-none-eabihf
    // runs on the DEVICE, results streamed back over RTT

/* --- LOGGING --- */
    defmt::trace!("entering state {}", state);
    defmt::debug!("adc = {=u16}", raw);
    defmt::info!("ready");
    defmt::warn!("retry {=u8}/{=u8}", n, max);
    defmt::error!("fault: {}", e);
    defmt::assert!(x < 10, "x too large: {}", x);

    #[derive(defmt::Format)]        // like Debug, for defmt
    struct Reading { temp: i16, humidity: u8 }

    // filter at build time:
    DEFMT_LOG=info cargo run --release

/* --- DEBUGGING --- */
    probe-rs run --chip STM32F411RETx target/.../fw
    probe-rs attach --chip STM32F411RETx
    cargo embed                     # a TUI with RTT

    # GDB, when you need it:
    probe-rs gdb --chip STM32F411RETx
    (gdb) target remote :1337
    (gdb) monitor reset halt
    (gdb) break main
    (gdb) continue

/* --- AND THE HARD FAULT HANDLER, which is worth writing
       properly: */
    #[exception]
    unsafe fn HardFault(ef: &ExceptionFrame) -> ! {
        defmt::error!("HardFault at pc={=u32:#x} lr={=u32:#x}",
                      ef.pc(), ef.lr());
        // and the fault status registers (ARM chapter 29)
        let cfsr = (*SCB::PTR).cfsr.read();
        defmt::error!("CFSR = {=u32:#x}", cfsr);
```

```
        loop {}
    }
/* Which turns "it hangs" into "it faulted at this address
   because of an unaligned access" - the same diagnosis
   process as ARM chapter 29, with the registers named.  */
```

How it shows up

Symptom	Cause and fix
"can't find crate for `std`"	A dependency needs std — set `default-features = false`
"`#[panic_handler]` function required"	Add `use panic_halt as _;` or write one
"language item required: `eh_personality`"	Set `panic = "abort"`
"undefined reference to `memcpy`"	Needs a `compiler_builtins` or the target's runtime
Linker error about `link.x` or memory regions	`memory.x` missing or not copied by `build.rs`
Binary far larger than expected	Profile not tuned, or `core::fmt` pulled in
Firmware hangs immediately	Stack overflow — use `flip-link`; or clocks not configured
Interrupt never fires	Not unmasked in the NVIC, or the handler name is wrong
Panic with no message	`panic-halt` — switch to `panic-probe` while developing
`Peripherals::take()` returns `None`	Called twice — by design (ch. 02)
Allocation fails at run time	Heap too small, or fragmented — prefer `heapless`
defmt output is garbled	The ELF and the running binary differ — reflash

Check yourself

- ✓ Distinguish `core`, `alloc` and `std`, and say what each needs.
- ✓ Write a minimal `no_std` firmware crate with an entry point and a panic handler.
- ✓ Explain what `cortex-m-rt` does before your `main` runs.
- ✓ Configure `Cargo.toml`, `.cargo/config.toml` and `memory.x`.
- ✓ Explain what `flip-link` prevents and why it is free.
- ✓ Name eight `std` facilities and their `no_std` replacements.
- ✓ Make a library build both with and without `std`, and test both in CI.
- ✓ Add a global allocator, and give three reasons not to.
- ✓ List six size-reduction techniques in order of effect.
- ✓ Explain why `defmt` is smaller than any alternative.
- ✓ Write a useful HardFault handler.

The embedded Rust ecosystem: PAC, HAL, RTIC, Embassy

The layered architecture that lets a driver written once run on every supported chip. This is the ecosystem's central achievement, and it has no equivalent in the C world where every vendor HAL is incompatible with every other.

The layers

```
+-------------------------------------------------+
|  APPLICATION                                    |
|  your firmware, or RTIC / Embassy tasks         |
+-------------------------------------------------+
|  DEVICE DRIVERS - portable                      |
|  generic over embedded-hal traits, so ONE driver  |
|  works on every chip                            |
+-------------------------------------------------+
|  embedded-hal   - THE TRAIT DEFINITIONS         |
|  SpiDevice, I2c, OutputPin, DelayNs, ...        |
+-------------------------------------------------+
|  HAL - per chip family                          |
|  stm32f4xx-hal, nrf52840-hal, esp-hal, rp2040-hal |
|  implements the traits; owns clocks, pins, DMA    |
+-------------------------------------------------+
|  PAC - Peripheral Access Crate                  |
|  GENERATED from the vendor's SVD file by svd2rust.|
|  Typed, safe register access. Contains the unsafe.|
+-------------------------------------------------+
|  cortex-m / riscv - the core itself             |
|  NVIC, SysTick, SCB, critical sections          |
+-------------------------------------------------+
|  cortex-m-rt - the startup and vector table     |
+-------------------------------------------------+

THE PAYOFF: a driver for an SPI display depends only on
embedded-hal. It compiles for STM32, nRF, ESP32 and RP2040
with no #ifdef, no porting layer, and no runtime cost -
because the concrete SPI type is a generic parameter,
monomorphised at the call site (chapter 06).

COMPARE C, where an ST driver uses HAL_SPI_Transmit, a
Nordic one uses nrfx_spim_xfer, and porting means
rewriting. crates.io has hundreds of sensor and display
drivers that work everywhere, because they were written
against one trait set.
```

The PAC

```
/* GENERATED from the vendor's CMSIS-SVD file - the same XML
   that generates the C headers - by svd2rust. So it covers
   every register and field the vendor documented.        */

    use stm32f4xx_hal::pac;

    let p = pac::Peripherals::take().unwrap();  // SINGLETON
                                                // (chapter 02)

    // enable the GPIOC clock
    p.RCC.ahb1enr.modify(|_, w| w.gpiocen().set_bit());

    // set PC13 as output
    p.GPIOC.moder.modify(|_, w| w.moder13().output());

    // write it
    p.GPIOC.bsrr.write(|w| w.bs13().set_bit());

    // read a field
    let mode = p.GPIOC.moder.read().moder13().bits();

/* THE THREE ACCESS METHODS, and the distinction matters: */
    reg.read()                  // -> R, with field accessors
    reg.write(|w| ...)          // RESET value, then your
                                // changes. Fields you do not
                                // mention are RESET.
    reg.modify(|r, w| ...)      // read-modify-write. Fields
                                // you do not mention are
                                // PRESERVED.
    unsafe { reg.write_with_zero(|w| ...) }   // start from
                                              // zero

/* USING `write` WHERE `modify` WAS MEANT is the commonest PAC
   bug: it silently resets every other field in the register.

/* WHAT THE TYPE SYSTEM GIVES YOU:
     · a field name for every documented bit
     · enum values for enumerated fields:
         w.moder13().output()  not  w.bits(0b01)
     · WRITE-ONLY fields cannot be read
     · READ-ONLY fields cannot be written
     · out-of-range values are compile errors
     · a register that does not exist on this part is not in
       the crate at all

/* GENERATE ONE for a chip that has no crate: */
    svd2rust -i vendor.svd --target cortex-m
    form -i lib.rs -o src/ && rm lib.rs
    cargo fmt

/* THE PAC IS TOO LOW-LEVEL FOR APPLICATION CODE - it is the
   register map, not a driver. Use the HAL, and drop to the
   PAC for the occasional register the HAL does not expose.
   Every HAL re-exports its PAC for exactly that.        */
```

The HAL

```
    use stm32f4xx_hal::{pac, prelude::*, gpio::Output,
                        spi::Spi};

    let dp = pac::Peripherals::take().unwrap();

    // 1. CLOCKS - a builder that VALIDATES the configuration
    let rcc = dp.RCC.constrain();
    let clocks = rcc.cfgr
        .use_hse(25.MHz())
        .sysclk(100.MHz())
        .pclk1(50.MHz())
        .freeze();              // computes the PLL settings,
                                // PANICS if impossible

    // 2. SPLIT the GPIO port into individual PINS
    let gpioa = dp.GPIOA.split();
    let gpioc = dp.GPIOC.split();

    // 3. CONFIGURE pins - the TYPE changes (chapter 02)
    let mut led = gpioc.pc13.into_push_pull_output();
    let sck  = gpioa.pa5.into_alternate();
    let miso = gpioa.pa6.into_alternate();
    let mosi = gpioa.pa7.into_alternate();

    // 4. CONSTRUCT a peripheral, CONSUMING the pins
    let spi = Spi::new(dp.SPI1, (sck, miso, mosi),
                       Mode { polarity: IdleLow,
                              phase: CaptureOnFirstTransition },
                       1.MHz(), &clocks);

    // gpioa.pa5 no longer exists - it was MOVED into the SPI.
    // Nothing else can reconfigure it. That is the ownership
    // model applied to hardware (chapter 02).

    led.set_high();
    spi.write(&[0x01, 0x02]).unwrap();

/* WHAT THE HAL ADDS OVER THE PAC:
     · clock tree configuration, computed and validated
     · pin type-states, so a misconfigured pin is a compile
       error
     · peripherals that CONSUME their pins, preventing
       conflicts
     · implementations of the embedded-hal traits
     · DMA integration
     · sensible defaults

/* AND THE TYPE-STATE PAYOFF: */
    let pin = gpioa.pa5.into_floating_input();
    spi = Spi::new(dp.SPI1, (pin, ...), ...);
    // ERROR: expected Pin<'A', 5, Alternate<5>>,
    //        found Pin<'A', 5, Input<Floating>>
/* A wrong pin configuration - the single commonest embedded
   bring-up bug - is caught by the compiler with a message
   naming the expected mode.                              */
```

OWNERSHIP APPLIED TO HARDWARE

The `Peripherals::take()` singleton, the `split()` that yields one value per pin, and constructors that *consume* their pins together mean that two drivers cannot claim the same hardware. Not by convention, not by review — the second attempt does not compile. That is the single most valuable thing the embedded Rust ecosystem does, and it is a direct application of chapter 02.

Writing a portable driver

```
use embedded_hal::spi::SpiDevice;
use embedded_hal::digital::OutputPin;
use embedded_hal::delay::DelayNs;

pub struct Display<SPI, DC, RST> {
    spi: SPI,
    dc: DC,
    rst: RST,
}

impl<SPI, DC, RST, E> Display<SPI, DC, RST>
where
    SPI: SpiDevice<Error = E>,
    DC:  OutputPin,
    RST: OutputPin,
{
    pub fn new(spi: SPI, dc: DC, rst: RST) -> Self {
        Self { spi, dc, rst }
    }

    pub fn init(&mut self, delay: &mut impl DelayNs)
            -> Result<(), Error<E>>
    {
        self.rst.set_low().map_err(|_| Error::Pin)?;
        delay.delay_ms(10);
        self.rst.set_high().map_err(|_| Error::Pin)?;
        delay.delay_ms(120);

        self.command(0x11)?;            // sleep out
        delay.delay_ms(120);
        self.command(0x29)?;            // display on
        Ok(())
    }

    fn command(&mut self, c: u8) -> Result<(), Error<E>> {
        self.dc.set_low().map_err(|_| Error::Pin)?;
        self.spi.write(&[c]).map_err(Error::Spi)
    }

    pub fn data(&mut self, d: &[u8]) -> Result<(), Error<E>> {
        self.dc.set_high().map_err(|_| Error::Pin)?;
        self.spi.write(d).map_err(Error::Spi)
    }
}

/* THIS COMPILES for STM32, nRF52, ESP32, RP2040 and every
   other chip with a HAL - unchanged. Publish it to crates.io
   and it works for everyone.

/* THE embedded-hal 1.0 TRAITS worth knowing: */
    digital::{InputPin, OutputPin, StatefulOutputPin}
    spi::{SpiBus, SpiDevice}        // Device includes CS
                                    // management
    i2c::I2c
    delay::DelayNs
    pwm::SetDutyCycle
    embedded-hal-async::*           // the async versions,
                                    // for Embassy
    embedded-io::{Read, Write}      // byte streams
    embedded-can, embedded-storage, embedded-nal
```

```
/* THE DRIVER-AUTHOR CONVENTIONS:
     · be generic over the traits, never over a concrete HAL
     · take ownership of the peripherals you need
     · define your own error enum, wrapping the bus error
     · provide both blocking and async versions where it
       matters
     · no_std, and no default features that need std
     · document the wiring in the crate docs             */
```

RTIC

```
use rtic::app;

#[app(device = stm32f4xx_hal::pac, peripherals = true,
      dispatchers = [EXTI0, EXTI1])]
mod app {
    use super::*;

    #[shared]                   // shared between tasks -
    struct Shared {             // access requires .lock()
        counter: u32,
    }

    #[local]                    // owned by exactly one task -
    struct Local {              // NO locking needed
        led: Output<'static>,
    }

    #[init]
    fn init(cx: init::Context) -> (Shared, Local) {
        let dp = cx.device;
        // ... configure clocks, pins, peripherals ...
        blink::spawn().unwrap();
        (Shared { counter: 0 }, Local { led })
    }

    #[task(binds = TIM2, shared = [counter], priority = 3)]
    fn on_timer(mut cx: on_timer::Context) {
        cx.shared.counter.lock(|c| *c += 1);
    }

    #[task(local = [led], priority = 1)]
    async fn blink(cx: blink::Context) {
        loop {
            cx.local.led.toggle();      // NO LOCK - it is
                                        // local
            Mono::delay(500.millis()).await;
        }
    }

    #[idle(shared = [counter])]
    fn idle(mut cx: idle::Context) -> ! {
        loop {
            let n = cx.shared.counter.lock(|c| *c);
            cortex_m::asm::wfi();       // sleep until an
                                        // interrupt
        }
    }
}

/* WHAT RTIC DOES AT COMPILE TIME:

   · PRIORITY ASSIGNMENT: each task has a fixed priority,
     mapped onto NVIC priorities.
   · RESOURCE ANALYSIS: it computes each shared resource's
     PRIORITY CEILING - the highest priority of any task
     using it - and `lock()` raises BASEPRI only to that
     ceiling.
   · SO: a resource shared only between tasks of EQUAL
     priority needs NO critical section at all, and lock()
     compiles to nothing. A resource shared between priority
```

```
    1 and 3 raises BASEPRI to 3 for the duration — blocking
    only what could conflict, not all interrupts.
  · DEADLOCK IS IMPOSSIBLE: the Stack Resource Policy
    guarantees it, and the analysis is done by the macro.
  · `#[local]` resources need no synchronisation at all,
    because the type system proves one owner.

  THIS IS A REAL-TIME KERNEL WITH NO RUNTIME. There is no
  scheduler loop, no task control blocks, no context
  switching code — the NVIC does the scheduling, and RTIC
  only computes the correct priority masks. The generated
  code is what a careful engineer would hand-write, and the
  analysis is what they would get wrong.                */
```

Embassy

```
use embassy_executor::Spawner;
use embassy_stm32::{gpio::{Level, Output, Speed}, i2c::I2c};
use embassy_sync::{channel::Channel,
                   blocking_mutex::raw::ThreadModeRawMutex};
use embassy_time::{Duration, Timer};

static CHANNEL: Channel<ThreadModeRawMutex, Reading, 8>
        = Channel::new();

#[embassy_executor::task]
async fn blink(mut led: Output<'static>) {
    loop {
        led.toggle();
        Timer::after_millis(500).await;
    }
}

#[embassy_executor::task]
async fn sensor(mut i2c: I2c<'static, Async>) {
    let mut buf = [0u8; 2];
    loop {
        // a real DMA transfer - the core SLEEPS during it
        i2c.write_read(0x48, &[0x00], &mut buf).await.unwrap();
        CHANNEL.send(Reading(i16::from_be_bytes(buf))).await;
        Timer::after_secs(1).await;
    }
}

#[embassy_executor::main]
async fn main(spawner: Spawner) {
    let p = embassy_stm32::init(Default::default());

    spawner.spawn(blink(Output::new(p.PC13, Level::Low,
                                    Speed::Low))).unwrap();
    spawner.spawn(sensor(i2c)).unwrap();

    loop {
        let r = CHANNEL.receive().await;
        defmt::info!("reading: {}", r.0);
    }
}

/* WHAT EMBASSY PROVIDES:
     · an async executor with no heap and no per-task stacks
       (chapter 14)
     · HALs for STM32, nRF, RP2040, ESP32 with ASYNC drivers
       that use DMA and interrupts rather than polling
     · embassy-time: timers, delays, timeouts
     · embassy-sync: Channel, Mutex, Signal, PubSub - all
       no-alloc
     · embassy-net: a full TCP/IP stack
     · embassy-usb: a USB device stack
     · AUTOMATIC POWER MANAGEMENT: the executor executes WFI
       when nothing is ready, so an idle system draws
       microamps with no code from you

/* RTIC OR EMBASSY?

     RTIC     PREEMPTIVE, priority-driven, hard real-time.
              Compile-time resource analysis. Best when
```

```
               latency bounds matter and the work is
               interrupt-shaped.

     EMBASSY   COOPERATIVE, async. Best when the work is
               I/O-shaped - network, USB, several sensors -
               and readability matters. Sequential-looking
               code for concurrent logic.

     BOTH TOGETHER: RTIC can run an Embassy executor in a
     low-priority task, giving hard real-time for the
     critical path and async for everything else. That
     combination is increasingly the answer for a complex
     device.                                                */
```

# --- MATURITY, honestly, as of 2026 ---
    EXCELLENT:  Cortex-M (STM32, nRF, RP2040/2350), ESP32,
                RISC-V
    GOOD:       Cortex-A bare metal, drivers for common
                sensors and displays
    EMERGING:   safety certification (Ferrocene is qualified
                for ISO 26262 and IEC 61508), vendor support,
                DSP-heavy work
    THIN:       obscure MCUs, some vendor radio stacks,
                certified medical and avionics toolchains

# CHECK THAT YOUR SPECIFIC CHIP HAS A MAINTAINED HAL before
# committing. A PAC alone is workable but means writing the
# HAL layer yourself.
```

How it shows up

Symptom	Cause and fix
`Peripherals::take()` returns `None`	Called twice — by design
"expected `Alternate<5>`, found `Input`"	Pin not configured for that peripheral — the type-state working
A register field was reset unexpectedly	Used `write` where `modify` was meant
The peripheral does nothing	Clock not enabled — the HAL usually does it, the PAC does not
`clocks.freeze()` panics	The requested clock tree is unachievable — read the constraint it names
A driver will not compile on another chip	It depends on a concrete HAL rather than `embedded-hal`
RTIC reports a priority error	A real ceiling violation, found at compile time
An RTIC task never runs	Not spawned, or no dispatcher interrupt free
Embassy task stalls everything	A blocking call or a loop with no await (ch. 14)
Power never drops	Polling instead of awaiting a real interrupt
No HAL for your chip	Generate a PAC with svd2rust and write the thin HAL layer

Check yourself

- ✓ Draw the layer diagram and say what each layer contributes.
- ✓ Explain what a PAC is generated from and what its type system prevents.
- ✓ Distinguish `read`, `write` and `modify`, and the bug from confusing two.
- ✓ Explain how `take`, `split` and consuming constructors prevent hardware conflicts.
- ✓ Show how pin type-states catch a misconfiguration at compile time.
- ✓ Write a driver generic over `embedded-hal` and say why it is portable and free.
- ✓ Explain what RTIC computes at compile time and why some locks cost nothing.
- ✓ Explain why RTIC cannot deadlock.
- ✓ Write an Embassy application with two tasks and a channel.
- ✓ Choose between RTIC and Embassy for two different products, and say when to use both.

Rust in the Linux kernel

Since 6.1 the kernel accepts Rust drivers. This chapter is what that actually means: how the abstractions are built, what a Rust driver looks like beside the C one from Linux chapter 19, and an honest account of the state of it.

Why the kernel accepted it

```
THE ARGUMENT, made over several years and finally
accepted:

  · roughly two thirds of kernel CVEs are memory safety
    issues - use-after-free, buffer overflow, race
    conditions on refcounts
  · drivers are the largest and least-reviewed part of the
    tree, and where most of those bugs live
  · the existing tooling - KASAN, lockdep, sparse, smatch,
    syzkaller (Linux chapter 27) - finds a great deal and
    still misses a great deal
  · a language that makes the class impossible is
    structurally better than one that makes it detectable

THE CONDITIONS ATTACHED, which shape everything below:

  1. NO REWRITE. C remains the kernel's language; Rust is
     for NEW code, chiefly drivers.
  2. NO SECOND ABI. Rust code calls the existing C
     interfaces through bindings; it does not define a
     parallel kernel API.
  3. C DEVELOPERS ARE NOT REQUIRED TO LEARN RUST. If a C
     change breaks Rust code, fixing it is the Rust
     maintainers' problem.
  4. NO PANICS. A kernel panic is unacceptable; the
     abstractions must return errors instead.
  5. NO IMPLICIT ALLOCATION FAILURE. Kernel allocation can
     fail, so the standard library's infallible
     collections are not usable - the kernel has its own.

TIMELINE:
  6.1 (2022)   the infrastructure merged
  6.3–6.7      abstractions grow; the first real drivers
  6.8+         Binder, the Nova GPU driver, PHY drivers,
               null_blk
  6.12+        Rust is production-supported on several
               architectures

AND THE REALISTIC STATUS in 2026: several shipping
drivers, an actively growing abstraction layer, and the
Android Binder rewrite as the flagship. Not yet routine,
and no longer experimental.
```

What differs from ordinary Rust

```
/* --- 1. NO std, NO alloc-as-you-know-it --- */
    #![no_std]
/* The kernel provides its own `kernel` crate, containing the
   allocation types, synchronisation primitives and
   abstractions. `alloc`'s infallible Vec::push is unusable
   because kernel allocation FAILS.                       */

    use kernel::alloc::{flags, KVec};

    let mut v = KVec::new();
    v.push(42, flags::GFP_KERNEL)?;     // FALLIBLE - returns
                                        // Result

/* NOTE the GFP flag as a parameter - the allocation context
   question from Linux chapter 06 is in the type system,
   where the compiler can see it.

/* --- 2. NO PANICS --- */
    v[0]                         // indexing PANICS - avoid
    v.get(0).ok_or(EINVAL)?      // this instead
/* The kernel builds with panic=abort, and an abort is a
   kernel panic. Every abstraction is written to return
   Result rather than panic, and the same discipline applies
   to driver code (chapter 07).

/* --- 3. THE ERROR TYPE IS AN ERRNO --- */
    use kernel::error::{code::*, Result};

    fn probe(...) -> Result {
        if bad { return Err(EINVAL); }
        let p = ioremap(addr).ok_or(ENOMEM)?;
        Ok(())
    }
/* `Result` defaults to `Result<()>` with the kernel's Error
   type, which wraps a negative errno - so it converts
   directly at the C boundary.

/* --- 4. PINNED INITIALISATION --- */
    #[pin_data]
    struct MyDevice {
        #[pin] lock: SpinLock<State>,
        base: IoMem<0x1000>,
    }
/* Kernel objects frequently contain self-referential
   structures - a list_head that points at itself, a lock
   with an address registered with lockdep. They cannot be
   moved after initialisation. The `pin-init` crate makes
   in-place, fallible construction expressible, which is
   machinery ordinary Rust rarely needs (chapter 14's Pin,
   applied).

/* --- 5. NO EXTERNAL CRATES --- */
/* Everything must be in-tree. No crates.io, no Cargo
   dependency resolution - the kernel build system compiles
   the Rust files directly.                               */
```

A driver, beside the C version

```
// SPDX-License-Identifier: GPL-2.0
//! A minimal platform driver.

use kernel::{
    c_str, device::Core, of, platform, prelude::*,
    sync::aref::ARef,
};

struct MyDriver {
    pdev: ARef<platform::Device>,
    base: IoMem<0x1000>,
}

kernel::of_device_table!(
    OF_TABLE,
    MODULE_OF_TABLE,
    <MyDriver as platform::Driver>::IdInfo,
    [
        (of::DeviceId::new(c_str!("vendor,my-device")), ()),
    ]
);

impl platform::Driver for MyDriver {
    type IdInfo = ();
    const OF_ID_TABLE: Option<of::IdTable<Self::IdInfo>>
        = Some(&OF_TABLE);

    fn probe(
        pdev: &platform::Device<Core>,
        _info: Option<&Self::IdInfo>,
    ) -> Result<Pin<KBox<Self>>> {
        dev_info!(pdev.as_ref(), "probing\n");

        let base = pdev.io_request_and_map(0, c_str!("mydev"))?;

        let id = base.read32(REG_ID);
        if id != EXPECTED_ID {
            dev_err!(pdev.as_ref(), "bad id {:#x}\n", id);
            return Err(ENODEV);
        }

        KBox::pin_init(
            try_pin_init!(MyDriver {
                pdev: pdev.into(),
                base,
            }),
            GFP_KERNEL,
        )
    }
}

impl Drop for MyDriver {
    fn drop(&mut self) {
        // the equivalent of remove() - runs automatically
        dev_info!(self.pdev.as_ref(), "removing\n");
    }
}

kernel::module_platform_driver! {
    type: MyDriver,
```

```
    name: "my_driver",
    author: "Your Name",
    description: "Example platform driver",
    license: "GPL",
}

/* COMPARE THE C VERSION (Linux chapter 19) POINT BY POINT:

   · NO GOTO LADDER. The `?` operator returns early, and Drop
     releases everything acquired so far. The error path
     cannot be wrong because it is not written
     (Linux chapter 26's devm_, but from the language).

   · NO remove() FUNCTION. Drop is the teardown, and it runs
     in reverse construction order, automatically.

   · io_request_and_map RETURNS A TYPE whose Drop unmaps.
     Forgetting is impossible.

   · IoMem<0x1000> CARRIES THE SIZE IN THE TYPE, so
     read32(offset) is bounds-checked at COMPILE TIME where
     the offset is a constant.

   · THE ID TABLE is checked by the macro rather than being a
     hand-written array with a sentinel that can be omitted
     (Linux chapter 17's classic crash).

   · dev_err! is the same dev_err(), with format checking.

   THE C DRIVER IS ABOUT 90 LINES; THE RUST ONE IS ABOUT 60,
   AND THE 30 LINES REMOVED ARE THE ERROR PATHS - which is
   exactly where the bugs were.                          */
```

WHAT THE ABSTRACTION LAYER IS DOING

Between the Rust driver and the C kernel sits a hand-written layer of `unsafe` code that wraps each C interface in a safe Rust API — checking null, enforcing lifetimes, tying refcounts to `Drop`. That layer is the project: writing it correctly, for each subsystem, is most of the work and most of the review. The driver above is safe *because* someone proved the wrapper's invariants once (chapter 11).

The abstractions

```
/* --- SYNCHRONISATION, with the guard pattern --- */
    use kernel::sync::{Mutex, SpinLock, new_mutex};

    #[pin_data]
    struct Shared {
        #[pin] data: Mutex<State>,
    }

    let guard = shared.data.lock();
    guard.field = 5;                    // the guard DEREFS to
                                        // State
    // unlocked when the guard drops - no unlock to forget

/* THE TYPE SYSTEM ENFORCES what lockdep checks at run time
   in C (Linux chapter 11): you cannot touch the data without
   the guard, and the guard cannot outlive the lock.

/* --- REFERENCE COUNTING --- */
    use kernel::sync::aref::ARef;

    let dev: ARef<Device> = pdev.into();
/* ARef is a refcounted reference to a kernel object whose
   Drop calls put_device(). The get/put imbalance that
   leaks a device or frees it early (Windows chapter 03 has
   the same failure mode) is not expressible.

/* --- MMIO --- */
    let base: IoMem<0x1000> = pdev.io_request_and_map(0,
                                        c_str!("mydev"))?;
    let v = base.read32(0x04);          // compile-time bounds
                                        // check
    base.write32(0x08, value);
    base.try_read32(offset)?;           // runtime check, for
                                        // a dynamic offset
/* Volatile by construction, sized by the type, and the
   mapping released on Drop.

/* --- WORK QUEUES, TIMERS, WAIT QUEUES --- */
    use kernel::workqueue::{self, Work, WorkItem};
    use kernel::time::{Delta, Instant};
    use kernel::sync::CondVar;

/* --- CHAR DEVICES and file operations --- */
    use kernel::miscdevice::{MiscDevice, MiscDeviceOptions};

    #[vtable]
    impl MiscDevice for MyDevice {
        type Ptr = Pin<KBox<Self>>;

        fn open(_file: &File, _misc: &MiscDeviceRegistration<Self>)
                -> Result<Self::Ptr> { ... }

        fn ioctl(me: Pin<&Self>, _file: &File,
                 cmd: u32, arg: usize) -> Result<isize> {
            match cmd {
                MY_IOCTL_GET => { ... }
                _ => Err(ENOTTY),
            }
        }
    }
```

```
/* --- USER MEMORY, where the type system earns its keep --- */
    use kernel::uaccess::{UserSlice, UserSliceReader};

    fn read_from_user(ptr: UserPtr, len: usize) -> Result<KVec<u8>> {
        let mut reader = UserSlice::new(ptr, len).reader();
        let mut buf = KVec::with_capacity(len, GFP_KERNEL)?;
        reader.read_all(&mut buf, GFP_KERNEL)?;
        Ok(buf)
    }
/* A UserPtr is a DISTINCT TYPE from a kernel pointer. You
   cannot dereference it; you must go through the checked
   readers. The `__user` annotation that sparse checks in C
   (Linux chapter 08) is a real type here, enforced by the
   compiler rather than by an optional static analyser.  */
```

Building it

```
# --- PREREQUISITES ---
    rustup override set $(scripts/min-tool-version.sh rustc)
    rustup component add rust-src
    cargo install --locked bindgen-cli
    rustup component add clippy rustfmt

# --- CHECK the toolchain is acceptable ---
    make LLVM=1 rustavailable
    # prints exactly what is missing if anything is

# --- CONFIGURE ---
    make LLVM=1 menuconfig
    #   General setup ---> Rust support   [*]
    #   (needs CONFIG_MODVERSIONS=n on some versions)

# --- BUILD ---
    make LLVM=1 -j$(nproc)
    make LLVM=1 rust-analyzer        # generates
                                     # rust-project.json for
                                     # IDE support

# --- THE SAMPLES, which are the best documentation ---
    samples/rust/rust_minimal.rs
    samples/rust/rust_print.rs
    samples/rust/rust_misc_device.rs
    samples/rust/rust_driver_platform.rs
    samples/rust/rust_driver_pci.rs

# --- THE SOURCE TO READ ---
    rust/kernel/            the abstraction layer
    rust/bindings/          bindgen output for the C headers
    rust/macros/            #[vtable], module!, pin_data
    Documentation/rust/     coding guidelines and the design
                            rationale

# --- WRITING A DRIVER ---
    drivers/foo/foo.rs
    # in the Makefile:
    obj-$(CONFIG_FOO) += foo.o
    # in Kconfig:
    config FOO
        tristate "Foo driver"
        depends on RUST

# LLVM=1 IS EFFECTIVELY REQUIRED: rustc uses LLVM, and mixing
# GCC-compiled C with LLVM-compiled Rust works but is less
# well tested, particularly for LTO.
```

An honest assessment

```
/* WHAT WORKS WELL TODAY:
     · character devices and misc devices
     · platform and PCI drivers
     · the synchronisation abstractions - Mutex, SpinLock,
       CondVar, ARef
     · allocation with proper failure handling
     · Binder (Android's IPC) - the largest Rust component in
       the kernel, and in production on millions of devices
     · the Nova GPU driver and several network PHY drivers

/* WHAT IS STILL THIN:
     · many subsystems have no abstractions yet - writing a
       driver for one means writing the wrapper too, which is
       the hard part
     · filesystems, block layer, and much of networking
     · documentation, compared with the C side
     · the abstraction API changes between releases, so
       out-of-tree Rust drivers churn more than C ones

/* THE POLITICAL SITUATION, stated neutrally: some
   maintainers welcome it and some do not, and the "no C
   developer is required to learn Rust" rule means the Rust
   side absorbs the maintenance cost of C changes. That
   arrangement has produced friction in specific subsystems.
   It has also produced shipping code.

/* WHAT IT MEANS FOR YOU:

     LEARNING IT: worthwhile. The abstractions are a
     well-written example of the safe-wrapper discipline
     (chapter 11), and reading rust/kernel/ teaches both Rust
     and the kernel.

     WRITING A DRIVER TODAY: reasonable IF your subsystem has
     abstractions. Check rust/kernel/ first. If it does not,
     you are writing the abstraction layer, which is a much
     larger project and needs to be upstreamed to be useful.

     FOR A PRODUCT: viable for Android-adjacent work, and
     early for most other things. The C path is still the
     default, and choosing Rust should be a decision with a
     reason rather than a preference.

     AND THE DIRECTION IS CLEAR: the trend across Android,
     Windows, and now Linux is that new systems code in
     memory-unsafe languages increasingly needs
     justification. That is worth positioning for regardless
     of what you write this year.                        */
```

How it shows up

Symptom	Cause and fix
`make rustavailable` fails	It names exactly what is missing — usually the rustc version or `rust-src`
"Rust support" not offered in menuconfig	Toolchain check failed, or a conflicting config option
Abstraction does not exist for your subsystem	You must write and upstream it — check `rust/kernel/` first

Symptom	Cause and fix
Code breaks on a kernel upgrade	The abstraction API is not stable — expect churn
Allocation compiles but should not	Use the kernel's fallible `KVec`, not `alloc`'s
A panic reaches the kernel	An `unwrap` or an index — use `get` and `?`
"cannot move out of pinned value"	Kernel objects are pinned — use `pin_init`
Cannot dereference a user pointer	Correct — go through `UserSlice`
Symbol not found at module load	The C symbol is not exported, or not bound in `rust/bindings`
Building with GCC produces oddities	Use `LLVM=1`

A project that uses all of this

OP-TEE chapter 25 builds a signing service in which every layer is Rust: a user-mode driver, a kernel module of the kind this chapter describes, and a trusted application in the secure world. It is also an honest look at the rough edges — the kernel module has to carry its own FFI bindings, because there is no `kernel::tee` abstraction upstream, and the `MiscDevice` and `UserSlice` APIs used here are still moving between releases.

Check yourself

- ✓ Give the argument for Rust in the kernel and the five conditions attached.
- ✓ Name five ways kernel Rust differs from ordinary Rust.
- ✓ Explain why `KVec::push` takes a GFP flag and returns `Result`.
- ✓ Write a platform driver and compare it point by point with the C version.
- ✓ Explain what replaces the `goto` ladder and the `remove()` function.
- ✓ Explain what the abstraction layer is and why it is the real work.
- ✓ Say what `ARef`, `IoMem` and `UserSlice` each make impossible.
- ✓ Explain why kernel objects need pinned initialisation.
- ✓ Build a kernel with Rust support and run a sample.
- ✓ Give an honest recommendation for three different project situations.

> **END OF THE RUST TRACK**
> Seventeen chapters, from ownership to the kernel. You have the model, the embedded ecosystem, the unsafe discipline and the FFI boundary — enough to write a firmware image or a driver and to judge when Rust is the right choice. Next: cryptography, where correctness matters more than anywhere else in this curriculum.

TRACK

Bare metal & RTOS

Cortex-M from the reset vector up: startup code, linker scripts, interrupts, peripherals, and a preemptive RTOS you build yourself.

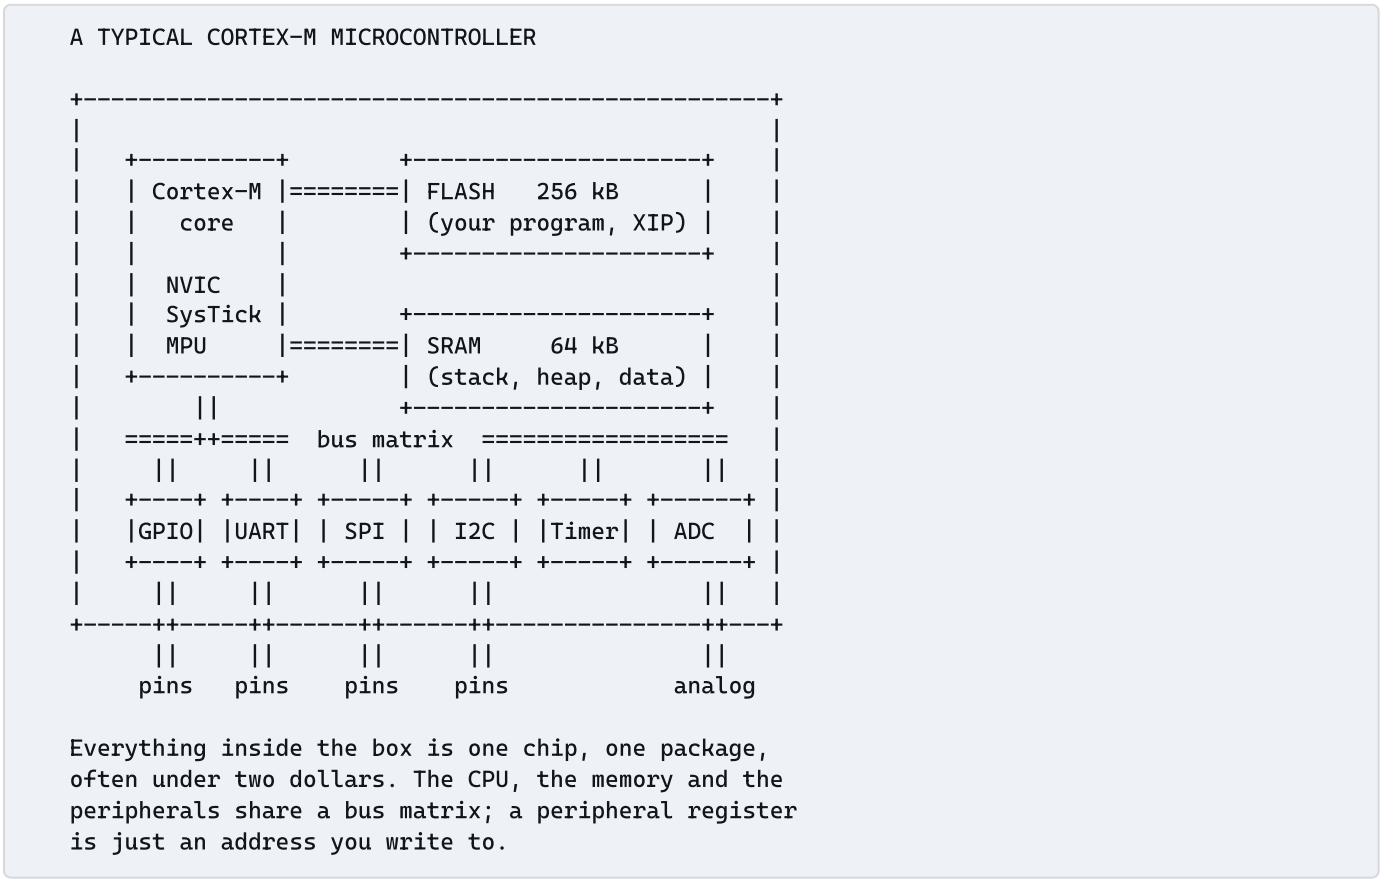
24 chapters

What a microcontroller is, and how it differs

Everything else on this site so far has assumed a processor with an MMU, hundreds of megabytes of DRAM and an operating system underneath you. A microcontroller has none of those. This chapter establishes what you actually get, because every technique in this track follows from the constraints.

One chip, one program

A microcontroller is a complete computer on a single die: a CPU core, its memory, and the peripherals that connect it to the outside world. It boots from its own on-chip flash into your code, and your code is the only code. There is no bootloader chain to negotiate with, no kernel to ask permission from, and no other process competing for the CPU — unless you write one.



The consequence that matters most: **there is no virtual memory**. A pointer holds a physical address. Address `0x40020000` is not "wherever the kernel decided to map the GPIO block" — it is the GPIO block, permanently, as documented in the reference manual. This makes the machine dramatically easier to reason about and dramatically less forgiving, in exactly the ways you would expect.

Against an application processor

	Microcontroller (Cortex-M)	Application processor (Cortex-A)
Clock	16–500 MHz	1–3 GHz
RAM	4 kB – 1 MB, on-chip SRAM	512 MB – 16 GB, external DRAM
Program store	On-chip flash, executed in place	eMMC or SSD, copied to DRAM

	Microcontroller (Cortex-M)	Application processor (Cortex-A)
MMU	None. An optional MPU with ~8 regions	Full MMU, multi-level page tables
Privilege levels	Two (Thread/Handler, privileged/unprivileged)	Four (EL0–EL3) plus secure world
Caches	Often none; sometimes a small I-cache	L1/L2/L3, coherent, with a whole protocol
Operating system	None, or an RTOS you link into your binary	Linux, measured in tens of millions of lines
Boot time	Microseconds to milliseconds	Hundreds of milliseconds to minutes
Interrupt latency	12 cycles, deterministic	Microseconds, and not guaranteed
Sleep current	Hundreds of nanoamps	Milliamps at best
Unit cost	$0.30 – $10	$5 – $200

> **THE TRADE IS DETERMINISM AGAINST CAPABILITY**
>
> A Cortex-A core is faster in every benchmark and worse at every deadline. Its caches, branch predictors, MMU and scheduler all improve *average* performance by introducing variance. A Cortex-M has no cache to miss, no TLB to walk and no scheduler to preempt you, so the time between an electrical edge on a pin and the first instruction of your handler is a number you can look up and rely on. When the requirement is "the motor commutates within 5 µs, every time, for ten years", that number is the whole product.

Execute in place, and why RAM is precious

Your program is not loaded into RAM. The CPU fetches instructions directly from flash over a dedicated bus — *execute in place*, XIP. Flash is comparatively plentiful and slow; SRAM is fast and scarce. That inverts habits learned on a desktop:

```
/* On a microcontroller these two lines have completely
   different costs.                                        */

const char msg[] = "sensor fault";       /* Ideally: flash. */
char       buf[] = "sensor fault";       /* Always: SRAM,   */
                                         /* AND a copy of   */
                                         /* the initialiser */
                                         /* in flash too.   */

/* The second costs 13 bytes of your 64 kB of SRAM, plus 13
   bytes of flash for the initialiser that startup code
   copies into it (chapter 06). If it does not need to be
   written, it must be const - that is not a style rule
   here, it is a memory budget.

   Toolchains will place const data in flash only if you let
   them. On AVR and some others you need an explicit
   attribute; on Cortex-M, const alone is enough.          */

const char *p = msg;    /* p is 4 bytes of SRAM pointing at flash */
```

A 64 kB SRAM budget sounds generous until you count: every task's stack, every DMA buffer, every driver's ring buffer, the heap if you have one, and every non-const global. Running out is not an `ENOMEM` you can handle — it is a stack that silently grows into your variables. Chapter 20 is about making that impossible rather than unlikely.

A peripheral is an address

On Linux you request a GPIO from a subsystem that arbitrates between drivers. Here, you write to a register. The entire abstraction is a struct overlaid on a fixed address:

```
/* Memory-mapped I/O, the whole idea in one block. */

#include <stdint.h>

typedef struct {
    volatile uint32_t MODER;    /* 0x00  mode: in/out/alt/analog */
    volatile uint32_t OTYPER;   /* 0x04  push-pull or open-drain */
    volatile uint32_t OSPEEDR;  /* 0x08  slew rate                */
    volatile uint32_t PUPDR;    /* 0x0C  pull-up / pull-down      */
    volatile uint32_t IDR;      /* 0x10  input data   (read-only) */
    volatile uint32_t ODR;      /* 0x14  output data              */
    volatile uint32_t BSRR;     /* 0x18  atomic set/reset         */
} GPIO_TypeDef;

#define GPIOA ((GPIO_TypeDef *) 0x40020000UL)

/* Set PA5 high. One store. No system call, no driver, no
   lock, and roughly two clock cycles.                     */
GPIOA->BSRR = (1U << 5);

/* volatile is mandatory, not decorative. Without it the
   compiler may cache the value in a register, reorder the
   access, or delete it entirely - all legal, because C's
   abstract machine has no concept of a wire attached to
   memory. See the C track, chapter 10.                    */
```

> **`VOLATILE` IS NECESSARY BUT NOT SUFFICIENT**
>
> It stops the *compiler* reordering and eliding accesses. It says nothing to the *hardware* about write buffers or bus ordering, and nothing about atomicity. Two `volatile` writes to different peripherals can still land out of order at the far side of a bus bridge. On Cortex-M that is rare enough to ignore for GPIO and common enough to matter when you are clearing an interrupt flag and returning from the handler — a case we return to in chapter 15.

Nothing underneath you

The most disorienting part of moving from Linux to bare metal is how much simply is not there.

```
WHAT YOU LOSE                  WHAT YOU GAIN

printf to a console       ->   a UART you configure first
                               (chapter 16 has cheaper options)

malloc that works         ->   a heap you must justify,
                               size, and usually avoid

"segmentation fault"      ->   silent corruption, or a
                               HardFault you must decode
                               yourself (chapter 15)

a scheduler               ->   a superloop, until you write
                               one (chapters 17-18)

drivers for everything    ->   the reference manual and
                               1200 pages of register tables

process isolation         ->   one address space; any bug
                               can reach any byte

time from the OS          ->   a timer you configure, whose
                               accuracy is your crystal's

The trade is total visibility. There is no layer between
your code and the silicon that you cannot read, single-step,
and change. Every problem is ultimately findable, because
there is nowhere for it to hide.
```

Choosing between them

The decision is usually made for you by three constraints, in this order:

- **Power.** If the product runs from a coin cell for a year, it is a microcontroller. No application processor idles in the microamp range. This one constraint decides more designs than any other.
- **Determinism.** If missing a deadline is a safety event rather than a dropped frame, you want a core with no cache and no scheduler — or a system that has both, with an MCU beside it doing the part that must not miss.
- **What the software needs.** A TCP/IP stack, a filesystem and a display fit on a modern MCU. A web browser, a camera pipeline and a package manager do not. If you need Linux's driver ecosystem, you need Linux, and you have chosen an application processor.

Plenty of real products contain both: an application processor for the interface and connectivity, and a microcontroller for the real-time control loop and power management, talking over SPI or I2C. Knowing both sides of that link, and why the split exists, is most of what this track and the next one are for.

How it shows up

Symptom	Cause
Variables change value with no code writing them	Stack overflow — no MMU means no guard page. Size the stacks (chapter 20)
A loop reading a status register never exits	Missing `volatile`; the compiler hoisted the load out of the loop
Program works in debug, fails at `-O2`	Almost always `volatile`, timing assumptions, or undefined behaviour the optimiser exploited

Symptom	Cause
Linker reports "region RAM overflowed"	Too many non-const globals or too large a buffer; check what should have been `const`
Adding one small array breaks unrelated code	You were already out of SRAM; the new array moved the collision somewhere visible
`printf` hangs or emits nothing	No console exists until you configure a UART and retarget the C library (chapter 16)
Code runs once then the chip appears dead	A fault handler with an empty `while(1)` — the default trap (chapter 15)
Timing differs between two identical boards	The crystal, its load capacitors, or the internal oscillator's tolerance (chapter 09)
Sleep current is 3 mA instead of 2 µA	A GPIO floating, a peripheral clock left enabled, or the debugger still attached (chapter 13)
Writing a peripheral register has no effect	Its clock is not enabled. On most MCUs a peripheral with no clock silently ignores writes (chapter 09)

Check yourself

- ✓ Name the four things a microcontroller integrates onto one die.
- ✓ Explain what "execute in place" means and why it makes SRAM the scarce resource.
- ✓ State what a pointer holds on a system with no MMU, and one consequence for debugging.
- ✓ Give three concrete differences between a Cortex-M and a Cortex-A that affect interrupt latency.
- ✓ Explain why `const` is a memory-budget decision here rather than a style preference.
- ✓ Say what `volatile` guarantees, and name one thing it does not.
- ✓ Describe what happens on a stack overflow with no MMU, and why it is hard to find.
- ✓ List the three constraints that usually decide MCU versus application processor.
- ✓ Explain why a peripheral register write can silently do nothing.
- ✓ Give an example of a product that would contain both kinds of processor, and say what each does.

The Cortex-M profile: ARMv7-M and ARMv8-M

The ARM track on this site covers the A profile — AArch64, exception levels, page tables. The M profile is a different architecture with a different instruction set, a different exception model and a different memory map. This chapter is the map of what M means, and which M you are holding.

Three profiles, one company

ARM defines three architecture profiles, and they are not variants of each other. Code, tooling and mental models transfer only partly between them.

Profile	For	Defining feature
A — Application	Phones, servers, anything running Linux	MMU, virtual memory, exception levels EL0–EL3
R — Real-time	Storage controllers, basebands, safety islands	MPU rather than MMU, but A-like performance and often lockstep cores
M — Microcontroller	Everything in this track	Thumb-only, hardware exception entry, deterministic latency, tiny gate count

The ARM architecture track teaches the A profile. Almost none of its exception-level material applies here: an M-profile core has no EL1, no `SPSR_EL1`, no vector base you set up with a table of branch instructions, and no MMU chapter to read. What transfers is the memory model vocabulary, the barrier instructions, and the general shape of a load/store architecture.

Which M profile is this chip?

```
ARCHITECTURE          CORES              WHAT IT ADDS

ARMv6-M               Cortex-M0          Thumb + a few
                      Cortex-M0+         32-bit instrs.
                      Cortex-M1          Smallest possible.
                                         No bit-banding,
                                         8 IRQ priorities
                                         (2 bits), fixed
                                         vector table.

ARMv7-M               Cortex-M3          Full Thumb-2,
                                         hardware divide,
                                         bit-banding,
                                         up to 256 IRQs,
                                         relocatable VTOR.

ARMv7E-M              Cortex-M4          + DSP (SIMD) instrs
                      Cortex-M7          + optional FPU
                                         M7: caches, dual
                                         issue, TCM.

ARMv8-M Baseline      Cortex-M23         v6-M + TrustZone-M

ARMv8-M Mainline      Cortex-M33         v7E-M + TrustZone-M
                      Cortex-M35P        + stack limit regs

ARMv8.1-M             Cortex-M55         + Helium (MVE),
                      Cortex-M85         vector extension
                                         for ML and DSP

The practical split: v6-M is deliberately minimal and you
will notice the missing instructions; v7-M and above are
comfortable. TrustZone-M appears only at v8-M.
```

READING A PART NUMBER

"STM32F407" tells you the vendor (ST), the family (F4) and the peripheral set — but the core is only implied. The reference manual's first pages state it: Cortex-M4 with FPU, ARMv7E-M. That distinction decides whether you can use `__disable_irq` with a BASEPRI level, whether `float` costs one cycle or forty, and whether the vector table can be moved. Establish it before writing a line of code.

Thumb-2, and only Thumb-2

An M-profile core executes Thumb instructions exclusively. There is no A32/ARM state to switch into, and no AArch64 at all. Attempting to switch to ARM state is not a mode change — it is a fault.

```
/* Thumb-2 mixes 16-bit and 32-bit encodings freely. The
   assembler picks; you can force it with .w and .n suffixes. */

    movs  r0, #1          @ 16-bit encoding, 2 bytes
    mov.w r0, #0x12345678 @ 32-bit encoding, 4 bytes
    add   r1, r2, r3      @ assembler chooses

/* Every branch target must be Thumb, and the architecture
   encodes that in the LOW BIT of the address:              */

    ldr   r0, =my_function + 1   @ bit 0 SET = Thumb
    bx    r0                     @ branch and exchange

/* This is why every entry in the vector table is an odd
   number, and why a function pointer that looks "one byte
   off" is correct. Clear that bit and the core takes a
   UsageFault with INVSTATE set - it believes you asked it to
   execute ARM-state code, which it cannot do.

   You will meet this exactly once, when hand-writing a
   vector table or a context switch, and it will cost you an
   afternoon if nobody warned you.                          */
```

The core peripherals are part of the architecture

This is the single most useful structural fact about the M profile, and it has no equivalent on Cortex-A. The interrupt controller, the system timer, the fault registers and the MPU are defined by the *architecture*, at fixed addresses, identically on every vendor's chip.

```
   THE ARCHITECTURALLY FIXED MEMORY MAP

   0x00000000  +---------------------------+
               | Code      (flash, XIP)    |  512 MB region
   0x20000000  +---------------------------+
               | SRAM                      |  512 MB region
   0x40000000  +---------------------------+
               | Peripheral (vendor's)     |  512 MB region
   0x60000000  +---------------------------+
               | External RAM              |
   0xA0000000  +---------------------------+
               | External device           |
   0xE0000000  +---------------------------+
               | Private Peripheral Bus    |  <-- the core's
               |   0xE000E010  SysTick     |      own blocks
               |   0xE000E100  NVIC        |
               |   0xE000ED00  SCB         |
               |   0xE000ED90  MPU         |
               |   0xE0001000  DWT         |
   0xFFFFFFFF  +---------------------------+

   Regions also carry default memory ATTRIBUTES: the
   Peripheral and Device regions are non-cacheable and
   strongly ordered, so a store to 0x40020000 is not
   buffered the way a store to SRAM might be. You get
   sane peripheral behaviour without configuring anything.
```

So `NVIC_EnableIRQ()` is the same code on an ST, an NXP and a Nordic part, because the NVIC is at `0xE000E100` on all of them. Everything above `0xE0000000` is ARM's; the `0x40000000` region is the vendor's, and that is where the reference manual takes over from the architecture reference manual.

> **TWO MANUALS, AND KNOWING WHICH ONE ANSWERS YOUR QUESTION**
> The *ARMv7-M Architecture Reference Manual* defines the core: instructions, exceptions, NVIC, SysTick, MPU, fault registers. The *vendor reference manual* defines everything hanging off the bus matrix: clocks, GPIO, UART, timers, DMA. When a fault register puzzles you, reach for ARM's manual. When a peripheral does not respond, reach for the vendor's. Reaching for the wrong one is the most common way to waste an hour.

Hardware exception entry

On Cortex-A, taking an exception gives you a branch to a vector and the job of saving state yourself, in assembly. On Cortex-M the hardware does it: it pushes eight registers onto the active stack, loads the handler's address from the vector table, and enters it. Your handler is an ordinary C function.

```
/* This is a complete, correct interrupt handler. There is no
   assembly wrapper, no manual register save, no eret.       */

void TIM2_IRQHandler(void)
{
    TIM2->SR = ~TIM_SR_UIF;   /* clear the flag in hardware */
    ticks++;
}

/* The hardware stacked R0-R3, R12, LR, PC and xPSR on entry
   and will unstack them on return. Those are exactly the
   caller-saved registers of the ARM procedure call standard,
   which is why a plain C function is a valid handler: the
   compiler already preserves everything else.

   This is the "AAPCS-compatible exception model", and it is
   the reason M-profile interrupt latency is a fixed 12
   cycles rather than "however long your prologue takes".    */
```

Chapter 07 covers the vector table and NVIC in detail, and chapter 08 covers what happens when a second interrupt arrives during the first — where tail-chaining and late-arrival make the model faster than the naive description suggests.

Floating point, DSP and Helium

```
/* Three separate optional extensions. Knowing which you have
   changes how you write numerical code.                      */

/* 1. FPU (M4F, M7, M33). Single precision in one cycle.
      Double precision is software on almost everything.     */
float  a = x * y + z;   /* 1 instruction: VFMA.F32          */
double b = x * y + z;   /* ~100 cycles: a library call       */

/* 2. DSP extension (M4, M7, M33). SIMD within 32-bit
      registers, and a single-cycle multiply-accumulate.     */
sum = __SMLAD(pair1, pair2, sum);  /* two 16x16 MACs at once */

/* 3. Helium / MVE (M55, M85). True 128-bit vectors,
      the M-profile answer to NEON.                          */

/* If the part has no FPU, every float operation becomes a
   call into libgcc. Code written assuming hardware float can
   be 40x slower on an M0 without a single warning - it
   compiles and runs, it is simply slow. This is the classic
   "port the algorithm to the cheaper chip" trap.

   Fixed-point arithmetic is the answer, and it is why Q15
   and Q31 formats persist in embedded DSP code.             */
```

> **AN FPU CHANGES YOUR CONTEXT SWITCH**
> The FPU adds 33 more registers. If more than one task uses floating point, the RTOS must save and restore them, which roughly triples context-switch cost. Cortex-M supports *lazy stacking* — reserving the space but only writing the registers when a second FP-using context actually appears — and it is enabled by default. If you hand-write a context switch (chapter 18) and forget the FP registers exist, you get corruption that only appears once two tasks both do float maths.

How it shows up

Symptom	Cause
UsageFault with `INVSTATE` set	Branched to an address with bit 0 clear — the core thinks you want ARM state
Hard fault immediately on the first interrupt	Vector table entries written without the Thumb bit set
Code from a tutorial does not compile for this part	It targets v7-M; you have a v6-M core without those instructions
Setting `VTOR` has no effect	ARMv6-M has no VTOR — the vector table is fixed at address 0
Float maths is inexplicably slow	No FPU, or the FPU is present but not enabled in `CPACR`
Enabling the FPU causes faults on first float use	`CPACR` written but no barrier before the next FP instruction
Corruption once two tasks use `float`	Context switch does not save the FP register bank
Priority levels behave coarsely	The part implements only 3 or 4 priority bits, not 8 (chapter 08)
Code portable between vendors, drivers are not	Correct and expected: the core is ARM's, the peripherals are the vendor's
`__disable_irq` works, BASEPRI does not	BASEPRI does not exist on ARMv6-M

Check yourself

- ✓ Name the three ARM architecture profiles and the defining feature of each.
- ✓ State which ARM architecture version introduced TrustZone-M.
- ✓ Explain why every vector table entry is an odd address.
- ✓ Say what happens if you branch to an address with bit 0 clear.
- ✓ Give the address of the NVIC and explain why it is the same on every vendor's chip.
- ✓ Explain which manual answers a question about a fault register, and which about a UART.
- ✓ List the eight registers the hardware stacks on exception entry, and say why those eight.
- ✓ Explain why an ordinary C function can serve as an interrupt handler on Cortex-M.
- ✓ Describe what lazy FP stacking does and the bug it hides in a hand-written context switch.
- ✓ Explain why a `double` can be a hundred times slower than a `float` here.

Registers, modes and the two stack pointers

Sixteen registers, two modes, two privilege levels and two stack pointers. That is the entire programmer's model, and the whole of an RTOS context switch is built from it. This chapter is the reference you will come back to when writing chapter 18.

The register file

```
+-------+
|  R0   |  \
|  R1   |   |  Caller-saved (AAPCS): arguments and
|  R2   |   |  scratch. The HARDWARE stacks these
|  R3   |  /   on exception entry.
+-------+
|  R4   |  \
|  R5   |   |
|  R6   |   |
|  R7   |   |  Callee-saved. The hardware does NOT
|  R8   |   |  stack these. If your context switch
|  R9   |   |  needs them saved, you save them.
|  R10  |   |
|  R11  |  /
+-------+
|  R12  |     IP, intra-procedure scratch. Hardware-stacked.
+-------+
|  R13  |     SP - banked! MSP or PSP (see below)
+-------+
|  R14  |     LR, link register. Hardware-stacked.
+-------+
|  R15  |     PC. Hardware-stacked.
+-------+
|  xPSR |     Program status. Hardware-stacked.
+-------+

The eight hardware-stacked registers are exactly
R0-R3, R12, LR, PC, xPSR. That set is chosen to match
the procedure call standard's caller-saved set, which
is what makes a plain C function a legal handler.
```

Note what is absent compared with AArch64: no `X0–X30`, no separate `SP_EL0` and `SP_EL1` per exception level, no `ELR`. The M profile is deliberately small.

xPSR: three registers at one address

```
/* xPSR is the union of three views, and you can read them
   individually or together.                                  */

/*  31 30 29 28 27      24        16      9  8       0
   +--+--+--+--+--+-----+--+-------+------+---------+
   | N| Z| C| V| Q|     |T |  ICI  |      | ISR_NUM |
   +--+--+--+--+--+-----+--+-------+------+---------+
     APSR (flags)        ^   EPSR         IPSR
                         |
                    THUMB BIT - must be 1, always.        */

/* APSR - condition flags, exactly as on any ARM core.
   Q is the DSP saturation sticky flag.

   IPSR - which exception is executing. 0 means Thread mode,
   i.e. ordinary code. This is how you answer "am I in an
   interrupt?" at runtime:                                  */

static inline int in_handler_mode(void)
{
    uint32_t ipsr;
    __asm volatile ("mrs %0, ipsr" : "=r" (ipsr));
    return ipsr != 0;
}

/* An RTOS uses precisely this to decide whether a call is
   the ISR-safe variant. FreeRTOS's configASSERT checks on
   xQueueSend versus xQueueSendFromISR come down to this
   register (chapter 19).

   EPSR - execution state, including the T bit. It cannot be
   written directly by software; it is restored from the
   stacked xPSR on exception return. Clearing the T bit in a
   stacked frame is a reliable way to fault on return.       */
```

Two modes, two privilege levels

```
                  PRIVILEGED          UNPRIVILEGED

   HANDLER mode   always here         cannot happen
   (in an
    exception)    Uses MSP.
                  IPSR != 0.

   THREAD mode    reset lands here    optional; set by
   (ordinary                          writing CONTROL.nPRIV
    code)         Uses MSP or PSP,
                  chosen by
                  CONTROL.SPSEL      An RTOS runs tasks
                                     here, with the MPU
                                     enforcing isolation
                                     (chapter 14).

   Handler mode is ALWAYS privileged. There is no way to take
   an interrupt into unprivileged code, which is why fault
   handlers can always reach the fault registers.
```

```
/* The CONTROL register - only three bits, both of which
   you will use in an RTOS.                                    */

/*   bit 2  FPCA   floating-point context active (read-only
                   to you; the hardware sets it)
     bit 1  SPSEL  0 = use MSP in Thread mode
                   1 = use PSP in Thread mode
     bit 0  nPRIV  0 = Thread mode privileged
                   1 = Thread mode unprivileged            */

static inline void switch_to_psp_unprivileged(void)
{
    __asm volatile ("msr control, %0" :: "r" (0x3) : "memory");
    __asm volatile ("isb");          /* MANDATORY - see below */
}

/* The ISB is not optional. Writing CONTROL changes how the
   very next instruction fetches its stack; without a barrier
   the pipeline may already hold instructions decoded under
   the old setting. This is the single most common omission
   in hand-written RTOS startup code, and it produces a fault
   that moves when you add a printf.                           */
```

> **YOU CANNOT RAISE YOUR OWN PRIVILEGE**
> `CONTROL.nPRIV` can be set from privileged code to drop to unprivileged, but unprivileged code cannot clear it — the write is ignored. The only way back to privileged execution is to take an exception, which is exactly what an `SVC` instruction is for. That is the entire system-call mechanism of an M-profile RTOS, and it is the same idea as `svc` on Cortex-A with about one percent of the machinery.

Two stack pointers, and why

R13 is banked: there are two physical registers, and which one you see as `SP` depends on the mode and `CONTROL.SPSEL`.

```
   MSP - Main Stack Pointer
     Reset value loaded from vector table entry 0.
     Used by: Handler mode, always.
              Thread mode when SPSEL = 0.
     Holds: interrupt frames, and the main() stack in a
            bare-metal program.

   PSP - Process Stack Pointer
     Not initialised by hardware; you set it.
     Used by: Thread mode when SPSEL = 1.
     Holds: the current task's stack in an RTOS.

   BARE METAL              RTOS
   +-----------+           +-----------+   +-----------+
   |   main()  | MSP       | task A    |   | task B    | PSP
   |   + ISRs  |           | stack     |   | stack     | (switched)
   +-----------+           +-----------+   +-----------+
                                 |
                           +-----------+
                           |   ISRs    | MSP (shared, one only)
                           +-----------+

   The split means an interrupt storm cannot overflow a
   task's stack into another task's data - ISRs have their
   own stack. It also means you size the MSP for the worst
   nesting depth of interrupts, and each PSP for one task.
   That is a far easier budget to get right than one stack
   for everything.
```

```
/* Reading and writing the banked pointers. */

static inline uint32_t get_psp(void)
{
    uint32_t r; __asm volatile ("mrs %0, psp" : "=r" (r)); return r;
}
static inline void set_psp(uint32_t v)
{
    __asm volatile ("msr psp, %0" :: "r" (v));
}

/* Note there is no barrier needed after MSR PSP itself -
   you are not changing WHICH stack pointer is in use, only
   its value. The barrier is needed after writing CONTROL,
   which changes the selection.                              */
```

EXC_RETURN: the magic LR value

On exception entry the hardware does not put a return address in `LR`. It puts a special pattern with the top 24 bits set, encoding which stack to unwind from and whether FP state is present.

```
/* EXC_RETURN values you will actually see (ARMv7-M):

   0xFFFFFFF1  return to Handler mode, MSP,  no FP frame
   0xFFFFFFF9  return to Thread  mode, MSP,  no FP frame
   0xFFFFFFFD  return to Thread  mode, PSP,  no FP frame
   0xFFFFFFE9  return to Thread  mode, MSP,  with FP frame
   0xFFFFFFED  return to Thread  mode, PSP,  with FP frame

     bit 2 = 1  ->  return uses PSP
     bit 4 = 0  ->  extended (FP) stack frame
     bit 3 = 1  ->  returning to Thread mode               */

/* Executing BX LR with this value in LR is what returns from
   an exception - there is no ERET instruction. The core sees
   the 0xFF... pattern in a branch target and interprets it
   as "unstack and return" rather than an address.

   A context switch works by CHANGING which stack PSP points
   at while inside PendSV, then returning with 0xFFFFFFFD.
   The hardware unstacks the new task's frame and the CPU is
   simply running different code. Chapter 18 builds this.    */
```

THIS IS THE WHOLE TRICK OF AN M-PROFILE CONTEXT SWITCH

There is no privileged "load all registers" instruction and no dedicated switch mechanism. You save R4–R11 by hand, change `PSP`, restore R4–R11 from the new stack, and `BX` to `EXC_RETURN`. The hardware's automatic unstacking does the rest. Once you see that the exception return path *is* the switch, the twenty lines of assembly in chapter 18 stop looking like magic.

Interrupt masking registers

```
/* Three ways to turn interrupts off, in increasing subtlety. */

/* PRIMASK - one bit. Blocks everything except NMI and
   HardFault. The blunt instrument.                          */
__disable_irq();          /* cpsid i  -> PRIMASK = 1 */
/* ... critical section ... */
__enable_irq();           /* cpsie i  -> PRIMASK = 0 */

/* FAULTMASK - like PRIMASK but also blocks HardFault.
   Cleared automatically on exception return. Rarely used
   outside fault recovery.                                   */

/* BASEPRI - block only interrupts at or below a priority.
   ARMv7-M and above only. This is what an RTOS uses, so
   that high-priority "zero-latency" interrupts keep running
   through kernel critical sections.                         */
__set_BASEPRI(5 << (8 - __NVIC_PRIO_BITS));
/* ... kernel critical section ...
   Interrupts of priority 0-4 still fire and must NOT call
   any RTOS API. Priorities 5+ are blocked and may.          */
__set_BASEPRI(0);

/* Note the shift. Priority bits are stored in the HIGH bits
   of the byte, so a part with 4 implemented bits treats
   0x50 and 0x5F identically. Forgetting the shift is why
   "my BASEPRI does nothing" is a common question - writing
   5 instead of 5<<4 sets a priority so low it blocks
   nothing. Chapter 08 covers this properly.                 */
```

How it shows up

Symptom	Cause
Fault a few instructions after writing `CONTROL`	Missing `ISB`; the pipeline still holds instructions decoded for the old stack
Fault moves or vanishes when you add a print	Same missing barrier — you changed the pipeline timing
Task stacks corrupt each other under interrupt load	Tasks and ISRs sharing MSP; move tasks to PSP
Unprivileged code cannot regain privilege	Correct and by design — use `SVC`
Context switch corrupts variables in some tasks	R4–R11 not saved; the hardware only stacks the caller-saved eight
Corruption appears only once two tasks use float	FP registers not saved; check `EXC_RETURN` bit 4
Fault on exception return	Stacked xPSR has the T bit clear, or `EXC_RETURN` was overwritten
`BASEPRI` appears to do nothing	Value not shifted into the implemented high priority bits
`BASEPRI` does not exist	ARMv6-M core — only `PRIMASK` is available
RTOS assert fires inside an ISR	Called the non-`FromISR` API; the kernel checked `IPSR`

Check yourself

- ✓ List the eight registers stacked by hardware and explain why that particular set.
- ✓ Say which registers a context switch must save by hand, and why.
- ✓ Explain how to determine at runtime whether you are in an interrupt.

- ✓ State the two modes and two privilege levels, and which combination cannot occur.
- ✓ Explain why an `ISB` is required after writing `CONTROL`.
- ✓ Give two concrete benefits of running tasks on PSP and interrupts on MSP.
- ✓ Explain how unprivileged code can legitimately reach privileged execution.
- ✓ Decode `0xFFFFFFFD` as an `EXC_RETURN` value.
- ✓ Describe how changing PSP inside PendSV performs a task switch.
- ✓ Explain the difference between PRIMASK and BASEPRI, and why an RTOS prefers the latter.

Reset: from power-on to your first instruction

On Linux the boot sequence is a chain of loaders you inherit. Here it is eleven microseconds long, entirely yours, and defined by two 32-bit words at address zero. This chapter follows the electrons from the power rail to `main()`.

The sequence

```
POWER APPLIED
     |
     v
+----------------------+
| Brown-out reset holds |  The BOR circuit keeps the core
| the core in reset     |  in reset until VDD crosses the
| until VDD is stable   |  threshold. Typically 1.7-2.0 V.
+----------------------+
     |
     v
+----------------------+
| Internal oscillator   |  The chip starts on an internal
| starts (HSI/MSI)      |  RC oscillator - fast to start,
|                       |  a few percent accurate. Your
|                       |  crystal is not running yet.
+----------------------+
     |
     v
+----------------------+
| Option bytes / boot   |  Boot pins or option bits select
| pins sampled          |  what is aliased to 0x00000000:
|                       |  main flash, system ROM (the
|                       |  vendor's serial bootloader), or
|                       |  SRAM.
+----------------------+
     |
     v
+----------------------+
| READ TWO WORDS        |  This is the whole handoff.
|  [0x00000000] -> MSP  |  Word 0: initial stack pointer
|  [0x00000004] -> PC   |  Word 1: Reset_Handler address
+----------------------+
     |
     v
Reset_Handler executes  (chapter 06 - copy .data, zero .bss)
     |
     v
SystemInit()            (chapter 09 - clocks and PLL)
     |
     v
main()

Elapsed: microseconds. There is no bootloader, no device
tree, no ELF loader, no relocation. The hardware loads two
registers and starts fetching.
```

> **THE FIRST TWO WORDS ARE THE ENTIRE BOOT PROTOCOL**
> Everything else — the vendor's HAL, CMSIS, your RTOS — is software convention layered on top. The architecture's contract is: at the address aliased to zero, put a stack pointer and an entry address. If the first word is not a valid, aligned, writable RAM address, the core faults before executing one instruction of your code, and it faults in a way that is very hard to debug because nothing of yours has run yet.

What actually sits at address zero

```
/* The start of a real vector table, in C. The array IS the
   boot protocol - the linker places it at the base of
   flash, and the hardware reads it directly.               */

extern uint32_t _estack;          /* from the linker script */
void Reset_Handler(void);
void NMI_Handler(void);
void HardFault_Handler(void);

__attribute__((section(".isr_vector"), used))
void (* const g_vectors[])(void) = {
    (void (*)(void)) &_estack,    /* 0x00: initial MSP      */
    Reset_Handler,                /* 0x04: entry point      */
    NMI_Handler,                  /* 0x08                   */

    UsageFault_Handler,           /* 0x18                   */
    0, 0, 0, 0,                   /* 0x1C-0x28 reserved     */
    SVC_Handler,                  /* 0x2C                   */
    DebugMon_Handler,             /* 0x30                   */
    0,                            /* 0x34 reserved          */
    PendSV_Handler,               /* 0x38                   */
    SysTick_Handler,              /* 0x3C                   */
    /* 0x40 onward: the vendor's peripheral interrupts      */
    WWDG_IRQHandler,
    PVD_IRQHandler,
    /* ... typically 60-100 more ...                        */
};

/* Two things that trip people up:

   1. The first entry is DATA (an address), not a function
      pointer. The cast is a lie that keeps the array one
      type. Some projects use a union to be honest about it.

   2. Every other entry is a function pointer, and the
      compiler automatically sets bit 0 for Thumb (chapter
      02). Hand-writing this table in assembly means setting
      that bit yourself, or faulting on the first interrupt.

   3. `used` matters. Nothing in C refers to g_vectors, so
      LTO or --gc-sections will happily delete it. The
      KEEP() directive in the linker script is the other
      half of this belt-and-braces (chapter 05).            */
```

Why the stack pointer points at the end of RAM

```
0x20010000  +------------------+  <- _estack (64 kB part)
            |                  |
            |   STACK          |  grows DOWNWARD
            |     |            |
            |     v            |
            |                  |
            |   (free)         |
            |                  |
            |     ^            |
            |     |            |
            |   HEAP           |  grows upward, if you
            |                  |  have one at all
            +------------------+  <- _end
            |   .bss           |  zeroed by startup
            +------------------+
            |   .data          |  copied from flash
0x20000000  +------------------+

The stack starts at the TOP because it grows down. Set
_estack to the last address + 1: on a part with 64 kB of
SRAM at 0x20000000, that is 0x20010000, not 0x2000FFFF.
The SP is pre-decremented on push, so the first push
writes to 0x2000FFFC - inside RAM. Off-by-one here gives
you a fault on the very first push.

Note what is NOT here: any guard between stack and heap.
When they meet, they simply overwrite each other. The MPU
(chapter 14) is how you get a real guard.
```

Boot mode selection

Almost every MCU can boot from somewhere other than your flash, and this is how a factory programs a blank chip and how you recover a brick.

Boot source	Selected by	Used for
Main flash	Default; BOOT0 low	Normal operation
System memory (ROM bootloader)	BOOT0 high, or an option byte	Factory programming and recovery over UART, USB DFU or CAN
SRAM	Boot pins, or a debugger writing it directly	Loading code without wearing out flash during development
External flash (QSPI)	Option bytes plus a memory-mapped controller	Programs too large for internal flash

> **THE ROM BOOTLOADER IS YOUR RECOVERY PATH — PROTECT ACCESS TO IT**
>
> If your firmware disables the debug port and then fails to boot, the ROM bootloader entered via BOOT0 is often the only way back. Designs that route BOOT0 to a test pad rather than a hard ground are field-recoverable; designs that tie it low permanently and also disable SWD are one bad update away from scrap. This is a schematic decision made in week one that determines whether a firmware bug costs an hour or a production run.

Moving the vector table

Address `0x00000000` is an *alias*. On most parts flash also appears at its true address (often `0x08000000`), and the alias points wherever the boot mode selected. Once running, you can relocate the table entirely with `VTOR`:

```
/* ARMv7-M and above. ARMv6-M has no VTOR - the table is
   fixed at 0, and a bootloader on M0 must use other tricks
   (usually remapping SRAM to address 0).                  */

#define SCB_VTOR (*(volatile uint32_t *) 0xE000ED08)

static void jump_to_application(uint32_t app_base)
{
    uint32_t app_sp  = *(volatile uint32_t *) (app_base + 0);
    uint32_t app_pc  = *(volatile uint32_t *) (app_base + 4);

    __disable_irq();                  /* no interrupts mid-jump   */
    /* ... de-init every peripheral the bootloader enabled ...     */

    SCB_VTOR = app_base;              /* point at the app's table  */
    __asm volatile ("dsb");
    __asm volatile ("isb");

    __set_MSP(app_sp);                /* adopt the app's stack     */
    ((void (*)(void)) app_pc)();      /* never returns             */
}

/* This is a complete bootloader-to-application handoff, and
   nearly every field-update mechanism ends in these lines.

   The classic bug: forgetting to de-initialise. A timer the
   bootloader left running fires an interrupt as soon as the
   application enables interrupts, vectors through the
   application's table to a handler the application never
   installed, and lands in the default infinite loop. The
   symptom is "the app works when flashed directly but hangs
   when launched from the bootloader" - and the cause is
   always something left enabled.

   VTOR also has an alignment requirement: the table must be
   aligned to the next power of two above its size. For 100
   entries (400 bytes) that means 512-byte alignment. Get it
   wrong and the low bits are ignored, so the table lands
   somewhere you did not intend.                            */
```

What the debugger does differently

Attaching a debugger changes the reset sequence, which is why "it works under the debugger" is such a common and such a misleading observation.

```
/* Under a debugger, a typical "load and run" does:

   1. Halt the core (possibly via a reset-and-halt sequence
      that catches the core before Reset_Handler).
   2. Write the .text and .data sections into flash.
   3. Set the PC and SP directly - often SKIPPING the
      hardware's read of the first two words.
   4. Release the core.

   Consequences you will meet:

   - A corrupt first word in the vector table works fine
     under the debugger and bricks on a cold boot, because
     the debugger set SP itself.

   - Peripherals keep their state across a warm reset that
     the debugger issues, but not across a power cycle. Code
     that depends on a peripheral's reset value can work in
     one and fail in the other.

   - The debug unit keeps clocks running in sleep modes to
     stay attached, so current measurements are meaningless
     with SWD connected (chapter 13).

   - Some parts hold the watchdog frozen while halted. Your
     code passes single-stepping and resets in the field.

   RULE: before believing anything about startup, power-cycle
   the board with the debugger detached. Every startup bug
   worth its name hides in the difference.                  */
```

How it shows up

Symptom	Cause
Faults before any of your code runs	First vector-table word is not a valid, aligned RAM address
Fault on the very first push	`_estack` set to last address rather than last address + 1
Works under debugger, dead on power-up	Debugger set SP and PC directly, masking a broken vector table
Vector table missing from the binary	No `KEEP()` in the linker script and no `used` attribute — garbage collected
Hard fault on the first interrupt	Hand-written table without the Thumb bit set in entries
App hangs only when launched from bootloader	A peripheral or interrupt left enabled by the bootloader
Setting `VTOR` partially works	Table not aligned to the next power of two above its size
`VTOR` does not exist	ARMv6-M core; relocate by remapping SRAM to address 0
Chip appears bricked after a bad update	Debug disabled and BOOT0 not accessible — the recovery path was designed out
Behaviour differs between warm and cold reset	Peripheral state persists across warm reset; test both

Check yourself

- ✓ State exactly what the hardware does with the first two words at the boot address.
- ✓ Explain why `_estack` is one past the last RAM address.
- ✓ Say why the first vector table entry is data while the rest are function pointers.
- ✓ Explain why the vector table needs `KEEP()` or `used`.

- ✓ Describe how boot mode selection works and why BOOT0 access matters for recovery.
- ✓ List the four steps of a bootloader-to-application handoff.
- ✓ Explain the most common bootloader hand-off bug and its symptom.
- ✓ State `VTOR`'s alignment requirement for a 400-byte table.
- ✓ Give three ways a debugger changes the startup sequence.
- ✓ Explain why you must power-cycle with the debugger detached before trusting startup code.

The memory map and the linker script

On a hosted system the linker script is a detail you never see. Here it is a design document: it decides what lives in flash, what lives in RAM, where the stack ends, and what happens when you run out. This chapter reads one line by line.

Why you cannot avoid this file

The compilers track covers linking in general: sections, symbols, relocation. What changes on bare metal is that *nothing supplies a default that works*. There is no loader to place your segments at run time, so the addresses baked in at link time are the addresses used forever. The linker script is where you state them.

```
THE THREE JOBS OF A BARE-METAL LINKER SCRIPT

1. Declare the physical memories and their sizes.
      "256 kB of flash at 0x08000000,
        64 kB of SRAM  at 0x20000000"

2. Assign each input section to one of them.
      .text   -> flash
      .rodata -> flash
      .data   -> RAM, but its INITIAL VALUES in flash
      .bss    -> RAM, no initial values at all

3. Export symbols so startup code can find the boundaries.
      _sdata, _edata, _sbss, _ebss, _estack, _sidata

Job 3 is the one that surprises people: the linker script
and the startup code (chapter 06) are two halves of one
mechanism. Neither makes sense alone.
```

Load address versus virtual address

This is the concept the whole file turns on, and the one that makes `.data` comprehensible.

```
A variable with an initial value:

    int counter = 42;

It must be WRITABLE, so at run time it must live in RAM.
But RAM is volatile - at power-on it contains garbage.
So the value 42 has to be stored somewhere non-volatile.

FLASH (what is programmed)      RAM (at run time)
+---------------------+         +------------------+
| .text  (code)       |         |                  |
+---------------------+         |                  |
| .rodata (consts)    |         |                  |
+---------------------+         +------------------+
| .data INITIALISERS  | ------> | .data  counter=42|
|   the value 42      |  copy   +------------------+
+---------------------+  at     | .bss   (zeroed)  |
                         boot   +------------------+

VMA - Virtual Memory Address: where the code EXPECTS the
      variable to be. For .data, that is in RAM.
LMA - Load Memory Address: where the value is STORED in
      the image. For .data, that is in flash.

For .text and .rodata, VMA == LMA - they are used where
they sit. For .data they differ, and the gap between them
is exactly the copy loop in Reset_Handler.

.bss has no LMA at all. It occupies no space in the image
because its contents are known: zero. That is why a
100 kB array of zeros adds nothing to your binary, and a
100 kB array of ones adds 100 kB.
```

A complete linker script

```
/* GNU ld script for a Cortex-M4 with 256 kB flash, 64 kB SRAM.
   This is the whole file - they are shorter than their
   reputation suggests.                                        */

ENTRY(Reset_Handler)

MEMORY
{

  } >RAM

  /* Prove at LINK TIME that stack and heap still fit.
     Without this you discover the overflow at run time,
     as corruption. With it, the build fails.                  */
  ._user_heap_stack :
  {
    . = ALIGN(8);
    PROVIDE ( end = . );
    . = . + _Min_Heap_Size;
    . = . + _Min_Stack_Size;
    . = ALIGN(8);
  } >RAM

  _estack = ORIGIN(RAM) + LENGTH(RAM);   /* top of RAM */

  /DISCARD/ : { libc.a ( * ) libm.a ( * ) libgcc.a ( * ) }
  .ARM.attributes 0 : { *(.ARM.attributes) }
}
```

THE `._USER_HEAP_STACK` SECTION IS THE BEST LINE IN THE FILE

It allocates nothing and generates no code. Its only purpose is to make the linker fail if the remaining RAM cannot hold your declared minimum stack and heap. Without it, an over-large array links successfully and corrupts the stack at run time — a bug that presents as random misbehaviour weeks later. With it, you get `region RAM overflowed by 312 bytes` at build time. Trading a runtime mystery for a compile error is the whole art of embedded engineering, and this is the cheapest such trade available.

Putting specific things in specific places

```
/* Four placements you will actually need. */

/* 1. A buffer in a particular RAM bank - often required
      because only one bank is reachable by the DMA engine,
      or because a second bank is faster.                    */
__attribute__((section(".sram2")))
static uint8_t dma_buffer[1024];
/* with, in the script:
     RAM2 (rw) : ORIGIN = 0x2001C000, LENGTH = 16K
     .sram2 (NOLOAD) : { *(.sram2) } >RAM2                   */

/* 2. Data that must SURVIVE a reset - a crash log, a boot
      counter. Place it in a NOLOAD section so startup code
      never zeroes it.                                       */
__attribute__((section(".noinit")))
static uint32_t crash_count;
/*   .noinit (NOLOAD) : { *(.noinit) } >RAM
     NOLOAD means: reserve the address range, put nothing in
     the image. Combined with excluding it from the .bss
     zeroing loop, the value survives a warm reset.          */

/* 3. Code that must run FROM RAM - a flash-erase routine
      cannot execute from the flash it is erasing.           */
__attribute__((section(".ramfunc"), long_call, noinline))
void erase_sector(uint32_t addr) { /* ... */ }
/*   .ramfunc : { *(.ramfunc) } >RAM AT> FLASH
     Same LMA/VMA trick as .data - startup copies it.        */

/* 4. A fixed-address configuration block the bootloader and
      application both know about.                           */
__attribute__((section(".config"), used))
const struct config cfg = { .magic = 0xC0FFEE };
/*   .config 0x0801F000 : { KEEP(*(.config)) } >FLASH        */
```

Reading the output

```
$ arm-none-eabi-size -A firmware.elf
section          size      addr
.isr_vector       428   0x8000000
.text           28964   0x80001ac
.rodata          1832   0x8007270
.data             264  0x20000000     <- counts against BOTH
.bss             8192  0x20000108
._user_heap_stack 2560  0x20002108

/* FLASH used = .isr_vector + .text + .rodata + .data
              = 428 + 28964 + 1832 + 264 = 31488 of 262144

   RAM used   = .data + .bss + heap + stack
              = 264 + 8192 + 2560 = 11016 of 65536

   .data is counted TWICE - once in flash for the
   initialisers, once in RAM for the variables. This is the
   single most common arithmetic error when budgeting.      */

$ arm-none-eabi-nm --size-sort -S firmware.elf | tail -5
20000908 00000800 b uart_rx_ring
20001108 00001000 b sensor_history
/* --size-sort finds what is eating your RAM. 'b' is .bss,
   'd' is .data, 't' is .text. When the linker says RAM
   overflowed, this command names the culprit in seconds.   */

$ arm-none-eabi-objdump -h firmware.elf
/* Shows VMA and LMA side by side. If .data's LMA is not in
   flash, your AT> clause is wrong and the initialisers are
   not in the image at all - variables will hold garbage.   */
```

> **THE MAP FILE IS WORTH MORE THAN IT LOOKS**
>
> Pass `-Wl,-Map=firmware.map` and you get a file naming every symbol, its address, its size, and crucially *which object file pulled it in*. When a 4 kB printf implementation appears in a project that never calls printf, the map file's "referenced by" chain is what tells you it came in through `assert`. This is the single most under-used diagnostic in embedded development.

How it shows up

Symptom	Cause
`region RAM overflowed by N bytes`	Working as intended — use `nm --size-sort` to find the largest objects
Initialised globals contain garbage	`.data` has no `AT>` clause, or startup does not run the copy loop
Globals are zero when they should be 42	Section landed in `.bss`; check the map file
Vector table absent from the binary	Missing `KEEP()` — `--gc-sections` removed it
Binary far larger than expected	A large array initialised to non-zero values lives in flash as well as RAM
DMA transfers silently produce nothing	Buffer in a RAM bank the DMA engine cannot reach — place it explicitly
Flash erase routine hangs the core	Code executing from the flash being erased; needs `.ramfunc`
Crash log cleared by the reset it recorded	Variable in `.bss`, so startup zeroed it; needs `.noinit`
Linker succeeds, stack corrupts at run time	No `._user_heap_stack` check — add it

Symptom	Cause
Unexplained 4 kB of code you never called	Pulled in transitively; the map file's reference chain names it

Check yourself

- ✓ State the three jobs of a bare-metal linker script.
- ✓ Define VMA and LMA and say which sections have them differ.
- ✓ Explain why `.bss` occupies no space in the image but `.data` does.
- ✓ Explain why an array of 100 kB of zeros is free but 100 kB of ones is not.
- ✓ Say what the `AT>` clause does and what breaks without it.
- ✓ Explain what `._user_heap_stack` achieves given it emits no code.
- ✓ Give the command that finds which symbols are consuming RAM.
- ✓ Explain why `.data` counts against both flash and RAM budgets.
- ✓ Describe when you need `NOLOAD` and when you need `.ramfunc`.
- ✓ Say what the map file tells you that `size` does not.

Startup code: .data, .bss and the C runtime

C promises that globals with initialisers hold their values and globals without them are zero. On a hosted system the loader keeps that promise. Here, roughly forty lines of code you own keep it — and if they are wrong, C stops being C.

The C runtime contract

```
WHAT THE C STANDARD PROMISES        WHO DELIVERS IT HERE

int a = 42;                         Reset_Handler's
  -> a == 42 at main()              copy loop

int b;                              Reset_Handler's
  -> b == 0 at main()               zero loop

static int c = 7;                   same copy loop
  -> c == 7 at main()

C++ global constructors run         Reset_Handler calling
  before main()                     __libc_init_array

Before Reset_Handler completes, NONE of these hold. Any
code that runs earlier - and on some parts SystemInit()
does - is running in a language that merely resembles C.
Globals read there return whatever the SRAM powered up
with, which on many parts is genuinely random.
```

THE RULE THAT FOLLOWS

Do not touch initialised globals before the copy and zero loops have run. This bites hardest in `SystemInit()`, which many vendor templates call *before* the loops so that clocks are up early. If `SystemInit()` writes `SystemCoreClock` — a global — the subsequent `.data` copy overwrites it with the flash initialiser, and every delay in your program is wrong by whatever ratio the reset clock differs from the configured one. It is a genuinely common bug and it looks like a hardware fault.

Reset_Handler, complete

```
/* Portable C startup. Every symbol here comes from the
   linker script in chapter 05.                              */

extern uint32_t _sidata;   /* .data initialisers, in flash  */
extern uint32_t _sdata;    /* .data start, in RAM           */
extern uint32_t _edata;    /* .data end,   in RAM           */
extern uint32_t _sbss;     /* .bss  start, in RAM           */
extern uint32_t _ebss;     /* .bss  end,   in RAM           */

extern void SystemInit(void);
extern void __libc_init_array(void);
extern int  main(void);

__attribute__((naked, noreturn)) void Reset_Handler(void)
{
    /* The stack pointer is already loaded by hardware from
       vector[0], so we may call functions immediately.

       'naked' because we must not have a prologue that
       touches a stack we have not validated, and because
       this function never returns.                          */

    /* 1. Copy .data from flash to RAM. */
    uint32_t *src = &_sidata;
    uint32_t *dst = &_sdata;
    while (dst < &_edata) {
        *dst++ = *src++;
    }

    /* 2. Zero .bss. */
    dst = &_sbss;
    while (dst < &_ebss) {
        *dst++ = 0;
    }

    /* 3. NOW globals are valid. Clocks may safely use them. */
    SystemInit();

    /* 4. Run C++ constructors and anything in .init_array.
          Harmless in a pure C project - the array is empty. */
    __libc_init_array();

    /* 5. Go. */
    (void) main();

    /* main() returning is a bug on bare metal - there is
       nothing to return to. Trap rather than fall off the
       end into whatever bytes follow.                       */
    for (;;) { }
}
```

> **WHY THE LOOPS ARE WORD-WIDE**
>
> The linker script aligns every boundary to 4 bytes, so copying `uint32_t` at a time is safe and four times faster than bytes. If you ever change those `ALIGN(4)` directives, these loops become unaligned accesses — which on Cortex-M0 is a fault, and on M3 and above is merely slow. Keep the two files in agreement; they are one mechanism, as chapter 05 argued.

Default handlers and the weak-symbol trick

The vector table names a hundred handlers. You will implement three. The remaining ninety-seven still need addresses, and the standard mechanism is weak aliasing.

```
/* Every handler is declared weak and aliased to one default.
   If you define a real one anywhere in the project, the
   linker prefers yours; otherwise the alias stands.        */

void Default_Handler(void)
{
    /* Deliberately NOT an empty while(1). See below. */
    __asm volatile ("bkpt #0");   /* halt if a debugger is attached */
    for (;;) { }
}

#define ALIAS_DEFAULT __attribute__((weak, alias("Default_Handler")))

void NMI_Handler(void)          ALIAS_DEFAULT;
void HardFault_Handler(void)    ALIAS_DEFAULT;
void SVC_Handler(void)          ALIAS_DEFAULT;
void PendSV_Handler(void)       ALIAS_DEFAULT;
void SysTick_Handler(void)      ALIAS_DEFAULT;
void USART1_IRQHandler(void)    ALIAS_DEFAULT;
/* ... and so on for every peripheral ... */

/* Now, elsewhere in the project:

     void USART1_IRQHandler(void) { ... }

   silently and correctly replaces the default. No
   registration call, no table edit. This is why adding an
   interrupt handler on Cortex-M is just defining a function
   with the right name - and why a TYPO in that name is such
   a nasty bug: your function is never called, the default
   handler runs instead, and nothing warns you.

   Guard against it: after enabling an interrupt, assert that
   the vector table entry is not Default_Handler.           */

void assert_handler_installed(IRQn_Type irq)
{
    uint32_t *vt = (uint32_t *) SCB->VTOR;
    void (*installed)(void) = (void (*)(void)) vt[16 + irq];
    configASSERT(installed != Default_Handler);
}
```

> **AN EMPTY `WHILE(1)` IS THE WORST POSSIBLE DEFAULT HANDLER**
> The chip stops, the watchdog eventually resets it, and the reset cause says "watchdog" — telling you nothing. A `bkpt` halts into the debugger if one is attached and is a no-op if not, so you land exactly at the fault with the stack intact. Better still, record the active `IPSR` to a `.noinit` variable first, so a field unit's next boot can report which unhandled interrupt killed it. Chapter 15 builds that out.

The same thing in assembly

Vendor templates usually ship assembly. It is worth being able to read it, because when the C version misbehaves the assembly is the reference.

```
    .syntax unified
    .cpu    cortex-m4
    .thumb

    .global Reset_Handler
    .type   Reset_Handler, %function
Reset_Handler:
    ldr   sp, =_estack          @ redundant - hardware did it,
                                @ but harmless and explicit

    movs  r1, #0                @ offset into .data
    b     LoopCopyDataInit

CopyDataInit:
    ldr   r3, =_sidata          @ source base (flash)
    ldr   r3, [r3, r1]          @ load word at source+offset
    str   r3, [r0, r1]          @ store to dest+offset
    adds  r1, r1, #4

LoopCopyDataInit:
    ldr   r0, =_sdata
    ldr   r3, =_edata
    adds  r2, r0, r1
    cmp   r2, r3
    bcc   CopyDataInit          @ branch if carry clear (unsigned <)

    ldr   r2, =_sbss
    b     LoopFillZerobss

FillZerobss:
    movs  r3, #0
    str   r3, [r2], #4          @ store and post-increment

LoopFillZerobss:
    ldr   r3, =_ebss
    cmp   r2, r3
    bcc   FillZerobss

    bl    SystemInit
    bl    __libc_init_array
    bl    main
    b     .                     @ trap if main returns

/* Same five steps. The 'bcc' (branch if carry clear) is the
   unsigned less-than test - a detail worth knowing because
   using 'blt' (signed) here is a real bug on parts where
   RAM addresses have the top bit set.                      */
```

Retargeting the C library

`printf`, `malloc` and `assert` all assume an operating system. Newlib resolves that by calling out to a small set of stubs you must supply.

```
/* The minimum set to make newlib link and behave. */

#include <errno.h>
#include <sys/stat.h>

/* Where printf's bytes go. */
int _write(int fd, char *buf, int len)
{
    (void) fd;
    for (int i = 0; i < len; i++) {
        uart_putc(buf[i]);
    }
    return len;
}

/* The heap. sbrk grows it; this version refuses to collide
   with the stack, which the naive vendor version does not. */
extern uint32_t _end;      /* end of .bss, from linker      */
extern uint32_t _estack;

void *_sbrk(ptrdiff_t incr)
{
    static char *brk = NULL;
    if (brk == NULL) {
        brk = (char *) &_end;
    }

    char *sp = (char *) __get_MSP();
    if (brk + incr > sp - 512) {      /* keep 512 B for stack */
        errno = ENOMEM;
        return (void *) -1;
    }

    char *prev = brk;
    brk += incr;
    return prev;
}

int _close(int fd)                { (void)fd; return -1; }
int _fstat(int fd, struct stat *st){ (void)fd; st->st_mode = S_IFCHR; return 0; }
int _isatty(int fd)               { (void)fd; return 1; }
int _lseek(int fd, int p, int w)  { (void)fd;(void)p;(void)w; return 0; }
int _read(int fd, char *b, int l) { (void)fd;(void)b;(void)l; return 0; }

/* Two things worth knowing:

   1. printf with %f pulls in roughly 8-10 kB of float
      formatting. Link with -u _printf_float only if you
      need it, or use a tiny printf implementation. On a
      part with 32 kB of flash this single decision can be
      a third of your budget.

   2. Use -specs=nano.specs for newlib-nano: a much smaller
      libc with a reduced printf. Almost always the right
      default on an MCU.                                  */
```

How it shows up

Symptom	Cause
Initialised globals hold garbage	Copy loop missing, or `_sidata` wrong because the `AT>` clause is absent

Symptom	Cause
A global set in `SystemInit()` reverts	`SystemInit()` ran before the copy loop and was overwritten by it
Uninitialised globals are not zero	Zero loop missing, or `_sbss` / `_ebss` not exported
Every delay is wrong by a fixed ratio	`SystemCoreClock` clobbered by the `.data` copy
C++ objects behave as if never constructed	`__libc_init_array()` not called
An ISR you wrote is never entered	Handler name misspelled; the weak default is still linked
Chip resets periodically, cause reads "watchdog"	An unhandled interrupt spinning in an empty default handler
Unaligned access fault in startup	Section boundaries not 4-byte aligned but loops copy words
`malloc` succeeds then the stack corrupts	Vendor `_sbrk` with no stack collision check
Binary grows 10 kB after adding one `printf`	Float formatting pulled in; use newlib-nano or a tiny printf

Check yourself

- ✓ List the five steps of `Reset_Handler` in order.
- ✓ Explain what the C standard promises about globals and who delivers it here.
- ✓ Say why touching globals in `SystemInit()` can be a bug.
- ✓ Explain why `Reset_Handler` is declared `naked`.
- ✓ Describe how weak aliasing lets you install a handler by defining a function.
- ✓ Explain the failure mode of a misspelled handler name and how to detect it.
- ✓ Give two reasons an empty `while(1)` is a bad default handler.
- ✓ Explain why the copy loops move words rather than bytes, and what constrains that.
- ✓ Name three newlib stubs and what each is for.
- ✓ Say what `-specs=nano.specs` changes and why it matters on a small part.

The vector table and the NVIC

The Nested Vectored Interrupt Controller is part of the ARM architecture, at a fixed address, identical on every vendor's chip. It is also the reason Cortex-M interrupt latency is a number you can quote rather than a distribution you must measure.

From pin to handler

```
A signal arrives. Six things must all be true or nothing
happens - and "nothing happens" is the most common
interrupt bug there is.

1. PERIPHERAL         The peripheral must generate the
   enable             event at all: clock on, configured,
                      running.
     |
     v
2. PERIPHERAL         The peripheral's own interrupt
   interrupt enable   enable bit (e.g. USART_CR1.RXNEIE).
     |                Separate from the event itself.
     v
3. Peripheral sets    A status flag latches. This flag is
   its STATUS FLAG    what you must clear in the handler.
     |
     v
4. NVIC ENABLE        NVIC_ISER bit for that IRQ number.
     |                Set with NVIC_EnableIRQ().
     v
5. NVIC PRIORITY      Must be numerically lower (= more
   versus current     urgent) than whatever is running,
   execution          and not blocked by BASEPRI/PRIMASK.
     |
     v
6. PRIMASK clear      Global enable. cpsie i.
     |
     v
HANDLER RUNS - and must clear the flag from step 3, or it
will run again immediately, forever.

Debugging checklist: read the peripheral status register,
NVIC_ISER, NVIC_ISPR (pending), and PRIMASK. One of those
four answers "why is my interrupt not firing" every time.
```

Two numbering schemes

Exception numbers and IRQ numbers are different, offset by 16, and mixing them up is a rite of passage.

```
/* EXCEPTION number: the index into the vector table.
   IRQ number:       what the NVIC API takes.

   exception = irq + 16

   Exception  Vector offset  IRQ    Name
      1        0x04          -      Reset
      2        0x08          -14    NMI
      3        0x0C          -13    HardFault
      4        0x10          -12    MemManage
      5        0x14          -11    BusFault
      6        0x18          -10    UsageFault
     11        0x2C           -5    SVCall
     14        0x38           -2    PendSV
     15        0x3C           -1    SysTick
     16        0x40            0    first peripheral IRQ
     17        0x44            1    second peripheral IRQ

   System exceptions get NEGATIVE IRQ numbers, which is how
   the CMSIS API distinguishes them - NVIC_SetPriority takes
   an IRQn_Type that may be negative, and internally routes
   to SHPR (system handler priority) instead of IPR.

   So to find the vector table slot for USART1 with IRQ 37:
       offset = (37 + 16) * 4 = 0xD4                        */

/* Reading the currently active exception at runtime: */
uint32_t active = SCB->ICSR & SCB_ICSR_VECTACTIVE_Msk;
/* This is an EXCEPTION number, so subtract 16 for the IRQ. */
```

The NVIC registers

```
/* All at 0xE000E100. Note the SET/CLEAR pair design: you
   never read-modify-write, so there is no race with an
   interrupt that fires between the read and the write.     */

/*  ISER[]  0xE000E100  Interrupt Set Enable   - write 1 to enable
    ICER[]  0xE000E180  Interrupt Clear Enable - write 1 to disable
    ISPR[]  0xE000E200  Interrupt Set Pending  - write 1 to force
    ICPR[]  0xE000E280  Interrupt Clear Pending- write 1 to drop
    IABR[]  0xE000E300  Interrupt Active (read only)
    IPR[]   0xE000E400  Interrupt Priority, one BYTE per IRQ    */

/* Writing 0 to any of these does nothing. That is the point:
   to disable IRQ 37 you write bit 37 of ICER, you do NOT
   read ISER, clear a bit and write it back. The latter would
   lose any interrupt enabled by a higher-priority handler
   that preempted you mid-sequence.                          */

static inline void my_enable_irq(int irq)
{
    NVIC->ISER[irq >> 5] = 1UL << (irq & 0x1F);
}
static inline void my_disable_irq(int irq)
{
    NVIC->ICER[irq >> 5] = 1UL << (irq & 0x1F);
    __asm volatile ("dsb");   /* ensure it takes effect...   */
    __asm volatile ("isb");   /* ...before the next instr    */
}

/* The barriers after DISABLE are the subtle part. Without
   them an interrupt already on its way can still be taken
   after your ICER write returns - the write is posted, the
   NVIC has not yet acted, and the pipeline continues. Code
   that disables an interrupt and then frees the buffer that
   interrupt uses will, rarely, use-after-free. This is one
   of the genuinely hard-to-reproduce bare-metal bugs.       */
```

SET/CLEAR REGISTER PAIRS ARE A HARDWARE IDIOM WORTH RECOGNISING

You will see the same design in GPIO (`BSRR`), in DMA, and in the GIC on Cortex-A. The reason is always the same: a single write that affects exactly the bits you name is atomic with respect to anything else touching that register, so no lock is needed. When you meet a peripheral with only a read-write control register and no set/clear pair, that is a signal you will need a critical section around it.

Pending, active, and the difference

```
PENDING  the NVIC has latched a request but the handler
         has not started. Bit in ISPR/ICPR.

ACTIVE   the handler has started and has not returned.
         Bit in IABR. Stays set through preemption.

Both can be set at once: a handler is running (active)
and the same interrupt has been requested again (pending).
When the handler returns, it is immediately re-entered.

time -->
         req         req2
          |           |
pending  _|--|________|-------|______
active   ____|--------|-------|______
             handler   handler
               #1        #2

This is why clearing the PERIPHERAL flag is not the same
as clearing the NVIC pending bit, and why the ORDER
matters:

  WRONG                       RIGHT
  NVIC_ClearPendingIRQ(n);    USARTx->ICR = flag;  /* source */
  USARTx->ICR = flag;         /* NVIC pending clears itself  */

Clear the source first. If you clear NVIC pending while
the peripheral flag is still asserted, the peripheral
immediately re-asserts it and you have achieved nothing.
```

The write-buffer race at handler exit

```
/* The most notorious Cortex-M interrupt bug. */

void USART1_IRQHandler(void)
{
    if (USART1->ISR & USART_ISR_RXNE) {
        ring_put(USART1->RDR);      /* reading RDR clears RXNE */
    }
    /* Handler returns here. */
}

/* On a part where the peripheral sits behind a write buffer
   or a slow bus bridge, the flag-clearing write may still be
   in flight when the exception return completes. The NVIC
   samples the (still asserted) line and re-enters the
   handler. The second entry finds nothing to do - a
   "spurious" interrupt. Usually harmless; occasionally it
   corrupts a state machine that counts entries.

   The fix is a barrier that forces the write to complete
   before the return:                                       */

void USART1_IRQHandler_fixed(void)
{
    if (USART1->ISR & USART_ISR_RXNE) {
        ring_put(USART1->RDR);
    }
    __asm volatile ("dsb");   /* drain the write buffer */
}

/* ARM's own guidance is that this is only required on
   specific parts, and vendors document it inconsistently.
   Pragmatically: if you see doubled interrupts under load,
   add the DSB before spending a day on anything else.
   The cost is a few cycles.                                */
```

Where the twelve cycles go

```
INTERRUPT LATENCY, Cortex-M3/M4, zero wait states:

cycle  0   request asserted
1–8        hardware stacks 8 registers (R0–R3, R12,
           LR, PC, xPSR) onto the current stack
(overlapped) vector fetch from the table
9–11       pipeline refill at the handler address
12         first instruction of your handler executes

TAIL-CHAINING: if a second interrupt is pending when the
first returns, the hardware does NOT unstack and restack.
It jumps straight to the next handler in 6 cycles.

LATE ARRIVAL: if a higher-priority interrupt arrives
DURING the stacking of a lower one, the hardware
redirects to the higher one without restarting the push.

+-------------+---------+-------------+
| naive model | stack 8 | unstack 8   |  ~24 cycles
+-------------+---------+-------------+   between handlers
| actual      | stack 8 | tail-chain  |  ~6 cycles
+-------------+---------+-------------+

Flash wait states change all of these numbers. At 168 MHz
with 5 wait states the vector fetch alone costs more than
the whole sequence above. Enable the flash prefetch and
ART accelerator, or put the vector table in SRAM if
latency truly matters.
```

How it shows up

Symptom	Cause
Interrupt never fires	One of the six gates — check peripheral enable, NVIC ISER, PRIMASK, in that order
Handler runs once then loops forever	Peripheral status flag never cleared in the handler
Handler runs twice per event	Write-buffer race at exit — add a `DSB`
Clearing NVIC pending has no effect	Peripheral flag still asserted; clear the source first
Wrong handler entered	Exception number used where an IRQ number was wanted, or vice versa (off by 16)
Disabling an interrupt does not take effect at once	Missing `DSB` / `ISB` after the `ICER` write
Rare use-after-free in an ISR-owned buffer	Same missing barrier — an in-flight interrupt arrived after disable
An interrupt is lost under load	Pending is one bit deep; a third request while one is active and one pending is dropped
Latency far worse than 12 cycles	Flash wait states; enable prefetch or move the table to SRAM
Enabling one interrupt disables another	Read-modify-write on `ISER` instead of a single-bit write

Check yourself

- ✓ List the six conditions that must hold for an interrupt to reach its handler.
- ✓ Convert IRQ number 37 to a vector table byte offset.

- ✓ Explain why system exceptions have negative IRQ numbers in CMSIS.
- ✓ Explain why NVIC uses set/clear register pairs rather than read-modify-write.
- ✓ Distinguish pending from active, and describe a state where both are set.
- ✓ Say which to clear first: the peripheral flag or the NVIC pending bit, and why.
- ✓ Describe the write-buffer race at handler exit and its fix.
- ✓ Explain why barriers are needed after disabling an interrupt.
- ✓ Explain tail-chaining and give its cycle count against the naive model.
- ✓ Name two things that make real latency worse than the architectural 12 cycles.

Priorities, preemption and tail-chaining

Interrupt priority on Cortex-M is where three separate confusions meet: lower numbers are more urgent, only the top bits of the priority byte are implemented, and the value splits into two fields whose boundary you configure. Getting all three right is what makes an RTOS safe.

Lower is more urgent

```
/* Priority 0 is the HIGHEST priority. This is inverted
   relative to almost every other scheduler you have met,
   including the RTOS running on top of it - FreeRTOS task
   priorities run the other way, where higher is more urgent.

   In a FreeRTOS project you therefore hold BOTH conventions
   in your head at once:

     NVIC priority 0   = most urgent interrupt
     FreeRTOS priority 0 = least urgent task (the idle task)

   Mixing them up is common enough that FreeRTOS ships an
   assertion specifically to catch it.                      */

NVIC_SetPriority(TIM2_IRQn,   0);  /* most urgent  */
NVIC_SetPriority(USART1_IRQn, 5);
NVIC_SetPriority(EXTI0_IRQn, 15);  /* least urgent */

/* Reset default is 0 for everything, meaning every interrupt
   starts at maximum urgency and none can preempt another.
   Leaving the defaults is a real design decision that you
   should make deliberately rather than by omission.        */
```

Only the top bits exist

```
The priority register is a byte per interrupt, but silicon
vendors implement only the top 3, 4 or 5 bits. The rest
read as zero and ignore writes.

A part with 4 implemented bits (STM32, most Cortex-M4):

 bit  7  6  5  4  3  2  1  0
     +--+--+--+--+--+--+--+--+
     |  IMPLEMENTED |  ZERO  |
     +--+--+--+--+--+--+--+--+
      <- 16 levels ->

So the usable values are 0x00, 0x10, 0x20 ... 0xF0.

CMSIS hides this. NVIC_SetPriority(irq, 5) shifts for you:

    IPR[irq] = (5 << (8 - __NVIC_PRIO_BITS)) & 0xFF
             = (5 << 4) = 0x50

But when you write BASEPRI YOURSELF, nothing shifts for
you, and this is the single most common bug in
hand-written critical sections:

  __set_BASEPRI(5);        /* WRONG - 5 = 0x05, and with  */
                           /* 4 bits implemented that is  */
                           /* priority 0. Blocks nothing  */
                           /* except... nothing.          */

  __set_BASEPRI(5 << 4);   /* RIGHT - blocks priority 5   */
                           /* and numerically higher.     */

Always write it as (n << (8 - __NVIC_PRIO_BITS)) so the
code survives a move to a part with different bits.
```

CHECK `__NVIC_PRIO_BITS` FOR YOUR PART BEFORE WRITING ANY PRIORITY CODE

It is defined in the vendor's device header. Cortex-M0 has 2 bits (4 levels), most M3/M4 parts have 4 (16 levels), some have 3 or 5. Code that assumes 4 and runs on a part with 3 silently collapses two of your priority levels into one, which turns a carefully designed preemption scheme into an unpredictable one — and the symptom is intermittent priority inversion under load, not a clean failure.

Group and sub-priority

The implemented bits split into two fields. Only the group field decides preemption; the sub-priority field breaks ties among simultaneously pending interrupts.

```
With 4 implemented bits and PRIGROUP set for 2/2:

 bit   7  6  5  4
     +----+----+
     |GRP |SUB |
     +----+----+
       ^     ^
       |     +-- ties only: which of two SIMULTANEOUSLY
       |         pending interrupts runs first. Does NOT
       |         allow preemption.
       |
       +-- preemption: an interrupt with a lower GROUP
           value preempts one that is running.

Example, groups 0-3 and subs 0-3:

  A: group 1, sub 3   ->  priority 0x70
  B: group 1, sub 0   ->  priority 0x40
  C: group 0, sub 3   ->  priority 0x30

B does NOT preempt A - same group. It waits.
C DOES preempt both  - lower group.
If A and B arrive together, B runs first (lower sub).

SCB->AIRCR PRIGROUP field sets the split:

  PRIGROUP  group bits  sub bits   (4-bit part)
     3          4          0        <- all preemption
     4          3          1
     5          2          2
     6          1          3
     7          0          4        <- no preemption at all

NVIC_SetPriorityGrouping(3) - all bits are group, no
sub-priority - is the sane default and what most RTOS
ports require. FreeRTOS's port assumes it and asserts if
you have configured otherwise.
```

Nesting, and what it costs

```
/* Preemption is automatic and needs no code. It also costs
   stack, and that is the part people forget.               */

/* Each nesting level consumes:
     32 bytes  basic frame (8 registers)
   + 72 bytes  if the FPU context is stacked too
   + whatever the handler's own locals need

   With 4 priority groups and FP in use, worst case is
   4 * (104 + locals) of MSP. If your MSP is 1 kB and each
   handler uses 100 bytes of locals, you are at 816 bytes
   before counting the code that was interrupted.

   This is why chapter 20 sizes the main stack from the
   interrupt nesting depth, not from a guess.               */

/* To FORBID nesting entirely, give every interrupt the same
   group priority. Simple, predictable, and adequate for
   most designs:                                            */

NVIC_SetPriorityGrouping(3);           /* 4 group bits      */
for (int irq = 0; irq < 82; irq++) {
    NVIC_SetPriority((IRQn_Type) irq, 5);   /* all equal    */
}
/* Now nothing preempts anything. Latency for the second
   interrupt becomes the duration of the first, which you
   must then bound - the classic trade.                     */
```

THE RTOS PRIORITY BOUNDARY

An RTOS kernel protects its data with `BASEPRI`, which means interrupts above that threshold run *through* kernel critical sections and therefore must never call a kernel API. This splits your interrupts into two populations, and the split is a design decision you make once:

```
    priority 0  +---------------------------+
                |  ZERO-LATENCY interrupts  |  Never blocked.
                |  Motor commutation, fault |  MUST NOT call
                |  detection, safety stop.  |  any RTOS API.
                |  Not blocked by BASEPRI.  |
    priority 4  +---------------------------+
                |  KERNEL-AWARE interrupts  |  Blocked during
                |  UART, SPI, timers, most  |  kernel critical
                |  peripheral handlers.     |  sections. MAY
                |  MAY call *FromISR APIs.  |  call FromISR.
    priority 15 +---------------------------+

    In FreeRTOS the boundary is
    configMAX_SYSCALL_INTERRUPT_PRIORITY. Calling an API from
    above the line corrupts kernel state in a way that
    manifests hours later; configASSERT catches it
    immediately, which is why you leave it enabled in
    development.
```

Tail-chaining and late arrival

```
NAIVE MODEL (what you would implement in software)

IRQ A ----+                    +---- IRQ B
          v                    v
[stack 8][handler A][unstack 8][stack 8][handler B][unstack 8]
 12 cyc              12 cyc     12 cyc              12 cyc

ACTUAL HARDWARE - TAIL-CHAINING

[stack 8][handler A][ 6 cyc ][handler B][unstack 8]
                     tail-chain: the frame on the stack
                     is already correct for B, so the
                     hardware skips unstack+restack.

LATE ARRIVAL

IRQ A arrives, hardware begins stacking...
     ...IRQ B (higher priority) arrives at cycle 4...
The hardware does NOT abandon or restart the push. It
completes the stacking and then vectors to B instead of
A. A remains pending and tail-chains after B.

Net effect: the expensive part (pushing 8 registers)
happens once per BURST of interrupts rather than once
per interrupt. Under heavy load a Cortex-M spends far
less time on entry/exit than the per-interrupt figure
suggests - which is precisely why the profile is used
for interrupt-dense control applications.
```

How it shows up

Symptom	Cause
Critical section protects nothing	`BASEPRI` written without shifting into the implemented bits
Two priority levels behave as one	Part implements fewer bits than assumed; check `__NVIC_PRIO_BITS`
A higher-priority interrupt does not preempt	Same group priority — only sub-priority differs, which never preempts
Nothing preempts anything	All priorities left at the reset default of 0
Stack overflow only under interrupt load	Nesting depth times frame size exceeds MSP; bound the depth
RTOS state corrupts hours into a run	An API called from an interrupt above the syscall threshold
`configASSERT` fires on an ISR call	Exactly the above, caught early — fix the priority or use the `FromISR` variant
Behaviour changes when priorities are renumbered	Priority grouping is not what you assumed; set it explicitly at startup
Latency fine in isolation, poor in the system	A lower-priority handler is long and cannot be preempted by an equal-group peer
FreeRTOS asserts at startup about grouping	Port requires all bits as group priority — call `NVIC_SetPriorityGrouping(3)`

Check yourself

- ✓ State which numeric direction is more urgent for NVIC, and for FreeRTOS tasks.
- ✓ Explain why only the top bits of the priority byte are implemented.

- ✓ Write a correct `BASEPRI` value for priority 5 on a part with 4 priority bits.
- ✓ Distinguish group priority from sub-priority in terms of preemption.
- ✓ Say what `NVIC_SetPriorityGrouping(3)` configures and why RTOS ports want it.
- ✓ Calculate worst-case MSP usage for 4 nesting levels with FP context stacked.
- ✓ Explain the two interrupt populations an RTOS creates and the rule for each.
- ✓ Describe tail-chaining and give its cycle cost against the naive model.
- ✓ Explain late arrival and what happens to the interrupt that was displaced.
- ✓ Give a way to forbid interrupt nesting entirely, and the cost of doing so.

The clock tree: oscillators, PLLs and dividers

Almost every "the peripheral does not respond" bug on a microcontroller is a clock bug. This chapter covers where clocks come from, how they are multiplied and divided to reach every block, and the two ordering rules that must never be violated.

Where clocks come from

```
FOUR SOURCES, in rough order of accuracy and cost:

INTERNAL RC  (HSI, MSI)      1–3% accurate, sometimes 0.1%
  +--[~~~]--+               after factory trim.
                            Starts in microseconds.
                            Drifts with temperature.
                            Free – no external parts.
                            THE CHIP BOOTS ON THIS.

CRYSTAL      (HSE)           10–50 ppm. Needs two load
  +--[X]--+                  capacitors chosen to match
                             the crystal's spec.
                             Starts in 1–10 ms.
                             Required for USB, Ethernet,
                             CAN and anything with a
                             protocol-defined bit rate.

LOW-SPEED    (LSE)           32.768 kHz, 20 ppm.
  +--[x]--+                  2^15 Hz, so a 15-bit counter
                             overflows at exactly 1 Hz.
                             Runs in the lowest power
                             modes; drives the RTC.

EXTERNAL     (bypass mode)   A clock signal from another
  --->                       chip. Used when one oscillator
                             serves a whole board.

Accuracy is a REQUIREMENT, not a preference. UART at 3%
error fails at 115200 baud (chapter bus-02 does the
arithmetic). USB requires 0.25%. Sleep-mode wake timing
needs the LSE or you drift seconds per day.
```

THE INTERNAL OSCILLATOR IS NOT GOOD ENOUGH FOR A UART, USUALLY

A 1% clock error plus a 1% error at the other end plus baud-rate rounding can exceed the ~2% that asynchronous serial framing tolerates. Many parts can trim the HSI against the LSE at runtime to reach 0.1%, which is enough. Otherwise you fit a crystal. "It works on my desk and fails in the cold chamber" is this problem: the RC oscillator's temperature coefficient moved you outside the window.

The PLL and the tree

```
A realistic STM32F4 clock tree, simplified:

HSI 16 MHz --+
             |    +----------------------------+
HSE  8 MHz --+-->-| /M  ->  xN  ->  /P         |--> PLLCLK
                  |  VCO input   VCO output    |     168 MHz
                  +----------------------------+
                     |
                     v
               +-----------+
HSI ---------> |  SYSCLK   |  <- mux: HSI, HSE or PLL
HSE ---------> |   MUX     |
PLL ---------> +-----------+
                     |
                     v  /AHBPRE (1,2,4...512)
               +-----------+
               |  HCLK     |  168 MHz -> core, DMA, memory
               +-----------+
                  |     |
       /APB1PRE   |     |   /APB2PRE
                  v     v
           +--------+ +--------+
           | PCLK1  | | PCLK2  |
           | 42 MHz | | 84 MHz |
           +--------+ +--------+
            I2C,UART2  UART1,SPI1
            TIM2-7     TIM1,TIM8

THE TIMER EXCEPTION, and it catches everyone:
if an APB prescaler is not 1, the TIMER clock on that bus
is PCLK x2, not PCLK. So with PCLK1 = 42 MHz, TIM2 counts
at 84 MHz. Getting this wrong makes every period exactly
half or double what you intended.

CONSTRAINTS the reference manual imposes on the PLL:
  VCO input  (HSE/M)     must be 1-2 MHz
  VCO output (that x N)  must be 100-432 MHz
  PLLCLK     (that /P)   must be <= 168 MHz
Pick M, N, P to satisfy all three simultaneously. Vendor
clock-configuration tools exist precisely because this is
a constraint-satisfaction problem, not a calculation.
```

Two ordering rules

```
/* RULE 1: raise flash wait states BEFORE raising the clock,
   and lower them AFTER lowering it.

   Flash cannot be read at 168 MHz with zero wait states. If
   you switch SYSCLK to the PLL while the flash controller
   still expects 16 MHz timing, the very next instruction
   fetch returns garbage and you fault - before any code of
   yours can report it.                                      */

void clock_init_168mhz(void)
{
    /* 1. Turn on HSE and WAIT for it. */
    RCC->CR |= RCC_CR_HSEON;
    while (!(RCC->CR & RCC_CR_HSERDY)) { }

    /* 2. Flash: 5 wait states + caches + prefetch, FIRST. */
    FLASH->ACR = FLASH_ACR_LATENCY_5WS
               | FLASH_ACR_PRFTEN
               | FLASH_ACR_ICEN
               | FLASH_ACR_DCEN;
    while ((FLASH->ACR & FLASH_ACR_LATENCY) != FLASH_ACR_LATENCY_5WS) { }

    /* 3. Bus prescalers BEFORE the core speeds up, so no bus
          ever momentarily exceeds its maximum.              */
    RCC->CFGR |= RCC_CFGR_HPRE_DIV1     /* AHB  = 168 MHz */
              |  RCC_CFGR_PPRE1_DIV4    /* APB1 =  42 MHz */
              |  RCC_CFGR_PPRE2_DIV2;   /* APB2 =  84 MHz */

    /* 4. Configure and start the PLL: 8/8 = 1, x336, /2. */
    RCC->PLLCFGR = (8u)            /* M */
                 | (336u << 6)     /* N */
                 | (0u   << 16)    /* P = 2, encoded as 0 */
                 | RCC_PLLCFGR_PLLSRC_HSE
                 | (7u << 24);     /* Q = 7, for USB 48 MHz */
    RCC->CR |= RCC_CR_PLLON;
    while (!(RCC->CR & RCC_CR_PLLRDY)) { }

    /* 5. Only now switch SYSCLK, and confirm it took. */
    RCC->CFGR &= ~RCC_CFGR_SW;
    RCC->CFGR |= RCC_CFGR_SW_PLL;
    while ((RCC->CFGR & RCC_CFGR_SWS) != RCC_CFGR_SWS_PLL) { }

    SystemCoreClock = 168000000u;
}

/* RULE 2: every WAIT loop above is mandatory. An oscillator
   takes milliseconds to stabilise; a PLL takes hundreds of
   microseconds to lock. Switching to an unlocked PLL gives
   you an unstable clock, which gives you behaviour that
   changes with temperature and supply voltage and looks
   exactly like a hardware fault.                            */
```

> **EVERY WAIT LOOP NEEDS A TIMEOUT IN PRODUCTION CODE**
>
> The loops above hang forever if the crystal never starts — a cracked crystal, a bad solder joint, or the wrong load capacitors. A field unit that hangs in `clock_init` is indistinguishable from a dead board. Real firmware counts iterations, and on timeout falls back to the internal oscillator and sets a fault flag, so the device boots degraded and can *report* the failure rather than appearing dead.

Peripheral clock gating

```
/* Every peripheral has an individual clock enable, and it
   is OFF at reset. A peripheral with no clock does not
   fault when you write its registers - it silently ignores
   them, and reads return zero.

   This is the number one cause of "my GPIO does nothing".  */

RCC->AHB1ENR |= RCC_AHB1ENR_GPIOAEN;

/* THE DELAY THAT IS NOT SUPERSTITION:
   the enable write is posted on the bus. On several ST
   families the peripheral needs a couple of clock cycles
   before its registers respond. Writing GPIOA->MODER on the
   very next instruction can be lost.

   The idiomatic fix is a dummy read-back, which forces the
   write to complete before proceeding:                    */

volatile uint32_t tmp = RCC->AHB1ENR;   /* read back */
(void) tmp;

/* ST's own HAL does exactly this, in the __HAL_RCC_*_CLK_ENABLE
   macros. If you write registers directly and skip it, you
   get an initialisation that works at -O0 and fails at -O2,
   because the optimiser tightened the instruction spacing.

   Gating is also your main static power lever: an unused
   peripheral with its clock off draws essentially nothing.
   Chapter 13 uses this heavily.                            */
```

Verifying the clock is what you think

```
/* NEVER trust the arithmetic. Measure. Two ways: */

/* 1. MCO - route a clock to a pin and put a scope on it.
      Almost every part can output SYSCLK/2, /4 etc.        */
RCC->CFGR |= RCC_CFGR_MCO1_1        /* source: PLL          */
          |  RCC_CFGR_MCO1PRE_DIV4; /* divide so it fits    */
/* configure PA8 as alternate function 0 - now PA8 carries
   SYSCLK/4 and one scope reading confirms the whole tree.  */

/* 2. Blink at a known rate and time it with a stopwatch.
      Crude, needs no equipment, and catches factor-of-two
      errors instantly - which are the errors you actually
      make (the APB timer doubling, or a /2 you forgot).    */
for (;;) {
    GPIOA->ODR ^= (1u << 5);
    for (volatile int i = 0; i < 168000000 / 20; i++) { }
}
/* Should toggle at roughly 10 Hz if SYSCLK is 168 MHz and
   the loop is ~2 cycles. If you count 5 Hz, you are at
   84 MHz and your PLL config is off by one divider.        */

/* SystemCoreClock is a VARIABLE, not a measurement. It is
   whatever the last line of your clock init assigned. If
   the PLL silently failed to lock and you fell back to HSI,
   SystemCoreClock still reads 168000000 and every delay in
   the system is wrong by 10x while the variable insists
   everything is fine.                                       */
```

How it shows up

Symptom	Cause
Peripheral registers read zero, writes ignored	Peripheral clock not enabled in the `RCC` gate register
Init works at `-O0`, fails at `-O2`	No read-back after the clock enable; the next write outran the bus
Hard fault immediately on switching to the PLL	Flash wait states not raised first
Every timer period is half or double	APB prescaler timer-doubling rule
Board hangs at boot, appears dead	A wait loop on an oscillator that never started, with no timeout
UART garbles at high baud, fine at low	Clock accuracy — internal RC where a crystal is needed
Works at room temperature, fails in the cold	RC oscillator drift moved baud error outside tolerance
Delays wrong by exactly 10x	PLL never locked, running on HSI, while `SystemCoreClock` still claims otherwise
USB enumerates intermittently or not at all	48 MHz USB clock not exact; check the PLL Q divider
RTC drifts seconds per day	Running from the internal oscillator rather than the 32.768 kHz LSE

Check yourself

- ✓ Name four clock sources and give one application that requires each.
- ✓ Explain why the chip boots on the internal RC oscillator.
- ✓ State the rule about flash wait states and clock changes, in both directions.
- ✓ Explain the APB timer-doubling rule and the bug it causes.

- ✓ List the three PLL constraints that must hold simultaneously.
- ✓ Say why every oscillator wait loop needs a timeout in shipped firmware.
- ✓ Explain what happens when you write a peripheral register with its clock gated off.
- ✓ Explain why a read-back after a clock-enable write is not superstition.
- ✓ Give two ways to verify the actual clock frequency on hardware.
- ✓ Explain why `SystemCoreClock` can be confidently wrong.

GPIO and pinmux from the register level

A pin is the only part of a microcontroller that touches the physical world, and it is massively multiplexed: one ball of solder, a dozen possible functions, and a set of electrical properties you must configure or regret. This is the simplest peripheral and the one worth understanding exactly.

What is behind a pin

```
                        VDD
                         |
                      [pull-up]  <- PUPDR
                         |
   alt.fn out --+        |        +---> IDR (input data)
   ODR ---------+-->[ P-MOS ]     |
                |    output    +--+---> alt.fn in
                |    driver    |  |
   MODER -------+-->[ N-MOS ]--+--+---> ADC (analog)
                         |         [Schmitt trigger]
                      [pull-down] <- PUPDR
                         |
                        GND
                         |
                      === PIN ===

FIVE independent decisions per pin:

MODER    input / output / alternate function / analog
OTYPER   push-pull (drives both rails) or open-drain
         (drives low only; needs a pull-up for high)
OSPEEDR  slew rate - how fast the edge is
PUPDR    internal pull-up, pull-down, or neither
AFR      WHICH alternate function, when MODER says AF

Getting MODER right and the other four wrong is the
normal failure mode: the pin half-works.
```

Configuring a pin properly

```
/* PA5 as a push-pull output - the LED case. */

RCC->AHB1ENR |= RCC_AHB1ENR_GPIOAEN;
(void) RCC->AHB1ENR;                  /* read back (ch 09)  */

/* Two bits per pin: clear then set. Never just OR - the
   reset value for some pins is not 00, notably the SWD
   pins PA13/PA14 which come up as alternate function.     */
GPIOA->MODER   &= ~(3u << (5 * 2));
GPIOA->MODER   |=  (1u << (5 * 2));   /* 01 = output       */

GPIOA->OTYPER  &= ~(1u << 5);         /* 0 = push-pull     */

GPIOA->OSPEEDR &= ~(3u << (5 * 2));   /* 00 = low speed    */
                                       /* for an LED this is */
                                       /* the RIGHT choice   */
GPIOA->PUPDR   &= ~(3u << (5 * 2));   /* 00 = no pull      */

/* PA9 as USART1_TX - an alternate function. */
GPIOA->MODER   &= ~(3u << (9 * 2));
GPIOA->MODER   |=  (2u << (9 * 2));   /* 10 = alt function */
GPIOA->OSPEEDR |=  (3u << (9 * 2));   /* fast edges for a  */
                                       /* real signal        */
/* AFR[0] covers pins 0-7, AFR[1] covers 8-15, 4 bits each. */
GPIOA->AFR[1]  &= ~(0xFu << ((9 - 8) * 4));
GPIOA->AFR[1]  |=  (7u   << ((9 - 8) * 4));  /* AF7=USART1 */

/* WHICH AF number? Not guessable. It is a table in the
   DATASHEET (not the reference manual) called "Alternate
   function mapping". Every pin has a different mapping, and
   a given peripheral appears on only a few pins. This table
   is what pin-planning tools automate.                    */
```

> **SLEW RATE IS AN EMC DECISION, NOT A PERFORMANCE ONE**
>
> A fast edge radiates. Setting every pin to maximum speed "to be safe" is how boards fail radiated-emissions testing, and the fix at that stage costs a respin or a pile of series resistors. Use the slowest setting that meets the timing requirement: low speed for LEDs and slow logic, high speed only for a clock or a bus running near its limit. Chapter bus-19 covers the physics.

BSRR: setting pins without a race

```
/* The obvious way is wrong in the presence of interrupts: */

GPIOA->ODR |=  (1u << 5);      /* read, modify, write      */

/* If an interrupt fires between the read and the write and
   changes another pin in the same port, that change is lost
   when this write completes. A classic lost-update race,
   and it produces LEDs that occasionally stay on and relays
   that occasionally do not fire.                           */

/* BSRR is a WRITE-ONLY register with set bits in the low
   half and reset bits in the high half. One store, no read,
   no race - and it affects only the bits you name.         */

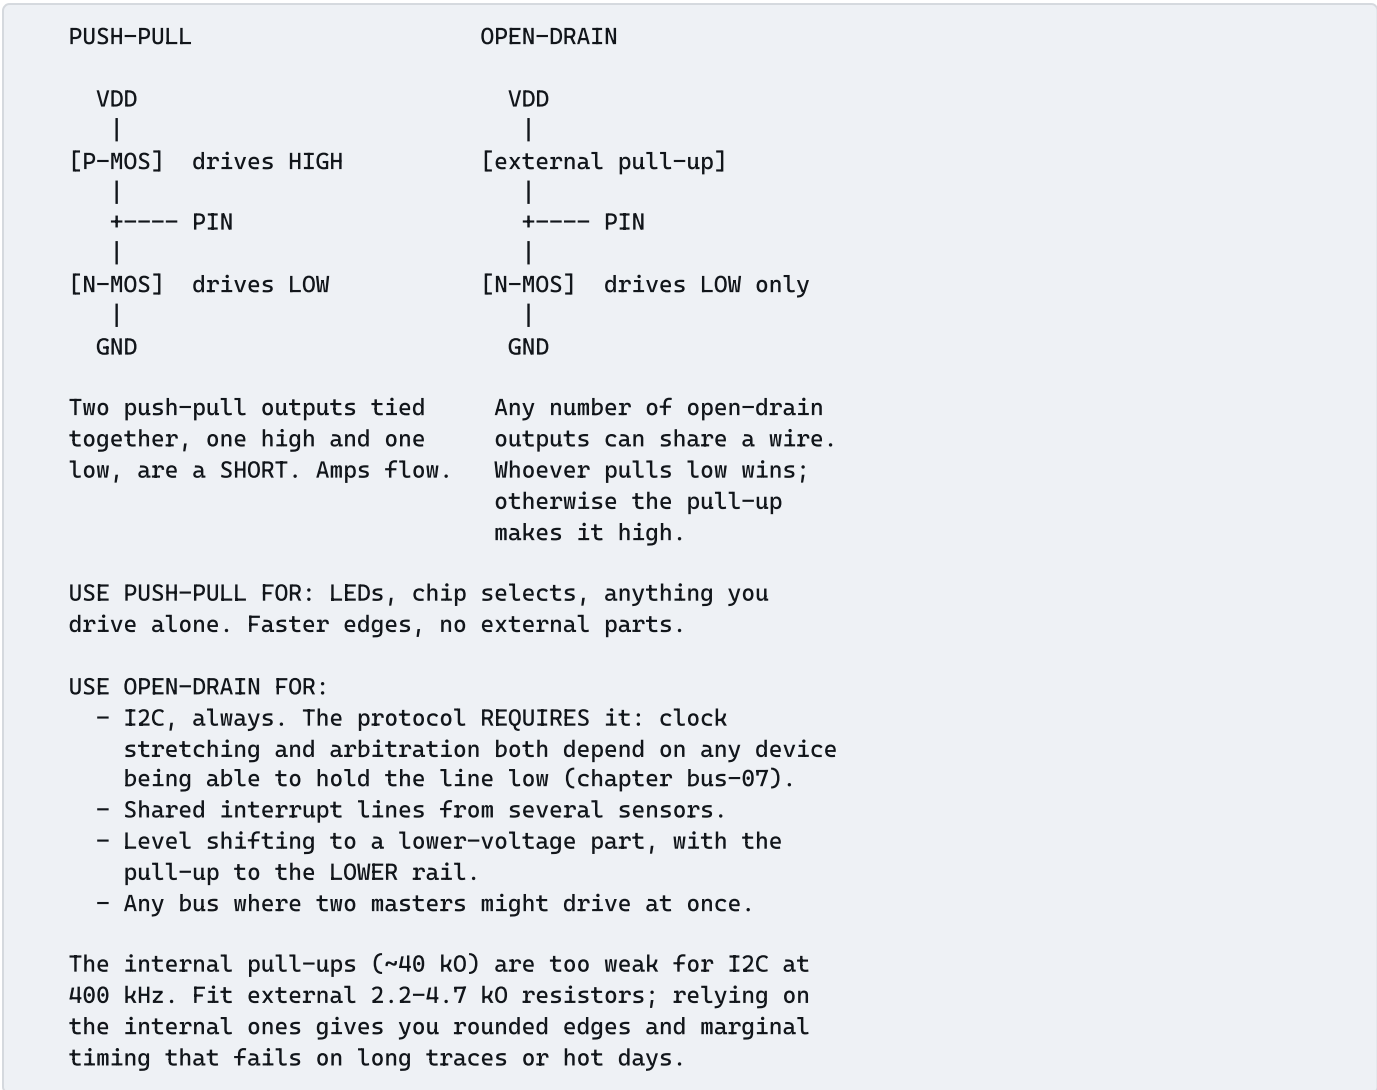
GPIOA->BSRR = (1u << 5);           /* set PA5              */
GPIOA->BSRR = (1u << (5 + 16));    /* clear PA5            */
GPIOA->BSRR = (1u << 5) | (1u << (6 + 16));  /* both, in
                                      the same instant     */

/* If both the set and reset bit for one pin are written,
   SET WINS. Documented, and occasionally useful.

   This is the same set/clear idiom as the NVIC's ISER/ICER
   (chapter 07). Recognising it is a general skill: when a
   peripheral offers a write-1-to-act register, use it and
   delete your critical section.                            */

/* Reading is unambiguous - IDR always reflects the PIN,
   even when the pin is configured as an output. That is
   how you detect a short: drive high, read low.            */
if (!(GPIOA->IDR & (1u << 5))) {
    fault_log(FAULT_LED_SHORTED);
}
```

Push-pull versus open-drain



Pins as interrupt sources

```
/* EXTI: external interrupt lines. The mux is per PIN NUMBER
   across ports, and that constraint bites.                */

/* Route PC13 to EXTI line 13. */
RCC->APB2ENR |= RCC_APB2ENR_SYSCFGEN;
SYSCFG->EXTICR[13 / 4] &= ~(0xFu << ((13 % 4) * 4));
SYSCFG->EXTICR[13 / 4] |=  (2u   << ((13 % 4) * 4));  /* port C */

EXTI->IMR  |=  (1u << 13);      /* unmask                   */
EXTI->FTSR |=  (1u << 13);      /* falling edge             */
EXTI->RTSR &= ~(1u << 13);      /* not rising               */

NVIC_SetPriority(EXTI15_10_IRQn, 10);
NVIC_EnableIRQ(EXTI15_10_IRQn);

/* THE CONSTRAINT: EXTI line N serves pin N of exactly ONE
   port. You can use PA0 or PB0 or PC0 as an interrupt - but
   not two of them at once. Discovering this after the PCB
   is made is a genuinely common and expensive mistake, and
   it is why pin assignment happens before layout.

   Note also that lines 5-9 and 10-15 SHARE a single NVIC
   vector, so the handler must demultiplex:                */

void EXTI15_10_IRQHandler(void)
{
    if (EXTI->PR & (1u << 13)) {
        EXTI->PR = (1u << 13);   /* write 1 to CLEAR */
        button_pressed();
    }
    if (EXTI->PR & (1u << 14)) {
        EXTI->PR = (1u << 14);
        lid_switch_changed();
    }
}

/* "Write 1 to clear" is a third register idiom, alongside
   read-modify-write and set/clear pairs. Writing 0 does
   nothing; writing ~0 clears everything, which is a
   convenient bug when you meant to clear one flag.        */
```

> **DEBOUNCING BELONGS IN SOFTWARE, AND NOT IN THE ISR**
>
> A mechanical switch bounces for 1–20 ms, producing dozens of edges. An EXTI handler that increments a counter will see all of them. The standard fix is to have the ISR disable its own EXTI line and start a one-shot timer; the timer's handler samples the pin once, acts, and re-enables EXTI. That gives you exactly one event per press, costs no polling, and keeps the ISR short. A `for`-loop delay inside the handler "works" and blocks every other interrupt for 20 ms — an eternity.

How it shows up

Symptom	Cause
Pin does nothing at all	GPIO port clock not enabled (chapter 09)
Debugger disconnects when you configure a pin	You reconfigured PA13/PA14 — the SWD pins, which default to alternate function

Symptom	Cause
Alternate function pin behaves as GPIO	`MODER` set to AF but `AFR` left at 0, selecting a different function
Occasional lost pin changes	Read-modify-write on `ODR` racing an ISR — use `BSRR`
Input reads as random noise	Floating pin — enable a pull-up or pull-down
I2C works at 100 kHz, fails at 400 kHz	Relying on internal pull-ups; fit external resistors
Two outputs get hot and the rail sags	Two push-pull outputs on one net, driving opposite
Board fails radiated emissions testing	Every pin set to maximum slew rate
One button press counts as several	Switch bounce, undebounced
PA0 and PB0 cannot both be interrupts	EXTI line 0 serves one port only — a layout-time constraint

Check yourself

- ✓ Name the five per-pin settings and what each controls.
- ✓ Explain why you clear before setting a two-bit `MODER` field.
- ✓ Explain what `BSRR` is for and the race it eliminates.
- ✓ Say what happens when both set and reset bits for a pin are written together.
- ✓ Give three situations that require open-drain and one that requires push-pull.
- ✓ Explain why internal pull-ups are inadequate for I2C at 400 kHz.
- ✓ Explain why slew rate is an EMC decision.
- ✓ State the EXTI multiplexing constraint and when it must be resolved.
- ✓ Describe a debouncing scheme that does not block in the ISR.
- ✓ Explain how to detect a shorted output pin in software.

Timers, PWM, input capture and SysTick

A timer is a counter with comparators attached, and almost every real-time behaviour you will ever build is one of four configurations of that idea. Once you see the shape, every vendor's 60-page timer chapter becomes navigable.

One counter, four uses

```
   THE CORE: a counter clocked by (timer clock / PSC+1),
   counting up to ARR, then wrapping and raising an update
   event.

   CNT
    ^
ARR |    /|    /|    /|
    |   / |   / |   / |
CCR |--/--|--/--|--/--|---  compare value
    | /   | /   | /   |
   0+-----+-----+-----+--> time
         UEV   UEV   UEV    update event (interrupt/DMA)

   FOUR USES OF THE SAME HARDWARE:

   1. PERIODIC INTERRUPT   ignore CCR, act on the update
                           event. Your system tick.

   2. PWM OUTPUT           the output pin is high while
                           CNT < CCR, low after. Duty
                           cycle = CCR/ARR. Set and forget:
                           no CPU involvement at all.

   3. INPUT CAPTURE        an edge on a pin COPIES CNT into
                           CCR and raises an interrupt. You
                           read a timestamp, not a value -
                           this is how you measure a pulse
                           without polling.

   4. OUTPUT COMPARE       toggle/set/clear a pin the instant
                           CNT reaches CCR, in hardware, with
                           zero jitter from interrupt latency.

   Configurations 2, 3 and 4 involve NO CPU once started.
   That is the entire point: the timer does the timing, and
   the CPU is free or asleep.
```

The arithmetic, done once

```
/* f_event = f_timer / ((PSC + 1) * (ARR + 1))

   Both registers hold "value minus one" because a counter
   from 0 to N inclusive has N+1 states. Forgetting the -1
   gives an error of one part in ARR - invisible at
   ARR=65535, badly wrong at ARR=1.                          */

/* GOAL: a 1 kHz update event from a 84 MHz timer clock.
   (Remember the APB doubling rule from chapter 09: PCLK1 is
   42 MHz, so TIM2's clock is 84 MHz.)

   84e6 / 1000 = 84000 counts needed.
   84000 > 65535, so it will not fit in ARR alone.

   PSC = 83  -> timer counts at 84e6/84 = 1 MHz
   ARR = 999 -> update every 1000 counts = 1 kHz          */

RCC->APB1ENR |= RCC_APB1ENR_TIM2EN;
(void) RCC->APB1ENR;

TIM2->PSC = 83;
TIM2->ARR = 999;

/* PSC is BUFFERED: writes take effect at the next update
   event, not immediately. To apply it now, force an update: */
TIM2->EGR = TIM_EGR_UG;
/* ...which also sets the update interrupt flag, so clear it
   before enabling the interrupt or you take one spurious
   interrupt the instant you enable it.                      */
TIM2->SR = ~TIM_SR_UIF;

TIM2->DIER |= TIM_DIER_UIE;
NVIC_EnableIRQ(TIM2_IRQn);
TIM2->CR1 |= TIM_CR1_CEN;

void TIM2_IRQHandler(void)
{
    TIM2->SR = ~TIM_SR_UIF;    /* clear FIRST (chapter 07)  */
    tick_count++;
}

/* Choosing PSC vs ARR when several combinations work:
   prefer the LARGEST ARR. Resolution is 1/ARR, so
   PSC=83, ARR=999 gives 0.1% duty steps for PWM, while
   PSC=8399, ARR=9 gives 10% steps. Same frequency, wildly
   different usefulness.                                     */
```

PWM, and why it needs no CPU

```
/* PWM on TIM3 channel 1 -> PA6, 20 kHz, for a motor or LED. */

TIM3->PSC = 0;                    /* full 84 MHz            */
TIM3->ARR = 4199;                 /* 84e6/4200 = 20 kHz     */

/* Mode 110 = PWM mode 1: active while CNT < CCR.
   OCxPE = preload enable: writes to CCR take effect at the
   next update, so a duty change never produces a runt
   pulse mid-cycle. Always enable it for PWM.               */
TIM3->CCMR1 |= (6u << 4) | TIM_CCMR1_OC1PE;
TIM3->CCER  |= TIM_CCER_CC1E;     /* enable the output      */
TIM3->CR1   |= TIM_CR1_ARPE;      /* preload ARR too        */
TIM3->EGR    = TIM_EGR_UG;
TIM3->CR1   |= TIM_CR1_CEN;

/* Duty cycle is now ONE STORE, any time, from anywhere: */
TIM3->CCR1 = 2100;                /* 50%                    */

/* No interrupt, no ISR, no jitter. The pin toggles at
   exactly the right instant because a comparator does it.

   ADVANCED TIMERS (TIM1, TIM8) add what motor control
   needs and general timers lack:

     - COMPLEMENTARY outputs (CH1 and CH1N) for a half
       bridge, with hardware DEAD TIME between them so the
       high and low transistors are never on together. That
       dead time is what stops a shoot-through that destroys
       the bridge - it must be hardware, because a software
       delay can be preempted.

     - BREAK INPUT: a fault pin that forces all outputs to a
       safe state in hardware, within nanoseconds, with no
       CPU involvement. This is a safety mechanism; software
       cannot react fast enough to save a motor.

     - REPETITION COUNTER: update event every N cycles
       rather than every cycle.                            */
TIM1->BDTR = (72u << 0)           /* dead time             */
           | TIM_BDTR_BKE         /* break enabled         */
           | TIM_BDTR_MOE;        /* master output enable  */
```

> **THE GENERAL PRINCIPLE: PUSH TIMING INTO HARDWARE**
>
> Any time you find yourself writing "wait, then toggle a pin", ask whether a timer channel can do it. Software timing is subject to interrupt latency, cache effects and scheduler jitter; a comparator is subject to none of them. The difference between a competent embedded design and an amateur one is very often just how much of the timing was handed to peripherals — and it is also what lets the CPU sleep, which chapter 13 depends on entirely.

Input capture: measuring without polling

```
/* Measure the period and duty of an incoming signal in
   hardware. PWM INPUT MODE uses two channels on one pin.  */

/* CH1 captures rising edges -> period
   CH2 captures falling edges -> high time                  */
TIM4->CCMR1 = (1u << 0)      /* CC1S: IC1 mapped to TI1    */
            | (2u << 8);     /* CC2S: IC2 mapped to TI1    */
TIM4->CCER  = TIM_CCER_CC1E              /* CH1 rising     */
            | TIM_CCER_CC2E | TIM_CCER_CC2P;  /* CH2 falling */
TIM4->SMCR  = (5u << 4)      /* TS: trigger = TI1FP1       */
            | (4u << 0);     /* SMS: reset mode            */
TIM4->CR1  |= TIM_CR1_CEN;

/* Now, with no CPU involvement at all:
     CCR1 = period in timer ticks
     CCR2 = high time in timer ticks
     duty = CCR2 / CCR1

   Reset mode means each rising edge zeroes the counter, so
   CCR1 is a period rather than a running timestamp. This is
   how you read an RC receiver, a tachometer, an ultrasonic
   rangefinder's echo pulse, or any sensor with a
   pulse-width output - accurately, while the CPU sleeps.

   THE OVERFLOW PROBLEM: if the signal stops, CNT wraps and
   CCR1 holds a stale value that looks plausible. Always
   enable the update interrupt as a timeout and treat "no
   capture since last update" as signal lost. Reading a
   dead sensor as a valid measurement is worse than reading
   an error.                                                */
```

SysTick, and why an RTOS wants it

```
/* SysTick is architectural (chapter 02): same registers on
   every Cortex-M, at 0xE000E010. A 24-bit down-counter.
   It exists so an RTOS port is portable across vendors.   */

SysTick->LOAD = (SystemCoreClock / 1000u) - 1u;  /* 1 ms   */
SysTick->VAL  = 0;
SysTick->CTRL = SysTick_CTRL_CLKSOURCE_Msk   /* core clock */
              | SysTick_CTRL_TICKINT_Msk
              | SysTick_CTRL_ENABLE_Msk;

volatile uint32_t g_ms;
void SysTick_Handler(void) { g_ms++; }   /* flag auto-clears */

/* 24 bits: at 168 MHz the maximum period is
   16777216/168e6 = 99.8 ms. It cannot be your only
   long-duration timer.

   THE OVERFLOW BUG, and the fix:                          */

/* WRONG - breaks when g_ms wraps at 49.7 days */
if (g_ms > deadline) { ... }

/* RIGHT - unsigned subtraction wraps correctly */
if ((int32_t)(g_ms - deadline) >= 0) { ... }

/* The second form works across the wrap because the
   subtraction is done modulo 2^32 and then interpreted as
   signed. It is correct for any interval under ~24 days.
   Every timekeeping bug of the "device fails after seven
   weeks of uptime" kind is the first form.                */

/* Reading g_ms outside the ISR needs care on a 32-bit
   counter it is a single aligned access, so it is atomic on
   Cortex-M. A 64-bit counter is NOT - it needs a critical
   section or a seqlock, or you will read a torn value once
   every few billion reads, which is once a week in a busy
   system.                                                  */
```

How it shows up

Symptom	Cause
Period is exactly half or double	APB timer-clock doubling rule (chapter 09)
Frequency off by one part in ARR	Forgot that PSC and ARR hold value minus one
Prescaler change has no effect	PSC is buffered — force an update with `EGR.UG`
One spurious interrupt right after enabling	`EGR.UG` set the update flag; clear it before enabling the interrupt
PWM duty steps are very coarse	ARR too small — trade prescaler for counter range
Glitch or runt pulse when changing duty	CCR preload (`OCxPE`) not enabled
PWM configured but the pin stays low	On an advanced timer, `BDTR.MOE` not set
Motor bridge destroys itself	No hardware dead time between complementary outputs
Dead sensor reads as a valid measurement	Stale capture register; no update-event timeout
Device misbehaves after 49.7 days	Tick comparison with `>` instead of wrap-safe subtraction

Check yourself

- ✓ Give the formula relating timer clock, PSC, ARR and event frequency.
- ✓ Explain why both PSC and ARR are stored as value minus one.
- ✓ Choose PSC and ARR for 1 kHz from an 84 MHz timer clock, and justify the split.
- ✓ Explain why `EGR.UG` is needed and the side effect it has.
- ✓ Explain what CCR preload prevents.
- ✓ Name the three features advanced timers add and what each is for.
- ✓ Explain why hardware dead time cannot be replaced by a software delay.
- ✓ Describe PWM input mode and what CCR1 and CCR2 hold.
- ✓ Explain the stale-capture failure and how to detect signal loss.
- ✓ Write a wrap-safe deadline comparison and explain why it works.

Polling, interrupts and DMA: three ways to move data

Every peripheral transfer is one of three mechanisms, and choosing wrongly is the most common cause of a design that works on the bench and falls over in the field. This chapter is the decision, with the arithmetic that makes it.

The three mechanisms

```
POLLING
  CPU: while (!(flag)) { }  then read
  Cost: 100% of a core, doing nothing useful
  Latency: as good as it gets - you are already looking
  Use when: the wait is shorter than an interrupt entry
            (~12 cycles + your prologue), or during init,
            or in a hard real-time loop that has nothing
            else to do.

INTERRUPT
  CPU: handler runs per BYTE or per EVENT
  Cost: ~20-40 cycles of overhead per event
  Latency: 12 cycles + whatever is blocking you
  Use when: events are infrequent relative to the
            overhead, or their timing is unpredictable.

DMA
  CPU: configure once, then nothing until the block ends
  Cost: bus bandwidth, contention with the CPU
  Latency: irrelevant per byte; one interrupt per BLOCK
  Use when: the data is a block, or the rate is high
            enough that per-event interrupts would
            saturate the CPU.

THE ARITHMETIC THAT DECIDES:

  UART at 115200 baud = 11520 bytes/s
    per-byte interrupt at 30 cycles = 345,600 cycles/s
    on a 168 MHz core = 0.2% CPU. Interrupts are fine.

  UART at 3 Mbaud = 300,000 bytes/s
    per-byte interrupt at 30 cycles = 9,000,000 cycles/s
    = 5.4% CPU, and 300k interrupts/s starves everything
    else. Use DMA.

  ADC at 1 Msample/s
    per-sample interrupt = 30,000,000 cycles/s = 18% CPU
    doing nothing but copying. Use DMA. Always.

Do this calculation. It takes thirty seconds and it is
the difference between a design that scales and one that
is rewritten under deadline.
```

Polling, done correctly

```
/* Polling gets a bad name because it is usually written
   without a timeout. This version cannot hang.            */

int uart_send_blocking(const uint8_t *p, size_t n, uint32_t ms)
{
    uint32_t deadline = g_ms + ms;

    for (size_t i = 0; i < n; i++) {
        while (!(USART1->ISR & USART_ISR_TXE)) {
            if ((int32_t)(g_ms - deadline) >= 0) {
                return -ETIMEDOUT;      /* the crucial part */
            }
        }
        USART1->TDR = p[i];
    }
    return 0;
}

/* Three rules for any polling loop that ships:

   1. A TIMEOUT, always. A peripheral that never sets its
      flag - because a clock is off, a cable is unplugged,
      or the far end died - turns a poll into a hang. This
      is the single most common cause of a field unit that
      "just stops".

   2. The flag variable must be volatile, or read through a
      volatile pointer. Otherwise the compiler may hoist the
      load out of the loop and spin forever on a stale value
      (see the C track, chapter 10).

   3. Consider what else is starved. A 10 ms poll with
      interrupts enabled is fine; the same poll inside a
      critical section delays every interrupt by 10 ms.     */
```

DMA: the controller does the copying

```
/* DMA is a second bus master. It reads and writes memory
   without the CPU, arbitrating for the bus alongside it.  */

/* UART receive into a circular buffer - the configuration
   worth memorising, because it never overruns.            */

DMA2_Stream5->PAR  = (uint32_t) &USART1->RDR;   /* source */
DMA2_Stream5->M0AR = (uint32_t) rx_buffer;      /* dest   */
DMA2_Stream5->NDTR = sizeof(rx_buffer);
DMA2_Stream5->CR   = (4u << 25)          /* channel 4      */
                   | DMA_SxCR_MINC       /* increment mem  */
                   | DMA_SxCR_CIRC       /* CIRCULAR       */
                   | DMA_SxCR_TCIE       /* half/full IRQ  */
                   | DMA_SxCR_HTIE;
USART1->CR3 |= USART_CR3_DMAR;
DMA2_Stream5->CR |= DMA_SxCR_EN;

/* CIRCULAR mode means NDTR reloads automatically at the end
   and the controller wraps to the buffer start. Combined
   with the half-transfer interrupt you get a classic
   double-buffer: process the first half while the second
   fills, and vice versa. The UART can now receive
   continuously, forever, with two interrupts per buffer
   instead of one per byte.

   Add the UART's IDLE-line interrupt and you also learn
   when a variable-length message ENDED, which is what makes
   this pattern work for protocols rather than just streams:

     bytes_received = sizeof(rx_buffer) - DMA2_Stream5->NDTR;

   That expression, read in the IDLE handler, tells you
   exactly how much arrived. This combination - circular DMA
   plus IDLE detection - is the standard high-performance
   UART receive design, and it is worth knowing by heart.  */
```

FOUR DMA RULES THAT ARE NOT OPTIONAL

1. THE BUFFER MUST BE REACHABLE.
   Many parts have RAM banks the DMA engine cannot see -
   CCM RAM on STM32F4 is the classic. A buffer there
   produces a transfer error or silent zeros. Place DMA
   buffers explicitly (chapter 05).

2. THE BUFFER MUST NOT BE ON THE STACK.
   A local array goes out of scope when the function
   returns; the DMA controller keeps writing to it. This
   corrupts whatever occupies that stack space next, at
   a delay, and is genuinely one of the hardest embedded
   bugs to find. Use static or heap.

3. CACHE MAINTENANCE ON M7.
   Cortex-M7 has data caches. Before a memory-to-
   peripheral transfer, CLEAN the cache so the DMA sees
   your writes. After a peripheral-to-memory transfer,
   INVALIDATE so the CPU does not read stale lines.
   Miss this and it works at -O0 and fails at -O2, or
   works until the buffer happens to stay in cache.

     SCB_CleanDCache_by_Addr((uint32_t*)buf, len);
     ... start TX DMA ...

     ... RX DMA completes ...
     SCB_InvalidateDCache_by_Addr((uint32_t*)buf, len);

   M0/M3/M4 have no data cache, so this is one of the
   few places where code does not port upward cleanly.

4. ALIGNMENT AND WIDTH MUST AGREE.
   A 32-bit peripheral width with a byte-aligned buffer
   is a transfer error, not a slow transfer.

The compiler does not know about DMA

```
/* DMA writes memory behind the compiler's back. Every
   variable the DMA controller touches must be volatile, and
   volatile alone is still not quite enough.               */

static volatile uint8_t rx_buffer[256];   /* volatile: yes */
static volatile int     rx_done;

void DMA2_Stream5_IRQHandler(void)
{
    DMA2->HIFCR = DMA_HIFCR_CTCIF5;
    rx_done = 1;
}

void consumer(void)
{
    while (!rx_done) { }        /* volatile: the load repeats */

    __asm volatile ("dmb");     /* ordering: see below        */
    process(rx_buffer);
}

/* The DMB matters. volatile guarantees the COMPILER does
   not reorder or elide the accesses. It says nothing about
   the memory system. On Cortex-M the core is largely
   in-order and this is usually benign, but write buffers
   and the bus matrix can still reorder the DMA's buffer
   writes relative to its completion signal.

   The rule: volatile for the compiler, a barrier for the
   hardware. They solve different problems and you often
   need both. This is exactly the distinction the ARM track
   makes in its barriers chapter, and it applies here in
   miniature.                                              */
```

A decision table

Situation	Mechanism	Why
Reading a status register during init	Polling	Happens once; an ISR would be more code than the wait
Waiting ~1 µs for a peripheral to be ready	Polling	Shorter than interrupt entry and exit
Button press	Interrupt	Rare and unpredictable; polling wastes power
UART console at 115200	Interrupt	0.2% CPU — simplicity wins
UART at 1 Mbaud or above	DMA	Interrupt rate would dominate the CPU
ADC sampling continuously	DMA, circular	Per-sample interrupts are unaffordable at any real rate
SPI display refresh	DMA	Large block, no per-byte decision to make
I2C register read of 2 bytes	Interrupt	DMA setup costs more than the transfer
Audio in or out	DMA, double-buffered	Hard deadline, continuous, unattended
Motor commutation on a hall edge	Interrupt, highest priority	Latency is the entire requirement

How it shows up

Symptom	Cause
Device stops responding, no crash	A polling loop with no timeout waiting on a flag that never sets
Poll loop never exits despite the flag setting	Missing `volatile`; the load was hoisted
DMA completes but the buffer holds zeros	Buffer in RAM the DMA engine cannot reach
Random corruption some time after a transfer	DMA buffer was a stack local that went out of scope
Works at `-O0`, fails at `-O2`, Cortex-M7	Missing cache clean or invalidate around the transfer
DMA reports a transfer error immediately	Alignment or width mismatch between peripheral and memory
UART drops bytes under load	Per-byte interrupts cannot keep up — move to circular DMA
Received message length is unknown	Use IDLE-line detection with `NDTR` to find the boundary
System responsive on the bench, not in the field	Interrupt load calculated for the demo rate, not the real one
Occasional stale data read after DMA completes	No barrier between the completion flag and the buffer read

Check yourself

- ✓ Give the CPU cost of per-byte interrupts for a 3 Mbaud UART on a 168 MHz core.
- ✓ State the three rules for a polling loop that ships.
- ✓ Explain why a polling loop without a timeout is a field-reliability problem.
- ✓ Describe circular DMA plus IDLE detection and what problem it solves.
- ✓ Write the expression that gives bytes received so far from `NDTR`.
- ✓ Explain why a DMA buffer must not be a stack local.
- ✓ State the cache maintenance required around DMA on Cortex-M7, in both directions.
- ✓ Explain why `volatile` and a barrier solve different problems.
- ✓ Choose a mechanism for a 2-byte I2C register read and justify it.
- ✓ Explain why DMA buffers sometimes must be placed in a specific RAM bank.

Low-power modes and the current budget

Battery life is arithmetic, not craft. This chapter covers the sleep modes a Cortex-M offers, the duty-cycle calculation that decides whether your product lasts a year or a fortnight, and the handful of mistakes that account for nearly every "why is it drawing 3 mA" question.

The modes

```
Typical STM32L4-class figures. Every vendor names these
differently; the STRUCTURE is universal.

MODE        CPU   RAM   PERIPH  WAKE     CURRENT  WAKE TIME
-----------------------------------------------------------
RUN         on    on    on      -        10 mA    -
SLEEP       off   on    on      any IRQ   2 mA    ~0 cycles
STOP        off   on    few     EXTI,RTC  2 uA    ~5 us
STANDBY     off   LOST  none    pin,RTC   0.3 uA  ~250 us
                  (few                             + full
                   backup                          reboot
                   regs                            from
                   survive)                        reset

THE TWO THINGS THAT CHANGE BETWEEN ROWS:

1. What still has a CLOCK. In SLEEP the core clock stops
   but peripherals run, so a UART keeps receiving and a
   DMA transfer keeps going. That is why SLEEP + DMA is
   such a powerful combination.

2. Whether SRAM keeps its CONTENT. STANDBY loses it.
   Waking from STANDBY re-runs Reset_Handler and your
   program starts from the top - it is a reboot, not a
   resume. Anything you must remember goes in backup
   registers or the RTC's domain.

The jump from SLEEP to STOP is a factor of a thousand.
That is the decision that matters; everything else is
refinement.
```

Entering a mode

```
/* WFI - wait for interrupt. The core halts until an
   interrupt arrives. This is the whole mechanism.         */

__WFI();

/* SLEEP-ON-EXIT: an elegant pattern for a purely
   event-driven device. The core re-enters sleep
   automatically when an ISR returns, so main() never runs
   again after setup and there is no idle loop at all.     */
SCB->SCR |= SCB_SCR_SLEEPONEXIT_Msk;

/* Deeper modes set SLEEPDEEP and then WFI. */
static void enter_stop_mode(void)
{
    /* Select STOP with the regulator in low-power mode. */
    PWR->CR1 &= ~PWR_CR1_LPMS;
    PWR->CR1 |=  PWR_CR1_LPMS_STOP2;

    SCB->SCR |= SCB_SCR_SLEEPDEEP_Msk;
    __DSB();                       /* drain writes first   */
    __WFI();
    SCB->SCR &= ~SCB_SCR_SLEEPDEEP_Msk;

    /* CRITICAL: STOP mode usually switches SYSCLK back to
       the internal oscillator on wake. Your 168 MHz PLL is
       off and every timing assumption is wrong until you
       restore it.                                          */
    clock_init_168mhz();
}
```

THE WFI RACE, AND THE STANDARD FIX

```
THE BUG

  while (!work_pending) {
      __WFI();          <-- interrupt fires HERE, between
  }                         the test and the WFI. The ISR
                            sets work_pending and returns.
                            WFI then sleeps anyway, and
                            nothing will wake us until the
                            NEXT interrupt - which may
                            never come.

Symptom: the device hangs roughly once a day, in a way
that never reproduces on the bench.

THE FIX: disable interrupts around the test. WFI wakes on
a pending interrupt even when PRIMASK masks it - that is
an architectural guarantee, and it exists precisely for
this pattern.

  __disable_irq();
  if (!work_pending) {
      __WFI();          /* wakes on pending IRQ even    */
  }                     /* though PRIMASK blocks entry  */
  __enable_irq();       /* NOW the ISR actually runs    */

The interrupt is taken immediately after the enable. No
window, no lost wakeup.
```

The arithmetic that decides the product

```
/* A sensor that wakes every 10 s, measures for 20 ms, and
   transmits for 100 ms once a minute.

   AVERAGE CURRENT = sum of (current * time) / period

   Per minute:
     6 wakes  x 20 ms x 10 mA  = 1200 mA-ms  measuring
     1 TX     x 100 ms x 30 mA = 3000 mA-ms  radio
     remainder: 60000 - 220 ms x 2 uA
                = 59780 ms x 0.002 mA = 120 mA-ms  sleeping
     ------------------------------------------------
     total = 4320 mA-ms per 60000 ms
     average = 0.072 mA = 72 uA

   A 220 mAh coin cell / 0.072 mA = 3055 hours = 127 days.

   NOW RAISE SLEEP CURRENT FROM 2 uA TO 50 uA - one pin left
   floating, say:
     sleep contribution = 59780 x 0.050 = 2989 mA-ms
     total = 7189, average = 0.120 mA
     battery life = 76 days.

   A single floating pin cost 40% of the product's life. It
   would never be noticed in testing, because the device
   works perfectly.

   THE LESSON: in a duty-cycled design the sleep current
   dominates the total even though it is the smallest
   number, because it is multiplied by the largest time.
   Optimise the term with the biggest product, which is
   almost never the one that feels slow.                  */
```

Where the microamps actually go

```
IN ROUGH ORDER OF HOW OFTEN THEY ARE THE CULPRIT:

1. THE DEBUGGER IS ATTACHED.
   SWD keeps clocks alive. Measurements with a debugger
   connected are meaningless - often 100x too high.
   Measure on battery, detached, always.

2. A FLOATING INPUT PIN.
   An unconnected CMOS input drifts near the switching
   threshold and both transistors conduct. Microamps to
   milliamps, per pin. EVERY unused pin must be an
   output, or an input with a pull enabled, or analog.
   Analog mode is the lowest of the three because it
   disconnects the Schmitt trigger entirely.

3. A PULL-UP FIGHTING A DRIVEN LOW.
   A 4.7 kO pull-up to 3.3 V held low is 700 uA,
   continuously. I2C buses idle high for this reason; if
   you sleep with SDA held low you pay for it all night.

4. A PERIPHERAL CLOCK LEFT ENABLED.
   Gate everything you are not using (chapter 09). Some
   peripherals also need explicit disabling, not just
   clock gating - an ADC's analog front end draws current
   from the reference regardless of its clock.

5. AN LED.
   2 mA is 30x your entire sleep budget. Indicator LEDs
   must be duty-cycled or omitted on battery products.

6. AN EXTERNAL SENSOR STILL POWERED.
   Its datasheet's "sleep current" may exceed your MCU's
   by an order of magnitude. Consider power-gating it
   with a MOSFET so its current is genuinely zero.

7. THE REGULATOR'S OWN QUIESCENT CURRENT.
   A regulator with 50 uA quiescent draw makes a 2 uA MCU
   irrelevant. This is a schematic decision that caps
   your achievable sleep current before firmware runs.
```

> **MEASURE, DO NOT MODEL**
>
> Sleep-current bugs are invisible to every software tool. You need an ammeter that resolves microamps and milliamps in the same trace — a dedicated low-power analyser, or a sense resistor and a scope. The characteristic finding is a device that sleeps beautifully in one state and not in another, because one code path leaves a peripheral enabled. Plot current against time across a full duty cycle and the extra current will be a visible plateau you can align with your code.

Waking up, and RTC scheduling

```
/* From STOP or STANDBY, the wake sources are limited to
   what still has a clock: the RTC, a handful of EXTI pins,
   and sometimes a low-power UART or comparator.           */

static void sleep_for_seconds(uint32_t s)
{
    RTC->WPR = 0xCA; RTC->WPR = 0x53;     /* unlock         */
    RTC->CR &= ~RTC_CR_WUTE;
    while (!(RTC->ISR & RTC_ISR_WUTWF)) { }

    RTC->WUTR = s - 1;                    /* 1 Hz clock     */
    RTC->CR |= RTC_CR_WUCKSEL_2;
    RTC->CR |= RTC_CR_WUTE | RTC_CR_WUTIE;
    RTC->WPR = 0xFF;                      /* relock         */

    EXTI->IMR  |= EXTI_IMR_MR22;          /* RTC wakeup line */
    EXTI->RTSR |= EXTI_RTSR_TR22;

    enter_stop_mode();
}

/* THE 32.768 kHz CRYSTAL EARNS ITS PLACE HERE. The internal
   low-speed RC drifts several percent with temperature, so
   a device that wakes "every 10 seconds" wakes every 9.7 to
   10.3. Over a day that is minutes of accumulated error -
   fatal for a synchronised sensor network, irrelevant for a
   thermostat. Know which you are building.

   WAKE TIME COSTS ENERGY TOO. Waking from STANDBY takes
   ~250 us at full run current before your code executes,
   plus PLL lock time. For very short duty cycles STOP can
   beat STANDBY despite its higher sleep current, because
   you spend less time paying the wake penalty. Compute
   both; the crossover is often around a 1-second period. */
```

How it shows up

Symptom	Cause
Sleep current 100x the datasheet figure	Debugger attached — measure detached, on battery
Current varies between identical units	Floating pins; the threshold is near the switching point
Device hangs about once a day	The WFI race — test the flag with interrupts disabled
Timing wrong after waking from STOP	Clock fell back to the internal oscillator; restore the PLL
Variables lost after a deep sleep	STANDBY loses SRAM — it is a reboot, not a resume
Battery life half the calculation	The sleep-current term dominates; find the extra microamps
Steady 700 µA that appears only at night	A pull-up fighting a line left driven low
Wake interval drifts over hours	RTC on the internal RC rather than the 32.768 kHz crystal
Sleep current fine, average current poor	Wake penalty dominates — compare STOP against STANDBY
Cannot get below 50 µA whatever you do	The regulator's quiescent current, not the MCU

Check yourself

- ✓ Name the four sleep modes and the two properties that change between them.
- ✓ Explain why SLEEP mode still allows a DMA transfer to complete.
- ✓ Say what is lost entering STANDBY and what that means for your program's structure.
- ✓ Describe the WFI race and write the correct pattern.
- ✓ Explain why WFI wakes on an interrupt that PRIMASK is masking.
- ✓ Compute average current for a device with a given duty cycle.
- ✓ Explain why sleep current dominates a duty-cycled budget despite being the smallest number.
- ✓ Give three reasons an unused pin costs current, and the best configuration for one.
- ✓ Explain why measurements with a debugger attached are meaningless.
- ✓ Say when STOP can beat STANDBY on average current.

The MPU: memory protection without an MMU

An MPU cannot translate addresses, so it gives you no virtual memory and no isolation between identical address spaces. What it does give you is the ability to turn silent corruption into an immediate, localised fault — which on a system with no `SIGSEGV` is worth a great deal.

What it is and is not

	MMU (Cortex-A)	MPU (Cortex-M)
Translates addresses	Yes — virtual to physical	No. Addresses are physical, always
Granularity	4 kB pages, millions of them	8 or 16 regions, sized by powers of two
Configuration store	Page tables in memory	A handful of registers
Per-process address space	Yes	No — one physical space, different permissions
Cost to reconfigure	TLB maintenance	A few register writes; cheap enough per context switch
What it buys you	Isolation and virtual memory	Fault-on-mistake, and privilege separation

So the MPU is not a security boundary in the way TrustZone is (that is a separate mechanism), and it is not virtual memory. It is a programmable set of rules about which addresses may be read, written or executed, and by whom.

The three things it is genuinely worth doing

```
1. STACK GUARD - the highest-value use by far.

   Place a small, no-access region immediately below each
   stack. Overflow hits it and takes a MemManage fault
   AT THE INSTRUCTION THAT OVERFLOWED, with the faulting
   task identifiable.

   Without it:  the stack grows into .bss, a variable
                changes for no reason, and you spend
                three days.
   With it:     an immediate fault naming the culprit.

   +----------------+ <- stack top
   |  task stack    |
   |       |        |
   |       v        |
   +----------------+ <- stack bottom
   |  GUARD 32 B    |  MPU: no access
   +----------------+
   |  other data    |
   +----------------+

2. EXECUTE NEVER on RAM and peripherals.

   Mark everything that is not flash as XN. A corrupted
   function pointer or a smashed return address then
   faults instead of executing whatever bytes it found.
   This is the single cheapest robustness measure
   available, and it costs one region.

3. READ-ONLY on .rodata and the vector table.

   Catches wild pointer writes at the instant they
   happen rather than when the corrupted value is later
   used.

Everything else - full task isolation, unprivileged
tasks, per-task peripheral permissions - is real but
costs regions and design effort. These three are close
to free.
```

Configuring a region

```
/* ARMv7-M MPU. Regions are numbered, sized by powers of two,
   and must be aligned to their own size - a 1 kB region
   must start on a 1 kB boundary. That constraint drives
   your linker script (chapter 05).                        */

static void mpu_region(uint32_t n, uint32_t base,
                       uint32_t size_log2, uint32_t attr)
{
    MPU->RNR  = n;
    MPU->RBAR = base & MPU_RBAR_ADDR_Msk;
    MPU->RASR = attr
              | ((size_log2 - 1u) << MPU_RASR_SIZE_Pos)
              | MPU_RASR_ENABLE_Msk;
}

/* Access permission field (AP), bits 24-26 of RASR:
     000  no access at all
     001  privileged RW,        unprivileged none
     010  privileged RW,        unprivileged RO
     011  full access           (RW for both)
     101  privileged RO,        unprivileged none
     110  read-only             (RO for both)             */

#define AP_NONE     (0u << 24)
#define AP_PRIV_RW  (1u << 24)
#define AP_FULL     (3u << 24)
#define AP_RO       (6u << 24)
#define XN          (1u << 28)
#define MEM_NORMAL  ((1u << 17) | (1u << 18))  /* C and B  */

void mpu_init(void)
{
    extern uint32_t _stack_guard;   /* from the linker script */

    MPU->CTRL = 0;                  /* disable while editing  */
    __DSB(); __ISB();

    /* 0: all of SRAM, full access, execute never.           */
    mpu_region(0, 0x20000000, 17, AP_FULL | XN | MEM_NORMAL);

    /* 1: the guard band below the stack. Higher-numbered
          regions WIN where they overlap, so this carves a
          hole out of region 0.                            */
    mpu_region(1, (uint32_t) &_stack_guard, 5, AP_NONE);

    /* 2: peripherals, privileged only, execute never.       */
    mpu_region(2, 0x40000000, 29, AP_PRIV_RW | XN);

    /* PRIVDEFENA: privileged code keeps the default memory
       map for anything no region covers. Without it, any
       address you did not explicitly describe faults - which
       is stricter, and a good way to discover you forgot
       the flash region.                                    */
    MPU->CTRL = MPU_CTRL_ENABLE_Msk | MPU_CTRL_PRIVDEFENA_Msk;
    __DSB(); __ISB();
}

/* THE BARRIERS ARE MANDATORY. Enabling the MPU changes how
   the very next fetch is permission-checked. Without DSB
```

```
   and ISB you get a fault whose address makes no sense,
   and which moves when you change unrelated code.         */
```

> **ARMV8-M REDESIGNED THIS, AND FOR THE BETTER**
> ARMv8-M (Cortex-M23/M33/M55) replaces power-of-two sizing with plain base and limit addresses, so a region can be any size at any 32-byte-aligned address. It also moves memory attributes into an indexed `MAIR` register, as on Cortex-A. If you have written v7-M MPU code, the v8-M version is substantially simpler and the alignment gymnastics disappear. Check which you have before copying an example — the register layouts are incompatible.

Per-task protection in an RTOS

```
/* The MPU is cheap enough to reprogram on every context
   switch, which is what FreeRTOS-MPU and Zephyr's userspace
   do. Each task carries its own region set.               */

typedef struct {
    uint32_t rbar;
    uint32_t rasr;
} mpu_region_t;

typedef struct {
    uint32_t     *stack_top;
    mpu_region_t  regions[3];   /* task stack + 2 private   */
} tcb_t;

/* Inside the context switch (chapter 18), after selecting
   the next task and before returning:                     */
static inline void mpu_load(const tcb_t *t)
{
    MPU->CTRL = 0;
    for (int i = 0; i < 3; i++) {
        MPU->RNR  = 4 + i;          /* task regions: 4,5,6  */
        MPU->RBAR = t->regions[i].rbar;
        MPU->RASR = t->regions[i].rasr;
    }
    MPU->CTRL = MPU_CTRL_ENABLE_Msk | MPU_CTRL_PRIVDEFENA_Msk;
    __DSB(); __ISB();
}

/* Roughly 20 cycles. Against a context switch of ~100
   cycles that is affordable, and it buys you a task that
   physically cannot corrupt another task's stack.

   THE HONEST LIMITATION: with 8 regions and 3-4 spent on
   global policy, you have 4-5 per task. A task needing its
   stack, a DMA buffer, two peripherals and a shared queue
   has already run out. Full isolation on Cortex-M is a real
   design constraint, not a checkbox - which is why most
   projects use the MPU for the three high-value cases above
   and stop there.                                          */
```

Reading a MemManage fault

```
/* The MPU reports through MemManage, which is a
   configurable fault - you must ENABLE it, or it escalates
   to HardFault and you lose the diagnostic detail.        */

SCB->SHCSR |= SCB_SHCSR_MEMFAULTENA_Msk;

void MemManage_Handler(void)
{
    uint32_t mmfsr = (SCB->CFSR & 0xFFu);

    /*  bit 0  IACCVIOL   instruction fetch violation - you
                          jumped into an XN region
        bit 1  DACCVIOL   data access violation
        bit 3  MUNSTKERR  fault while unstacking on return
        bit 4  MSTKERR    fault while STACKING on entry -
                          this is your stack guard firing
        bit 7  MMARVALID  MMFAR holds the faulting address  */

    uint32_t addr = (mmfsr & (1u << 7)) ? SCB->MMFAR : 0xFFFFFFFF;

    fault_record(mmfsr, addr, current_task_id());
    __asm volatile ("bkpt #0");
}

/* MSTKERR is the one to recognise on sight: the hardware
   could not push the exception frame because the stack
   pointer had already run into the guard region. That is a
   stack overflow, caught at the moment it happened, naming
   the task. Compare with the alternative - silent
   corruption discovered days later - and the MPU has paid
   for itself with this one bit.                            */
```

How it shows up

Symptom	Cause
Fault immediately on enabling the MPU	A region you need is not covered and `PRIVDEFENA` is off
Fault address makes no sense	Missing `DSB` / `ISB` after writing `CTRL`
Region appears to have no effect	Base address not aligned to the region size — low bits ignored
Two regions overlap unexpectedly	Higher region number wins; check the ordering
MemManage never fires, HardFault does	`MEMFAULTENA` not set — the fault escalated
`MMFAR` holds nonsense	`MMARVALID` is clear; the address was not captured
Stack overflow still silent	Guard region sized smaller than one exception frame — use at least 32 bytes
Example code does not compile for this part	ARMv8-M MPU registers differ from ARMv7-M entirely
Run out of regions adding one task	The real constraint — reduce per-task regions or drop full isolation
Faults appear only after enabling optimisation	Inlining moved a buffer; the region no longer covers it

Check yourself

- ✓ State two things an MPU does not do that an MMU does.
- ✓ Name the three highest-value uses of an MPU and why each is nearly free.

- ✓ Explain how a stack guard region converts a silent bug into an immediate fault.
- ✓ State the alignment rule for an ARMv7-M region and its effect on the linker script.
- ✓ Say which region wins where two overlap.
- ✓ Explain what `PRIVDEFENA` does and the trade-off in leaving it off.
- ✓ Explain why `DSB` and `ISB` are required around MPU changes.
- ✓ Say what `MSTKERR` means and why it is the most useful fault bit.
- ✓ Explain why MemManage faults sometimes appear as HardFaults.
- ✓ Give the practical limit on per-task isolation with 8 regions.

Decoding a HardFault

A HardFault is not a mystery. The hardware records what happened, where, and in which instruction — you simply have to read four registers and know where the stack frame is. This chapter turns the most feared event on Cortex-M into a five-minute procedure.

The fault taxonomy

```
CONFIGURABLE FAULTS - specific, informative, and DISABLED
at reset:

  MemManage   MPU permission violation (chapter 14)
  BusFault    the bus said no: bad address, peripheral
              with no clock, external memory not ready
  UsageFault  undefined instruction, illegal state,
              unaligned access, divide by zero

HARDFAULT - the catch-all. You land here when:

  a) the specific fault is not enabled (the default!), so
     it ESCALATES; or
  b) a fault occurs inside a fault handler; or
  c) a fault occurs at a priority that cannot be
     preempted - "priority escalation".

FIRST ACTION IN ANY NEW PROJECT: enable the specific
faults, so you get the informative one instead of the
catch-all.

  SCB->SHCSR |= SCB_SHCSR_USGFAULTENA_Msk
             |  SCB_SHCSR_BUSFAULTENA_Msk
             |  SCB_SHCSR_MEMFAULTENA_Msk;

This one line converts "HardFault, no information" into
"UsageFault, UNALIGNED, at address X" and saves hours on
every future bug.
```

The Configurable Fault Status Register

```
/* CFSR at 0xE000ED28 packs all three status bytes. */

/*  MMFSR   bits 0-7    MemManage
      0  IACCVIOL   instruction fetch from XN region
      1  DACCVIOL   data access violation
      3  MUNSTKERR  fault unstacking on exception return
      4  MSTKERR    fault stacking on entry = STACK OVERFLOW
      5  MLSPERR    fault during lazy FP stacking
      7  MMARVALID  MMFAR is valid

    BFSR    bits 8-15   BusFault
      8  IBUSERR       instruction bus error
      9  PRECISERR     data error, BFAR holds the address
     10  IMPRECISERR   data error, address UNKNOWN (see below)
     11  UNSTKERR      unstacking error
     12  STKERR        stacking error
     13  LSPERR        lazy FP stacking error
     15  BFARVALID     BFAR is valid

    UFSR    bits 16-31  UsageFault
     16  UNDEFINSTR    undefined instruction
     17  INVSTATE      invalid state - usually the Thumb bit
     18  INVPC         invalid PC on exception return
     19  NOCP          coprocessor absent - FPU not enabled
     24  UNALIGNED     unaligned access
     25  DIVBYZERO     divide by zero (if DIV_0_TRP set)  */

/* The three that account for most real faults:

   PRECISERR + BFARVALID
     A bad pointer, and BFAR names the address. Usually a
     null pointer (address near 0) or a peripheral whose
     clock is off (address in 0x4xxxxxxx).

   IMPRECISERR
     The write was buffered; the core moved on before the
     bus reported the error, so the address is LOST. Fix by
     putting a DSB after suspect writes to force precision
     while debugging, or set DISDEFWBUF in ACTLR to disable
     write buffering entirely - slow, but every fault
     becomes precise.

   MSTKERR
     Stack overflow, caught by an MPU guard region. The most
     valuable single bit on the chip.                      */
```

Reading the stacked frame

The hardware pushed eight registers before entering the handler. The stacked PC is the instruction that faulted, and that is what you actually want.

```
/* Step 1: a naked handler that finds the right stack and
   hands it to C. EXC_RETURN bit 2 says which one.         */

__attribute__((naked)) void HardFault_Handler(void)
{
    __asm volatile (
        "tst   lr, #4            \n"  /* bit 2 of EXC_RETURN */
        "ite   eq                \n"
        "mrseq r0, msp           \n"  /* clear -> MSP        */
        "mrsne r0, psp           \n"  /* set   -> PSP        */
        "b     hardfault_report  \n"
    );
}

/* Step 2: the frame, in the order the hardware pushed it. */
typedef struct {
    uint32_t r0, r1, r2, r3;
    uint32_t r12;
    uint32_t lr;      /* return address of the faulting fn */
    uint32_t pc;      /* THE FAULTING INSTRUCTION          */
    uint32_t psr;
} frame_t;

void hardfault_report(frame_t *f)
{
    uint32_t cfsr = SCB->CFSR;
    uint32_t hfsr = SCB->HFSR;

    /* HFSR bit 30 = FORCED: a configurable fault escalated.
       If this is set, CFSR tells you the real cause.      */

    fault_log_t *log = &g_crash_log;      /* in .noinit    */
    log->magic = 0xDEADBEEF;
    log->pc    = f->pc;
    log->lr    = f->lr;
    log->cfsr  = cfsr;
    log->hfsr  = hfsr;
    log->bfar  = (cfsr & (1u << 15)) ? SCB->BFAR : 0;
    log->mmfar = (cfsr & (1u << 7))  ? SCB->MMFAR : 0;

    __asm volatile ("bkpt #0");   /* halt if debugger present */
    NVIC_SystemReset();           /* otherwise reboot          */
}

/* Step 3: turn the PC into a line of source.

     $ arm-none-eabi-addr2line -e firmware.elf -f -C 0x080012a4
     i2c_read
     /home/user/proj/src/i2c.c:142

   That is the whole procedure. Fault -> PC -> source line,
   in about a minute once the handler is in place.         */
```

PUT THE CRASH LOG IN `.NOINIT` AND REPORT IT AFTER REBOOT

A fault handler that only halts is useful on your desk and useless in the field. Writing the log to a `.noinit` section (chapter 05) means it survives the reset; early in the next boot you check the magic number, transmit or store the record, and clear it. Now a unit that crashed in a customer's cabinet tells you the faulting PC when it comes back up. This costs about forty lines and is the difference between diagnosing a field failure and asking for the unit back.

What actually causes them

Fault bits	Almost always means
`PRECISERR`, BFAR near 0	Null pointer dereference — an `malloc`/lookup that returned NULL and went unchecked
`PRECISERR`, BFAR in 0x4xxxxxxx	Peripheral register accessed with its clock gated off
`IMPRECISERR`	A buffered write went bad earlier; add `DSB` or disable write buffering to localise it
`MSTKERR`	Stack overflow — the MPU guard did its job
`INVSTATE`	Branch to an address with the Thumb bit clear — a corrupted or hand-built function pointer
`UNDEFINSTR`	Executing data: a wild jump, or a corrupted return address
`NOCP`	Float instruction with the FPU not enabled in `CPACR`
`UNALIGNED`	A packed struct member or a cast to a wider type at an odd address
`INVPC`	Corrupted `EXC_RETURN`, usually a context-switch bug
`FORCED` only, CFSR zero	A fault inside a fault handler — check that your handler does nothing that can fault

The imprecise fault, and how to corner it

```
/* IMPRECISERR is the frustrating one: the address is gone
   and the stacked PC points several instructions past the
   real culprit. Three techniques, in order of cost:       */

/* 1. Disable the write buffer. Every fault becomes precise.
      Costs perhaps 10-20% performance - fine for a debug
      build.                                               */
SCnSCB->ACTLR |= SCnSCB_ACTLR_DISDEFWBUF_Msk;

/* 2. Bisect with barriers. Put __DSB() after groups of
      suspect writes; the fault becomes precise at whichever
      barrier follows the bad one.                          */

/* 3. Use the DWT watchpoint unit to trap writes to a
      specific address, which catches the corruptor rather
      than the victim - covered in chapter 16.              */

/* The single most common source: writing to a peripheral
   whose clock you have not enabled. The write is posted,
   the bus rejects it later, and the fault arrives with no
   address. If you see IMPRECISERR in code that just
   initialised a peripheral, check the RCC enable and the
   read-back (chapter 09) before anything else.            */
```

How it shows up

Symptom	Cause
HardFault with CFSR all zero	Fault inside a handler, or a double fault — check `HFSR`
Always HardFault, never a specific fault	Configurable faults not enabled in `SHCSR`
Stacked PC points at innocent code	Imprecise bus fault — disable write buffering to localise
Fault handler itself faults	It touched a peripheral, used floating point, or overflowed the stack further
Debugger shows the handler but no frame	Read the frame via MSP/PSP as the naked handler above does

Symptom	Cause
Fault only in release builds	Inlining changed stack usage, or exposed undefined behaviour
Fault on the first floating-point operation	`NOCP` — enable the FPU in `CPACR` with a barrier after
Fault after a context switch	`INVPC` — `EXC_RETURN` or the saved frame is corrupt
Unit crashes in the field, works on the bench	Add a `.noinit` crash log and report it after reboot
Crash log is empty after reset	Log placed in `.bss`, so startup zeroed it

Check yourself

- ✓ Name the three configurable faults and say why they are usually disabled.
- ✓ Give the one line that makes future faults far more informative.
- ✓ List three ways a fault escalates to HardFault.
- ✓ Explain how to determine which stack pointer holds the exception frame.
- ✓ Give the layout of the stacked frame and say which field you want most.
- ✓ Give the command that turns a faulting PC into a source line.
- ✓ Distinguish `PRECISERR` from `IMPRECISERR` and say why one loses the address.
- ✓ Name two techniques for localising an imprecise fault.
- ✓ Say what `MSTKERR` indicates and what must be configured for it to occur.
- ✓ Explain how to make a crash log survive the reset that follows it.

Debugging bare metal: SWD, breakpoints and semihosting

There is no `gdb` attaching to a process here — there is a two-wire connection to the silicon itself, and a debug unit built into the core. This chapter covers what that unit can do, and the techniques that work when stopping the CPU is not an option.

SWD and what is behind it

```
Two wires plus ground. SWCLK and SWDIO.

HOST                    TARGET
+--------+  SWCLK   +---------------------------------+
| probe  |--------->--| SW-DP  (debug port)            |
| ST-Link|  SWDIO   |    |                            |
| J-Link |<-------->--|    +-- AHB-AP (memory access)  |
| CMSIS  |          |    |      |                     |
| -DAP   |          |    |      +--> the whole bus:   |
+--------+          |    |           RAM, flash,      |
                    |    |           peripherals      |
                    |    |                            |
                    |    +-- core debug registers:    |
                    |         halt, step, breakpoints |
                    |                                 |
                    |    FPB   6 hardware breakpoints |
                    |    DWT   4 watchpoints, cycle   |
                    |          counter, profiling     |
                    |    ITM   instrumentation trace  |
                   +---------------------------------+

The key property: the AHB-AP is a BUS MASTER. The probe
can read and write any address WITHOUT halting the core.
That is what makes live variable watching possible, and
it is the basis of the best debugging techniques here.
```

Breakpoints and watchpoints are finite

```
/* HARDWARE BREAKPOINTS: the FPB unit compares the fetch
   address against a small set of registers. Cortex-M3/M4
   give you SIX. Cortex-M0 gives you FOUR.

   They work in flash, which software breakpoints cannot -
   a software breakpoint replaces the instruction with BKPT,
   and you cannot rewrite flash cheaply. So on an MCU the
   limit is hard: your seventh breakpoint silently does not
   work, or your debugger refuses.

   WATCHPOINTS: the DWT unit, FOUR comparators, trigger on a
   data ADDRESS being read or written. These are the most
   under-used feature in embedded debugging.               */

/* THE CANONICAL USE: "this variable is being corrupted and
   I have no idea by what."                                */

(gdb) watch g_sensor_state
(gdb) continue
/* Hardware Watchpoint 2: g_sensor_state
   Old value = 3
   New value = 51966
   memcpy () at string.c:71                                */

/* Three seconds instead of three days. A watchpoint answers
   "who wrote here" directly, and it is the correct first
   move for any corruption bug rather than the last resort
   it usually is.

   You can also set one from code, which is useful when the
   corruption happens before the debugger connects:        */
DWT->COMP0     = (uint32_t) &g_sensor_state;
DWT->MASK0     = 0;
DWT->FUNCTION0 = (6u << 0);   /* watch for writes */
```

> **HALTING CHANGES THE SYSTEM**
> Stopping the core stops your code, but not the world. A motor keeps spinning, a PWM output freezes at whatever level it held, a UART peer times out, a watchdog fires, and any peripheral with a FIFO overflows. For anything with a control loop or a protocol partner, halting produces a state that could never occur at run time — and you then debug the artefact rather than the bug. This is why the non-stop techniques below matter more on an MCU than on a workstation.

Getting output, cheapest first

```
/* 1. A GPIO PIN AND A SCOPE.  Cost: ~2 cycles.
      The fastest instrumentation that exists. Toggle a pin
      at the top and bottom of an ISR and you can MEASURE
      its duration and jitter directly - something no
      software tool gives you.                              */
#define PROBE_HI()  (GPIOB->BSRR = (1u << 0))
#define PROBE_LO()  (GPIOB->BSRR = (1u << 16))

void TIM2_IRQHandler(void) {
    PROBE_HI();
    /* ... work ... */
    PROBE_LO();
}
/* The scope now shows execution time, frequency, and
   whether two ISRs ever overlap. For real-time work this
   beats every other technique.                             */

/* 2. ITM / SWO.  Cost: ~5 cycles per word.
      A dedicated trace pin. Non-blocking: writes go to a
      FIFO and are dropped if it is full, so your timing is
      barely perturbed.                                     */
static inline void itm_putc(char c) {
    if ((ITM->TCR & 1) && (ITM->TER & 1)) {
        while (ITM->PORT[0].u32 == 0) { }
        ITM->PORT[0].u8 = (uint8_t) c;
    }
}
/* SWO needs the trace clock configured to match the probe's
   expectation - the usual reason "SWO produces garbage".   */

/* 3. RTT (Segger's Real Time Transfer).  Cost: ~1 us.
      A ring buffer in RAM that the probe reads over SWD
      WITHOUT halting - using the AHB-AP's bus mastering.
      No extra pin, works on any part with SWD, and is
      roughly a thousand times faster than semihosting.
      For most projects this is the right answer.           */

/* 4. UART printf.  Cost: 87 us per character at 115200.
      Blocking, and slow enough to change timing profoundly.
      A printf in an ISR that runs at 10 kHz is an instant
      system failure. Use DMA if you must have it.          */

/* 5. SEMIHOSTING.  Cost: MILLISECONDS per call.
      The core executes BKPT 0xAB and the DEBUGGER performs
      the I/O. Convenient, needs no hardware, and:

        - HALTS THE CPU for every character
        - HANGS THE CHIP if no debugger is attached, because
          BKPT with no debugger escalates to HardFault

      That second point ships products that work on the
      bench and brick in the field. Use semihosting for
      early bring-up only, and make sure it cannot survive
      into a release build.                                 */
```

Measuring time exactly

```
/* The DWT cycle counter is a free, exact, 32-bit tally of
   core cycles. It is the correct tool for micro-benchmarks
   and for proving a deadline is met.                      */

static void cycle_counter_init(void)
{
    CoreDebug->DEMCR |= CoreDebug_DEMCR_TRCENA_Msk;
    DWT->LAR   = 0xC5ACCE55;      /* unlock on some parts   */
    DWT->CYCCNT = 0;
    DWT->CTRL  |= DWT_CTRL_CYCCNTENA_Msk;
}

uint32_t t0 = DWT->CYCCNT;
do_the_thing();
uint32_t elapsed = DWT->CYCCNT - t0;   /* wrap-safe subtraction */

/* At 168 MHz one cycle is 5.95 ns, and the counter wraps
   every 25.6 seconds. The subtraction above is correct
   across the wrap for any interval shorter than that.

   Use it to record a WORST CASE rather than an average -
   the maximum is what a deadline cares about:             */
static uint32_t worst;
if (elapsed > worst) { worst = elapsed; }

/* This turns "the ISR is fast enough" from an opinion into
   a number you can assert on. Combined with the priority
   analysis of chapter 08, it is most of what real-time
   verification amounts to on a small system.              */
```

When there is no debugger at all

```
   The situations that actually matter in production:

   FIELD FAILURE          -> .noinit crash log, reported on
                             the next boot (chapter 15)

   TIMING-DEPENDENT BUG   -> GPIO probe + scope; halting
                             would destroy the evidence

   HAPPENS ONCE A WEEK    -> RTT ring buffer left running,
                             read whenever it triggers

   DEBUG PORT DISABLED    -> a fault log over whatever
   (security)                interface the product already
                             has, gated behind
                             authentication

   BOOTS AND DIES BEFORE  -> toggle a pin at successive
   THE PROBE CONNECTS        points in startup; the last
                             one that toggles brackets it.
                             Crude, and it always works.

   The common thread: design the observability in before you
   need it. A product with a crash log, a probe pin and an
   RTT buffer is debuggable in the field. One without them
   requires the unit back on your desk - and it will then
   fail to reproduce.
```

How it shows up

Symptom	Cause
Seventh breakpoint does not trigger	Only six hardware comparators exist; flash cannot hold software breakpoints
Chip hangs when run without a debugger	Semihosting left enabled — `BKPT` escalates to HardFault
Bug disappears while single-stepping	Halting changed the timing; use a GPIO probe instead
Motor runs away when you hit a breakpoint	Peripherals do not halt with the core — configure debug-freeze bits
Watchdog resets during a debug session	Enable the debug freeze for the watchdog in `DBGMCU`
SWO output is garbage	Trace clock frequency does not match the probe's setting
Adding `printf` makes the bug vanish	UART output is slow enough to change the timing you are chasing
Cannot connect after flashing new firmware	Code reconfigured or disabled the SWD pins — use connect-under-reset
Cycle counter always reads zero	`TRCENA` not set, or the DWT lock not written
Corruption source unknown after days of work	A watchpoint would have named it in seconds — use it first

Check yourself

- ✓ Explain what the AHB-AP allows a probe to do without halting the core.
- ✓ State how many hardware breakpoints and watchpoints a typical Cortex-M4 provides.
- ✓ Explain why software breakpoints are not an option in flash.
- ✓ Give the first debugging move for a variable being corrupted by unknown code.
- ✓ List three things that go wrong in the system when you halt the core.
- ✓ Rank GPIO, ITM, RTT, UART and semihosting by cost per output.
- ✓ Explain why semihosting can brick a device in the field.
- ✓ Show how to measure a function's worst-case duration in cycles.
- ✓ Explain why the DWT counter subtraction is safe across its wrap.
- ✓ Name three observability features worth designing in before you need them.

Why you need a scheduler: the superloop and its limits

Most embedded products ship with no RTOS at all, and that is often the right decision. This chapter covers the architectures between "one loop" and "preemptive kernel", what each costs, and the specific symptom that tells you it is time to move up.

The superloop

```
/* The architecture behind more shipped firmware than every
   RTOS combined.                                            */

int main(void)
{
    clock_init();
    gpio_init();
    uart_init();

    for (;;) {
        poll_sensors();
        update_control();
        service_comms();
        update_display();
    }
}

/* WHAT IS GOOD ABOUT IT

   - No concurrency. Nothing preempts anything, so there are
     no races between the four functions and no locks. Every
     data-sharing bug you have ever read about is absent by
     construction.
   - Trivially analysable. The worst-case loop time is the
     sum of four numbers.
   - No kernel: no scheduler RAM, no per-task stacks, no
     kernel code. On a part with 8 kB of RAM this is not a
     preference, it is the only option.
   - Nothing to learn or misconfigure.

   WHAT IS BAD ABOUT IT

   - LATENCY IS THE WHOLE LOOP. If update_display() takes
     40 ms, the control loop cannot respond faster than that,
     no matter how urgent.
   - One slow function degrades everything.
   - Any blocking call is fatal to responsiveness.        */
```

THE RULE THAT MAKES A SUPERLOOP WORK

Every function in the loop must return quickly and never block. That single discipline is what keeps the architecture viable, and it is why superloop code is written as state machines rather than sequences. A function that waits — for a UART byte, an I2C transfer, a sensor conversion — has stolen the whole loop's responsiveness. The moment you cannot express something without waiting, you have found the boundary of the architecture.

Non-blocking state machines

```
/* THE BLOCKING VERSION - 210 ms of the loop, unavailable
   to everything else.                                      */
void read_sensor_blocking(void)
{
    i2c_write(ADDR, CMD_START);
    delay_ms(200);                    /* conversion time    */
    value = i2c_read16(ADDR, REG_DATA);
}

/* THE STATE MACHINE - returns in microseconds, every time. */
typedef enum { S_IDLE, S_WAIT, S_READ } sensor_state_t;

void read_sensor_step(void)
{
    static sensor_state_t st = S_IDLE;
    static uint32_t       t0;

    switch (st) {
    case S_IDLE:
        i2c_write(ADDR, CMD_START);
        t0 = g_ms;
        st = S_WAIT;
        break;

    case S_WAIT:
        if ((int32_t)(g_ms - (t0 + 200)) >= 0) {   /* wrap-safe */
            st = S_READ;
        }
        break;                        /* returns immediately */

    case S_READ:
        value = i2c_read16(ADDR, REG_DATA);
        st = S_IDLE;
        break;
    }
}

/* This is the central skill of superloop design, and it is
   also its central cost: the CONTROL FLOW IS INSIDE OUT.
   The sequence "start, wait, read" is obvious in the
   blocking version and scattered across a switch in the
   non-blocking one. With three such sequences interleaved,
   each with error handling and timeouts, the state count
   multiplies and the code becomes genuinely hard to follow.

   THAT is the real argument for an RTOS. Not performance -
   readability. An RTOS lets you write the blocking version
   and have it be correct, because the kernel switches away
   from a blocked task instead of the whole system waiting. */
```

The spectrum

```
1. SUPERLOOP
   for(;;) { a(); b(); c(); }
   Latency: whole loop.  RAM: one stack.
   Use when: every function is short, few deadlines.

2. SUPERLOOP + INTERRUPTS  <- most shipped firmware
   ISRs handle urgent work; the loop handles the rest;
   they communicate through flags and ring buffers.
   Latency: microseconds for ISR work, whole loop for
            the rest. RAM: one stack + ISR frames.
   Use when: the urgent work is SHORT. This covers a
            remarkable proportion of real products.

3. COOPERATIVE SCHEDULER
   Tasks yield explicitly; the scheduler picks the next.
   No preemption, so still no data races between tasks.
   Latency: longest run between yields.
   RAM: one stack per task.
   Use when: you want task structure but cannot afford
            preemption's synchronisation burden.

4. PREEMPTIVE RTOS
   The kernel switches on a tick or an event; a
   high-priority task runs as soon as it is ready.
   Latency: bounded by the kernel, typically a few us.
   RAM: one stack per task + kernel overhead (2-10 kB).
   Cost: RACES ARE NOW POSSIBLE. Every shared variable
         needs a mutex, a queue, or an atomic.
   Use when: multiple independent deadlines, or blocking
            sequences you want written as sequences.

Moving from 2 to 4 buys bounded latency and pays for it
in synchronisation bugs. That is a real trade and the
step should be deliberate.
```

The pattern that delays the decision

```
/* Most "we need an RTOS" moments are actually "we need to
   get work out of the ISR". Deferred processing solves that
   without a kernel.                                        */

static volatile uint8_t  ring[256];
static volatile uint8_t  head, tail;   /* single producer,  */
                                       /* single consumer   */

void USART1_IRQHandler(void)           /* PRODUCER: ISR     */
{
    uint8_t next = (uint8_t)(head + 1);
    if (next != tail) {                /* drop if full      */
        ring[head] = (uint8_t) USART1->RDR;
        head = next;                   /* publish LAST      */
    }
}

void service_comms(void)               /* CONSUMER: loop    */
{
    while (tail != head) {
        parse_byte(ring[tail]);
        tail = (uint8_t)(tail + 1);
    }
}

/* WHY THIS IS SAFE WITHOUT A LOCK:
   - exactly one writer of head (the ISR), one writer of
     tail (the loop);
   - both are single bytes, so reads and writes are atomic
     on Cortex-M;
   - head is published AFTER the data is written, so the
     consumer never sees an index for a byte not yet
     stored. On Cortex-M's ordering this holds; on a weakly
     ordered core you would need a release barrier here,
     which is exactly what the ARM track's barriers chapter
     is about.
   - the size is a power of two, so the wrap is free and
     the index arithmetic cannot go wrong.

   THE ISR IS NOW ~10 CYCLES. All the parsing happens in the
   loop, at whatever rate it manages, and a burst is
   absorbed by the buffer. This single pattern removes the
   need for an RTOS in a large fraction of designs.        */
```

When to actually move up

Symptom	Fix
One function occasionally takes 50 ms and everything stutters	Split it into a state machine first; an RTOS only hides the problem
ISR does too much work	Deferred processing with a ring buffer — no kernel needed
Two independent deadlines that cannot both be met by one loop	A preemptive RTOS. This is the real reason
Sequential protocols with many wait states become unreadable	A preemptive RTOS, for readability
A third-party stack (TCP/IP, BLE, USB) demands one	Use the one it expects — fighting it costs more than it saves

Symptom	Fix
You want "threads" because it feels more professional	Not a reason. The superloop is a legitimate architecture
RAM is under 8 kB	You cannot afford a preemptive kernel; stay with 1 or 2
Safety certification is required	Either — but the superloop is far easier to argue for, which is why safety-critical code often uses it

AN RTOS DOES NOT MAKE A SLOW SYSTEM FAST

If your control loop misses its deadline because the computation takes too long, adding a scheduler adds overhead and changes nothing. An RTOS reallocates *latency*, letting urgent work preempt unimportant work. It cannot create CPU time. Diagnose which problem you have — measure with the cycle counter from chapter 16 — before assuming a kernel is the answer.

How it shows up

Symptom	Cause
Response time equals the slowest function	Inherent to a superloop — that is the architecture
Display update makes the control loop jitter	A long non-blocking-but-slow function; split it
Serial bytes lost during a long operation	No ring buffer; the ISR had nowhere to put them
Adding a feature broke unrelated timing	Loop time grew; every deadline is coupled to every function
Code became unreadable after three state machines	The genuine signal to consider an RTOS
Races appeared right after adopting an RTOS	Expected — preemption is what you bought; add proper synchronisation
RTOS added and the system got slower	The problem was throughput, not latency
Kernel does not fit in RAM	Below roughly 8 kB a preemptive kernel is not viable
Ring buffer occasionally loses a byte	Index published before the data was written, or a size that is not a power of two
Two producers into one ring buffer corrupt it	The lock-free argument holds for one producer only

Check yourself

- ✓ State the one discipline that makes a superloop viable.
- ✓ Give two genuine advantages of a superloop over an RTOS.
- ✓ Convert a blocking sensor read into a non-blocking state machine.
- ✓ Explain the real cost of state machines, and why it argues for an RTOS.
- ✓ Name the four architectures on the spectrum and the latency of each.
- ✓ Explain why the single-producer ring buffer needs no lock on Cortex-M.
- ✓ Say why the head index must be published after the data.
- ✓ Give the one symptom that genuinely calls for a preemptive kernel.
- ✓ Explain why an RTOS cannot fix a throughput problem.
- ✓ Say what a preemptive kernel costs you that a superloop does not.

The context switch, PendSV and the scheduler core

Twenty instructions separate "a program" from "an operating system". This chapter builds the switch itself: why it must run in PendSV, why PendSV must be the lowest priority in the system, and what the hardware does for you at each end.

The whole idea in one picture

```
A "context" is just a stack with registers saved on it.
Switching tasks means changing which stack PSP points at.

TASK A's STACK              TASK B's STACK
+--------------+            +--------------+
|   xPSR       | \          |   xPSR       | \
|   PC         |  |         |   PC         |  |  hardware
|   LR         |  | pushed  |   LR         |  |  pushes
|   R12        |  | by HW   |   R12        |  |  and pops
|   R3         |  |         |   R3         |  |  these 8
|   R2         |  |         |   R2         |  |
|   R1         |  |         |   R1         |  |
|   R0         | /          |   R0         | /
+--------------+            +--------------+
|   R11        | \          |   R11        | \
|   R10        |  |         |   R10        |  |  YOU push
|   R9         |  | pushed  |   R9         |  |  and pop
|   R8         |  | by YOU  |   R8         |  |  these 8
|   R7         |  |         |   R7         |  |
|   R6         |  |         |   R6         |  |
|   R5         |  |         |   R5         |  |
|   R4         | /          |   R4         | /
+--------------+ <- saved    +--------------+ <- saved
     PSP_A         in TCB        PSP_B         in TCB

THE SWITCH:
  1. hardware pushed 8 registers onto A's stack already
  2. push R4-R11 onto A's stack
  3. save PSP into A's TCB
  4. pick the next task
  5. load PSP from B's TCB
  6. pop R4-R11 from B's stack
  7. BX to EXC_RETURN - hardware pops B's 8 registers

Step 7 returns to whatever B was doing, because B's PC is
in the frame the hardware just popped. There is no jump
to task B; you simply return from an interrupt into it.
```

Why PendSV

```
PendSV is an exception whose ONLY purpose is deferring
work to the lowest priority. Set its priority to 0xFF -
the lowest possible - and it runs only when no other
exception is active.

WITHOUT PendSV, switching directly in SysTick:

  SysTick fires -> switch to task B -> return
  But an interrupt was PREEMPTED by SysTick and is still
  ACTIVE. Returning into task B while that interrupt's
  frame is on the stack corrupts the exception nesting,
  and the core takes a UsageFault (INVPC) or worse.

WITH PendSV:

time -->
  UART IRQ  |====================|
  SysTick        |==|  (sets PendSV pending, returns)
  PendSV                         |=====|  switch here
  task B                               |=========

  Every other exception drains first. PendSV runs last,
  with a clean nesting state, and the switch is safe.

THE RULE: PendSV must be the LOWEST priority exception in
the system. If anything is lower, it can be preempted by
the switch and the same corruption returns.

  NVIC_SetPriority(PendSV_IRQn, 0xFF);
  NVIC_SetPriority(SysTick_IRQn, 0xFE);

This is why every Cortex-M RTOS port uses PendSV. It is
not a convention; it is the only correct place.
```

The switch, in full

```
/* This is a complete, working PendSV handler for ARMv7-M.
   'naked' because we must control every instruction - a
   compiler prologue would corrupt the frame we are building. */

__attribute__((naked)) void PendSV_Handler(void)
{
    __asm volatile (
    /* --- SAVE the outgoing task ------------------------- */
    "   mrs   r0, psp              \n"  /* current task SP   */
    "   cbz   r0, restore          \n"  /* first switch: no  */
                                        /* task to save      */
    "   subs  r0, r0, #32          \n"  /* room for R4-R11   */
    "   stm   r0, {r4-r11}         \n"

    "   ldr   r1, =current_tcb     \n"
    "   ldr   r2, [r1]             \n"  /* r2 = current TCB  */
    "   str   r0, [r2]             \n"  /* TCB->sp = r0      */
                                        /* sp is at offset 0 */

    /* --- CHOOSE the next task --------------------------- */
    "restore:                      \n"
    "   push  {lr}                 \n"  /* EXC_RETURN        */
    "   bl    scheduler_next       \n"  /* C function        */
    "   pop   {lr}                 \n"

    /* --- RESTORE the incoming task ---------------------- */
    "   ldr   r1, =current_tcb     \n"
    "   ldr   r2, [r1]             \n"
    "   ldr   r0, [r2]             \n"  /* r0 = TCB->sp      */
    "   ldm   r0, {r4-r11}         \n"
    "   adds  r0, r0, #32          \n"
    "   msr   psp, r0              \n"

    "   isb                        \n"
    "   bx    lr                   \n"  /* EXC_RETURN ->     */
                                        /* hardware unstacks */
    );
}

/* Points worth dwelling on:

   - scheduler_next() is ordinary C. It reads the ready list
     and writes current_tcb. All the policy lives there; the
     assembly is pure mechanism.

   - LR must be preserved across the call, hence push/pop.
     It holds EXC_RETURN, and losing it means you cannot
     return from the exception at all.

   - 'sp' is deliberately the FIRST member of the TCB, so
     the offset is zero and the assembly needs no knowledge
     of the struct layout. Every RTOS does this.

   - This code does NOT save the FP registers. On a part
     with an FPU where two tasks use float, add:

         tst   lr, #0x10          @ EXC_RETURN bit 4
         it    eq
         vstmdbeq r0!, {s16-s31}  @ save if FP frame present
```

```
    and the mirror on restore. Omitting it is the classic
    bug that only appears when a second task uses float
    (chapter 02).                                          */
```

Manufacturing the first stack frame

A task that has never run has no saved context. You fabricate one that looks exactly like a real switch, so the first restore starts it at its entry point.

```
uint32_t *task_stack_init(uint32_t *stack_top,
                          void (*entry)(void *), void *arg)
{
    /* 8-byte alignment is required by AAPCS. */
    uint32_t *sp = (uint32_t *)((uint32_t) stack_top & ~7u);

    /* --- the frame the HARDWARE will pop, in its order --- */
    *(--sp) = 0x01000000u;            /* xPSR: THUMB BIT SET */
    *(--sp) = (uint32_t) entry & ~1u; /* PC                  */
    *(--sp) = (uint32_t) task_exit;   /* LR: where a task    */
                                      /* goes if it returns  */
    *(--sp) = 0x12121212u;            /* R12                 */
    *(--sp) = 0x03030303u;            /* R3                  */
    *(--sp) = 0x02020202u;            /* R2                  */
    *(--sp) = 0x01010101u;            /* R1                  */
    *(--sp) = (uint32_t) arg;         /* R0 = first argument */

    /* --- the registers WE pop ---------------------------- */
    *(--sp) = 0x11111111u;            /* R11                  */
    *(--sp) = 0x10101010u;            /* R10                  */
    *(--sp) = 0x09090909u;            /* R9                   */
    *(--sp) = 0x08080808u;            /* R8                   */
    *(--sp) = 0x07070707u;            /* R7                   */
    *(--sp) = 0x06060606u;            /* R6                   */
    *(--sp) = 0x05050505u;            /* R5                   */
    *(--sp) = 0x04040404u;            /* R4                   */

    return sp;                        /* store in TCB->sp    */
}

/* THREE THINGS THAT MUST BE RIGHT:

   1. xPSR MUST have bit 24 (T) set. Clear it and the core
      faults with INVSTATE the instant the task starts
      (chapter 02). This is the single most common bug when
      writing a scheduler from scratch.

   2. The PC entry must have bit 0 CLEAR here, even though
      function pointers carry it set. The hardware takes the
      T state from xPSR, not from the PC, and a set bit 0 in
      the stacked PC is architecturally unpredictable.

   3. LR should point at a function that handles a task
      returning. A task that falls off the end otherwise
      branches to whatever 0x0E0E0E0E-style filler you put
      there. Make it explicit:                              */

static void task_exit(void)
{
    task_delete(current_tcb);
    for (;;) { }        /* never reached; the switch away
                           happens inside task_delete       */
}

/* The recognisable filler values are a debugging gift: in a
   fault dump, seeing 0x07070707 in R7 tells you instantly
   that this task has never actually run.                   */
```

Starting the scheduler

```
/* Getting from main() - running on MSP, privileged - into
   the first task on PSP is a one-time bootstrap.          */

void scheduler_start(void)
{
    NVIC_SetPriority(PendSV_IRQn,  0xFF);   /* lowest       */
    NVIC_SetPriority(SysTick_IRQn, 0xFE);

    current_tcb = scheduler_highest_ready();

    /* Point PSP at the first task's frame, skipping the 8
       registers the hardware will pop for us.              */
    __set_PSP((uint32_t) current_tcb->sp + 32);

    /* Switch Thread mode to PSP. */
    __set_CONTROL(0x02);
    __ISB();                    /* MANDATORY (chapter 03)   */

    systick_init(1000);         /* 1 kHz tick               */

    /* Jump to the task entry. From here the only way back
       into main() is a bug.                                */
    void (*entry)(void *) = current_tcb->entry;
    entry(current_tcb->arg);
}

/* THE TICK. SysTick does no switching itself - it accounts
   for time and, if that changed who should run, requests a
   PendSV. That request is a single register write:        */

void SysTick_Handler(void)
{
    g_ticks++;
    if (scheduler_tick()) {                 /* returns 1 if
                                               a switch is
                                               needed      */
        SCB->ICSR = SCB_ICSR_PENDSVSET_Msk;  /* request it  */
    }
}

/* Any code, including any ISR, can request a switch with
   that one store. A UART handler that unblocks a waiting
   task does exactly this, which is how a task becomes
   runnable "immediately" rather than at the next tick.    */
```

> **MECHANISM AND POLICY ARE CLEANLY SEPARATED**
>
> The assembly above is the entire *mechanism*, and it never changes. Round-robin, fixed-priority preemptive, rate-monotonic, or EDF are all just different implementations of `scheduler_next()` — ordinary C, testable on a host, with no assembly involved. When you read FreeRTOS or Zephyr, this is the seam to look for first: `port.c` holds the twenty instructions, and everything else is policy on top.

How it shows up

Symptom	Cause
Fault the instant the first task starts	T bit not set in the fabricated xPSR
UsageFault with `INVPC`	Corrupted `EXC_RETURN` — usually LR not preserved across the scheduler call
Fault when switching from inside an ISR	Switching somewhere other than PendSV
Rare corruption under interrupt load	PendSV is not the lowest priority exception
Variables corrupt across switches	R4–R11 not saved, or the wrong number of words adjusted
Corruption only when two tasks use float	FP registers not saved; test `EXC_RETURN` bit 4
Task runs once then the system dies	Task returned; LR in the fabricated frame pointed at nothing valid
First switch faults, later ones work	No null check for "no outgoing task" on the very first entry
Scheduler never runs after `CONTROL` write	Missing `ISB`
Registers full of `0x07070707` in a dump	The task never ran — your filler values telling you exactly that

Check yourself

- ✓ State which eight registers the hardware saves and which eight you must save.
- ✓ Explain why the switch must happen in PendSV rather than SysTick.
- ✓ Say what priority PendSV must have and what breaks otherwise.
- ✓ Explain why returning with `EXC_RETURN` starts the new task.
- ✓ Explain why `sp` is the first member of the TCB.
- ✓ List the three things that must be right in a fabricated first frame.
- ✓ Say why the stacked PC must have bit 0 clear while function pointers have it set.
- ✓ Explain why LR must be pushed around the call to the scheduler.
- ✓ Give the single store that requests a context switch from any ISR.
- ✓ Explain the mechanism/policy split and where to find it in a real RTOS.

RTOS primitives: queues, semaphores and ISR-safe APIs

The concurrency track covers mutexes and condition variables in general. What is different on a microcontroller is that half your concurrency is with interrupts rather than tasks — and an interrupt cannot block, which changes every API it touches.

Why ISRs need their own API

```
A TASK that cannot proceed BLOCKS: the kernel removes it
from the ready list and switches to someone else. It
resumes later, where it left off.

AN ISR CANNOT DO THIS. There is nothing to switch to -
an interrupt is not a schedulable entity, it has no TCB
and no stack of its own to preserve. Blocking in an ISR
would suspend whatever task happened to be interrupted,
which is not the ISR and has done nothing wrong.

So every kernel splits its API:

  xQueueSend(q, &item, portMAX_DELAY)
     may block. TASK ONLY.

  xQueueSendFromISR(q, &item, &woken)
     never blocks; returns pdFAIL if full. ISR ONLY.

And the FromISR variants have an extra job: reporting
whether they made a higher-priority task ready, so the
ISR can request a context switch on the way out.

  void UART_IRQHandler(void)
  {
      BaseType_t woken = pdFALSE;
      xQueueSendFromISR(q, &byte, &woken);
      portYIELD_FROM_ISR(woken);   /* sets PendSV if so  */
  }

Omit that last line and the woken task waits until the
next tick - up to a full millisecond of latency, for no
reason, and only under some timings. It is a classic
intermittent-latency bug.
```

THE PRIORITY CEILING FOR ISR CALLS

An ISR may only call kernel APIs if its priority is at or below `configMAX_SYSCALL_INTERRUPT_PRIORITY` (chapter 08). Above that line the kernel's `BASEPRI` critical sections do not block it, so it can interrupt the kernel mid-update and corrupt a list. The damage appears much later, in unrelated code. Keep `configASSERT` enabled in development — FreeRTOS checks this on every ISR API call and catches the mistake immediately rather than three weeks later.

The queue is the primitive you want

```
/* A queue copies data and handles the blocking, the
   waking, and the mutual exclusion in one object. Prefer
   it over a shared buffer plus a semaphore almost always. */

QueueHandle_t sensor_q;

void app_init(void)
{
    sensor_q = xQueueCreate(10, sizeof(sensor_reading_t));
}

/* PRODUCER - an ISR. */
void ADC_IRQHandler(void)
{
    BaseType_t woken = pdFALSE;
    sensor_reading_t r = { .ts = g_ticks, .value = ADC1->DR };

    /* Never blocks. If the queue is full the reading is
       dropped, and that is a DESIGN DECISION you should
       make explicitly - count the drops.                  */
    if (xQueueSendFromISR(sensor_q, &r, &woken) != pdTRUE) {
        g_dropped++;
    }
    portYIELD_FROM_ISR(woken);
}

/* CONSUMER - a task. */
void sensor_task(void *arg)
{
    sensor_reading_t r;
    for (;;) {
        if (xQueueReceive(sensor_q, &r, pdMS_TO_TICKS(100))) {
            process(&r);
        } else {
            handle_sensor_timeout();     /* the timeout is  */
        }                                /* not optional    */
    }
}

/* WHY A QUEUE BEATS A SHARED BUFFER:
   - it COPIES, so there is no lifetime question about the
     producer's data;
   - the blocking receive means the consumer uses zero CPU
     while waiting, which is what lets the system sleep;
   - full and empty are handled once, correctly, rather
     than in every caller;
   - a timeout is available, so a stuck producer becomes a
     reported error rather than a hang.

   THE COST IS THE COPY. For large items, queue a POINTER
   to a buffer from a pool instead - but then you own the
   lifetime again, and the pool needs its own discipline. */
```

Semaphores, mutexes, and the difference that matters

```
/* BINARY SEMAPHORE - signalling. No owner.
   Use for: ISR says "something happened" to a task.        */
SemaphoreHandle_t data_ready;

void DMA1_IRQHandler(void) {
    BaseType_t woken = pdFALSE;
    xSemaphoreGiveFromISR(data_ready, &woken);
    portYIELD_FROM_ISR(woken);
}
void consumer(void *a) {
    for (;;) {
        xSemaphoreTake(data_ready, portMAX_DELAY);
        process_buffer();
    }
}

/* COUNTING SEMAPHORE - resource pools, or counting events
   that may arrive faster than they are consumed.          */
SemaphoreHandle_t slots = xSemaphoreCreateCounting(5, 5);

/* MUTEX - mutual exclusion. HAS AN OWNER, and that is the
   whole difference.                                       */
SemaphoreHandle_t spi_lock = xSemaphoreCreateMutex();

void use_spi(void) {
    xSemaphoreTake(spi_lock, portMAX_DELAY);
    spi_transfer(...);
    xSemaphoreGive(spi_lock);
}

/* BECAUSE A MUTEX HAS AN OWNER IT CAN DO TWO THINGS A
   SEMAPHORE CANNOT:

   1. PRIORITY INHERITANCE. While a low-priority task holds
      a mutex a high-priority task wants, the holder is
      temporarily raised to the waiter's priority. This
      bounds priority inversion - the failure that reset
      Mars Pathfinder (see the concurrency track, chapter
      15). A binary semaphore has no owner, so it cannot
      do this, and using one for mutual exclusion silently
      gives up the protection.

   2. RECURSION. xSemaphoreCreateRecursiveMutex lets the
      owner take it again without deadlocking.

   THE RULE:
     mutual exclusion -> MUTEX, always.
     signalling       -> BINARY SEMAPHORE.
   Using a semaphore as a lock is the single most common
   RTOS design error, and it works fine until the day a
   priority inversion costs you a deadline.

   NEVER take a mutex from an ISR. There is no owner to
   record, no priority to inherit, and no way to block.
   There is deliberately no xSemaphoreTakeFromISR.         */
```

Task notifications: the cheap path

```
/* A direct-to-task signal with no separate kernel object.
   Roughly 45x faster than a semaphore and it costs no RAM
   beyond a word already in the TCB.                        */

void DMA1_IRQHandler(void)
{
    BaseType_t woken = pdFALSE;
    vTaskNotifyGiveFromISR(dma_task_handle, &woken);
    portYIELD_FROM_ISR(woken);
}

void dma_task(void *arg)
{
    for (;;) {
        /* pdTRUE = clear the count on exit, i.e. act as a
           binary semaphore.                                 */
        if (ulTaskNotifyTake(pdTRUE, pdMS_TO_TICKS(500))) {
            process_buffer();
        } else {
            dma_timeout_recovery();
        }
    }
}

/* THE LIMITATION that decides whether you can use it: a
   notification targets ONE SPECIFIC TASK. There is no
   broadcast and no queueing of senders. If two tasks might
   wait for the same event, or the sender does not know the
   receiver, use a semaphore or queue.

   For the extremely common ISR-to-one-task pattern -
   which is most of embedded signalling - notifications are
   strictly better and under-used.                          */
```

Choosing

Need	Use	Not
ISR hands data to one task	Queue, or notification if the data fits in a word	A global plus a flag
ISR signals one known task	Task notification	Semaphore — slower, more RAM
ISR signals whichever task is waiting	Binary semaphore	Notification — it needs a specific target
Protect a shared peripheral	Mutex	Binary semaphore — no priority inheritance
Limit concurrent users of a pool	Counting semaphore	A hand-rolled counter
Wait for several conditions	Event group	Several semaphores and polling
Producer/consumer of large buffers	Queue of pointers plus a pool	Queue of the buffers themselves — the copy cost
Mutual exclusion inside an ISR	Disable interrupts briefly	Any kernel object — ISRs cannot block

How it shows up

Symptom	Cause
Latency sometimes a full tick longer than expected	`portYIELD_FROM_ISR` omitted after a `FromISR` call
Kernel lists corrupt after hours of running	An ISR above the syscall priority called a kernel API
`configASSERT` fires on an ISR API call	Exactly that, caught early — fix the priority
System hangs when a task holds a lock	Blocking API called from an ISR, or a mutex taken recursively without the recursive variant
A high-priority task misses deadlines under load	Binary semaphore used for mutual exclusion — no priority inheritance
Queue sends fail silently under burst load	Queue full and the return value ignored — count the drops
Task waits forever	`portMAX_DELAY` with no timeout path; a lost signal is unrecoverable
Data corrupt when queueing pointers	Producer freed or reused the buffer before the consumer finished
Notification lost when two tasks wait	Notifications target one task only
Everything works until a third task is added	An implicit assumption about who runs when — usually a missing lock

Check yourself

- ✓ Explain why an ISR cannot block, in terms of what blocking actually does.
- ✓ Say what the extra out-parameter of a `FromISR` call is for.
- ✓ Describe the bug caused by omitting `portYIELD_FROM_ISR`.
- ✓ State the priority rule for ISRs that call kernel APIs, and why.
- ✓ Give three reasons a queue beats a shared buffer plus a flag.
- ✓ State the two capabilities a mutex has that a binary semaphore lacks.
- ✓ Explain why there is no `xSemaphoreTakeFromISR`.
- ✓ Say when a task notification is the right choice and when it is not.
- ✓ Explain the risk of queueing pointers rather than data.
- ✓ Give the correct mutual-exclusion mechanism inside an ISR.

Stack sizing, priority assignment and inversion

Two numbers per task decide whether a system is reliable: how much stack it gets and what priority it runs at. Both are usually guessed. This chapter replaces the guessing with measurement for one and a theorem for the other.

Why stack sizing is hard here

```
ON LINUX                        ON AN MCU

8 MB default stack              512 bytes to 4 kB
Guard page: overflow            Nothing. The stack grows
traps immediately               into the next task's data
Grows on demand                 Fixed at creation
One bad recursion = crash       One bad recursion = a
                                variable changes somewhere
                                else, hours later

WHAT CONSUMES A TASK'S STACK:

  local variables in every frame of the deepest call path
+ saved registers at each call (up to 32 bytes)
+ compiler temporaries and spills
+ ONE EXCEPTION FRAME if an interrupt lands while this
  task runs (32 bytes, or 104 with FP state)
+ the nesting depth of interrupts, IF they run on the
  task stack

That last point is why PSP matters (chapter 03): with
tasks on PSP and interrupts on MSP, interrupt nesting is
charged to ONE main stack you size once, rather than to
every task stack separately. Without the split, every
task stack must carry the worst-case interrupt depth.
```

Measuring, three ways

```
/* 1. WATERMARKING - the standard technique. Fill the stack
      with a pattern at creation; later, count how much is
      still intact.                                          */

void stack_fill(uint32_t *base, size_t words)
{
    for (size_t i = 0; i < words; i++) {
        base[i] = 0xA5A5A5A5u;
    }
}

size_t stack_unused_words(const uint32_t *base, size_t words)
{
    size_t i = 0;
    while (i < words && base[i] == 0xA5A5A5A5u) {
        i++;
    }
    return i;      /* words never touched */
}

/* FreeRTOS does this for you:
     uxTaskGetStackHighWaterMark(handle)
   returns the minimum free WORDS ever observed. Print it
   for every task after a long soak test under peak load.

   THE TRAP: this reports the worst case SEEN, not the
   worst case POSSIBLE. If the error path that calls
   snprintf never ran during your test, its 200 bytes are
   not in the number. Exercise error paths deliberately
   before trusting a watermark.                           */

/* 2. STATIC ANALYSIS - the only way to bound the worst
      case rather than sample it.                            */

/*   $ arm-none-eabi-gcc -fstack-usage ...
     produces a .su file per translation unit:

       i2c.c:142:5:i2c_read    48   static
       parse.c:88:1:parse_msg  120  dynamic,bounded

     Combine with the call graph and you get a true maximum.
     Tools: puncover, StackAnalyzer, or a script over the
     .su files plus objdump's call graph.

     "dynamic" entries - alloca, VLAs, recursion - cannot be
     bounded. That is the real reason those constructs are
     banned in embedded coding standards, MISRA included.  */

/* 3. THE MPU GUARD - not a measurement, a safety net.
      A no-access region below each stack (chapter 14)
      converts overflow into an immediate, attributable
      fault. Use it alongside watermarking, not instead:
      watermarking tells you how close you are, the guard
      catches the day you are wrong.                         */
```

A PRACTICAL PROCEDURE

Start every task at 1 kB. Run the system under peak load, including every error path you can provoke, for long enough to see the rare cases. Read the high-water marks. Set each stack to the observed maximum plus 50%, rounded up to a sensible boundary. Add an MPU guard region. Re-check the watermarks in every release. This is not elegant, but it is what reliable products actually do, and it beats both guessing and the false confidence of a single short test run.

Assigning priorities: rate-monotonic

```
/* There IS a right answer for periodic tasks, and it is a
   theorem rather than an opinion.

   RATE-MONOTONIC: the shorter the period, the higher the
   priority. Not "the more important" - the more FREQUENT.

   Liu and Layland proved this is OPTIMAL among fixed-
   priority schemes: if any fixed-priority assignment can
   meet all deadlines, rate-monotonic can.

   SCHEDULABILITY TEST:

     U = sum(Ci / Ti)          C = worst-case compute time
                               T = period

     Schedulable if U <= n(2^(1/n) - 1)

       n=1  100%      n=4  75.7%
       n=2  82.8%     n=5  74.3%
       n=3  78.0%     n->inf  69.3%   (ln 2)

   WORKED EXAMPLE:

     control loop   T=10 ms   C=2 ms   ->  0.200
     sensor read    T=50 ms   C=5 ms   ->  0.100
     comms          T=100 ms  C=20 ms  ->  0.200
     display        T=200 ms  C=30 ms  ->  0.150
                                           -----
                                    U =    0.650

     n=4 bound is 0.757, and 0.650 <= 0.757, so ALL
     deadlines are met with priorities in period order:
     control > sensor > comms > display.

   The bound is SUFFICIENT, not necessary: above it a system
   may still be schedulable, but you must then do exact
   response-time analysis rather than the simple test.

   THIS IS WHY 69% IS A FAMOUS NUMBER. A fixed-priority
   real-time system that must always meet deadlines cannot
   safely be planned above roughly 70% CPU utilisation.
   Designing for 95% is designing for missed deadlines.   */
```

Priority inversion, in miniature

```
   The concurrency track covers this fully (chapter 15).
   The MCU-specific points:

   1. USE A MUTEX, NOT A SEMAPHORE, for mutual exclusion.
      Only a mutex has an owner, so only a mutex can
      implement priority inheritance (chapter 19).

   2. CHECK IT IS ENABLED.
        configUSE_MUTEXES = 1
      Without it xSemaphoreCreateMutex is compiled out and
      you silently get a binary semaphore.

   3. THE ISR IS ALWAYS HIGHEST.
      Any interrupt outranks every task, always. A long ISR
      delays your most urgent task no matter what priority
      you gave it. Interrupt duration is therefore part of
      your schedulability arithmetic, not separate from it:

        U = sum(Ci/Ti) for tasks
          + sum(Ei/Pi) for INTERRUPTS

      A 20 us ISR at 10 kHz is 20% utilisation before any
      task runs. This is routinely forgotten, and it is
      why a system that analyses as 65% utilised misses
      deadlines at 85%.

   4. MEASURE C, DO NOT ESTIMATE IT.
      Use the DWT cycle counter (chapter 16) and record the
      MAXIMUM, not the average. A deadline cares only about
      the worst case, and the worst case is often 5-10x the
      typical one because of a cache miss, a flash wait
      state, or an error path.
```

Rules that survive contact with real systems

Rule	Why
Fewer tasks is better	Each costs a stack, a TCB and a synchronisation surface. Two tasks that always run together should be one
Never `portMAX_DELAY` without a recovery path	A lost signal becomes a permanently blocked task and a silent partial failure
The idle task must actually run	If it never does, you are at 100% CPU and have no margin — and cannot sleep
Keep ISRs to tens of microseconds	They preempt every task; their duration is everyone's jitter
Do not use priority to express importance	Priority expresses urgency. An important but slow task belongs low
Avoid dynamic creation after startup	Fragmentation and unbounded failure modes; create everything up front
One priority per task, no two equal	Equal priorities mean round-robin, which makes response times depend on arrival order
Budget for 70%, not 95%	The rate-monotonic bound — above it, deadlines are not guaranteed

How it shows up

Symptom	Cause
A variable in another task changes spontaneously	Stack overflow — add MPU guards and check watermarks
Crash only when an error path runs	That path's stack usage was never in the watermark
Stack usage cannot be bounded statically	Recursion, `alloca` or a VLA — remove them
Deadlines missed at 85% CPU despite analysis	Interrupt time not included in the utilisation sum
System analyses fine but misses deadlines rarely	Worst-case compute times estimated rather than measured
High-priority task blocked by a low one	Priority inversion — use a mutex and enable inheritance
Mutex behaves like a semaphore	`configUSE_MUTEXES` is 0
A task never runs again	Blocked on `portMAX_DELAY` for a signal that was lost
Response time depends on which task started first	Two tasks at equal priority round-robining
Device cannot enter sleep	The idle task never runs; something polls instead of blocking

Check yourself

- ✓ List five things that consume a task's stack.
- ✓ Explain why running tasks on PSP reduces total stack requirements.
- ✓ Describe watermarking and state its one important limitation.
- ✓ Explain why recursion and VLAs are banned by embedded coding standards.
- ✓ State the rate-monotonic priority rule in one sentence.
- ✓ Give the schedulability bound for four tasks and apply it to an example.
- ✓ Explain why 69% is a significant number for fixed-priority systems.
- ✓ Show how interrupt time enters the utilisation calculation.
- ✓ Explain why you must measure worst-case rather than average compute time.
- ✓ Give three rules for priority assignment and justify each.

FreeRTOS in practice

FreeRTOS is the most widely deployed RTOS in the world, and its whole configuration surface is one header file. This chapter covers the settings that matter, the port layer where chapter 18's assembly actually lives, and the handful of mistakes that account for most FreeRTOS bugs.

The shape of it

```
FreeRTOS-Kernel/
  tasks.c        the scheduler, ready lists, TCBs
  queue.c        queues, semaphores, mutexes - all one
                 implementation underneath
  timers.c       software timers, run by a daemon task
  event_groups.c
  list.c         the intrusive linked list everything uses
  portable/
    GCC/ARM_CM4F/
      port.c     <- chapter 18's PendSV_Handler lives here
      portmacro.h   critical sections, BASEPRI, yields
    MemMang/
      heap_1.c   allocate only, never free
      heap_2.c   free, no coalescing (deprecated)
      heap_3.c   wraps malloc/free
      heap_4.c   free WITH coalescing  <- the usual choice
      heap_5.c   heap_4 across several memory regions

Your project adds exactly one file:
  FreeRTOSConfig.h

Reading tasks.c and port.c is genuinely worthwhile - it
is a few thousand lines of clear C, and after chapter 18
the port layer will look familiar rather than magical.
```

The settings that matter

```
/* FreeRTOSConfig.h - the ones worth understanding. */

#define configCPU_CLOCK_HZ            168000000
#define configTICK_RATE_HZ            1000    /* 1 ms tick   */
#define configMAX_PRIORITIES          8
#define configMINIMAL_STACK_SIZE      128     /* WORDS = 512 B */
#define configTOTAL_HEAP_SIZE         (24 * 1024)

/* ---- THE TWO THAT CAUSE THE MOST TROUBLE ---------------- */

/* Must match the silicon. Read it from the vendor header;
   do not assume 4 (chapter 08).                            */
#define configPRIO_BITS               4

/* The ISR priority ceiling. Interrupts numerically BELOW
   this value (= higher urgency) must NEVER call an API.

   Note this is the RAW value, shifted into the implemented
   bits - not the CMSIS-style logical priority.             */
#define configLIBRARY_MAX_SYSCALL_INTERRUPT_PRIORITY  5
#define configMAX_SYSCALL_INTERRUPT_PRIORITY \
    (configLIBRARY_MAX_SYSCALL_INTERRUPT_PRIORITY << (8 - configPRIO_BITS))

/* ---- KEEP THESE ON IN DEVELOPMENT ----------------------- */

#define configASSERT(x) if ((x) == 0) { taskDISABLE_INTERRUPTS(); \
                                        for (;;); }
/* configASSERT catches: API called from a too-high-priority
   ISR, blocking call from an ISR, invalid priority, and
   several others - each of which is otherwise a bug that
   appears hours later in unrelated code. Turning it off to
   save flash is a false economy until you are shipping.    */

#define configCHECK_FOR_STACK_OVERFLOW   2   /* pattern check */
#define configUSE_MALLOC_FAILED_HOOK     1
#define configUSE_MUTEXES                1   /* or mutexes    */
                                             /* become binary */
                                             /* semaphores    */
#define configUSE_TRACE_FACILITY         1
#define configGENERATE_RUN_TIME_STATS    1

void vApplicationStackOverflowHook(TaskHandle_t t, char *name)
{
    /* Record to .noinit and reset - chapter 15. */
    strncpy(g_crash.task, name, sizeof(g_crash.task));
    g_crash.magic = CRASH_MAGIC_STACK;
    NVIC_SystemReset();
}
```

THREE LINES THAT MUST BE IN YOUR CONFIG, AND USUALLY ARE NOT

The FreeRTOS Cortex-M port installs its own SVC, PendSV and SysTick handlers. If your vendor's startup file also defines them — and ST's does — you get either a duplicate-symbol error or, worse, the vendor's stubs silently winning. The standard fix is these three defines, which redirect the names:

```
#define vPortSVCHandler      SVC_Handler
#define xPortPendSVHandler   PendSV_Handler
#define xPortSysTickHandler  SysTick_Handler
```

Omitting them produces a system that builds cleanly and never switches tasks. It is the most common first-time FreeRTOS failure by a wide margin.

Static allocation

```
/* Dynamic creation is convenient and, in a system that must
   not fail, a liability: xTaskCreate can return failure at
   run time, and a heap can fragment. Static allocation
   moves every failure to LINK TIME.                        */

#define configSUPPORT_STATIC_ALLOCATION  1
#define configSUPPORT_DYNAMIC_ALLOCATION  0   /* no heap at all */

static StaticTask_t  sensor_tcb;
static StackType_t   sensor_stack[512];

static StaticQueue_t reading_q_buf;
static uint8_t       reading_q_storage[10 * sizeof(reading_t)];

void app_init(void)
{
    TaskHandle_t h = xTaskCreateStatic(
        sensor_task, "sensor", 512, NULL, 3,
        sensor_stack, &sensor_tcb);
    configASSERT(h != NULL);        /* cannot actually fail  */

    QueueHandle_t q = xQueueCreateStatic(
        10, sizeof(reading_t), reading_q_storage, &reading_q_buf);
    configASSERT(q != NULL);
}

/* With dynamic allocation disabled entirely, the linker
   reports your true RAM usage and there is no heap to
   exhaust, fragment, or analyse. Safety-critical and
   certified projects require this; ordinary projects
   benefit from it and rarely bother.

   The cost: everything must be sized at compile time, which
   is a constraint you would want anyway on a part with
   64 kB of RAM.                                            */
```

The idle task and tickless sleep

```
/* The idle hook runs whenever nothing else is ready. It is
   where a battery-powered product sleeps.                  */

void vApplicationIdleHook(void)
{
    __WFI();       /* wake on the next interrupt or tick    */
}

/* But a 1 kHz tick wakes the core a thousand times a second
   whether or not there is work - which on a battery product
   dominates the current budget (chapter 13).

   TICKLESS IDLE fixes this: the kernel computes how long
   until the next task is due, programs a wake-up timer for
   exactly that, sleeps deeply, and then CORRECTS the tick
   count on waking so time still adds up.                   */

#define configUSE_TICKLESS_IDLE            1
#define configEXPECTED_IDLE_TIME_BEFORE_SLEEP  5   /* ticks   */

/* The generic implementation uses SysTick, which does not
   run in STOP mode. For real low power you supply
   portSUPPRESS_TICKS_AND_SLEEP() yourself, using the RTC as
   the wake source. Vendor ports usually provide one - check
   before writing it.

   Verify with an ammeter, not by reading the code. The
   difference between "tickless is enabled" and "tickless is
   working" is a factor of a hundred in average current, and
   only a current trace tells you which you have.           */
```

Debugging aids worth enabling

```
/* 1. RUN-TIME STATS - where the CPU actually goes. */
vTaskGetRunTimeStats(buf);
/*   Task        Abs Time      % Time
     IDLE        14893921      89%
     sensor        892134       5%
     comms         721002       4%
     display       201883       1%

   Needs a timer 10-100x faster than the tick, wired up via
   portCONFIGURE_TIMER_FOR_RUN_TIME_STATS. Worth the effort:
   it answers "is there headroom" definitively, and the idle
   percentage is your real margin.                          */

/* 2. HIGH WATER MARKS - chapter 20's measurement. */
UBaseType_t free_words = uxTaskGetStackHighWaterMark(handle);

/* 3. TASK LIST */
vTaskList(buf);
/*   Name      State  Prio  Stack  Num
     sensor    B      3     412    1      B = Blocked
     comms     R      2     288    2      R = Ready
     display   B      1     501    3      S = Suspended

   A task stuck in R that never becomes X (running) is a
   priority problem. A task in B forever is a lost signal.  */

/* 4. TRACEALYZER / SystemView
   Instrumented trace showing every switch, block and ISR on
   a timeline. This is how you SEE priority inversion rather
   than infer it, and it is worth the licence cost on any
   project where timing is the difficulty.                  */
```

How it shows up

Symptom	Cause
Scheduler starts, no task ever runs	Handler name defines missing; the vendor's stub handlers won
Hard fault as soon as the scheduler starts	Interrupt priority grouping not all-preemption; call `NVIC_SetPriorityGrouping(3)`
`configASSERT` fires in `port.c`	Usually an ISR priority above the syscall ceiling — read the line, it is precise
Mutexes give no priority inheritance	`configUSE_MUTEXES` is 0
`xTaskCreate` returns failure	Heap exhausted — raise `configTOTAL_HEAP_SIZE` or go static
Random corruption, no pattern	Stack overflow — enable `configCHECK_FOR_STACK_OVERFLOW` 2
Tickless enabled but current unchanged	Generic implementation using SysTick, which stops in deep sleep
Timings wrong by a constant factor	`configCPU_CLOCK_HZ` does not match the actual clock
Software timer callbacks are late	The timer daemon task's priority is too low
Everything works until heap fragments	`heap_2` in use — switch to `heap_4` or static

Check yourself

✓ Name the five heap implementations and say which is the usual choice.

- ✓ Explain what the three handler-name defines do and what happens without them.
- ✓ Explain the difference between the logical and raw forms of the syscall priority.
- ✓ Give four things `configASSERT` catches.
- ✓ Explain why `configUSE_MUTEXES` being 0 is dangerous rather than merely limiting.
- ✓ State two advantages of static allocation over dynamic.
- ✓ Explain what tickless idle does and why it needs tick correction.
- ✓ Say why enabling tickless idle may not reduce current, and how to check.
- ✓ Describe what run-time stats tell you that stack watermarks do not.
- ✓ Interpret a task shown as Blocked forever in `vTaskList`.

Zephyr in practice

Zephyr is not FreeRTOS with more features — it is a different proposition. FreeRTOS gives you a scheduler and leaves the system to you; Zephyr gives you a whole operating system with device drivers, a device tree, a build system and a networking stack, and asks you to work its way.

The essential difference

	FreeRTOS	Zephyr
What it is	A scheduler and IPC primitives	A complete RTOS with drivers, subsystems and a build system
Hardware description	Your code, vendor HAL	Device tree, as in Linux
Configuration	One header	Kconfig, as in Linux
Build	Your Makefile or IDE	`west` plus CMake
Drivers	Vendor HAL, per-chip	Portable driver API across all supported chips
Footprint	~6 kB flash minimum	~20 kB minimum, realistically much more
Learning curve	An afternoon	Genuinely a week or two
Board support	You write it	750+ boards supported upstream

The trade is legibility against leverage. FreeRTOS is small enough to read in a day; you will never wonder what it is doing. Zephyr abstracts the hardware so completely that the same application source builds for an nRF52, an STM32 and a RISC-V part — but understanding why something does not work means learning device tree, Kconfig and the driver model first.

Device tree: hardware as data

```
/* Zephyr borrows the device tree wholesale from Linux (see
   the Linux track, chapter 18). Hardware is DESCRIBED, not
   coded.                                                    */

/* boards/arm/my_board/my_board.dts */
/ {
    aliases {
        status-led = &led0;
        sensor-bus = &i2c1;
    };

    leds {
        compatible = "gpio-leds";
        led0: led_0 {
            gpios = <&gpioa 5 GPIO_ACTIVE_HIGH>;
            label = "Status LED";
        };
    };
};

&i2c1 {
    status = "okay";
    clock-frequency = <I2C_BITRATE_FAST>;

    bme280@76 {
        compatible = "bosch,bme280";
        reg = <0x76>;
    };
};

/* The application never names a pin, a port or a register: */

#include <zephyr/drivers/gpio.h>

static const struct gpio_dt_spec led =
    GPIO_DT_SPEC_GET(DT_ALIAS(status_led), gpios);

int main(void)
{
    if (!gpio_is_ready_dt(&led)) {
        return -ENODEV;
    }
    gpio_pin_configure_dt(&led, GPIO_OUTPUT_ACTIVE);

    for (;;) {
        gpio_pin_toggle_dt(&led);
        k_msleep(500);
    }
}

/* This source is portable across every supported board. Move
   to different silicon and you change the .dts, not the
   application. That is the leverage Zephyr is selling, and
   on a product line with several hardware variants it is a
   very large saving.

   The macros are resolved at COMPILE time - devicetree.h is
   generated from the .dts during the build - so there is no
   runtime parsing cost, unlike Linux.                       */
```

> **DEVICE TREE ERRORS ARE COMPILE-TIME AND CRYPTIC**
> A missing node or a typo'd alias produces an error inside a generated header, pointing at a macro expansion rather than your `.dts`. The habit that saves hours: after any device tree change, read `build/zephyr/zephyr.dts` — the fully merged and resolved tree — rather than your fragment. It shows what the build actually concluded, including everything the SoC's own `.dtsi` files contributed.

The kernel API

```
/* Same concepts as chapter 19, different spelling, and
   static definition is idiomatic rather than exceptional.  */

#include <zephyr/kernel.h>

/* Threads. Note K_THREAD_DEFINE creates it at BOOT with no
   runtime allocation - the Zephyr default style.           */
K_THREAD_DEFINE(sensor_tid, 1024, sensor_thread,
                NULL, NULL, NULL,
                5,        /* priority: LOWER = more urgent,
                             the OPPOSITE of FreeRTOS and the
                             same as the NVIC. Cooperative
                             priorities are negative.        */
                0, 0);

/* Message queue - the queue of chapter 19. */
K_MSGQ_DEFINE(sensor_q, sizeof(struct reading), 10, 4);

void sensor_thread(void *a, void *b, void *c)
{
    struct reading r;
    while (1) {
        if (k_msgq_get(&sensor_q, &r, K_MSEC(100)) == 0) {
            process(&r);
        }
    }
}

/* From an ISR - note there is no separate FromISR API.
   Zephyr's calls detect ISR context themselves and require
   only that you pass K_NO_WAIT.                            */
void my_isr(const void *arg)
{
    struct reading r = read_hw();
    k_msgq_put(&sensor_q, &r, K_NO_WAIT);   /* must not block */
}

/* Other primitives, mapping onto chapter 19:
     k_mutex      mutex, with priority inheritance
     k_sem        counting semaphore
     k_event      event flags
     k_fifo/lifo  linked-list queues, no copy
     k_work       deferred work to a system workqueue -
                  the standard "get it out of the ISR"
                  mechanism, equivalent to a Linux workqueue

   K_FOREVER, K_NO_WAIT and K_MSEC(n) replace FreeRTOS's
   portMAX_DELAY and tick arithmetic, and are type-safe.    */
```

Kconfig and west

```
# prj.conf — application configuration, Kconfig syntax
CONFIG_GPIO=y
CONFIG_I2C=y
CONFIG_SENSOR=y
CONFIG_BME280=y
CONFIG_LOG=y
CONFIG_LOG_DEFAULT_LEVEL=3
CONFIG_MAIN_STACK_SIZE=2048
CONFIG_THREAD_ANALYZER=y          # stack watermarks, ch 20
CONFIG_THREAD_ANALYZER_AUTO=y

# Build and flash
$ west build -b nucleo_f429zi app/
$ west flash
$ west debug

# Inspect what Kconfig actually resolved to — symbols have
# dependencies, and one you set may be silently disabled
# because its prerequisite is off. This file is the truth:
$ less build/zephyr/.config

# Change configuration interactively, which also SHOWS the
# dependency that is blocking a symbol:
$ west build -t menuconfig

/* The most common Zephyr frustration by far: "I set
   CONFIG_FOO=y and it had no effect." Almost always FOO
   depends on BAR which is not enabled, and Kconfig silently
   dropped it. menuconfig's search (press /) tells you the
   dependency chain immediately.                          */
```

Choosing between them

Situation	Choice
32 kB flash, one board, fixed scope	FreeRTOS, or no RTOS at all
You need BLE, Wi-Fi, USB or TCP/IP	Zephyr — the stacks are integrated and maintained
Several hardware variants of one product	Zephyr — the device tree pays for itself quickly
Vendor supplies a FreeRTOS BSP and examples	FreeRTOS — swimming with the current
You must read and justify every line for certification	FreeRTOS, or a certified kernel like SAFERTOS
Long-lived product needing upstream security fixes	Zephyr — an active foundation and a real release cadence
Team already knows Linux device tree and Kconfig	Zephyr — the concepts transfer directly
You need it working this week	FreeRTOS

How it shows up

Symptom	Cause
`CONFIG_FOO=y` has no effect	An unmet Kconfig dependency; check `build/zephyr/.config`
Cryptic error inside a generated header	Device tree node or alias missing — read the merged `zephyr.dts`
`gpio_is_ready_dt` returns false	The controller's node has `status = "disabled"`

Symptom	Cause
Device not found at runtime	Driver not enabled in Kconfig even though the node exists
Priorities behave backwards versus FreeRTOS	Zephyr uses lower = more urgent, and negative for cooperative
Kernel call hangs the system from an ISR	A timeout other than `K_NO_WAIT` passed in interrupt context
Build succeeds, board does nothing	Wrong board target — the binary is for different silicon
Binary far larger than expected	Logging, shell or asserts left enabled in a release build
Stack overflow in the system workqueue	Long work items — raise `CONFIG_SYSTEM_WORKQUEUE_STACK_SIZE`
Cannot find where a pin is configured	It is in the pinctrl node of the board's `.dts`, not in code

Check yourself

- ✓ State the essential difference in what FreeRTOS and Zephyr each provide.
- ✓ Explain what the device tree buys you and what it costs.
- ✓ Say why Zephyr's device tree has no runtime parsing cost, unlike Linux's.
- ✓ Give the file to read when a device tree change does not behave as expected.
- ✓ State Zephyr's priority direction and contrast it with FreeRTOS.
- ✓ Explain why Zephyr has no separate `FromISR` API.
- ✓ Name the Zephyr equivalent of deferring work out of an ISR.
- ✓ Describe the most common Kconfig frustration and how to diagnose it.
- ✓ Give three situations that clearly favour Zephyr.
- ✓ Give three situations that clearly favour FreeRTOS.

Project: bare-metal bring-up, every register explained

A complete firmware image with no vendor HAL, no CMSIS beyond the register definitions, and no library you did not write. It boots, configures its clocks, drives a UART, samples an ADC over DMA, and reports. Roughly 400 lines, and every one of them is explainable.

What it does, and what to run it on

```
TARGET: STM32F411 "Black Pill" or any Nucleo-F4. The
register names below are F4-family; the STRUCTURE ports
to any Cortex-M with a page of renaming.

NO HARDWARE? QEMU emulates several Cortex-M boards:

  qemu-system-arm -M netduinoplus2 -cpu cortex-m4 \
                  -nographic -kernel firmware.elf

The QEMU model implements the core, NVIC, SysTick and
USART faithfully. It does NOT model the RCC clock tree
or the ADC properly, so parts 3 and 6 need real silicon
to be meaningful. Everything else runs.

BEHAVIOUR:
  - boots to a 100 MHz PLL clock
  - blinks an LED at exactly 1 Hz from SysTick
  - prints a banner and a reading once a second over
    UART at 115200
  - samples an internal temperature sensor via DMA
  - reports its own stack high-water mark
  - decodes and reports any fault, then resets

BUILD:
  $ make
  $ arm-none-eabi-size firmware.elf
  $ st-flash write firmware.bin 0x08000000
```

The files

```
project/
  Makefile
  linker.ld          chapter 05
  startup.c          chapters 04, 06 - vectors + Reset_Handler
  main.c             the application
  clock.c            chapter 09
  uart.c             chapters 10, 12
  adc_dma.c          chapter 12
  fault.c            chapter 15
  stm32f411.h        register definitions (from CMSIS, or
                     write the handful you need)

/* Makefile - the whole thing. */

    txb[txhead] = (uint8_t) c;
    txhead = next;                  /* publish AFTER the data */
    USART2->CR1 |= USART_CR1_TXEIE; /* kick the ISR           */
}

void USART2_IRQHandler(void)
{
    if (USART2->SR & USART_SR_TXE) {
        if (txtail != txhead) {
            USART2->DR = txb[txtail];
            txtail = (uint16_t)((txtail + 1u) & (TXBUF - 1u));
        } else {
            USART2->CR1 &= ~USART_CR1_TXEIE;   /* nothing left */
        }
    }
}

/* uart_putc returns in nanoseconds unless the buffer is
   full, so main() is never blocked by 87 us per character.
   The single-producer/single-consumer argument from chapter
   17 applies: one writer of txhead, one of txtail.        */
```

Part 4: main

```
/* main.c */

volatile uint32_t g_ms;
void SysTick_Handler(void) { g_ms++; }

int main(void)
{
    /* SysTick: 1 kHz from whatever clock we ended up with. */
    SysTick->LOAD = (SystemCoreClock / 1000u) - 1u;
    SysTick->VAL  = 0;
    SysTick->CTRL = 7u;      /* core clock | tick int | enable */

    RCC->AHB1ENR |= RCC_AHB1ENR_GPIOCEN;
    (void) RCC->AHB1ENR;
    GPIOC->MODER = (GPIOC->MODER & ~(3u << 26)) | (1u << 26);

    uart_init(115200);
    adc_dma_init();

    fault_report_previous();     /* chapter 15's .noinit log */

    uart_puts("\r\n=== bare-metal bring-up ===\r\n");
    if (g_clock_degraded) {
        uart_puts("WARNING: HSE failed, running on HSI\r\n");
    }
    uart_printf("SYSCLK  %lu Hz\r\n", SystemCoreClock);

    uint32_t next = 0;
    for (;;) {
        if ((int32_t)(g_ms - next) >= 0) {   /* wrap-safe    */
            next += 500u;
            GPIOC->ODR ^= (1u << 13);       /* 1 Hz square   */

            uart_printf("t=%lus  temp=%d.%02u C  stack_free=%u\r\n",
                        g_ms / 1000u,
                        adc_temperature_c() / 100,
                        (unsigned)(adc_temperature_c() % 100),
                        (unsigned) stack_unused_bytes());
        }
        __WFI();      /* sleep until SysTick or the UART ISR */
    }
}

/* The __WFI() is the point. This loop uses well under 1% of
   the CPU: everything is interrupt- or DMA-driven, and the
   core sleeps between events. That is what all twenty-two
   preceding chapters were building toward.                */
```

Exercises, in order of difficulty

- **Verify the clock.** Route MCO to a pin and confirm 100 MHz with a scope, or time the LED against a stopwatch for 60 seconds. Do not trust `SystemCoreClock`.
- **Break the vector table.** Corrupt the first word, flash it, and observe the difference between running under the debugger and cold booting (chapter 04).
- **Provoke each fault.** Write to address 0, execute from RAM, divide by zero with `DIV_0_TRP` set. Confirm your handler decodes each correctly (chapter 15).

- **Measure the ISR.** Toggle a spare pin at the top and bottom of the UART handler and read its duration on a scope. Then compute the maximum baud rate this design supports.
- **Add the MPU stack guard** from chapter 14, then deliberately recurse until it fires.
- **Convert the UART to DMA** (chapter 12) and compare CPU load at 921600 baud.
- **Make it sleep properly.** Move to STOP mode between samples with an RTC wake-up, and measure the average current. Aim for under 10 µA.

How it shows up

Symptom	Cause
Nothing at all happens	Vector table missing — check `KEEP()` and the map file
Works under debugger, dead on power-up	Vector table word 0 wrong; the debugger set SP itself
UART emits garbage	`BRR` computed from the wrong clock — check the APB prescaler
UART emits nothing	GPIO alternate function number wrong; verify AF7 in the *datasheet*
LED blinks at half or double rate	`SystemCoreClock` does not match reality; measure it
Board hangs before the banner	A wait loop with no timeout — this project's `wait_flag` exists for that
Fault handler itself faults	It called `uart_printf`, which touches a peripheral; log to `.noinit` instead
Stack free reads as the whole stack	Fill pattern written after the stack was already used
ADC reads a constant value	DMA buffer in unreachable RAM, or the ADC clock is gated
Everything works, current is 20 mA	No `__WFI()`, or a debugger still attached

Check yourself

- ✓ Explain every line of the vector table, including the designated initialisers.
- ✓ Say why `SystemInit()` is called after the `.data` copy.
- ✓ Explain how a cracked crystal leaves this firmware still able to report the fault.
- ✓ Justify computing `BRR` from `SystemCoreClock` rather than a constant.
- ✓ Explain why `uart_putc` does not block in normal operation.
- ✓ Explain why `txhead` is published after the data byte is stored.
- ✓ Explain the wrap-safe comparison in the main loop.
- ✓ Say what `__WFI()` achieves here and what would break without it.
- ✓ Explain why `-Werror` is a reasonable default on bare metal.
- ✓ Describe how you would verify the clock frequency without trusting any variable.

Project: a preemptive RTOS from scratch

About 300 lines gives you a real preemptive kernel: fixed-priority scheduling, blocking delays, mutexes with priority inheritance, and message queues. Writing one is the fastest way to stop finding FreeRTOS mysterious, because every line of it will be something you have already decided.

Scope

```
WHAT IT HAS                    WHAT IT DELIBERATELY LACKS

fixed-priority preemption      dynamic task creation
round-robin within a priority  task deletion
k_sleep with a tick wheel      software timers
counting semaphores            event groups
mutexes + priority inheritance recursive mutexes
fixed-size message queues      stack overflow detection
idle task with WFI             (add the MPU guard from
                                chapter 14 as an exercise)

Everything is STATICALLY allocated - tasks are declared at
compile time. That removes an entire class of failure and
keeps the code readable.

Target: any Cortex-M3/M4. Runs under QEMU:
  qemu-system-arm -M netduinoplus2 -cpu cortex-m4 \
                  -nographic -kernel kernel.elf
```

Part 1: the task control block

```
/* kernel.h */

#define MAX_TASKS      8
#define MAX_PRIO       8

typedef enum {
    T_READY, T_RUNNING, T_BLOCKED, T_SLEEPING
} tstate_t;

typedef struct tcb {
    uint32_t     *sp;          /* MUST be offset 0 - ch 18   */
    tstate_t      state;
    uint8_t       prio;        /* current, may be inherited  */
    uint8_t       base_prio;   /* what it was declared with  */
    uint32_t      wake_tick;
    struct tcb   *next;        /* ready or wait list link    */
    void         *wait_obj;    /* what it is blocked on      */
    uint32_t     *stack_base;
    uint32_t      stack_words;
    const char   *name;
} tcb_t;

extern tcb_t *current_tcb;     /* the assembly reads this    */

/* Ready lists: one singly-linked list per priority, plus a
   bitmap so "highest ready priority" is one instruction.   */
static tcb_t   *ready[MAX_PRIO];
static uint32_t ready_bits;

static inline int highest_ready(void)
{
    /* CLZ: count leading zeros. Bit 31 = priority 0.
       31 - clz gives the highest set bit, and one
       instruction replaces a loop. This is exactly the
       trick FreeRTOS uses in its optimised port.           */
    return ready_bits ? (31 - __builtin_clz(ready_bits)) : -1;
}

static void ready_add(tcb_t *t)
{
    t->state = T_READY;
    t->next  = ready[t->prio];
    ready[t->prio] = t;
    ready_bits |= (1u << t->prio);
}

static tcb_t *ready_pop(int prio)
{
    tcb_t *t = ready[prio];

{
    uint32_t s = enter_critical();

    if (!m->locked) {
        m->locked = 1;
        m->owner  = current_tcb;
        exit_critical(s);
        return;
    }

    /* THE INHERITANCE. If we outrank the owner, lend it our
       priority so it cannot be preempted by anything in
       between - which is exactly the unbounded inversion of
       the concurrency track, chapter 15.                   */
    if (current_tcb->prio > m->owner->prio) {
        /* remove, re-prioritise, re-insert: the owner may be
           sitting in a ready list under its old priority.   */
        ready_remove(m->owner);
        m->owner->prio = current_tcb->prio;
        if (m->owner->state == T_READY) { ready_add(m->owner); }
    }

    current_tcb->state    = T_BLOCKED;
    current_tcb->wait_obj = m;
```

```
    current_tcb->next     = m->waiters;
    m->waiters            = current_tcb;

    exit_critical(s);
    yield();
}

void mutex_unlock(mutex_t *m)
{
    uint32_t s = enter_critical();

    /* Drop any inherited priority first. */
    current_tcb->prio = current_tcb->base_prio;

    tcb_t *best = NULL, **link = &m->waiters;
    for (tcb_t **p = &m->waiters; *p; p = &(*p)->next) {
        if (!best || (*p)->prio > best->prio) { best = *p; link = p; }
    }

    if (best) {
        *link     = best->next;
        m->owner  = best;
        ready_add(best);
    } else {
        m->locked = 0;
        m->owner  = NULL;
    }

    exit_critical(s);
    yield();
}
```

WHERE THIS KERNEL IS HONESTLY SIMPLIFIED

Inheritance here is one level deep: if the owner is itself blocked on a second mutex, the boost does not propagate down the chain. Real kernels handle that transitively. The kernel also has no deadlock detection, no timeout on `mutex_lock`, and an O(n) tick. Each is a deliberate omission you can now see the shape of — which is the point of writing one. Read FreeRTOS's `xTaskPriorityInherit` afterwards and it will read as a careful version of code you have already written.

Part 5: it running

```
static uint32_t s_hi[256], s_lo[256], s_idle[64];
static tcb_t    t_hi, t_lo, t_idle;
static mutex_t  bus;

static void hi_task(void *a)
{
    for (;;) {
        k_sleep(100);
        uint32_t t0 = DWT->CYCCNT;
        mutex_lock(&bus);
        use_shared_bus();
        mutex_unlock(&bus);
        record_max(DWT->CYCCNT - t0);   /* blocking time     */
    }
}

static void lo_task(void *a)
{
    for (;;) {
        mutex_lock(&bus);
        busy_work(50);           /* hold it a long time      */
        mutex_unlock(&bus);
        k_sleep(10);
    }
}

static void idle_task(void *a) { for (;;) { __WFI(); } }

int main(void)
{
    clock_init();  uart_init(115200);  cycle_counter_init();

    task_create(&t_hi,   "hi",   hi_task,   NULL, 5, s_hi,   256);
    task_create(&t_lo,   "lo",   lo_task,   NULL, 2, s_lo,   256);
    task_create(&t_idle, "idle", idle_task, NULL, 0, s_idle,  64);

    NVIC_SetPriority(PendSV_IRQn,  0xFF);   /* LOWEST - ch 18 */
    NVIC_SetPriority(SysTick_IRQn, 0xFE);

    current_tcb = ready_pop(highest_ready());
    current_tcb->state = T_RUNNING;
    __set_PSP((uint32_t) current_tcb->sp + 32);
    __set_CONTROL(0x02);
    __ISB();                                /* MANDATORY      */

    SysTick->LOAD = (SystemCoreClock / 1000u) - 1u;
    SysTick->VAL  = 0;
    SysTick->CTRL = 7u;

    ((void (*)(void *)) hi_task)(NULL);      /* never returns  */
    for (;;) { }
}

/* THE EXPERIMENT WORTH RUNNING: add a medium-priority task
   at priority 3 that does nothing but busy_work. Then
   disable the inheritance block in mutex_lock and compare
   the recorded worst-case blocking time of hi_task.

   Without inheritance it grows without bound as the medium
   task takes more CPU - that is unbounded priority
```

```
    inversion, reproduced on your own desk in about twenty
    lines. Re-enable inheritance and it collapses to the
    length of lo_task's critical section. Seeing that number
    change is worth more than any amount of reading about
    Mars Pathfinder.                                        */
```

Exercises

- **Reproduce unbounded inversion** as described above, and plot worst-case blocking against the medium task's CPU share.
- **Add a message queue** with blocking send and receive, and the wake-on-send that makes a waiting receiver runnable immediately rather than at the next tick.
- **Replace the O(n) tick** with a delta list sorted by wake time.
- **Add the MPU stack guard** from chapter 14, one region per task, reloaded in `scheduler_next`. Then recurse until it fires and confirm the fault names the right task.
- **Add FP context saving** and verify with two tasks doing float maths that corruption appears without it and vanishes with it.
- **Make inheritance transitive** across a chain of two mutexes.
- **Measure the switch.** Toggle a pin in PendSV and count cycles with DWT. Compare against FreeRTOS on the same board.

How it shows up

Symptom	Cause
Fault the moment the first task starts	T bit missing from the fabricated xPSR
Faults after the first switch, not before	No null check for the first entry, or `sp` not at TCB offset 0
Corruption under interrupt load	PendSV not the lowest priority exception
Scheduler picks the wrong task	`ready_bits` not cleared when a list empties
Everything hangs when all tasks sleep	No idle task — `highest_ready()` returns −1
System stops after ~49 days of ticks	Tick comparison not wrap-safe
A woken task waits up to a full tick	No `yield()` after making it ready
Priority stays boosted after unlock	`base_prio` not restored in `mutex_unlock`
Inheritance has no effect	Owner left in a ready list under its old priority — remove and re-add
Corruption once two tasks use `float`	FP registers not saved in the switch

Check yourself

- ✓ Explain why `sp` must be the first member of the TCB.
- ✓ Explain the CLZ trick for finding the highest ready priority.
- ✓ Say why an idle task is structurally required, not merely convenient.
- ✓ Explain why critical sections use BASEPRI rather than PRIMASK.
- ✓ Describe what priority inheritance does and why the owner must be re-inserted.
- ✓ Explain why `base_prio` is stored separately from `prio`.

- ✓ Say why the tick's sleep scan is wrap-safe and what it costs at scale.
- ✓ Describe the experiment that demonstrates unbounded priority inversion.
- ✓ Name three ways this kernel is simplified relative to FreeRTOS.
- ✓ Explain why `yield()` is safe to call from an ISR.

TRACK

Peripherals & buses

The serial protocols an embedded engineer touches daily — UART, SPI, I2C, CAN, USB and MIPI — at the bit level, and how to debug them.

21 chapters

How a peripheral attaches: registers, IRQs and DMA

Every serial controller in this track — UART, SPI, I2C, CAN, USB — presents the same four surfaces to software. Learn the shape once and each new peripheral becomes a question of which bits, not how it works.

The universal shape

```
FOUR SURFACES, and every peripheral has all four.

1. CONTROL registers     you write: enable, mode, speed
2. STATUS registers      you read:  ready, busy, error
3. DATA registers        the actual bytes, in and out
4. INTERRUPT enables     which status bits raise an IRQ

+-------------------------------------------------+
|  CPU        writes CR1  ---------------+        |
|             reads  SR   <----------+   |        |
|             writes DR   -------+   |   |        |
+--------------------------------|--|---|--------+
                                 v  |   v
+-------------------------------------------------+
|  PERIPHERAL                                     |
|    +---------+   +-----------+   +------------+ |
|    | control |   |  SHIFT    |   |   status   | |
|    | logic   |-->|  REGISTER |-->|   flags    | |
|    +---------+   +-----------+   +------------+ |
|                       |               |         |
+-----------------------|---------------|---------+
                        v               v
                      PINS            NVIC

THE SHIFT REGISTER IS THE HEART. A serial peripheral is a
parallel-to-serial converter with timing logic: you write
a byte, it clocks the bits out one at a time at the
configured rate. Everything else is bookkeeping around
that.

THE DOUBLE BUFFER that confuses everyone:

  DR (data register)  -->  SHIFT REGISTER  --> pin

Two stages. "TXE" (transmit empty) means DR is free for
the NEXT byte - the previous one is still shifting out.
"TC" (transmission complete) means the shift register is
empty too and the line is genuinely idle.

Get these confused and you disable the transmitter, or
turn off an RS-485 driver, while the last byte is still
on the wire. Truncated final characters are ALWAYS this
bug (chapter 14).
```

Reading a register map

```
/* Vendor headers give you a struct; the reference manual
   gives you the meaning. Both are needed.                  */

typedef struct {
    volatile uint32_t CR1;    /* control 1: enable, parity   */
    volatile uint32_t CR2;    /* control 2: stop bits, addr  */
    volatile uint32_t CR3;    /* control 3: flow, DMA        */
    volatile uint32_t BRR;    /* baud rate divisor           */
    volatile uint32_t GTPR;
    volatile uint32_t RTOR;
    volatile uint32_t RQR;
    volatile uint32_t ISR;    /* status - READ ONLY          */
    volatile uint32_t ICR;    /* interrupt CLEAR             */
    volatile uint32_t RDR;    /* receive data  - READ ONLY   */
    volatile uint32_t TDR;    /* transmit data - WRITE ONLY  */
} USART_TypeDef;

/* FOUR CLEARING IDIOMS, and you must know which applies:

   1. WRITE 1 TO CLEAR (w1c)
        USART1->ICR = USART_ICR_TCCF;
      Writing 0 does nothing. Writing ~0 clears everything -
      an easy accidental bug.

   2. READ TO CLEAR
        (void) USART1->RDR;        // clears RXNE
      Dangerous: a debugger displaying the register CLEARS
      THE FLAG. "It works until I watch it" is this.

   3. READ ONE, THEN READ/WRITE ANOTHER
        status = USART1->SR; (void) USART1->DR;
      The classic F1-era sequence. Skipping the first read
      leaves the flag set forever.

   4. WRITE 0 TO CLEAR (rc_w0)
        TIM2->SR = ~TIM_SR_UIF;
      Note the complement: write ones everywhere EXCEPT the
      bit you are clearing. Writing 0 directly would clear
      every flag, including ones set since you read.

   Using the wrong idiom gives you an interrupt that fires
   forever, or a flag you never see. Check the "Access"
   column in the reference manual's register table - it is
   there for exactly this.                                  */
```

> **READ-TO-CLEAR REGISTERS AND DEBUGGERS DO NOT MIX**
> If a status flag clears on read, then a debugger's register view, a watch expression, or a memory window covering that address will clear it behind your back. The peripheral then behaves differently under observation. When a bug vanishes the moment you look at a peripheral register, this is nearly always why — close the register view and use a variable you copy the status into instead.

The initialisation order that always works

```
/* Get this order wrong and the peripheral silently ignores
   you. It is the same for every controller in this track.  */

/* 1. ENABLE THE PERIPHERAL CLOCK, and read it back.
      Without a clock, register writes are discarded and
      reads return zero (mcu chapter 09).                   */
RCC->APB1ENR |= RCC_APB1ENR_USART2EN;
(void) RCC->APB1ENR;

/* 2. CONFIGURE THE PINS - mode, alternate function, speed,
      pull. Do this BEFORE enabling the peripheral, or the
      first edge it drives comes from an unconfigured pin
      (mcu chapter 10).                                     */
gpio_config_af(GPIOA, 2, AF7, PUSHPULL, FAST);

/* 3. CONFIGURE THE PERIPHERAL WHILE IT IS DISABLED.
      Most controllers latch configuration only when going
      from disabled to enabled, and many IGNORE writes to
      config fields while enabled - silently.               */
USART2->CR1 = 0;                      /* ensure disabled   */
USART2->BRR = brr_for(115200);
USART2->CR2 = 0;                      /* 1 stop bit        */
USART2->CR3 = 0;

/* 4. ENABLE INTERRUPTS AT THE PERIPHERAL, then set priority
      and enable at the NVIC. This order matters if the line
      could already be active.                              */
USART2->CR1 |= USART_CR1_RXNEIE;
NVIC_SetPriority(USART2_IRQn, 6);
NVIC_EnableIRQ(USART2_IRQn);

/* 5. ENABLE THE PERIPHERAL LAST. */
USART2->CR1 |= USART_CR1_UE | USART_CR1_TE | USART_CR1_RE;

/* THE RULE: clock, pins, config, interrupts, enable.
   Deviating from it produces "works sometimes" behaviour
   that depends on optimisation level and what the pin was
   doing beforehand.                                        */
```

Synchronous, asynchronous, and why it decides everything

```
SYNCHRONOUS - a clock line is transmitted alongside data.
  SPI, I2C, USB (embedded in the encoding), MIPI.

  The receiver samples on the clock edge the transmitter
  provided, so the two need no agreement about rate.
  Speed can be changed freely and can reach hundreds of
  MHz. Costs a pin.

    CLK  __|--|__|--|__|--|__
    DATA ___X====X====X====X_
             ^    ^    ^     sampled here

ASYNCHRONOUS - no clock line. Both ends must independently
  agree on the rate BEFORE any data flows.
  UART, RS-485, CAN.

  The receiver finds the start edge, then samples at
  pre-agreed intervals based on its OWN clock.

    DATA --|_______X===X===X===X---
           start   ^   ^   ^   ^
                   sampled on internal timing

  This is why UART needs an accurate clock and SPI does
  not (mcu chapter 09), why UART has a baud rate you must
  configure identically at both ends, and why UART tops
  out in the low megabits while SPI reaches 100 Mbit.

THE THIRD CATEGORY: self-clocking codes. CAN and USB
embed clock information in the data by guaranteeing
transitions - bit stuffing in CAN, NRZI plus stuffing in
USB. The receiver recovers the clock from the edges, so
you get asynchronous wiring with synchronous accuracy.
Chapters 09 and 12 cover these.
```

Error flags are the real interface

```
/* Every peripheral in this track has an error status you
   are supposed to check and most code ignores.            */

void USART2_IRQHandler(void)
{
    uint32_t isr = USART2->ISR;

    /* CHECK ERRORS FIRST. An overrun leaves RXNE set with
       stale data; handling the byte before the error means
       you process garbage and never clear the condition.  */
    if (isr & (USART_ISR_ORE | USART_ISR_FE |
               USART_ISR_NE  | USART_ISR_PE)) {
        if (isr & USART_ISR_ORE) { stats.overrun++; }
        if (isr & USART_ISR_FE)  { stats.framing++; }
        if (isr & USART_ISR_NE)  { stats.noise++;   }
        if (isr & USART_ISR_PE)  { stats.parity++;  }

        USART2->ICR = USART_ICR_ORECF | USART_ICR_FECF |
                      USART_ICR_NECF  | USART_ICR_PECF;
        (void) USART2->RDR;         /* discard the bad byte */
        return;
    }

    if (isr & USART_ISR_RXNE) {
        ring_put((uint8_t) USART2->RDR);
    }
}

/* WHAT EACH ERROR ACTUALLY TELLS YOU - this is diagnosis,
   not bookkeeping:

     OVERRUN   your software is too slow. The fix is DMA or
               a higher interrupt priority, not more retries.
     FRAMING   the stop bit was not high: baud rate mismatch,
               a clock error, or noise. Check both ends.
     NOISE     the three samples per bit disagreed. Electrical:
               long wires, no ground, missing termination.
     PARITY    a bit flipped. Rare, and means real corruption.

   Counting these in a struct you can print is one of the
   highest-value things you can add to a driver. Without it
   "the link is unreliable" is unactionable; with it you
   know within seconds whether the problem is your code,
   the baud rate, or the cable.                            */
```

How it shows up

Symptom	Cause
Register writes have no effect, reads give zero	Peripheral clock not enabled
Configuration ignored	Written while the peripheral was enabled
Last character of every message lost	Waited for TXE rather than TC before disabling
Interrupt fires continuously	Wrong clearing idiom for that status register
Bug vanishes when the debugger shows the register	Read-to-clear flag being cleared by the debugger
Flag never clears despite writing to it	Register is read-to-clear, or needs the two-step sequence

Symptom	Cause
All flags cleared when you meant to clear one	Wrote 0 to an `rc_w0` register instead of the complement
Receive stops permanently after a burst	Overrun set and never cleared — the flag blocks further reception
Spurious first byte on startup	Peripheral enabled before its pins were configured
"The link is unreliable"	No error counters — add them before doing anything else

Check yourself

- ✓ Name the four register surfaces every serial peripheral presents.
- ✓ Explain the difference between TXE and TC and the bug that confuses them.
- ✓ List the four flag-clearing idioms and how to tell which applies.
- ✓ Explain why read-to-clear registers misbehave under a debugger.
- ✓ Give the five-step initialisation order and what breaks if you reorder it.
- ✓ Explain why a synchronous bus needs no clock accuracy agreement.
- ✓ Say why UART tops out far below SPI in achievable rate.
- ✓ Explain what self-clocking codes achieve and name two buses that use them.
- ✓ Say what an overrun error tells you about your software, specifically.
- ✓ Distinguish framing, noise and parity errors as diagnostic signals.

UART: framing, baud rate and error budget

The oldest interface still in daily use, and the one where an arithmetic error of two percent turns working communication into garbage. This chapter covers the frame, the sampling, and the calculation that tells you in advance whether a given clock can reach a given baud rate.

The frame

```
Idle line is HIGH. One character, 8N1, value 0x41 ('A'):

     idle    start  b0 b1 b2 b3 b4 b5 b6 b7  stop  idle
----------+      +--+--+--+--+--+--+--+--+     +---------
          |      |  |  |  |  |  |  |  |  |     |
          +------+  +--+--+--+--+--+--+--+-----+
           START   1  0  0  0  0  0  1  0   STOP
                   <-- LSB FIRST -->

0x41 = 0100 0001 binary, sent LSB first: 1,0,0,0,0,0,1,0

THE START BIT IS THE WHOLE MECHANISM. It is the only
guaranteed edge, and everything the receiver does is
timed from it. An idle line and a start bit are
distinguishable because idle is high and start is low -
that is why the idle state is defined as high.

FRAME NOTATION: 8N1 = 8 data bits, No parity, 1 stop bit.
Others exist (7E1, 8N2, 9-bit for addressing) but 8N1 is
the overwhelming default.

OVERHEAD: 10 bits carry 8 bits of data. So
  bytes/second = baud / 10
115200 baud = 11520 bytes/s. This division by ten is the
most useful UART arithmetic you will do.
```

How the receiver stays aligned

```
The receiver has NO clock from the transmitter. It
oversamples - typically 16x the bit rate.

1. Wait for the falling edge (start bit).
2. Count 8 sample-clocks to reach the MIDDLE of the
   start bit. Verify it is still low; if not, it was
   noise - abandon and resume hunting.
3. Thereafter sample every 16 clocks, taking three
   samples around the centre (7, 8, 9) and majority-voting
   them. Disagreement sets the NOISE flag.
4. After the last data bit, check the stop bit is HIGH.
   If not: FRAMING ERROR.

     start bit
---+        +----
   |        |
   +--------+
   ^   ^^^  ^
   |   789  |
 edge  vote |
detected    next bit boundary

WHY ERROR ACCUMULATES: the receiver re-synchronises only
on the START bit. Over the following 9 bit times, any
difference between the two clocks accumulates. By the
stop bit the sampling point has drifted by 9.5 bit times
times the total error.

TOLERANCE: the sample must still land inside the correct
bit, so the accumulated drift must stay under half a bit:

  9.5 x total_error < 0.5
  total_error < 5.3%

In practice, with the three-sample vote needing all of
its window inside the bit, the usable budget is about
+/-2%, SHARED between the two ends. So roughly 1% each -
which is why the internal RC oscillator is marginal and
a crystal is not a luxury (mcu chapter 09).
```

Computing the divisor, and its error

```
/* The divisor is an integer, so almost no baud rate is
   exactly achievable. The question is always: how far off?  */

/*   BRR = f_pclk / baud       (rounded to nearest)
     actual_baud = f_pclk / BRR
     error = (actual - wanted) / wanted                    */

static uint16_t brr_for(uint32_t pclk, uint32_t baud)
{
    return (uint16_t)((pclk + baud / 2u) / baud);   /* round */
}

/* WORKED: 16 MHz PCLK, 115200 baud.

     16000000 / 115200 = 138.89
     rounded            = 139
     actual = 16000000 / 139 = 115108 baud
     error  = (115108 - 115200) / 115200 = -0.08%

   Excellent. Now 8 MHz PCLK, 115200 baud:

     8000000 / 115200 = 69.44
     rounded          = 69
     actual = 8000000 / 69 = 115942
     error  = +0.64%

   Still fine alone, but add a 1% RC oscillator at each end
   and you are at 2.6% - outside budget, and it will fail
   intermittently and temperature-dependently.

   Now the classic disaster, 8 MHz and 921600:

     8000000 / 921600 = 8.68
     rounded          = 9
     actual = 8000000 / 9 = 888889
     error  = -3.55%

   Broken before you add any oscillator error at all. The
   divisor is small, so rounding it costs an enormous
   fraction. THIS IS WHY HIGH BAUD RATES NEED HIGH CLOCKS:
   not for throughput, but for divisor RESOLUTION.         */

/* ALWAYS CHECK AT COMPILE TIME. */
#define BAUD        115200u
#define PCLK        16000000u
#define BRR_VAL     ((PCLK + BAUD/2u) / BAUD)
#define ACTUAL      (PCLK / BRR_VAL)
#define ERR_PPT     (((int32_t)ACTUAL - (int32_t)BAUD) * 1000 / (int32_t)BAUD)
_Static_assert(ERR_PPT < 15 && ERR_PPT > -15,
               "UART baud error exceeds 1.5% - pick another "
               "clock or baud rate");

/* Twelve lines that turn an intermittent field failure into
   a build error. Put this in every UART driver you write. */
```

WHY 115200, AND WHY THE ODD NUMBERS

The classic rates are divisions of 1.8432 MHz, the crystal fitted to the original 8250 UART, chosen precisely because it divides evenly to 110, 300, 1200, 9600, 19200, 38400, 57600 and 115200 with zero error. When you fit a 8 MHz or 16 MHz crystal instead you inherit rounding error at every rate. Parts intended for serial work often offer 7.3728 MHz or 11.0592 MHz crystals for this reason — they are 1.8432 MHz multiples, and they make the error exactly zero.

Fractional dividers and oversampling

```
/* Modern UARTs improve resolution two ways. */

/* 1. FRACTIONAL BRR. The divisor has a fractional part -
      on STM32, 4 bits of sixteenths.                      */
/*   BRR = mantissa << 4 | fraction
     16 MHz, 115200: 138.89 -> mantissa 138, fraction 14/16
                     = 138.875, actual = 115207 baud
                     error = +0.006%
   An order of magnitude better than integer rounding.     */

/* 2. OVERSAMPLING BY 8 INSTEAD OF 16. Halves the divisor,
      doubling the maximum baud rate for a given clock.     */
USART1->CR1 |= USART_CR1_OVER8;
/*   Costs noise immunity: with 8 samples per bit the vote
     window is narrower and the tolerance drops from about
     3.5% to 2%. Use it only when you need the rate and the
     link is short and clean.                              */

/* 3. AUTOBAUD. Some UARTs measure the rate from a known
      first character - typically 0x55 ('U'), which is
      alternating bits and gives the most edges to measure. */
USART1->CR2 |= USART_CR2_ABREN | USART_CR2_ABRMODE_0;
/*   Useful when the peer's rate is unknown or configurable.
     The peer must send the sync character first, so both
     ends need to agree on the protocol even if not the
     rate.                                                 */
```

Parity, and what it is worth

```
/* Parity adds one bit making the count of ones even or odd.
   It detects any ODD number of bit errors and misses every
   even number.                                              */

USART1->CR1 |= USART_CR1_PCE;      /* parity enable          */
USART1->CR1 &= ~USART_CR1_PS;      /* 0 = even, 1 = odd      */

/* THE TRAP: on most STM32 UARTs the parity bit is taken
   from the DATA LENGTH, not added to it. For 8 data bits
   plus parity you must set the word length to NINE:         */
USART1->CR1 |= USART_CR1_M0;       /* 9-bit word             */
/*   Forget this and you send 7 data bits plus parity, and
     every byte above 0x7F is corrupted while ASCII appears
     to work perfectly. A memorable afternoon.               */

/* IS IT WORTH IT? Rarely, on a modern link.
   - It costs 10% of your throughput (11 bits per byte).
   - It catches only single-bit errors, and real-world
     serial corruption is usually a burst that flips
     several bits.
   - Any protocol carrying data worth protecting should have
     a CRC over the whole message, which is strictly better.

   Use parity when a legacy peer demands it. For new
   designs, a CRC-16 over the frame gives far better
   detection for similar overhead on messages of any
   length.                                                   */
```

How it shows up

Symptom	Cause
Consistent garbage, same wrong bytes each time	Baud rate mismatch — a specific ratio, often 2x
Mostly correct with occasional wrong characters	Baud error near the tolerance limit; check the divisor arithmetic
Works at 9600, fails at 115200	Divisor resolution — the error grows as the divisor shrinks
Works warm, fails cold	RC oscillator drift pushed total error outside budget
Framing errors on every byte	Wrong stop-bit count, wrong word length, or inverted polarity
ASCII works, bytes above 0x7F corrupt	Parity enabled without extending word length to 9
Noise flag set frequently	Electrical: long unshielded wire, missing ground, or no common reference
Nothing received at all, TX works	TX and RX not crossed, or the peer expects a null modem crossover
Occasional single-character loss under load	Overrun — move to DMA or raise the ISR priority
Autobaud never locks	Peer's first character is not the expected sync pattern

Check yourself

- ✓ Draw an 8N1 frame for a given byte, LSB first, with correct idle levels.
- ✓ Explain why the idle state is high and what that buys the start bit.
- ✓ Convert a baud rate to bytes per second and say why the factor is ten.
- ✓ Describe the receiver's oversampling and majority vote.

- ✓ Derive the tolerance limit from the accumulated drift over 9.5 bit times.
- ✓ Compute the baud error for 8 MHz at 921600 and explain why it fails.
- ✓ Explain why high baud rates need high peripheral clocks.
- ✓ Say why 1.8432 MHz and its multiples appear on serial-oriented boards.
- ✓ State the cost of oversampling by 8 rather than 16.
- ✓ Explain the parity word-length trap and its characteristic symptom.

UART in practice: flow control, DMA and ring buffers

The frame from the previous chapter is the easy part. Making a UART link that does not drop bytes under load, recovers from a peer that disappears, and finds message boundaries in a byte stream is the engineering — and it is the same work for every stream protocol you will meet.

Why bytes get lost

```
A UART has ONE receive holding register (or a shallow
FIFO). At 115200 baud a byte arrives every 87 us. If your
software has not read the previous byte by then, it is
OVERWRITTEN and the OVERRUN flag sets.

87 us is a long time - about 14,000 cycles at 168 MHz -
which is why interrupt-per-byte works fine at this rate.

At 3 Mbaud a byte arrives every 3.3 us: 550 cycles. An
ISR with a 12-cycle entry, a prologue, a ring-buffer
write and an exit is perhaps 40 cycles, so it still fits
- until something disables interrupts for 10 us. Then you
lose three bytes and the protocol desynchronises.

WHAT DISABLES INTERRUPTS LONG ENOUGH TO HURT:
  - a flash write or erase (can stall the bus for MS)
  - a long critical section in another driver
  - a higher-priority ISR doing too much
  - a debugger halting the core

THE FIX IS NOT "OPTIMISE THE ISR". It is DMA, which
removes software from the per-byte path entirely. Once
the DMA controller is writing to memory, an interrupt
disabled for 10 us costs you nothing at all.
```

The ring buffer, done right

```
/* Single producer (ISR), single consumer (task). Power-of-
   two size so the mask is free. No lock needed - the
   argument is in the mcu track, chapter 17.               */

#define RXSZ 512                       /* MUST be 2^n       */
typedef struct {
    uint8_t  buf[RXSZ];
    volatile uint16_t head;            /* written by ISR    */
    volatile uint16_t tail;            /* written by task   */
    volatile uint32_t dropped;
} ring_t;

static inline int ring_put(ring_t *r, uint8_t c)
{
    uint16_t next = (uint16_t)((r->head + 1u) & (RXSZ - 1u));
    if (next == r->tail) {
        r->dropped++;                  /* COUNT it          */
        return -1;
    }
    r->buf[r->head] = c;
    r->head = next;                    /* publish AFTER     */
    return 0;
}

static inline int ring_get(ring_t *r, uint8_t *c)
{
    if (r->tail == r->head) { return -1; }
    *c = r->buf[r->tail];
    r->tail = (uint16_t)((r->tail + 1u) & (RXSZ - 1u));
    return 0;
}

/* THREE THINGS THAT MAKE THIS CORRECT:

   1. head is published AFTER the data byte is stored. The
      consumer therefore never sees an index for a byte not
      yet written.

   2. The buffer is full when next == tail, which wastes one
      slot but avoids the ambiguity of head == tail meaning
      both empty and full. The alternative - a separate
      count - is a variable BOTH sides write, and needs a
      lock.

   3. dropped is counted, not ignored. A link that silently
      discards data under load is unbudgetable; one that
      reports it tells you exactly how much bigger the
      buffer needs to be.

   SIZING: buffer must cover the longest time the consumer
   can be delayed, times the byte rate.
     115200 baud = 11.5 bytes/ms
     consumer delayed up to 20 ms
     -> 230 bytes minimum. Round up to 512.              */
```

Circular DMA plus IDLE: the design worth memorising

```
/* This combination receives continuously, at any rate, with
   no per-byte software, AND tells you where messages end.
   It is the standard answer for a serious UART link.      */

static uint8_t dma_buf[512];
static uint16_t last_pos;

void uart_dma_rx_init(void)
{
    /* Circular DMA: NDTR reloads and the address wraps. */
    DMA1_Stream5->PAR  = (uint32_t) &USART2->RDR;
    DMA1_Stream5->M0AR = (uint32_t) dma_buf;
    DMA1_Stream5->NDTR = sizeof(dma_buf);
    DMA1_Stream5->CR   = (4u << 25) | DMA_SxCR_MINC
                       | DMA_SxCR_CIRC | DMA_SxCR_TCIE
                       | DMA_SxCR_HTIE;
    DMA1_Stream5->CR  |= DMA_SxCR_EN;

    USART2->CR3 |= USART_CR3_DMAR;
    USART2->CR1 |= USART_CR1_IDLEIE;   /* THE KEY PIECE     */
}

/* IDLE fires when the line has been quiet for one full
   character time after data. That is exactly "the message
   ended", for any protocol with gaps between messages.   */
void USART2_IRQHandler(void)
{
    if (USART2->ISR & USART_ISR_IDLE) {
        USART2->ICR = USART_ICR_IDLECF;
        uart_process_upto(sizeof(dma_buf) - DMA1_Stream5->NDTR);
    }
}

/* NDTR counts DOWN from the buffer size, so
     bytes_written_so_far = size - NDTR
   and the new data is everything between last_pos and that
   position, handling the wrap.                            */
static void uart_process_upto(uint16_t pos)
{
    if (pos == last_pos) { return; }

    if (pos > last_pos) {
        parse(&dma_buf[last_pos], pos - last_pos);
    } else {                                  /* wrapped    */
        parse(&dma_buf[last_pos], sizeof(dma_buf) - last_pos);
        if (pos > 0) { parse(&dma_buf[0], pos); }
    }
    last_pos = pos;
}

/* Also call uart_process_upto from the DMA half-transfer
   and transfer-complete interrupts, so a message longer
   than half the buffer is processed before it is
   overwritten. Three interrupt sources, one function.

   RESULT: zero per-byte CPU, message boundaries detected in
   hardware, and a link that survives the CPU being busy for
   milliseconds. This handles 3 Mbaud comfortably on a part
   that could not manage 921600 with per-byte interrupts.  */
```

> **IDLE DETECTION IS THE ANSWER TO "HOW DO I KNOW THE MESSAGE ENDED?"**
> A UART is a byte stream with no framing above the character. Every protocol on top must delimit messages somehow, and there are only four options: a fixed length, a length field near the start, a terminator byte, or a timing gap. IDLE detection implements the last of these in hardware, for free, and it is why Modbus RTU (chapter 14) specifies a 3.5-character silent interval as its frame delimiter — it was designed for exactly this mechanism.

Flow control

```
HARDWARE (RTS/CTS) - two extra wires, and the only kind
that works reliably.

  Device A                    Device B
  RTS (out) ----------------> CTS (in)
  CTS (in)  <---------------- RTS (out)

  "RTS" now means "I am Ready To Receive" (the name is
  historical and misleading). A drives RTS low when its
  buffer has room; B's UART checks CTS before starting
  each character and pauses if it is high.

  ENTIRELY IN HARDWARE once enabled:
    USART1->CR3 |= USART_CR3_RTSE | USART_CR3_CTSE;

  The peripheral asserts RTS from its own FIFO level, so
  it works even if your software is completely stalled.
  This is the only flow control that survives a
  millisecond-long interrupt lockout.

SOFTWARE (XON/XOFF) - in-band, no extra wires.
  Receiver sends 0x13 (XOFF) to pause, 0x11 (XON) to
  resume. Problems:
    - those two byte values can never appear in your data,
      so it is unusable for binary
    - the XOFF itself takes a character time to send and
      another to be noticed, so several bytes still
      arrive after it
    - if XON is lost, the link deadlocks permanently
  Use only with legacy equipment that requires it.

NONE - the default, and correct when the receiver is
  always faster than the sender, or the protocol has its
  own acknowledgement and retry at a higher layer.
```

Making the link survive reality

```
/* Four things that separate a driver that works on the
   bench from one that works in a cabinet for five years. */

/* 1. NEVER BLOCK FOREVER. */
int uart_send(const uint8_t *p, size_t n, uint32_t timeout_ms)
{
    uint32_t deadline = g_ms + timeout_ms;
    while (n--) {
        while (!(USART2->ISR & USART_ISR_TXE)) {
            if ((int32_t)(g_ms - deadline) >= 0) { return -ETIMEDOUT; }
        }
        USART2->TDR = *p++;
    }
    return 0;
}

/* 2. RECOVER FROM ERRORS, DO NOT JUST COUNT THEM.
      An overrun on some parts BLOCKS further reception
      until cleared. If your error path forgets to clear it,
      the link dies permanently after the first burst.     */
static void uart_error_recover(void)
{
    uint32_t isr = USART2->ISR;
    if (isr & (USART_ISR_ORE|USART_ISR_FE|USART_ISR_NE|USART_ISR_PE)) {
        USART2->ICR = USART_ICR_ORECF | USART_ICR_FECF
                    | USART_ICR_NECF  | USART_ICR_PECF;
        (void) USART2->RDR;
        stats.resyncs++;
        parser_reset();          /* the stream is desynced  */
    }
}

/* 3. RESYNCHRONISE THE PARSER. After any error the byte
      stream has lost alignment. A parser that keeps its
      state machine across an error will mis-frame every
      subsequent message. Reset to hunting-for-header.     */

/* 4. TIME OUT A PARTIAL MESSAGE. If a header arrives and
      the rest never does, the parser must not wait
      indefinitely holding a buffer.                       */
if (parser.state != HUNTING &&
    (int32_t)(g_ms - parser.started_ms - 100) >= 0) {
    stats.partial_timeouts++;
    parser_reset();
}

/* Every one of these four is learned the hard way. A UART
   link with no timeout, no error recovery, no resync and
   no partial-message timeout will work perfectly until the
   day a connector is jostled, and then stay broken until
   someone power-cycles it.                                */
```

How it shows up

Symptom	Cause
Link dies permanently after a burst	Overrun flag never cleared — it blocks further reception
Bytes lost only when writing to flash	Flash operations stall the bus; use DMA for receive

Symptom	Cause
Every message after an error is mis-framed	Parser state not reset on error
Task blocks forever holding a lock	A send with no timeout and a peer that stopped reading
Ring buffer occasionally corrupt	Head published before the data, or two producers
Buffer never reports full but data is missing	Drops not counted — add the counter
Messages merge together	No delimiter; use IDLE detection or a length field
DMA works but long messages corrupt	Half-transfer interrupt not handled — data overwritten before processing
XON/XOFF corrupts binary data	0x11 and 0x13 appearing in the payload
Flow control enabled but bytes still lost	RTS/CTS wired straight through instead of crossed

Check yourself

- ✓ Compute the inter-byte time at 3 Mbaud and say why DMA becomes necessary.
- ✓ Explain why DMA makes a 10 µs interrupt lockout harmless.
- ✓ Give the three properties that make the single-producer ring buffer correct.
- ✓ Explain why the buffer wastes one slot rather than using a count.
- ✓ Size a receive buffer from baud rate and worst-case consumer delay.
- ✓ Write the expression for bytes received so far from `NDTR`.
- ✓ Explain what IDLE detection does and name the four ways to delimit messages.
- ✓ Explain why RTS/CTS works when software flow control does not.
- ✓ Say why XON/XOFF cannot carry binary data.
- ✓ List the four robustness measures a shipping UART driver needs.

SPI: modes 0-3, chip select and timing

SPI is the simplest bus in this track and the one most often mis-wired, because it has no addressing, no acknowledgement, no error detection, and four clock configurations of which exactly one is right for your device.

Four wires and a shift register

```
MASTER                          SLAVE
+----------+                    +----------+
|  SCLK  --+------------------->-+-- SCLK   |
|  MOSI  --+------------------->-+-- MOSI   |
|  MISO  <-+-------------------<-+-- MISO   |
|  CS    --+------------------->-+-- CS     |  active LOW
+----------+                    +----------+

IT IS ONE CIRCULAR SHIFT REGISTER SPANNING BOTH CHIPS:

  master reg [10110010] --MOSI--> slave reg [01001101]
                 ^                              |
                 +---------MISO-----------------+

Every clock edge shifts one bit out of each and into the
other. After 8 clocks the two bytes have been EXCHANGED.

CONSEQUENCE THAT SURPRISES EVERYONE: you cannot receive
without transmitting. To read a byte you must clock out
a dummy byte - conventionally 0x00 or 0xFF. There is no
"read" operation, only "exchange".

uint8_t spi_xfer(uint8_t out) {
    while (!(SPI1->SR & SPI_SR_TXE)) { }
    *(volatile uint8_t *)&SPI1->DR = out;
    while (!(SPI1->SR & SPI_SR_RXNE)) { }
    return *(volatile uint8_t *)&SPI1->DR;
}
uint8_t v = spi_xfer(0xFF);      /* "read" */

NO ADDRESSING - selection is the CS pin, so N devices
need N chip-select pins.
NO ACKNOWLEDGEMENT - the master cannot tell whether a
slave is present, powered, or listening.
NO ERROR DETECTION - none at all.
NO SPEED NEGOTIATION - you must know the slave's limit.

In exchange: full duplex, trivially simple, and fast.
50-100 MHz is routine.
```

The four modes

```
Two independent bits give four combinations:

CPOL - clock polarity: idle level of SCLK
       0 = idle low,  1 = idle high
CPHA - clock phase:   which edge SAMPLES
       0 = sample on the FIRST edge
       1 = sample on the SECOND edge

MODE 0  CPOL=0 CPHA=0   sample on RISING    <- most common
  SCLK  ___|--|__|--|__
  MOSI  X====X====X====
        ^    ^    ^        sampled on rising edge

MODE 1  CPOL=0 CPHA=1   sample on FALLING
  SCLK  ___|--|__|--|__
  MOSI  X====X====X====
           ^    ^          sampled on falling edge

MODE 2  CPOL=1 CPHA=0   idle high, sample FALLING
  SCLK  ---|__|--|__|--
        ^    ^    ^

MODE 3  CPOL=1 CPHA=1   idle high, sample RISING
  SCLK  ---|__|--|__|--
           ^    ^

MODE 0 and MODE 3 cover the large majority of devices.

THE RULE: data is SET UP on one edge and SAMPLED on the
other. Both ends must agree, and the datasheet always
states it - usually as a timing diagram rather than a
mode number, so you may have to read the diagram and
derive the mode yourself.

WRONG MODE SYMPTOMS, and they are diagnostic:
  - every byte shifted by one bit (0x55 reads as 0xAA
    or 0x2A) -> CPHA is wrong
  - first byte wrong, rest correct -> CPHA wrong, and
    the device recovered
  - all 0x00 or all 0xFF -> often CS, wiring, or power,
    not mode
  - works at low speed, fails fast -> timing, not mode
    (see below)
```

Configuring it

```
void spi_init(uint32_t hz)
{
    RCC->APB2ENR |= RCC_APB2ENR_SPI1EN;
    (void) RCC->APB2ENR;

    /* PA5 SCK, PA6 MISO, PA7 MOSI - AF5. CS is a plain GPIO
       we drive ourselves (see below).                      */
    gpio_af(GPIOA, 5, 5); gpio_af(GPIOA, 6, 5); gpio_af(GPIOA, 7, 5);
    gpio_output(GPIOB, 6);                 /* CS            */
    GPIOB->BSRR = (1u << 6);               /* idle HIGH     */

    /* Prescaler: PCLK2 / 2^(BR+1). At 84 MHz PCLK2,
       BR=3 gives 84/16 = 5.25 MHz.                         */
    uint32_t br = 0;
    while ((84000000u >> (br + 1)) > hz && br < 7) { br++; }

    SPI1->CR1 = SPI_CR1_MSTR              /* master         */
              | (br << 3)
              | SPI_CR1_SSM | SPI_CR1_SSI /* software NSS   */
              /* CPOL=0, CPHA=0 -> mode 0: both bits clear  */
              ;
    SPI1->CR2 = 0;                        /* 8-bit          */
    SPI1->CR1 |= SPI_CR1_SPE;
}

/* SSM + SSI IS NOT OPTIONAL. Without software slave
   management the hardware NSS input, if it goes low,
   silently demotes the peripheral from master to slave and
   everything stops. This is one of the most common
   first-time SPI failures on STM32, and the symptom -
   "MOSI never toggles" - gives no hint of the cause.      */
```

> **DRIVE CHIP SELECT YOURSELF, IN SOFTWARE**
> Hardware CS on most microcontrollers deasserts between bytes, which breaks any device expecting a multi-byte transaction to be framed by one continuous CS assertion — which is almost all of them. A GPIO you control explicitly lets you hold CS low across a command byte, an address and a data burst. It also lets you meet the setup and hold times a datasheet specifies around the CS edges.

A transaction, with the timing that matters

```
/* Reading a register from a typical sensor. */

uint8_t sensor_read_reg(uint8_t reg)
{
    uint8_t v;

    CS_LOW();
    delay_ns(50);              /* t_CSS: CS setup before
                                  the first clock edge     */

    (void) spi_xfer(reg | 0x80);   /* bit 7 = read         */
    v = spi_xfer(0xFF);             /* dummy out, data in   */

    /* CRITICAL: wait for the shift register to EMPTY before
       raising CS. TXE means the DATA REGISTER is free, not
       that the byte has left the pin (chapter 01).        */
    while (SPI1->SR & SPI_SR_BSY) { }
    delay_ns(50);              /* t_CSH: CS hold           */
    CS_HIGH();

    return v;
}

/* RAISING CS ON TXE INSTEAD OF BSY TRUNCATES THE LAST BYTE.
   The symptom is a device that mostly works but ignores
   the final byte of every write - so single-register
   writes fail while burst writes appear to work except for
   the last register. Memorably confusing.

   BURST TRANSFERS: most devices auto-increment their
   internal address, so one CS assertion can read many
   registers. This is much faster than N transactions and
   is how you read a FIFO:                                 */

void sensor_read_burst(uint8_t start, uint8_t *dst, size_t n)
{
    CS_LOW();
    (void) spi_xfer(start | 0xC0);    /* read + increment  */
    while (n--) { *dst++ = spi_xfer(0xFF); }
    while (SPI1->SR & SPI_SR_BSY) { }
    CS_HIGH();
}
```

Why it works slowly and fails fast

```
The most common SPI failure after mode errors.

THE ROUND TRIP that limits speed:

  master drives SCLK edge
    -> propagates down the trace        (~5 ns / metre...
                                         but 1-2 ns typical)
    -> slave's t_V: time to put data
       on MISO after the edge           (often 20-40 ns!)
    -> propagates back
    -> must arrive before the master's
       setup time at the NEXT edge

  So:  t_prop_out + t_V + t_prop_back + t_setup < half a
       clock period

  With t_V = 30 ns and small propagation, half a period
  must exceed ~35 ns, so the period is 70 ns and the
  maximum clock is about 14 MHz - regardless of what the
  master can generate.

THIS IS WHY "it works at 1 MHz and fails at 20 MHz" is
almost never a software problem. Check:
  - the slave's maximum SCLK in its datasheet
  - t_V (output valid delay) which often binds first
  - trace length, especially through a connector or
    ribbon cable
  - whether MISO has a weak pull-up fighting the driver

RULES OF THUMB:
  - on-board, short traces: 10-25 MHz usually fine
  - through a connector or 10 cm of ribbon: 1-4 MHz
  - always bring a new device up at 1 MHz, confirm it
    works, THEN raise the clock while watching for
    errors. Starting fast conflates wiring bugs with
    timing bugs.
```

How it shows up

Symptom	Cause
Every byte shifted by one bit	Wrong CPHA
Reads return all 0x00	MISO not connected, device unpowered, or CS never asserted
Reads return all 0xFF	MISO floating with a pull-up; the device is not driving
MOSI and SCLK never toggle	NSS pulled low without `SSM` / `SSI` — demoted to slave
Last byte of every write ignored	CS raised on TXE instead of waiting for `BSY`
Multi-byte transactions fail, single bytes work	Hardware CS deasserting between bytes
Works at 1 MHz, fails at 10 MHz	Slave's output valid delay or trace length — a timing budget
Works with a scope probe attached	The probe's capacitance changed edge timing — you are marginal
Two devices, one always fails	Both chip selects asserted, or a shared CS
Data corrupt only during other activity	DMA or interrupt disturbing a bit-banged CS, or a shared bus without a lock

Check yourself

- ✓ Explain why SPI cannot read without writing.
- ✓ Define CPOL and CPHA and give the four mode combinations.
- ✓ Say which two modes cover most devices.
- ✓ Give the diagnostic symptom of a wrong CPHA setting.
- ✓ Explain why chip select should be a software GPIO.
- ✓ Explain what `SSM` and `SSI` do and the failure without them.
- ✓ Explain why you must wait for `BSY` rather than TXE before raising CS.
- ✓ Describe the round-trip timing budget that limits SPI clock speed.
- ✓ Explain why a device may work at 1 MHz and fail at 20 MHz.
- ✓ Give the bring-up procedure for a new SPI device.

SPI in practice: DMA, multi-slave and quad SPI

SPI's simplicity means all the engineering lives outside the protocol: how to move a megabyte without occupying the CPU, how to share one bus between drivers that do not know about each other, and what changes when the bus grows to four data lines.

Full-duplex DMA

```
/* SPI always exchanges, so a DMA transfer needs BOTH
   directions configured even if you only care about one.
   Miss the RX stream and the receive FIFO overruns, which
   on most parts wedges the peripheral.                    */

static uint8_t tx_buf[256], rx_buf[256];

void spi_dma_xfer(const uint8_t *tx, uint8_t *rx, size_t n)
{
    /* RX FIRST. It must be armed before any clock edge, or
       the first bytes arrive with nowhere to go.          */
    DMA2_Stream0->PAR  = (uint32_t) &SPI1->DR;
    DMA2_Stream0->M0AR = (uint32_t) rx;
    DMA2_Stream0->NDTR = n;
    DMA2_Stream0->CR   = (3u << 25) | DMA_SxCR_MINC
                       | DMA_SxCR_TCIE;      /* periph->mem */
    DMA2_Stream0->CR  |= DMA_SxCR_EN;

    DMA2_Stream3->PAR  = (uint32_t) &SPI1->DR;
    DMA2_Stream3->M0AR = (uint32_t) tx;
    DMA2_Stream3->NDTR = n;
    DMA2_Stream3->CR   = (3u << 25) | DMA_SxCR_MINC
                       | DMA_SxCR_DIR_0;     /* mem->periph */
    DMA2_Stream3->CR  |= DMA_SxCR_EN;

    CS_LOW();
    SPI1->CR2 |= SPI_CR2_RXDMAEN | SPI_CR2_TXDMAEN;
}

/* COMPLETION IS THE RX INTERRUPT, NOT TX. TX completes when
   the last byte enters the shift register; RX completes
   when the last byte has fully arrived. Raising CS on TX
   completion truncates the transfer (chapter 04).        */

void DMA2_Stream0_IRQHandler(void)
{
    DMA2->LIFCR = DMA_LIFCR_CTCIF0;
    while (SPI1->SR & SPI_SR_BSY) { }     /* belt and braces */
    CS_HIGH();
    SPI1->CR2 &= ~(SPI_CR2_RXDMAEN | SPI_CR2_TXDMAEN);
    xfer_done = 1;
}

/* WRITE-ONLY TRANSFERS still need somewhere for the
   incoming bytes to go. Two options:
     - a real rx buffer you ignore, or
     - a ONE-BYTE dummy with MINC cleared, so every incoming
       byte overwrites the same location. This is the
       idiomatic trick and it costs one byte of RAM:      */
DMA2_Stream0->M0AR = (uint32_t) &dummy;
DMA2_Stream0->CR   = (3u << 25) | DMA_SxCR_TCIE;  /* no MINC */

/* READ-ONLY transfers use the mirror image: a single
   constant 0xFF source with MINC cleared on the TX stream. */
```

CORTEX-M7 CACHE MAINTENANCE APPLIES HERE IN FULL

Before a transmit DMA, clean the cache so the controller sees your data. After a receive DMA, invalidate so the CPU does not read stale lines. Both operations work on cache-line granularity (32 bytes), so a buffer that shares a cache line with another variable can have that variable clobbered by the invalidate. Align DMA buffers to 32 bytes and pad their length to a multiple of 32 — the alternative is a corruption bug that depends on the linker's variable placement.

Sharing the bus

```
MULTI-SLAVE: one bus, N chip selects.

           +-------- SCLK/MOSI/MISO --------+
           |            |            |      |
MASTER  CS1|         CS2|         CS3|      |
  |--------+            |            |      |
  |---------------------+            |      |
  |----------------------------------+      |
                                        sensor A
                                        sensor B
                                        flash

THE RULE: exactly one CS low at any instant. Two devices
driving MISO simultaneously is a short between two
push-pull outputs.

THE PROBLEM: devices may need DIFFERENT modes and speeds.
Sensor A wants mode 0 at 10 MHz; the flash wants mode 3
at 50 MHz. The controller has one configuration.

THE SOLUTION: reconfigure per transaction, under a lock.
This is exactly what Linux's SPI subsystem does with
spi_transfer and per-device spi_device structs (see the
Linux track, chapter 19) - and the reason that
abstraction exists is this problem.
```

```
/* A bus manager. In an RTOS this is a mutex; bare metal, a
   flag plus a critical section.                          */

typedef struct {
    uint32_t cr1;               /* mode + speed for this   */
    GPIO_TypeDef *cs_port;
    uint16_t      cs_pin;
} spi_device_t;

static SemaphoreHandle_t spi_lock;

int spi_transact(const spi_device_t *dev,
                 const uint8_t *tx, uint8_t *rx, size_t n)
{
    if (xSemaphoreTake(spi_lock, pdMS_TO_TICKS(100)) != pdTRUE) {
        return -EBUSY;          /* TIMEOUT, not forever    */
    }

    /* Reconfigure for THIS device. SPE must be off to
       change mode - the peripheral latches CR1 on enable
       (chapter 01).                                       */
    SPI1->CR1 &= ~SPI_CR1_SPE;
    SPI1->CR1  = dev->cr1;
    SPI1->CR1 |= SPI_CR1_SPE;

    dev->cs_port->BSRR = dev->cs_pin << 16;   /* CS low     */
    int r = spi_xfer_blocking(tx, rx, n);
    while (SPI1->SR & SPI_SR_BSY) { }
    dev->cs_port->BSRR = dev->cs_pin;         /* CS high    */

    xSemaphoreGive(spi_lock);
    return r;
}

/* WITHOUT THE LOCK: two tasks interleave, the mode changes
   mid-transaction, and two chip selects end up low at once.
   The symptom is corruption that appears only when both
   devices are used concurrently - which is to say, only in
   the integrated system and never in the unit test.       */
```

Daisy chaining

```
Some devices - shift registers, LED drivers, some ADCs -
support chaining, so N devices need only ONE chip select.

MASTER MOSI -->[ dev 1 ]-->[ dev 2 ]-->[ dev 3 ]--> MISO
                    ^           ^           ^
                    +-----------+-----------+
                            CS (shared)

Data shifts THROUGH each device into the next. To load
three 8-bit devices you clock 24 bits with CS low, then
raise CS - which latches each device's own byte.

THE ORDER IS REVERSED: the FIRST byte you send ends up in
the LAST device, because it has been pushed furthest
along the chain.

  uint8_t frame[3] = { dev3_data, dev2_data, dev1_data };
  CS_LOW();
  spi_write(frame, 3);
  while (SPI1->SR & SPI_SR_BSY) { }
  CS_HIGH();          /* latches all three at once      */

Getting the order backwards is the universal first bug,
and it looks like the devices are wired in the wrong
sequence.

TRADE-OFF: one CS pin and simultaneous update, against
having to rewrite the whole chain to change one device
and a maximum length set by accumulated propagation
delay.
```

Quad SPI

```
/* When SPI is used for program storage, one data line is
   the bottleneck. Quad SPI uses four bidirectional lines. */

/*   SPI      1 bit  per clock
     DUAL     2 bits per clock
     QUAD     4 bits per clock
     OCTAL    8 bits per clock  (xSPI / HyperBus)

   At 100 MHz: single = 12.5 MB/s, quad = 50 MB/s.

   THE KILLER FEATURE IS MEMORY-MAPPED MODE. The controller
   translates bus reads into flash commands automatically,
   so external flash appears at an address:               */

QUADSPI->CCR = QUADSPI_CCR_FMODE       /* memory-mapped    */
             | (3u << 24)              /* 4-line data      */
             | (2u << 8)               /* 1-line address   */
             | 0xEB;                   /* fast read quad   */

/* Now this just works, executing directly from external
   flash (execute-in-place, mcu chapter 01):              */
const uint8_t *font = (const uint8_t *) 0x90000000;
uint8_t glyph = font[offset];

/* WHAT IT COSTS:
   - reads are slower than internal flash, so cache matters
     enormously; on M7 enable the D-cache for that region
   - the first access after idle pays the command overhead
   - you CANNOT write while executing from it, so a
     firmware update to QSPI must run from internal flash
     or RAM (the .ramfunc trick, mcu chapter 05)
   - erase takes hundreds of milliseconds during which
     nothing can read it

   That last point is the design constraint people miss:
   put code and rarely-changing assets in QSPI, and never
   put anything you must write during normal operation
   alongside code you must execute.                       */
```

How it shows up

Symptom	Cause
SPI wedges after the first DMA transfer	RX DMA not configured; the receive FIFO overran
Last bytes of a DMA transfer lost	CS raised on TX completion rather than RX
DMA corrupts a nearby variable on M7	Cache invalidate hit a shared cache line — align and pad buffers to 32 bytes
Corruption only when two devices are used together	No bus lock; mode changed mid-transaction
Mode change has no effect	Written while `SPE` was set
Two devices respond at once	Two chip selects low — check every CS is deasserted on init
Daisy chain devices show each other's data	Byte order reversed — the first byte sent travels furthest
QSPI memory-mapped reads return garbage	Wrong read command opcode or dummy-cycle count for that flash
System hangs during a QSPI erase	Code executing from the flash being erased
Throughput far below the clock rate	Per-byte CPU overhead; the bus is idle between bytes

Check yourself

- ✓ Explain why a write-only SPI DMA transfer still needs an RX stream.
- ✓ Give the one-byte trick for discarding received data.
- ✓ Say which DMA completion signals the end of a transfer, and why.
- ✓ Explain the cache-line hazard for DMA buffers on Cortex-M7.
- ✓ State the invariant for chip selects on a shared bus.
- ✓ Explain why per-device reconfiguration needs a lock.
- ✓ Explain why `SPE` must be cleared to change mode.
- ✓ Describe daisy chaining and the byte-order rule.
- ✓ Say what memory-mapped QSPI enables and give its throughput advantage.
- ✓ Explain why a firmware update to QSPI cannot execute from QSPI.

I2C: start, stop, addressing and ACK

Two wires, up to 127 devices, and an acknowledgement on every byte — I2C gives you far more than SPI for two fewer pins, and charges for it in protocol complexity and a set of failure modes that have no SPI equivalent.

Two wires, open drain

```
                  VDD
                   |
             +-----+------+
             |            |
           [Rp]          [Rp]        2.2k - 4.7k
             |            |
SDA ---------+------------|----------+----------+
SCL ---------------------- +----------|----------|--+
             |            |          |          |  |
         +---+---+     +---+---+  +---+---+  +---+--+--+
         |MASTER |     |slave 1|  |slave 2|  | slave 3 |
         +-------+     +-------+  +-------+  +---------+

EVERY DEVICE IS OPEN-DRAIN: it can pull a line LOW, or
release it. Nobody ever DRIVES a line high - the pull-up
resistors do that (mcu chapter 10).

THIS ONE DECISION EXPLAINS ALMOST EVERYTHING ABOUT I2C:

- Two devices can transmit simultaneously without damage,
  because low always wins. That makes ARBITRATION
  possible (chapter 07).
- A slave can hold SCL low to say "wait", which is CLOCK
  STRETCHING (chapter 07).
- A receiver can pull SDA low during the 9th bit to
  ACKNOWLEDGE.
- Rise time is set by Rp and the bus capacitance, so the
  RESISTOR VALUE LIMITS THE SPEED. This is why the
  internal pull-ups (~40 kO) cannot do 400 kHz.

  t_rise ~ 0.8 x Rp x C_bus
  400 kHz needs t_rise < 300 ns
  With C_bus = 100 pF:  Rp < 3.75 kO

SPEEDS: 100 kHz standard, 400 kHz fast, 1 MHz fast-plus,
3.4 MHz high-speed (rare, needs a current-source pull-up).
```

Start, stop, and the bytes between

```
START and STOP are the only times SDA changes while SCL
is HIGH. During data, SDA may only change while SCL is
LOW. That distinction is the entire framing mechanism.

START:  SDA falls while SCL high
STOP:   SDA rises while SCL high

  SDA  ---+                          +---
          |                          |
          +--------------------------+
  SCL  ------+                    +------
             |                    |
             +--------------------+
           ^                        ^
        START                    STOP

A COMPLETE WRITE OF ONE BYTE TO REGISTER 0x10:

S | 0x76<<1|W | A | 0x10 | A | 0x42 | A | P
^       ^       ^    ^      ^    ^     ^   ^
|       |       |    |      |    |     |   stop
|       |       |    |      |    |     slave ACKs data
|       |       |    |      |    data byte
|       |       |    |      slave ACKs register
|       |       |    register address
|       |       slave ACKs its address
|       address + direction bit (0 = write)
start

THE 9TH BIT OF EVERY BYTE IS THE ACKNOWLEDGEMENT. The
transmitter releases SDA; the receiver pulls it LOW to
say "got it". A high 9th bit is a NACK.

ACK = 0 (SDA low). This inversion catches everyone.
```

The repeated start

```
Reading a register needs BOTH directions: write the
register number, then read the value. A STOP between them
would release the bus and let another master interleave -
so I2C provides a REPEATED START, which changes direction
without releasing.

S | addr|W | A | 0x10 | A | Sr | addr|R | A | data | N | P
                            ^                      ^
                            |                      master
                            repeated start,        NACKs the
                            no STOP first          LAST byte

THE MASTER NACKS THE FINAL BYTE IT READS. This is how it
says "stop sending" - the slave sees the NACK and
releases SDA so the master can generate a STOP. ACK the
last byte instead and the slave keeps driving SDA,
the STOP cannot be generated, and the bus hangs.

Multi-byte read: ACK every byte except the last.

  for (i = 0; i < n; i++) {
      data[i] = i2c_read_byte(i < n - 1);   /* ack flag */
  }

THE ALTERNATIVE some code uses - stop, then start again -
works with most devices and fails with some, because it
allows another master in between and because a few
devices reset their internal address pointer on STOP.
Use a repeated start; it is what the datasheet's timing
diagram shows.
```

Addressing

```
/* 7-bit addresses, shifted left, with the direction bit in
   position 0. This shift is the single most common source
   of confusion in I2C code.                              */

/*   Datasheet says: "the device address is 0x76"
     On the wire:     0xEC for write (0x76 << 1 | 0)
                      0xED for read  (0x76 << 1 | 1)

   Some datasheets quote the SHIFTED value, so "address
   0xEC" means the same device. If a scan finds a device at
   half your expected address - or double it - this is why.

   ALWAYS SCAN. Twelve lines that answer "is it even there":  */

void i2c_scan(void)
{
    for (uint8_t a = 0x08; a < 0x78; a++) {   /* reserved
                                                 outside     */
        i2c_start();
        int ack = i2c_send_byte(a << 1);      /* write        */
        i2c_stop();
        if (ack) { printf("found 0x%02X\r\n", a); }
    }
}

/* RESERVED ADDRESSES - do not use, and do not scan:
     0x00       general call / start byte
     0x01       CBUS
     0x02-0x03  reserved
     0x04-0x07  Hs-mode master code
     0x78-0x7B  10-bit addressing
     0x7C-0x7F  reserved

   ADDRESS COLLISIONS are I2C's practical limit. Many sensors
   offer only two addresses via an ADDR pin, so three
   identical sensors will not fit on one bus. Solutions:
     - a second I2C peripheral
     - an I2C multiplexer (TCA9548A and similar)
     - devices with more address pins
   Discovering this after the PCB is made is a common and
   expensive mistake - check address availability during
   schematic review, not bring-up.                         */
```

NACK IS INFORMATION, NOT FAILURE

A NACK on the address byte means no device answered — wrong address, unpowered, or not connected. A NACK on a data byte means the device is refusing, usually because it is busy: an EEPROM performing an internal write cycle NACKs its address until the write completes, and the correct response is to retry. This is called acknowledge polling, and it is the documented way to wait for an EEPROM write rather than a fixed delay. Treat NACK as a status code with a meaning that depends on when it arrived.

A blocking master transaction

```
/* Every step has a timeout. An I2C bus with a confused
   slave WILL hang otherwise, and hang forever.            */

#define I2C_TIMEOUT_MS 10

static int wait_flag(volatile uint32_t *r, uint32_t m, int set)
{
    uint32_t deadline = g_ms + I2C_TIMEOUT_MS;
    while (((*r & m) != 0) != (set != 0)) {
        if ((int32_t)(g_ms - deadline) >= 0) { return -ETIMEDOUT; }
    }
    return 0;
}

int i2c_write_reg(uint8_t addr, uint8_t reg, uint8_t val)
{
    int rc;

    I2C1->CR2 = (addr << 1) | (2u << 16)     /* 2 bytes      */
              | I2C_CR2_START | I2C_CR2_AUTOEND;

    if ((rc = wait_flag(&I2C1->ISR, I2C_ISR_TXIS, 1)) < 0) { goto err; }
    if (I2C1->ISR & I2C_ISR_NACKF) { rc = -ENXIO; goto err; }
    I2C1->TXDR = reg;

    if ((rc = wait_flag(&I2C1->ISR, I2C_ISR_TXIS, 1)) < 0) { goto err; }
    I2C1->TXDR = val;

    if ((rc = wait_flag(&I2C1->ISR, I2C_ISR_STOPF, 1)) < 0) { goto err; }
    I2C1->ICR = I2C_ICR_STOPCF;
    return 0;

err:
    i2c_recover();          /* chapter 07 - do NOT skip this */
    return rc;
}

int i2c_read_regs(uint8_t addr, uint8_t reg, uint8_t *d, size_t n)
{
    /* Phase 1: write the register pointer, NO autoend -
       we want a repeated start.                            */
    I2C1->CR2 = (addr << 1) | (1u << 16) | I2C_CR2_START;
    if (wait_flag(&I2C1->ISR, I2C_ISR_TXIS, 1) < 0) { goto err; }
    if (I2C1->ISR & I2C_ISR_NACKF) { goto err; }
    I2C1->TXDR = reg;
    if (wait_flag(&I2C1->ISR, I2C_ISR_TC, 1) < 0) { goto err; }

    /* Phase 2: repeated start, read direction. */
    I2C1->CR2 = (addr << 1) | I2C_CR2_RD_WRN | (n << 16)
              | I2C_CR2_START | I2C_CR2_AUTOEND;

    for (size_t i = 0; i < n; i++) {
        if (wait_flag(&I2C1->ISR, I2C_ISR_RXNE, 1) < 0) { goto err; }
        d[i] = (uint8_t) I2C1->RXDR;
    }
    if (wait_flag(&I2C1->ISR, I2C_ISR_STOPF, 1) < 0) { goto err; }
    I2C1->ICR = I2C_ICR_STOPCF;
    return 0;

err:
```

```
    i2c_recover();
    return -EIO;
}

/* The v2 peripheral handles ACK/NACK of the final byte from
   the NBYTES count, which is why the loop above has no
   explicit ack flag. Older peripherals require you to clear
   the ACK bit before reading the second-to-last byte -
   check which generation you have.                        */
```

How it shows up

Symptom	Cause
Scan finds a device at half the expected address	Datasheet quoted the shifted 8-bit address
NACK on the address byte	No device there — wrong address, unpowered, or not connected
NACK on a data byte to an EEPROM	Internal write in progress; retry (acknowledge polling)
Bus hangs after a multi-byte read	Last byte ACKed instead of NACKed; the slave still drives SDA
Works at 100 kHz, fails at 400 kHz	Pull-up too weak — rise time exceeds the specification
Nothing works, both lines read low	No pull-ups fitted at all
Reads return the previous register's value	STOP used instead of a repeated start; the pointer reset
Three identical sensors will not fit	Address collision — needs a mux or a second bus
Driver hangs forever on one bad transaction	A wait loop with no timeout
First transaction after reset always fails	Bus left mid-transaction by the previous run — needs recovery (chapter 07)

Check yourself

- ✓ Explain why open-drain wiring is required and name three capabilities it enables.
- ✓ Compute the maximum pull-up resistance for 400 kHz with 100 pF of bus capacitance.
- ✓ State the rule distinguishing START and STOP from data transitions.
- ✓ Explain why ACK is a low level rather than a high one.
- ✓ Explain what a repeated start is for and what breaks if you use STOP instead.
- ✓ Say why the master must NACK the last byte it reads.
- ✓ Explain the address-shift confusion and how a bus scan resolves it.
- ✓ Distinguish a NACK on the address byte from a NACK on a data byte.
- ✓ Describe acknowledge polling and what it replaces.
- ✓ Explain why every I2C wait loop needs a timeout.

I2C: clock stretching, arbitration and bus recovery

I2C's open-drain wiring gives it three capabilities no other simple bus has, and each brings a failure mode. A stuck bus that needs software to unstick it is the one every embedded engineer eventually meets at three in the morning.

Clock stretching

```
A slave that needs more time HOLDS SCL LOW after the
acknowledge bit. The master, which only RELEASES SCL and
waits for it to rise, sees it stay low and waits.

  master releases SCL --+
                        |
  SCL  ______/----------+__________/------
                        ^          ^
                slave holds it   slave releases,
                low here         clock resumes

Entirely automatic in hardware IF the master implements
it: the master must read SCL back after releasing it and
not proceed until it is actually high.

WHO STRETCHES:
  - EEPROMs during an internal write
  - sensors computing a conversion
  - MCUs acting as I2C slaves, between the interrupt and
    the software loading the next byte - this one can
    stretch for a LONG time
  - bit-banged slaves, unpredictably

THE HAZARDS:

1. SOME MASTERS DO NOT SUPPORT IT. A bit-banged master
   that drives SCL push-pull instead of releasing it will
   fight the slave, and both are damaged or the data is
   corrupt. Bit-banged I2C MUST use open-drain or
   input/output-low switching, never push-pull high.

2. IT CAN BE UNBOUNDED. A slave that stretches forever -
   because its firmware crashed mid-transaction - hangs
   the master indefinitely. This is why every wait needs
   a timeout (chapter 06) and why SMBus, unlike I2C,
   specifies a 25 ms maximum.

3. SOME PERIPHERALS HAVE ERRATA. Several MCU I2C blocks
   have documented bugs when a slave stretches at a
   particular moment. Read the errata sheet - this is one
   of the few times it genuinely matters.
```

Multi-master arbitration

```
Two masters may start transmitting at the same instant.
Because the bus is open-drain, LOW ALWAYS WINS, and that
is enough to resolve it with no extra protocol.

Master A sends address 0x50 = 1010000
Master B sends address 0x44 = 1000100

bit:        6  5  4  3  2  1  0
A drives:   1  0  1  0  0  0  0
B drives:   1  0  0  0  1  0  0
BUS is:     1  0  0  ...
                  ^
                  A wanted 1, bus shows 0.

At bit 4, A releases SDA (writing a 1) but reads back a
0 - B is pulling it low. A has LOST ARBITRATION. It
immediately stops driving and becomes a slave for the
rest of the transaction.

PROPERTIES THAT MAKE THIS ELEGANT:
  - no data is lost: B's message continues uncorrupted,
    and B does not even know a collision occurred
  - no time is wasted on a retry of the winner
  - lower addresses win, so priority is implicit

This is the same mechanism CAN uses, and for the same
reason (chapter 09). Both are "wired-AND" buses where a
dominant level overrides a recessive one.

IN PRACTICE multi-master I2C is uncommon and often
avoided, because the error handling is fiddly and few
designs need it. But the ARBITRATION LOST flag still
fires in single-master systems - and when it does, it
means something is corrupting SDA. Treat it as a wiring
or noise diagnosis, not a multi-master event.
```

The stuck bus, and how to unstick it

```
THE FAILURE:

1. The master is reading. The slave is transmitting and
   has pulled SDA LOW for a zero bit.
2. The MASTER RESETS - watchdog, crash, debugger, or
   power glitch on the master only.
3. The master restarts and stops clocking.
4. The slave is still mid-byte, still holding SDA low,
   waiting for the clock that will never come.
5. SDA is stuck low. The master cannot generate a START,
   because START requires SDA to FALL - and it is already
   low. The bus is dead until power-cycled.

This is extremely common in development, because you
reset the master constantly and the sensor never does.
"I2C only works after a full power cycle" is exactly
this.

THE RECOVERY, from the I2C specification:

1. Switch SCL and SDA to GPIO, open-drain.
2. Clock SCL up to 9 times, checking SDA after each.
   The slave advances through its byte and, after at
   most 9 clocks, finishes and releases SDA.
3. Once SDA is high, generate a manual STOP: SDA low,
   SCL high, then SDA high.
4. Re-initialise the peripheral.

RUN THIS AT EVERY BOOT, unconditionally, before the
first transaction. It costs 100 microseconds and it
eliminates a whole class of "needs a power cycle" bug.
```

```
/* The recovery, complete. */

void i2c_bus_recover(void)
{
    /* Peripheral off; take the pins as open-drain GPIO. */
    I2C1->CR1 &= ~I2C_CR1_PE;
    gpio_open_drain_output(SCL_PORT, SCL_PIN);
    gpio_open_drain_output(SDA_PORT, SDA_PIN);
    SDA_HIGH(); SCL_HIGH();
    delay_us(10);

    /* Up to 9 clocks to walk the slave out of its byte. */
    for (int i = 0; i < 9 && !SDA_READ(); i++) {
        SCL_LOW();  delay_us(5);
        SCL_HIGH(); delay_us(5);
    }

    /* Manual STOP: SDA must RISE while SCL is high. */
    SDA_LOW();  delay_us(5);
    SCL_HIGH(); delay_us(5);
    SDA_HIGH(); delay_us(5);

    if (!SDA_READ()) {
        /* Still stuck: the slave is not merely mid-byte, it
           is crashed or the line is shorted. If the design
           has a power-gate FET on the sensor rail, this is
           where you use it - the ONLY remaining fix.       */
        stats.i2c_unrecoverable++;
        sensor_power_cycle();
    }

    gpio_af(SCL_PORT, SCL_PIN, I2C_AF);
    gpio_af(SDA_PORT, SDA_PIN, I2C_AF);
    i2c_init();
}

/* THE DESIGN LESSON: put a MOSFET in the sensor's supply.
   It costs a few cents and turns "unrecoverable, RMA the
   unit" into "power-cycle that rail and continue". Any
   product with an I2C sensor it cannot reach physically
   should have one.                                        */
```

NEVER LEAVE I2C WITHOUT A TIMEOUT AND A RECOVERY PATH

Of all the buses in this track, I2C is the one that hangs. A slave holding SCL, a slave holding SDA, a missing pull-up, a noise glitch that desynchronises a state machine — each produces a wait that never ends. A driver that blocks forever in a wait loop turns a recoverable bus glitch into a dead product. Every wait gets a deadline; every timeout calls the recovery above; every recovery failure is counted and reported.

Electrical realities

```
I2C IS THE MOST ELECTRICALLY FRAGILE BUS HERE. It is slow,
high-impedance, and has no error detection whatsoever -
a corrupted bit is simply wrong data with a valid ACK.

THE BUS CAPACITANCE BUDGET: 400 pF maximum, total.
  - each device pin        ~10 pF
  - PCB trace           ~1 pF per cm
  - a ribbon cable      ~50-100 pF per metre

So 30 cm of PCB plus six devices is ~90 pF: fine. Add a
metre of ribbon and you are at 190 pF and the rise time
has doubled. Two metres and you are out of specification
entirely.

I2C WAS DESIGNED FOR CHIPS ON ONE BOARD. Running it
between boards, through a connector, or down a cable is
the single most common cause of intermittent I2C. If you
must:
  - lower the speed to 100 kHz
  - lower the pull-ups to 2.2k (more current, faster edge)
  - use a bus buffer/extender (P82B715 and similar)
  - or use a bus designed for it: RS-485 or CAN
    (chapters 14, 09)

ENABLE THE DIGITAL NOISE FILTER if the peripheral has one:
  I2C1->CR1 |= (2u << I2C_CR1_DNF_Pos);   /* 2 clocks   */
It suppresses spikes shorter than N clock periods, at the
cost of a little timing margin. Cheap insurance.
```

How it shows up

Symptom	Cause
Works only after a full power cycle	Bus stuck from a master reset mid-read — add boot-time recovery
SDA measured low with nothing running	A slave mid-byte, waiting for clocks
Master hangs forever on one transaction	Slave stretching indefinitely, and no timeout
Arbitration-lost flag in a single-master system	Noise or a wiring fault corrupting SDA — not a protocol event
Bit-banged master corrupts data with some slaves	SCL driven push-pull, fighting a stretching slave
Intermittent failures with a cable	Bus capacitance over budget; slow down or use a buffer
Fails only when a motor runs	Coupled noise; add the digital filter and check grounding
Occasional wrong sensor values, no error flags	I2C has no error detection — add a checksum at the protocol level or sanity-check the range
Recovery clocks do not free the bus	Slave is crashed rather than mid-byte; power-cycle the rail
Works on the bench, fails in the enclosure	Longer wiring, more capacitance, more coupled noise

Check yourself

- ✓ Explain clock stretching and what the master must do to support it.
- ✓ Give three kinds of device that stretch and one that may stretch unboundedly.

- ✓ Explain why a bit-banged master must never drive SCL push-pull high.
- ✓ Walk through arbitration between two masters and say which wins.
- ✓ Explain what an arbitration-lost flag means in a single-master system.
- ✓ Describe exactly how a bus becomes stuck with SDA low.
- ✓ Give the four steps of the standard bus recovery, and say why nine clocks.
- ✓ Explain why a power-gate FET on the sensor rail is worth its cost.
- ✓ State the bus capacitance budget and estimate it for a metre of ribbon cable.
- ✓ Explain why a corrupted I2C bit produces wrong data rather than an error.

Choosing between UART, SPI and I2C

Three buses, overlapping capabilities, and a choice usually made by whichever the sensor happens to support. When you do have a choice — and in your own designs you always do — these are the axes that matter.

Side by side

	UART	SPI	I2C
Wires (2 devices)	2 (+ 2 for flow control)	4	2
Wires (N devices)	2 per device	3 + N	2, always
Typical speed	115 kbit – 3 Mbit	10–100 Mbit	100 k – 1 Mbit
Duplex	Full	Full	Half
Clock	None — both ends must agree	Shared	Shared
Addressing	None (point to point)	Chip select pin	7-bit address
Acknowledgement	None	None	Per byte
Error detection	Parity, framing, noise flags	None	None
Multi-master	No	No	Yes, with arbitration
Distance	Metres (more with RS-485)	Centimetres	Centimetres
Can hang the bus	No	No	Yes
Driver complexity	Low	Very low	High

The decision, in order

```
1. IS THE PEER OFF-BOARD OR MORE THAN ~30 CM AWAY?
     -> NOT SPI, NOT I2C. Both are chip-to-chip buses on
        one board. Use UART, or RS-485/CAN for real
        distance (chapters 14, 09).

2. DO YOU NEED MORE THAN ~1 MBIT/S?
     -> SPI. Nothing else here comes close. Displays,
        external flash, high-rate ADCs, radio modules.

3. ARE PINS THE BINDING CONSTRAINT?
     -> I2C. Ten sensors on two wires versus thirteen
        pins for SPI. On a 20-pin part this decides it.

4. IS THIS A CONSOLE, A LOG, OR A MODEM-STYLE DEVICE?
     -> UART. GPS, GSM, Bluetooth modules and debug
        consoles are all UART by convention, and fighting
        the convention costs more than it saves.

5. DOES THE DEVICE NEED TO INITIATE?
     -> UART, or add an interrupt line. SPI and I2C
        slaves cannot speak unprompted; the near-universal
        solution is a separate INT pin that tells the
        master to come and read - which quietly costs you
        the pin you saved by choosing I2C.

6. OTHERWISE
     -> I2C for slow sensors, SPI for anything else.

AND THE HONEST ANSWER MOST OF THE TIME: the sensor you
want supports one bus, and that decides it. The choice
above matters when you are designing the protocol between
two chips you control - an MCU talking to an application
processor, or two MCUs in one product.
```

The interrupt line nobody counts

```
/* SPI and I2C are strictly master-driven. A sensor with new
   data has no way to say so, which leaves three options.  */

/* 1. POLLING - simple, wasteful, and adds latency. */
for (;;) {
    if (i2c_read_reg(ADDR, STATUS) & DATA_READY) {
        read_and_process();
    }
    delay_ms(10);          /* 100 transactions/s doing
                              nothing, and up to 10 ms of
                              latency                     */
}

/* 2. AN INTERRUPT PIN - one extra wire, and the right
      answer nearly always.                               */
void EXTI9_5_IRQHandler(void)
{
    EXTI->PR = (1u << 7);
    /* Do NOT do I2C in the ISR - it blocks for hundreds of
       microseconds. Signal a task (mcu chapter 19).       */
    vTaskNotifyGiveFromISR(sensor_task, &woken);
    portYIELD_FROM_ISR(woken);
}

/* Now: zero bus traffic when idle, microseconds of latency,
   and the CPU can sleep. The pin you spent buys back more
   than it cost.

   SHARED INTERRUPT LINES: several open-drain INT outputs
   can share one MCU pin with a pull-up - any device pulling
   low signals, and the handler polls each device's status
   to find out who. This is exactly the wired-OR idea from
   chapter 06, and it keeps the pin count at one regardless
   of device count.                                        */

/* 3. A FIFO IN THE SENSOR - increasingly common and the
      best of both. The device buffers 32-512 samples and
      interrupts only when the FIFO passes a watermark. The
      master then reads a burst.

      This is how a modern IMU is used: instead of 1000
      interrupts per second for 1000 samples, you get 10
      interrupts and read 100 samples each time. The CPU
      sleeps 99% of the time and the bus carries the same
      data in a tenth of the transactions.

      If a sensor offers a FIFO, use it. It is usually the
      difference between a design that meets its power
      budget and one that does not.                       */
```

COUNT THE REAL PIN COST

I2C's two-wire claim assumes no interrupt lines and no address conflicts. Three sensors that each need an interrupt pin cost 2 + 3 = 5 pins, against SPI's 3 + 3 = 6 — and if two of them share a fixed address you also need a multiplexer, which costs a part, board area and another two wires. Do this arithmetic with the actual devices before committing the schematic, not after.

Mixing them, and level shifting

```
A real board runs all three at once, and the interesting
problem becomes voltage domains.

MCU at 3.3 V, sensor at 1.8 V:

PUSH-PULL BUSES (SPI, UART) need a proper level shifter -
a dedicated translator IC, or a resistor divider for
3.3 -> 1.8 in the slow direction only. A divider cannot
shift UP, and it slows the edge, so it is unsuitable for
fast SPI.

OPEN-DRAIN BUSES (I2C) shift with ONE MOSFET PER LINE:

     3.3V                    1.8V
      |                       |
    [4.7k]                  [4.7k]
      |                       |
SDA_3V3 ----+           +---- SDA_1V8
            |           |
          +-+-----------+-+
          | G   MOSFET    |    gate tied to 1.8 V
          | S           D |
          +---------------+

Either side pulling low pulls the other low, through the
body diode and then the channel. Elegant, cheap, and the
standard solution - the BSS138 in this configuration
appears on an enormous number of boards.

THIS IS ANOTHER CONSEQUENCE OF OPEN-DRAIN, and a real
advantage of I2C in mixed-voltage designs.

ALWAYS CHECK: is the sensor 5 V tolerant? Many 3.3 V
parts are not, and an I2C bus pulled up to 5 V will
damage them - slowly, so the board works for a week.
```

How it shows up

Symptom	Cause
I2C unreliable between two boards	Wrong bus for the distance — use UART, RS-485 or a buffer
SPI display too slow to refresh	Clock too low, or per-byte CPU overhead; use DMA
Ran out of pins late in the design	Interrupt lines not counted in the original bus choice
High CPU load just polling a sensor	No interrupt line and no FIFO — add one
Power budget missed by a wide margin	Waking per sample instead of per FIFO watermark
Two identical sensors cannot coexist	Fixed I2C address; needs a mux or a different bus
Level shifter works for I2C, not for SPI	MOSFET shifters are for open-drain only
Board works for a week then a sensor dies	Non-5 V-tolerant part on a 5 V pulled-up bus
Sensor data always one sample stale	Polling loop reading before the conversion completes
ISR takes hundreds of microseconds	Bus transaction inside the interrupt handler — defer it to a task

Check yourself

- ✓ Give the wire count for five devices on each of the three buses.
- ✓ Say which of the three can hang the bus and why.
- ✓ State the first question to ask when choosing, and what it rules out.
- ✓ Explain why a slave device cannot initiate on SPI or I2C.
- ✓ Describe the three ways to learn that a sensor has new data.
- ✓ Explain how a shared open-drain interrupt line works.
- ✓ Explain why a sensor FIFO can decide whether a power budget is met.
- ✓ Do the real pin arithmetic for three interrupt-driven sensors on I2C versus SPI.
- ✓ Explain why one MOSFET level-shifts I2C but not SPI.
- ✓ Say what to check before pulling an I2C bus up to 5 V.

CAN: arbitration and the bit-level protocol

CAN was designed for a car in 1986 and every design decision shows it: no addresses, no master, priority resolved without losing a bit of bandwidth, and error handling that assumes nodes will fail and the bus must survive. It is the most thoroughly engineered bus in this track.

The physical layer

```
A DIFFERENTIAL PAIR, terminated at both ends.

node A        node B        node C
  |             |             |
[xcvr]        [xcvr]        [xcvr]
  |  |          |  |          |  |
[120]+----------+--+----------+--[120]
  CANH ==================================
  CANL ==================================

TWO BUS STATES, and the naming is the key to everything:

RECESSIVE (logical 1)   CANH = CANL = 2.5 V
                        differential = 0 V
                        This is what the bus does when
                        NOBODY drives it.

DOMINANT  (logical 0)   CANH = 3.5 V, CANL = 1.5 V
                        differential = 2 V
                        Any node driving dominant
                        OVERRIDES every recessive node.

IT IS A WIRED-AND BUS: dominant wins, exactly like I2C's
open-drain low (chapter 07). Everything below follows
from that one property.

DIFFERENTIAL SIGNALLING is why CAN works in a car: noise
couples equally into both wires, so the DIFFERENCE is
unaffected. Common-mode rejection of tens of volts, over
40 metres, next to an ignition coil.

TERMINATION: 120 ohms at each END of the bus, not at each
node. Two resistors total, giving 60 ohms as seen by a
transmitter. Missing one causes reflections and
intermittent errors; fitting three drops the impedance
too low and transmitters cannot pull the bus dominant.
"Measure 60 ohms across a powered-down bus" is the first
diagnostic anyone does.
```

The frame

```
STANDARD DATA FRAME (11-bit identifier):

+---+-----------+---+---+------+--------+-----+---+---+---+
|SOF| ID 11 bits|RTR|IDE| r0   | DLC 4  |DATA |CRC|ACK|EOF|
+---+-----------+---+---+------+--------+-----+---+---+---+
  1      11      1   1    1        4    0-64   16  2   7

SOF   start of frame, one dominant bit
ID    IDENTIFIER - not an address. It names the MESSAGE,
      not the sender or receiver.
RTR   remote transmission request (asking for data)
IDE   0 = 11-bit ID, 1 = 29-bit extended
DLC   data length, 0-8 bytes
CRC   15-bit CRC + delimiter
ACK   THE CLEVER BIT - see below
EOF   7 recessive bits

THERE IS NO SOURCE OR DESTINATION ADDRESS. A node
broadcasts "engine speed is 3000 rpm" with ID 0x0C0, and
every node that cares filters for that ID. Adding a
listener requires no change anywhere else - which is why
a car can gain a new module without reflashing the
others.

THE ACK SLOT: the transmitter sends a RECESSIVE bit, and
EVERY node that received the frame with a valid CRC
drives it DOMINANT. So:

  - one ACK bit is enough for any number of receivers
  - the transmitter learns "at least one node heard me"
  - it does NOT learn who, or whether the intended
    recipient did

A SINGLE NODE ALONE ON A BUS CANNOT TRANSMIT SUCCESSFULLY
- nobody acknowledges, so it retries forever and
eventually goes error-passive (chapter 10). This is the
most common CAN bring-up confusion: your code is correct,
but you need a second node, or loopback mode, to test.
```

Arbitration without losing bandwidth

```
Every node may start transmitting when the bus is idle.
Collisions are resolved DURING the identifier, bit by bit.

Node A sends ID 0x123 = 001 0010 0011
Node B sends ID 0x121 = 001 0010 0001

bit:      10 9 8 7 6 5 4 3 2 1 0
A drives:  0 0 1 0 0 1 0 0 0 1 1
B drives:  0 0 1 0 0 1 0 0 0 0 1
BUS:       0 0 1 0 0 1 0 0 0 0 ...
                           ^
                      A sends recessive(1),
                      reads back dominant(0).
                      A LOSES, stops immediately.

Every transmitter monitors the bus while sending. Sending
recessive and reading dominant means someone with a lower
ID is talking; you withdraw at once and retry later.

WHY THIS IS BETTER THAN ETHERNET'S APPROACH:
  - NON-DESTRUCTIVE: B's frame continues uncorrupted. No
    collision, no backoff, no wasted bus time.
  - DETERMINISTIC: the lowest ID always wins, so the
    highest-priority message has a computable worst-case
    latency. Ethernet's CSMA/CD has none.
  - FREE: it costs no extra bits; the identifier does
    double duty as the priority.

LOWER ID = HIGHER PRIORITY. This makes ID assignment a
REAL-TIME DESIGN DECISION, not an arbitrary labelling.
Safety-critical messages get low IDs; diagnostics get
high ones. Get it backwards and a diagnostic tool can
delay a brake message.

THE COST: a node with a high ID can be starved
indefinitely on a busy bus. Bus load is therefore budgeted
- 30-40% is a normal design target, and above 70% the
low-priority messages become unpredictable.
```

BIT RATE IS CAPPED BY THE PHYSICS OF ARBITRATION

For arbitration to work, every node must sample each identifier bit *after* the signal has propagated to the far end of the bus and back. So one bit time must exceed the round-trip delay — which ties bit rate to bus length: 1 Mbit/s for 40 m, 500 kbit/s for 100 m, 125 kbit/s for 500 m. This is not a signal integrity limit you can engineer around with better cable; it is inherent to resolving arbitration within a bit. CAN FD (chapter 11) works around it by switching to a faster rate only *after* arbitration has finished.

Bit stuffing and self-clocking

```
/* CAN has no clock line, and no start bit per byte. The
   receiver recovers timing from EDGES - so the protocol
   guarantees edges happen.                                */

/* BIT STUFFING: after 5 consecutive bits of the same value,
   the transmitter inserts one bit of the OPPOSITE value.
   The receiver removes it.

     data:    1 1 1 1 1 1 1 0 0 0 0 0 0
     on wire: 1 1 1 1 1 0 1 1 0 0 0 0 0 1
                        ^             ^
                    stuffed       stuffed

   CONSEQUENCES:

   1. A frame's duration is VARIABLE. The same 8 bytes take
      different times depending on the bit pattern. Worst
      case for a standard frame is about 135 bit times
      against a nominal 111. Real-time analysis must use the
      worst case, not the nominal - a 20% error otherwise.

   2. SIX consecutive identical bits is by definition an
      ERROR, and that is exactly how errors are signalled:
      an ERROR FRAME is six dominant bits, deliberately
      violating the stuffing rule so every node notices
      immediately.

   3. Stuffing does not apply to the CRC delimiter, ACK and
      EOF fields, which are fixed-form.                    */

/* THE ERROR FRAME is what makes CAN robust. Any node that
   detects a violation - stuff error, CRC error, form error,
   ACK error, or bit error - immediately transmits six
   dominant bits. This DESTROYS the frame in progress for
   everyone, so all nodes discard it consistently and the
   transmitter retries automatically.

   No software involvement. A corrupted message is retried
   in microseconds by hardware. This is why CAN is used
   where it is, and it is also why a single faulty node can
   destroy every frame on the bus - which is what error
   confinement in chapter 10 exists to prevent.            */
```

How it shows up

Symptom	Cause
Single node cannot transmit anything	Nobody to ACK — add a second node or use loopback mode
Bus reads 120 Ω instead of 60 Ω	One terminator missing
Bus reads 40 Ω	Three terminators fitted — only the two ends should have one
Works on the bench, errors in the vehicle	Bit rate too high for the bus length, or a stub too long
Low-priority messages sometimes never sent	Bus load too high — starvation is inherent to priority arbitration
Timing analysis wrong by ~20%	Nominal frame length used instead of the worst case with stuffing

Symptom	Cause
One faulty node kills all traffic	It is generating error frames — error confinement should eventually silence it (chapter 10)
A diagnostic tool delays control messages	ID assignment backwards — diagnostics need high IDs
Frames received with wrong data	Bit timing sample point misconfigured (chapter 10)
Node transmits but nothing receives	CANH and CANL swapped

Check yourself

- ✓ Define dominant and recessive and say which wins.
- ✓ Explain why CAN uses differential signalling.
- ✓ State how many terminators a bus needs, where, and what to measure.
- ✓ Explain what a CAN identifier names, given there are no addresses.
- ✓ Explain the ACK slot and why one bit serves any number of receivers.
- ✓ Say why a single node alone on a bus cannot transmit.
- ✓ Walk through arbitration between two IDs and say which wins and why.
- ✓ Give two reasons CAN arbitration beats Ethernet's collision handling.
- ✓ Explain bit stuffing and its effect on worst-case frame duration.
- ✓ Explain how an error frame works and why it needs no software.

CAN: bit timing, error states and bus-off

Two things distinguish a CAN node that works from one that mostly works: a sample point set where the standard wants it, and an understanding of the error counters that decide whether a misbehaving node is allowed to keep talking.

The bit, divided

```
A CAN bit is divided into TIME QUANTA (tq), and the
division is what you configure - not a baud rate divisor.

|<--------------- one bit time ------------------>|
+--------+-----------------+--------------------+
|  SYNC  |    PROP + PS1   |        PS2         |
|  1 tq  |                 |                    |
+--------+-----------------+--------------------+
                           ^
                      SAMPLE POINT

SYNC_SEG   always 1 tq. Edges are expected here.
PROP_SEG   compensates for the physical propagation
           delay to the far end of the bus and back.
PHASE_SEG1 buffer, can be LENGTHENED to resync.
PHASE_SEG2 buffer, can be SHORTENED to resync.

SAMPLE POINT = (SYNC + PROP + PS1) / total, as a
percentage of the bit.

TARGET: 75-80% for most rates; CANopen and DeviceNet
specify 87.5%. LATE, not in the middle - because
arbitration requires the signal to have propagated to
the far end AND BACK before anyone samples (chapter 09).

THIS IS THE SINGLE MOST COMMON CAN CONFIGURATION ERROR.
A sample point at 50% works perfectly on a short bench
bus and fails on a long vehicle harness, because the
round trip no longer fits. The symptom is a bus that
works until the cable gets longer.

SJW (SynchronisationJumpWidth): how many tq the resync
may adjust by, 1-4. It absorbs the accumulated difference
between two nodes' oscillators. Set it to 1 for tight
clocks, higher if you must tolerate sloppy ones.
```

Calculating it

```
/* GOAL: 500 kbit/s from a 42 MHz peripheral clock, sample
   point at 87.5%.                                          */

/*  tq per bit is chosen first. More tq gives finer control
    of the sample point; fewer allows higher bit rates.
    8–25 is the usual range; 16 is a good default.

    prescaler = f_clk / (bitrate * tq_per_bit)
              = 42e6 / (500000 * 16)
              = 5.25            -> NOT AN INTEGER.

    Try tq = 14:
              = 42e6 / (500000 * 14) = 6      -> exact.

    Now divide 14 tq to place the sample point:
      SYNC = 1
      TSEG1 (prop + ps1) = 11
      TSEG2 (ps2)        = 2
      total = 1 + 11 + 2 = 14
      sample = (1 + 11) / 14 = 85.7%     -> close enough

    Registers hold "value minus one" (mcu chapter 11):     */

CAN1->BTR = ((6u - 1u)  << 0)      /* BRP  = 6            */
          | ((11u - 1u) << 16)     /* TS1  = 11 tq        */
          | ((2u - 1u)  << 20)     /* TS2  = 2 tq         */
          | ((1u - 1u)  << 24);    /* SJW  = 1 tq         */

/* VERIFY BY MEASUREMENT, not by arithmetic. Put a scope on
   CANH and measure one bit's width: it must be 2.00 us for
   500 kbit/s. An error of even 1% will cause errors on a
   long bus with a node at the tolerance limit.

   EVERY NODE ON THE BUS MUST USE THE SAME BIT RATE, and
   should use a similar sample point. They need NOT use the
   same tq count or prescaler - only the resulting bit time
   and a compatible sample point matter.

   ONLINE CALCULATORS EXIST and are worth using: the
   constraint set (integer prescaler, tq range, sample point
   target, SJW) is genuinely fiddly and errors are silent. */
```

BIT TIMING CAN ONLY BE CHANGED IN INITIALISATION MODE

The `BTR` register is writable only while the peripheral is in initialisation mode, and writes are silently ignored otherwise. Code that configures timing after starting the controller produces a node running at whatever the reset default was — usually wrong, and usually diagnosed as a wiring problem. Set timing before leaving init, and read the register back to confirm it took.

Error confinement

```
CAN assumes nodes will fail, and contains them
automatically. Two counters per node:

  TEC - transmit error counter
  REC - receive error counter

ROUGHLY: an error while transmitting adds 8 to TEC; an
error while receiving adds 1 to REC; a SUCCESS subtracts
1 from the relevant counter.

The 8:1 asymmetry is deliberate: a node that is itself
broken accumulates errors eight times faster than the
innocent nodes that merely witness them. The faulty node
is therefore confined first, and the bus survives.

THREE STATES:

ERROR ACTIVE      TEC < 128 and REC < 128
  Normal. Transmits ACTIVE error frames (6 dominant
  bits), which destroy the offending frame for everyone.

ERROR PASSIVE     TEC >= 128 or REC >= 128
  Still communicates, but transmits PASSIVE error frames
  (6 RECESSIVE bits) which do not disturb others. It
  also waits 8 extra bit times before transmitting,
  yielding to healthy nodes.

BUS-OFF           TEC >= 256
  Disconnected. Transmits nothing, ACKs nothing, has no
  effect on the bus at all.

+---------------+  TEC or REC >= 128   +----------------+
| ERROR ACTIVE  |--------------------> | ERROR PASSIVE  |
|               | <------------------- |                |
+---------------+  both < 128          +----------------+
                                                |
                                     TEC >= 256 |
                                                v
                                       +----------------+
                                       |    BUS-OFF     |
                                       +----------------+
                                                |
                         128 x 11 recessive bits, |
                         and software permission  |
                                                v
                                          ERROR ACTIVE

RECOVERY FROM BUS-OFF requires observing 128 occurrences
of 11 consecutive recessive bits - i.e. the bus being
idle - which takes at least 128 x 11 bit times. At
500 kbit/s that is about 2.8 ms.
```

Handling bus-off in software

```
/* Whether recovery is automatic is a configuration choice,
   and the right answer depends on the product.            */

/* AUTOMATIC (ABOM): the hardware recovers as soon as the
   128x11 condition is met. Convenient, and it hides the
   fault - a node with a broken transceiver will cycle
   in and out of bus-off forever, and nobody notices.      */
CAN1->MCR |= CAN_MCR_ABOM;

/* MANUAL: software decides. Preferred in anything that
   must report faults, because it lets you count and
   rate-limit.                                             */
void CAN1_SCE_IRQHandler(void)
{
    uint32_t esr = CAN1->ESR;

    if (esr & CAN_ESR_BOFF) {
        stats.bus_off_count++;
        stats.last_lec = (esr >> 4) & 7u;   /* last error code */

        if (stats.bus_off_count < 5) {
            can_restart();                  /* try again    */
        } else {
            /* Repeated bus-off is a HARDWARE fault: a
               shorted bus, a missing terminator, a wrong
               bit rate, or a dead transceiver. Retrying
               forever hides it. Report and stay off.      */
            fault_latch(FAULT_CAN_BUS);
        }
    }
}

/* THE LAST ERROR CODE names the cause, and it is genuinely
   diagnostic:

     1 STUFF   more than 5 identical bits -> noise, or a
               node at the wrong bit rate
     2 FORM    a fixed-form field was wrong -> bit rate or
               a node speaking a different protocol
     3 ACK     nobody acknowledged -> you are alone on the
               bus, or the others are bus-off, or CANH/CANL
               are swapped
     4 BIT1    sent recessive, read dominant -> another
               node is stuck dominant, or a short to ground
     5 BIT0    sent dominant, read recessive -> your
               transceiver is not driving; check its
               standby pin and supply
     6 CRC     corruption in transit -> noise or termination

   ACK error on a bench setup with one node is normal and
   expected (chapter 09). ACK error in a running vehicle
   means everyone else has gone quiet.                     */
```

Acceptance filters

```
/* A busy bus carries thousands of frames per second, and
   most are not yours. Filtering in HARDWARE is essential -
   waking the CPU for every frame would dominate the load. */

/* MASK MODE: check only the bits the mask selects.
     accept if (received_id & mask) == (filter_id & mask)  */

/* Accept 0x100-0x10F: the low nibble is "don't care".     */
CAN1->sFilterRegister[0].FR1 = (0x100u << 21);   /* id      */
CAN1->sFilterRegister[0].FR2 = (0x7F0u << 21);   /* mask    */

/* LIST MODE: accept exactly these identifiers, no mask.
   Use when you want a handful of unrelated IDs.           */

/* DESIGN CONSEQUENCE: assign IDs so that the messages one
   node cares about share a bit pattern. If a node needs
   0x101, 0x205 and 0x3C2, no single mask captures them and
   you burn three filter banks. If those messages were
   numbered 0x110, 0x111, 0x112 one filter does it.

   This is why CAN ID allocation is a system design task
   done up front, in a spreadsheet, balancing:
     - priority (lower = more urgent, chapter 09)
     - filterability (group by consumer)
     - room to grow

   Retrofitting an ID scheme after the software is written
   is genuinely painful, which is why standard higher-layer
   protocols - CANopen, J1939 - specify one for you.       */
```

How it shows up

Symptom	Cause
Works on the bench, fails with a long harness	Sample point too early — set it to 75–87.5%
Bit timing register has no effect	Written outside initialisation mode
Errors between two specific nodes only	Their bit rates differ slightly; measure a bit with a scope
Node goes bus-off immediately	Alone on the bus (ACK error), or CANH/CANL swapped
LEC reads BIT0 persistently	Transceiver not driving — check its standby/enable pin and supply
LEC reads BIT1 persistently	Another node stuck dominant, or a short to ground
Node cycles in and out of bus-off unnoticed	Automatic recovery hiding a hardware fault — count and latch
CPU saturated by receive interrupts	Filters too permissive; filter in hardware
Cannot filter the messages a node needs	ID allocation not designed for filterability
One node's errors kill the whole bus	It is error-active and sending error frames; wait for confinement or find it

Check yourself

- ✓ Name the four segments of a CAN bit and say which two absorb resynchronisation.
- ✓ Explain why the sample point is late rather than centred.
- ✓ Calculate BRP, TSEG1 and TSEG2 for 500 kbit/s from a 42 MHz clock.

- ✓ Say what must match between nodes and what need not.
- ✓ Explain the 8:1 asymmetry between transmit and receive error counters.
- ✓ Name the three error states and the thresholds between them.
- ✓ Explain the difference between active and passive error frames.
- ✓ State what bus-off recovery requires and how long it takes at 500 kbit/s.
- ✓ Interpret an ACK error, a BIT0 error and a BIT1 error as diagnoses.
- ✓ Explain why CAN ID allocation must consider filterability, not just priority.

CAN FD, and CAN in a vehicle

Classical CAN carries 8 bytes at 500 kbit/s, which was generous in 1991 and is not now. CAN FD raises both limits without giving up arbitration — and the higher-layer protocols built on top are where an embedded engineer actually works.

What CAN FD changes

```
TWO CHANGES, and the first is the clever one.

1. DUAL BIT RATE. Arbitration happens at the classical
   rate; the data phase switches to a faster one.

   |<-- arbitration -->|<--- data --->|<-- ack -->|
   |     500 kbit/s    |   2-8 Mbit/s  | 500 kbit/s|
   +-------------------+---------------+-----------+
    ID, RTR, control    DATA + CRC      ACK, EOF

   WHY THIS WORKS: the round-trip constraint (chapter 09)
   applies only while several nodes might be driving at
   once - during arbitration. Once one node has won, it
   is alone on the bus and no round trip is needed, so
   the bit time can shrink to whatever the physical layer
   supports.

   A genuinely elegant piece of protocol design: it
   removes the bandwidth limit without touching the
   property that made CAN worth using.

2. LONGER FRAMES. Up to 64 bytes rather than 8. DLC
   values above 8 are encoded non-linearly:
     9-15 mean 12, 16, 20, 24, 32, 48, 64 bytes.
   So the jump is 8, 12, 16, 20, 24, 32, 48, 64 - you
   cannot ask for 40.

ALSO: a stronger CRC (17 or 21 bit), and no RTR frames.

THROUGHPUT: 8 bytes at 500 kbit/s is about 3.6 kB/s of
payload after overhead. 64 bytes with a 2 Mbit/s data
phase is roughly 25x that, and it means a firmware
update over CAN goes from hours to minutes.
```

CLASSICAL AND FD NODES CANNOT SHARE A BUS

A classical CAN controller sees an FD frame's control bits as a form error and transmits an error frame, destroying it — so one legacy node makes FD traffic impossible. Some transceivers and controllers support "CAN FD tolerant" mode, where classical nodes ignore FD frames instead of objecting, but this must be supported by every node on the bus. In practice a vehicle migrates one whole bus segment at a time, with a gateway translating between them.

The higher-layer protocols

```
Raw CAN gives you 8 (or 64) bytes with an identifier.
Everything else is a protocol on top, and you will
almost always be implementing one of these:

ISO-TP (ISO 15765-2) - TRANSPORT
  Segments messages longer than one frame, up to 4095
  bytes, with flow control. The foundation of diagnostics.

    SINGLE FRAME    [0x0n][ up to 7 bytes ]
    FIRST FRAME     [0x1L][LL][ 6 bytes ]
    FLOW CONTROL    [0x30][BS][STmin]     <- receiver
    CONSECUTIVE     [0x2n][ 7 bytes ]        controls
                                             the rate

  The receiver dictates block size and minimum separation
  time, so a slow ECU can throttle a fast tester. This is
  the piece people re-implement badly; use a library.

UDS (ISO 14229) - DIAGNOSTICS
  Request/response services over ISO-TP. Read fault
  codes, read data by identifier, flash firmware, run
  routines. Service 0x22 (ReadDataByIdentifier) and 0x2E
  (WriteDataByIdentifier) are most of what a tool does.

J1939 - HEAVY VEHICLES
  29-bit IDs carrying structured meaning: priority,
  PGN (parameter group number), source address. Standard
  PGNs mean engine speed is the same message on every
  truck, regardless of manufacturer.

CANopen - INDUSTRIAL
  Object dictionary, PDOs for real-time data, SDOs for
  configuration, standard device profiles. Common in
  motion control and industrial automation.

AUTOSAR - AUTOMOTIVE SOFTWARE ARCHITECTURE
  Not a CAN protocol as such, but the framework most
  automotive ECU software is written inside, with CAN as
  one of its communication stacks.
```

ISO-TP, because you will meet it

```
/* Receiving a multi-frame message. The state machine is
   small; the timeouts are what make it correct.          */

typedef enum { TP_IDLE, TP_RECEIVING } tp_state_t;

typedef struct {
    tp_state_t state;
    uint8_t    buf[4095];
    uint16_t   expected, received;
    uint8_t    next_sn;          /* sequence number 0-15   */
    uint32_t   last_frame_ms;
} tp_rx_t;

void tp_on_frame(tp_rx_t *tp, const uint8_t *d, uint8_t len)
{
    uint8_t type = d[0] >> 4;

    switch (type) {
    case 0x0:                                  /* SINGLE   */
        deliver(&d[1], d[0] & 0x0F);
        tp->state = TP_IDLE;
        break;

    case 0x1:                                  /* FIRST    */
        tp->expected = (uint16_t)(((d[0] & 0x0F) << 8) | d[1]);
        if (tp->expected > sizeof(tp->buf)) {
            tp_send_fc_overflow();             /* refuse    */
            return;
        }
        memcpy(tp->buf, &d[2], 6);
        tp->received = 6;
        tp->next_sn  = 1;
        tp->state    = TP_RECEIVING;
        tp->last_frame_ms = g_ms;
        tp_send_flow_control(0 /* BS: unlimited */, 0 /* STmin */);
        break;

    case 0x2: {                                /* CONSEC   */
        if (tp->state != TP_RECEIVING) { return; }  /* stray */

        uint8_t sn = d[0] & 0x0F;
        if (sn != tp->next_sn) {
            /* A frame was LOST. The sequence number exists
               precisely to detect this; abort rather than
               deliver a message with a hole in it.        */
            stats.tp_sequence_errors++;
            tp->state = TP_IDLE;
            return;
        }
        tp->next_sn = (uint8_t)((sn + 1u) & 0x0F);

        uint16_t n = tp->expected - tp->received;
        if (n > 7) { n = 7; }
        memcpy(&tp->buf[tp->received], &d[1], n);
        tp->received += n;
        tp->last_frame_ms = g_ms;

        if (tp->received >= tp->expected) {
            deliver(tp->buf, tp->expected);
            tp->state = TP_IDLE;
```

```
        }
        break;
    }
    default:
        break;
    }
}

/* THE TIMEOUT IS NOT OPTIONAL. If the sender dies mid
   message, this state machine waits forever holding a 4 kB
   buffer. ISO 15765-2 specifies N_Cr = 1000 ms between
   consecutive frames.                                    */
void tp_poll(tp_rx_t *tp)
{
    if (tp->state == TP_RECEIVING &&
        (int32_t)(g_ms - tp->last_frame_ms - 1000) >= 0) {
        stats.tp_timeouts++;
        tp->state = TP_IDLE;
    }
}
```

What a vehicle bus actually looks like

```
A car has SEVERAL buses, segregated by criticality, with
a gateway between them.

+-----------------------------------------------------+
|                     GATEWAY ECU                     |
+--+--------------+--------------+-------------+-----+
   |              |              |             |
POWERTRAIN     CHASSIS         BODY         DIAGNOSTIC
500 kbit/s     500 kbit/s      125 kbit/s   OBD-II port
or CAN FD                      or LIN
   |              |              |
engine ECU     ABS            doors, lights
transmission   steering       climate, seats
               airbag

WHY SEGREGATED:
  - a fault on the body bus must not affect braking
  - bandwidth: the powertrain bus carries 10 ms cyclic
    messages; the body bus can be far slower and cheaper
  - SECURITY: the OBD-II port is physically accessible
    to anyone, so the gateway is a firewall. The famous
    2015 Jeep Cherokee remote attack pivoted from the
    infotainment system onto the CAN bus - after which
    the protocol offers no defence at all, because CAN
    has NO AUTHENTICATION WHATSOEVER.

THIS IS THE SECURITY REALITY OF CAN: any node can
transmit any identifier. There is no source
authentication, no encryption, and no way for a receiver
to know a frame is genuine. Security must come from:
  - segmentation and a gateway that filters
  - SecOC (AUTOSAR Secure Onboard Communication), which
    adds a truncated MAC and a freshness counter to
    critical messages
  - physical access control

If you are designing a CAN system today and it carries
anything that matters, assume the bus is hostile and
authenticate at the application layer. The cryptography
track's MAC chapter is directly relevant.
```

How it shows up

Symptom	Cause
FD frames destroyed by error frames	A classical node on the bus objecting to FD control bits
Cannot request a 40-byte frame	FD lengths are quantised: 32 then 48
FD works at low data rate, fails at 5 Mbit/s	Transceiver not rated for it, or stub lengths too long
Multi-frame messages truncated	Sequence number wrap not handled — it is modulo 16
ISO-TP holds a buffer forever	No N_Cr timeout between consecutive frames
Fast tester overruns a slow ECU	Flow control STmin ignored by the sender
Diagnostics work on one tool, not another	Block size or separation time handling differs
Firmware update over CAN takes hours	Classical CAN at 500 kbit/s — this is what FD is for
Spoofed messages accepted as genuine	CAN has no authentication; add SecOC or authenticate at the application layer

Symptom	Cause
A body-bus fault affects the powertrain	Buses not segregated, or the gateway is not filtering

Check yourself

- ✓ Explain why CAN FD can use a faster bit rate during the data phase.
- ✓ State the two limits CAN FD raises and by how much.
- ✓ Explain why FD data lengths above 8 bytes are quantised.
- ✓ Say what happens when a classical node shares a bus with FD traffic.
- ✓ Name the four ISO-TP frame types and what each carries.
- ✓ Explain what flow control lets the receiver dictate, and why that matters.
- ✓ Explain the purpose of the sequence number and the correct response to a gap.
- ✓ Say why the N_Cr timeout is required and what it protects.
- ✓ Give two reasons a vehicle has several segregated CAN buses.
- ✓ State CAN's security properties and name two ways to compensate.

USB: the bus, descriptors and enumeration

USB is by far the most complex bus in this track, and the one where a microcontroller almost never implements the hard parts itself. What you must understand is the model — endpoints, transfer types and descriptors — because that is the vocabulary every USB stack expects you to speak.

The model

```
USB IS STRICTLY HOST-DRIVEN. A device NEVER initiates.
The host polls; the device answers. Even an "interrupt"
endpoint is polled - the name is historical.

HOST                                DEVICE
+--------+                          +--------------+
|        |  ---- token: IN, ep 1 ---> | endpoint 1 IN|
|        |  <--- data packet -------- |              |
|        |  ---- ACK --------------->  |              |
+--------+                          +--------------+

ENDPOINT: a buffer in the device with a number (0-15) and
a direction. IN means device-to-host; OUT means
host-to-device. Directions are ALWAYS named from the
HOST's point of view, which is the first thing to get
straight.

ENDPOINT 0 is special: bidirectional, always present, and
carries all control traffic including enumeration.

INTERFACE: a group of endpoints implementing one function.
CONFIGURATION: a set of interfaces. Devices almost always
have exactly one configuration; the flexibility is
rarely used.

A composite device - say a USB headset - has several
interfaces in one configuration: audio out, audio in,
and HID for the volume buttons.
```

Four transfer types

Type	Guarantees	Used for
Control	Reliable, retried; 10% of bandwidth reserved	Enumeration and configuration, on endpoint 0
Bulk	Reliable, retried; no timing guarantee at all	Mass storage, serial ports, printers — anything where correctness beats latency
Interrupt	Reliable, retried; guaranteed poll interval	Keyboards, mice, sensors — small data at a bounded latency
Isochronous	Guaranteed bandwidth, *no retries*, no error recovery	Audio and video, where a late packet is worse than a lost one

```
THE TRADE-OFF THAT DEFINES USB:

  BULK gets whatever bandwidth is left over, but it never
  loses data. A mass-storage transfer may stall for
  milliseconds if the bus is busy; it will not corrupt.

  ISOCHRONOUS reserves bandwidth in every frame and
  never retries. A dropped audio sample is a click; a
  late one would be a gap in playback, which is worse.
  So it simply does not retry.

Choosing wrongly is a common design error: implementing
an audio device over bulk gives you glitch-free data with
unpredictable latency, which for audio is exactly the
wrong trade.

SPEEDS:
  Low   1.5 Mbit/s   HID only, 8-byte packets
  Full  12 Mbit/s    most MCU peripherals, 64-byte max
  High  480 Mbit/s   needs a ULPI PHY, 512-byte bulk
  Super 5 Gbit/s+    a different physical layer entirely,
                     essentially never on an MCU
```

Enumeration, step by step

```
What happens in the second after you plug the cable in.

1. ATTACH. The device pulls D+ (full speed) or D- (low
   speed) to 3.3 V through 1.5 kO. The host sees the
   line go high and knows something is there - and which
   speed it claims.

2. RESET. The host drives both lines low for 10 ms. The
   device resets its USB state machine and adopts
   ADDRESS 0.

3. GET_DESCRIPTOR (Device), 8 bytes. The host asks for
   the first 8 bytes only, because byte 7 is
   bMaxPacketSize0 and it does not yet know how large a
   packet the device can accept.

4. RESET again.

5. SET_ADDRESS. The host assigns 1-127. The device must
   complete the STATUS stage of this request at the OLD
   address, then switch. Getting that ordering wrong is
   a classic stack bug.

6. GET_DESCRIPTOR (Device), all 18 bytes. Now the host
   has VID, PID and class.

7. GET_DESCRIPTOR (Configuration), 9 bytes, then again
   for the full length reported. This returns the
   configuration, all interfaces, and all endpoints as
   ONE concatenated blob.

8. GET_DESCRIPTOR (String) for manufacturer, product,
   serial - in UTF-16LE.

9. The host matches VID/PID/class against its drivers
   and loads one.

10. SET_CONFIGURATION(1). The device is now CONFIGURED
    and its non-zero endpoints become usable.

IF ENUMERATION FAILS the host reports "device not
recognised" and gives you nothing else. A protocol
analyser or Wireshark's USB capture is the only
practical way to see which step failed.
```

Descriptors are the device's declaration

```
/* Descriptors are packed structs the device returns. They
   ARE the device's interface contract - everything the host
   knows comes from them.                                    */

typedef struct __attribute__((packed)) {
    uint8_t  bLength;             /* 18                     */
    uint8_t  bDescriptorType;     /* 1 = DEVICE             */
    uint16_t bcdUSB;              /* 0x0200 = USB 2.0       */
    uint8_t  bDeviceClass;        /* 0 = see interface      */
    uint8_t  bDeviceSubClass;
    uint8_t  bDeviceProtocol;
    uint8_t  bMaxPacketSize0;     /* 8, 16, 32 or 64        */
    uint16_t idVendor;            /* assigned by USB-IF     */
    uint16_t idProduct;
    uint16_t bcdDevice;
    uint8_t  iManufacturer;       /* string INDEX, not text */
    uint8_t  iProduct;
    uint8_t  iSerialNumber;
    uint8_t  bNumConfigurations;  /* almost always 1         */
} usb_device_descriptor_t;

/* A CDC-ACM (virtual serial port) configuration, as the
   host receives it - one contiguous blob.                */
static const uint8_t config_desc[] = {
    /* Configuration: 9 bytes, total length 67, 2 interfaces */
    9, 0x02, 67, 0, 2, 1, 0, 0xC0, 50,

    /* Interface 0: communications class, 1 endpoint      */
    9, 0x04, 0, 0, 1, 0x02, 0x02, 0x01, 0,
    /*   CDC functional descriptors (5+4+5+5 bytes)       */
    5, 0x24, 0x00, 0x10, 0x01,
    4, 0x24, 0x02, 0x02,
    5, 0x24, 0x06, 0, 1,
    5, 0x24, 0x01, 0, 1,
    /*   Endpoint 0x82: interrupt IN, 8 bytes, 255 ms     */
    7, 0x05, 0x82, 0x03, 8, 0, 255,

    /* Interface 1: CDC data, 2 endpoints                 */
    9, 0x04, 1, 0, 2, 0x0A, 0, 0, 0,
    /*   Endpoint 0x01: bulk OUT, 64 bytes                */
    7, 0x05, 0x01, 0x02, 64, 0, 0,
    /*   Endpoint 0x81: bulk IN, 64 bytes                 */
    7, 0x05, 0x81, 0x02, 64, 0, 0,
};

/* ENDPOINT ADDRESS ENCODING: bit 7 is direction.
     0x01 = endpoint 1, OUT
     0x81 = endpoint 1, IN
   These are DIFFERENT endpoints that share a number.

   THE TOTAL LENGTH FIELD (67 here) MUST BE EXACT. The host
   requests that many bytes; if the descriptors actually sum
   to a different number, enumeration fails in a way that
   gives no useful error. Compute it with sizeof() rather
   than by hand:

     #define CONFIG_TOTAL_LEN (sizeof(config_desc))
     ... and place it with a _Static_assert to check.     */
```

> **VENDOR IDS COST MONEY, AND THERE IS A LEGITIMATE ALTERNATIVE**
> A USB Vendor ID from the USB-IF costs several thousand dollars, and using someone else's without permission means your device can collide with theirs and cannot legally carry the USB logo. For hobby and internal work, pid.codes allocates free PIDs under a shared VID for open-source projects. For a product, budget for a real VID — or use a USB-to-serial bridge chip whose vendor's VID/PID you are licensed to use by buying the chip.

What this means on a microcontroller

```
/* You will use a stack. TinyUSB, the vendor's middleware,
   or Zephyr's - not your own. USB is a case where writing
   it yourself is a month of work to reach parity.

   WHAT YOU ACTUALLY DO:                                    */

/* 1. Provide descriptors. */
uint8_t const *tud_descriptor_device_cb(void) {
    return (uint8_t const *) &device_desc;
}

/* 2. Implement class callbacks. */
void tud_cdc_rx_cb(uint8_t itf) {
    uint8_t buf[64];
    uint32_t n = tud_cdc_read(buf, sizeof(buf));
    handle_input(buf, n);
}

/* 3. Service the stack, from a task or the main loop. */
for (;;) {
    tud_task();
    application_step();
}

/* THE HARDWARE REQUIREMENTS people underestimate:

   - AN ACCURATE CLOCK. USB full speed needs 0.25%. The
     internal RC oscillator is not sufficient unless the
     part has crystal-less USB, where it trims the RC
     against the host's start-of-frame packets. Otherwise:
     a crystal, and one whose frequency divides to exactly
     48 MHz (mcu chapter 09).

   - CORRECT D+/D- ROUTING. 90 ohm differential impedance,
     matched lengths, no stubs. USB is fast enough that
     layout matters - this is not a bus you can wire with
     jumper leads and expect to work.

   - VBUS SENSING if bus-powered, so the device knows when
     it is actually attached.

   - THE 1.5k PULL-UP, ideally software-controlled so the
     device can force a re-enumeration by dropping off the
     bus and reattaching. Without it, changing descriptors
     requires physically unplugging.                        */
```

How it shows up

Symptom	Cause
"Device not recognised", nothing else	Enumeration failed — capture it with a protocol analyser or Wireshark
Enumeration fails after the configuration request	`wTotalLength` does not match the actual descriptor bytes
Works on one host, not another	Descriptor that is technically invalid; Linux is more forgiving than Windows
Device enumerates then disconnects repeatedly	Clock accuracy — check the crystal and the 48 MHz derivation
Intermittent at high data rates only	D+/D− routing: impedance, length matching, or a stub
Endpoint 0x81 and 0x01 confused	Bit 7 is direction; they are different endpoints
Audio clicks and dropouts	Bulk used where isochronous is needed
Descriptor change needs a physical unplug	No software control of the D+ pull-up
Device works only when self-powered	VBUS sensing absent or miswired
Windows caches an old descriptor	It keys on VID/PID — bump `bcdDevice` or clear the registry entry during development

Check yourself

- ✓ Explain why a USB device can never initiate a transfer.
- ✓ Say whose point of view IN and OUT are named from.
- ✓ Name the four transfer types and the guarantee each makes.
- ✓ Explain why isochronous transfers do not retry.
- ✓ Explain why the host asks for only 8 bytes of the device descriptor first.
- ✓ Say what must happen at the old address during SET_ADDRESS.
- ✓ Explain what `wTotalLength` covers and the failure when it is wrong.
- ✓ Decode endpoint addresses 0x01 and 0x81.
- ✓ State USB full speed's clock accuracy requirement and two ways to meet it.
- ✓ Explain why a software-controlled pull-up is worth having.

USB device classes and writing a device

The single most valuable thing to know about USB is which standard class to claim, because claiming the right one means every operating system already has your driver. Getting this choice right is the difference between shipping a product and shipping a product plus three signed drivers.

The classes worth knowing

Class	Driver on Windows/macOS/Linux	Use for
CDC-ACM (serial)	Built in everywhere; Windows needs an INF before 10	A virtual COM port — debug consoles, legacy replacement
HID	Built in, no driver, no INF, ever	Keyboards, mice, and *any* low-rate custom data
MSC (mass storage)	Built in everywhere	Exposing a filesystem — logs, firmware drop-in
Audio (UAC)	Built in; UAC1 more compatible than UAC2	Speakers, microphones
Video (UVC)	Built in everywhere	Cameras
DFU	Needs WinUSB or a tool like dfu-util	Firmware update
Vendor-specific	WinUSB via a WCID descriptor; libusb elsewhere	High throughput custom protocols

```
THE DECISION:

Need a debug console?          -> CDC-ACM
Custom data, under ~64 kB/s?   -> HID
Custom data, high rate?        -> vendor-specific + WCID
Exposing files?                -> MSC
Firmware update?               -> DFU, or MSC drag-and-drop

HID IS UNDERRATED FOR CUSTOM DATA. It needs no driver, no
INF, no signing and no administrator rights on any
operating system, and browsers can talk to it directly
through WebHID. The cost is throughput: 64 KB/s at full
speed, 24 MB/s at high speed but only with careful
descriptor work.

For a configuration tool, a dongle, or a sensor that
reports a few kilobytes a second, HID removes an entire
category of deployment problem. Reach for it before
reaching for a vendor-specific interface.
```

Making a vendor-specific device driverless on Windows

```
/* Historically a vendor-specific device meant shipping a
   signed .inf and .cat. Microsoft OS descriptors (WCID)
   remove that: the device TELLS Windows to bind WinUSB.  */

/* Windows requests string descriptor 0xEE at enumeration.
   Return this magic string and it will follow up with
   vendor requests.                                       */
static const uint8_t msos_string[] = {
    0x12, 0x03,
    'M',0, 'S',0, 'F',0, 'T',0, '1',0, '0',0, '0',0,
    MSOS_VENDOR_CODE, 0x00
};

/* Then answer the compatible-ID request with "WINUSB". */
static const uint8_t msos_compat_id[] = {
    0x28,0,0,0,        /* dwLength = 40                   */
    0x00,0x01,         /* bcdVersion 1.0                  */
    0x04,0x00,         /* wIndex: compatible ID           */
    0x01,              /* one section                     */
    0,0,0,0,0,0,0,     /* reserved                        */
    0x00,              /* interface 0                     */
    0x01,              /* reserved                        */
    'W','I','N','U','S','B',0,0,   /* compatible ID       */
    0,0,0,0,0,0,0,0,               /* sub-compatible ID   */
    0,0,0,0,0,0                    /* reserved            */
};

/* Result: plug it in and Windows binds WinUSB with no
   driver install and no administrator rights. libusb then
   talks to it identically on Windows, macOS and Linux.

   ADD A DEVICE INTERFACE GUID via the extended properties
   descriptor and your application can find the device by
   GUID rather than enumerating everything.

   THIS IS THE MODERN ANSWER for custom USB devices, and
   it is much less widely known than it should be. TinyUSB
   and most stacks support it with a few lines of
   configuration.                                         */
```

A custom HID device

```
/* The HID report descriptor is a small stack-based language
   describing your data's structure. It is the fiddliest
   part of HID and the reason people avoid it - but a
   generic in/out report is a fixed template you can copy. */

static const uint8_t hid_report_desc[] = {
    0x06, 0x00, 0xFF,   /* Usage Page (vendor-defined)      */
    0x09, 0x01,         /* Usage (1)                        */
    0xA1, 0x01,         /* Collection (Application)         */

    0x09, 0x02,         /*   Usage (2) - input report       */
    0x15, 0x00,         /*   Logical Minimum (0)            */
    0x26, 0xFF, 0x00,   /*   Logical Maximum (255)          */
    0x75, 0x08,         /*   Report Size (8 bits)           */
    0x95, 0x40,         /*   Report Count (64 bytes)        */
    0x81, 0x02,         /*   Input (Data,Var,Abs)           */

    0x09, 0x03,         /*   Usage (3) - output report      */
    0x15, 0x00,
    0x26, 0xFF, 0x00,
    0x75, 0x08,
    0x95, 0x40,
    0x91, 0x02,         /*   Output (Data,Var,Abs)          */

    0xC0                /* End Collection                   */
};

/* 64 bytes in and 64 bytes out, opaque to the host. Now:  */

void tud_hid_set_report_cb(uint8_t itf, uint8_t id,
                           hid_report_type_t type,
                           uint8_t const *buf, uint16_t len)
{
    handle_command(buf, len);          /* host -> device   */
}

void send_reading(const reading_t *r)
{
    uint8_t rpt[64] = {0};
    memcpy(rpt, r, sizeof(*r));
    tud_hid_report(0, rpt, sizeof(rpt));   /* device -> host */
}

/* USE A DESCRIPTOR TOOL. The HID Descriptor Tool from
   USB-IF, or hidrd, will validate what you write. A subtly
   wrong report descriptor produces a device that enumerates
   successfully and then delivers reports the host silently
   discards - which is a miserable thing to debug by
   inspection.                                              */
```

WINDOWS CACHES DESCRIPTORS AGAINST VID/PID

During development, changing your descriptors and re-plugging often changes nothing, because Windows remembers the device from the first time it saw that VID/PID and does not re-read. Increment `bcdDevice` on every descriptor change, or delete the device from Device Manager with "delete the driver software" ticked, or use a different PID for each iteration. Hours are lost to this every year, and the symptom — "my change had no effect" — points at your code rather than the host.

Debugging USB

```
IN ORDER OF WHAT YOU SHOULD REACH FOR:

1. lsusb -v (Linux) / USB Tree View (Windows)
   Shows the descriptors as the host parsed them. If
   your device appears with the right VID/PID and the
   endpoints you expect, enumeration succeeded and the
   problem is above that layer.

2. WIRESHARK WITH usbmon (Linux) or USBPcap (Windows)
   Every packet, free, no hardware. This shows you which
   control transfer failed, and it is the tool that
   answers "why does it not enumerate".

3. dmesg (Linux)
   The kernel narrates enumeration failures in plain
   language: "device descriptor read/64, error -71".
   Often names the problem outright.

4. A HARDWARE PROTOCOL ANALYSER
   Beagle, Ellisys and similar. Needed only for
   electrical or timing problems - a device that
   enumerates on one host and not another, or one that
   fails at high speed. Expensive, and rarely the first
   resort.

5. GPIO + SCOPE inside your callbacks
   When the stack's behaviour itself is in question,
   toggling a pin in the endpoint callback tells you
   whether it is being called at all, and how often
   (mcu chapter 16).

THE ORDER MATTERS. People reach for the analyser first
and Wireshark last, when Wireshark answers the question
nine times out of ten and costs nothing.
```

How it shows up

Symptom	Cause
Descriptor changes have no effect	Windows cached the device — bump `bcdDevice` or remove it in Device Manager
Enumerates but the host discards every report	HID report descriptor subtly invalid — validate it with a tool
Needs a driver install on Windows	Vendor-specific without WCID — add the Microsoft OS descriptors
Works on Linux, not Windows	Descriptor technically invalid; Linux is more tolerant
Throughput far below expectations on HID	Poll interval too long, or report size too small for the rate
CDC device needs an INF on old Windows	Expected before Windows 10; ship one or use HID
Device disappears under load	Stack not serviced often enough — call the task loop more frequently
`dmesg` shows "error -71"	Electrical or clock problem, not a descriptor problem
Audio device stutters	Isochronous endpoint not filled every frame — the deadline is hard
Cannot open the device without root on Linux	Missing udev rule — ship one with the product

Check yourself

- ✓ Name four standard classes with built-in drivers on every OS.
- ✓ Explain why HID is attractive for custom low-rate data.
- ✓ State HID's practical throughput limit at full speed.
- ✓ Explain what WCID descriptors achieve on Windows.
- ✓ Say which string descriptor index Windows requests for OS descriptors.
- ✓ Explain what a HID report descriptor is and the failure mode when it is wrong.
- ✓ Describe why Windows appears to ignore your descriptor changes.
- ✓ Give the order in which to reach for USB debugging tools, and why.
- ✓ Say what `lsusb -v` tells you about whether enumeration succeeded.
- ✓ Explain when a hardware protocol analyser is actually necessary.

RS-485, Modbus and industrial serial

A UART reaches a few metres. RS-485 takes the same UART and carries it a kilometre, to 32 devices, through a factory full of electrical noise — for the cost of one transceiver chip and one piece of software discipline you must get exactly right.

What RS-485 changes

```
RS-232 (what a plain UART pin is, roughly)
  Single-ended: the voltage is measured against GROUND.
  Noise couples onto the signal wire and is
  indistinguishable from data. Ground offset between two
  buildings can exceed the signal itself.
  Reach: ~15 m at 9600 baud. One device per wire.

RS-485
  DIFFERENTIAL: two wires, A and B. The receiver reads
  the DIFFERENCE. Noise couples equally onto both and
  cancels. Same idea as CAN (chapter 09).
  Reach: 1200 m at 100 kbit/s. 32 standard loads,
  more with low-load transceivers.

           +--[120]--+                    +--[120]--+
           |         |                    |         |
  A  ------+---------+--------------------+---------+---
  B  ------+---------+--------------------+---------+---
           |         |                    |
        +---+---+  +--+----+           +---+---+
        |master |  |slave 1|    ...    |slave n|
        +-------+  +-------+           +-------+

HALF DUPLEX, and this is the crucial difference from
everything else in this track: ONE PAIR, shared, and only
one transmitter may be enabled at a time. There is NO
arbitration - unlike CAN or I2C, two simultaneous
transmitters simply corrupt each other and may damage the
drivers.

So the protocol on top MUST guarantee that only one node
talks at a time. In practice that means a master polls
and slaves answer only when addressed - which is exactly
what Modbus does.

RS-422 is the full-duplex cousin: two pairs, one master
transmitting to many receivers. No direction control
needed, but no multi-drop from the slaves either.
```

Direction control, the thing everyone gets wrong

```
/* The transceiver has a DRIVER ENABLE pin. Assert it to
   transmit, release it to listen. The timing of the
   RELEASE is where the bugs live.                          */

#define DE_HIGH()  (GPIOB->BSRR = (1u << 1))       /* TX     */
#define DE_LOW()   (GPIOB->BSRR = (1u << (1 + 16)))/* RX     */

/* WRONG - truncates the last byte, always.                 */
void rs485_send_broken(const uint8_t *p, size_t n)
{
    DE_HIGH();
    while (n--) {
        while (!(USART2->ISR & USART_ISR_TXE)) { }
        USART2->TDR = *p++;
    }
    DE_LOW();          /* TXE means the DATA REGISTER is
                          free. The last byte is STILL IN
                          THE SHIFT REGISTER (chapter 01).
                          Disabling the driver now cuts it
                          off mid-character.                */
}

/* RIGHT - wait for TRANSMISSION COMPLETE.                  */
void rs485_send(const uint8_t *p, size_t n)
{
    DE_HIGH();
    delay_us(1);                       /* driver settle    */

    while (n--) {
        while (!(USART2->ISR & USART_ISR_TXE)) { }
        USART2->TDR = *p++;
    }

    while (!(USART2->ISR & USART_ISR_TC)) { }   /* THE FIX  */
    DE_LOW();
}

/* BETTER STILL - let the hardware do it. Many modern UARTs
   drive the DE pin themselves with programmable setup and
   hold times, which removes the software race entirely.  */
USART2->CR3 |= USART_CR3_DEM;              /* DE mode      */
USART2->CR1 |= (8u << USART_CR1_DEAT_Pos)  /* assertion    */
            |  (8u << USART_CR1_DEDT_Pos); /* deassertion  */
/* Now DE is an alternate function pin and the timing is
   exact regardless of interrupts. If your part has this,
   use it - it eliminates a whole class of intermittent
   "the last byte is sometimes wrong" bugs.

   WITH DMA the same trap appears: the DMA transfer-complete
   interrupt fires when the last byte enters the UART, not
   when it leaves the pin. Wait for TC in the DMA callback
   before dropping DE.                                      */
```

FAIL-SAFE BIASING: AN IDLE BUS IS NOT A SAFE BUS

When no driver is enabled, the A/B pair floats. Noise then flips the receiver randomly and every node sees garbage that may resemble a start bit — so every node's UART reports framing errors continuously, and a receiver may lock onto noise as though it were a frame. The fix is fail-safe biasing: a pull-up on A and a pull-down on B, typically 560 Ω to 1 kΩ, fitted *once* on the bus, holding the idle state at a defined logical high. Many transceivers include internal fail-safe; many do not. If an RS-485 bus produces garbage when nothing is transmitting, this is the first thing to check.

Modbus RTU

```
Published in 1979 and still the default in industrial
automation, because it is simple enough to implement in
an afternoon and everything supports it.

FRAME:
+---------+----------+---------------+---------+
| ADDRESS | FUNCTION |      DATA     | CRC-16  |
|  1 byte |  1 byte  |   0-252 bytes | 2 bytes |
+---------+----------+---------------+---------+

FRAMING BY SILENCE: a frame starts after 3.5 character
times of silence and ends the same way. There is no start
or end delimiter byte at all.

AT 9600 BAUD, 8N1: one character is 11 bits = 1.146 ms
  t3.5 = 4.01 ms
  t1.5 = 1.72 ms  (max gap WITHIN a frame)

ABOVE 19200 BAUD the standard fixes these at 1.75 ms and
750 us rather than scaling them, because the character
times become impractically short.

THIS IS EXACTLY WHAT UART IDLE DETECTION IS FOR
(chapter 03). Modbus RTU was designed around a timing
gap, and the IDLE interrupt implements it in hardware.
The alternative - a timer restarted on every byte - works
but costs an interrupt per character.

COMMON FUNCTION CODES:
  0x01  read coils            (bits, read/write)
  0x02  read discrete inputs  (bits, read only)
  0x03  read holding registers  (16-bit, read/write)
  0x04  read input registers    (16-bit, read only)
  0x05  write single coil
  0x06  write single register
  0x10  write multiple registers

ADDRESS 0 IS BROADCAST - all slaves act, none reply.
Addresses 1-247 are valid slaves.

EXCEPTION RESPONSE: the slave replies with the function
code OR 0x80, plus an exception code. 0x02 is "illegal
data address", which is what you get when your register
map does not match the master's expectation - the single
most common Modbus integration problem.
```

```
/* CRC-16/MODBUS. Note the reflected polynomial 0xA001 and
   the 0xFFFF seed - both are specific to Modbus and using
   the wrong CRC-16 variant is a classic error, because
   there are at least a dozen of them.                    */

static uint16_t modbus_crc(const uint8_t *d, size_t n)
{
    uint16_t crc = 0xFFFFu;
    while (n--) {
        crc ^= *d++;
        for (int i = 0; i < 8; i++) {
            crc = (crc & 1u) ? (uint16_t)((crc >> 1) ^ 0xA001u)
                             : (uint16_t)(crc >> 1);
        }
    }
    return crc;                     /* transmitted LOW byte
                                       first - the ONLY
                                       little-endian field
                                       in the protocol      */
}

/* EVERYTHING ELSE IN MODBUS IS BIG-ENDIAN. Register values,
   addresses, counts: all high byte first. The CRC alone is
   low byte first. This inconsistency is a permanent source
   of bugs and it is not a mistake in your reading - it
   really is like that.                                    */

/* A slave, receiving via IDLE-triggered DMA (chapter 03). */
void modbus_on_frame(const uint8_t *f, uint16_t len)
{
    if (len < 4) { return; }                /* runt        */
    if (f[0] != MY_ADDRESS && f[0] != 0) { return; }

    uint16_t rx_crc = (uint16_t)(f[len-2] | (f[len-1] << 8));
    if (rx_crc != modbus_crc(f, len - 2u)) {
        stats.crc_errors++;
        return;               /* SILENTLY DISCARD - a bad
                                 CRC may mean the frame was
                                 not even for us            */
    }

    switch (f[1]) {
    case 0x03: handle_read_holding(f, len);  break;
    case 0x06: handle_write_single(f, len);  break;
    default:
        modbus_exception(f[1], 0x01);       /* illegal fn  */
    }
}

/* NEVER REPLY TO A BAD CRC. You cannot trust the address
   byte either, so replying risks two slaves transmitting
   at once - which on a half-duplex bus corrupts the next
   valid exchange too.                                     */
```

How it shows up

Symptom	Cause
Last byte of every reply corrupt	DE dropped on TXE instead of TC
Continuous framing errors when idle	No fail-safe biasing — the bus floats

Symptom	Cause
Works with two nodes, fails with ten	Termination, biasing, or too many unit loads
Intermittent errors at the far end only	Missing terminator, or a stub too long
Exception code 0x02 on every read	Register map offset — vendors disagree about 0-based versus 1-based
CRC never matches	Wrong CRC-16 variant, or byte order of the CRC field
Values are byte-swapped	Modbus is big-endian except the CRC
Two slaves reply at once	Duplicate addresses, or a slave replying to a bad CRC
Frames merge together	Inter-frame silence not enforced — use IDLE detection
Master times out on a slow slave	Response timeout shorter than the slave's processing time

Check yourself

- ✓ Explain why differential signalling reaches a kilometre where single-ended reaches fifteen metres.
- ✓ Say why RS-485 has no arbitration and what that requires of the protocol above it.
- ✓ Explain the difference between TXE and TC for driver-enable timing.
- ✓ Describe hardware DE control and why it is preferable.
- ✓ Explain fail-safe biasing and the symptom of its absence.
- ✓ State how Modbus RTU delimits frames and compute t3.5 at 9600 baud.
- ✓ Say which UART feature implements Modbus framing in hardware.
- ✓ Give the byte order of Modbus fields, including the exception.
- ✓ Explain why a slave must not reply to a frame with a bad CRC.
- ✓ Say what exception code 0x02 usually indicates in an integration.

MIPI CSI-2 and camera interfaces

A 12-megapixel sensor at 30 frames per second produces about 5 gigabits every second. No bus in the preceding chapters is within two orders of magnitude of that, which is why camera interfaces are a different kind of engineering — and why the control path and the data path are separate buses.

Why cameras need their own interface

```
THE ARITHMETIC:

  4000 x 3000 pixels x 10 bits x 30 fps
    = 3.6 Gbit/s of raw sensor data

SPI at 100 Mbit/s would need 36 lanes.
USB high speed at 480 Mbit/s cannot do it at all.

THE OLD ANSWER - PARALLEL DVP (digital video port):

  D0-D7 (or D0-D11)   data
  PCLK                pixel clock
  HSYNC               line valid
  VSYNC               frame valid

  12-16 pins, and every one of them switching at the
  pixel clock. At VGA/30fps that is fine; at anything
  modern the pin count and the EMI are both unacceptable.
  Still common on small MCU-class sensors (OV7670 and
  similar) and worth recognising.

THE MODERN ANSWER - MIPI CSI-2 over D-PHY:

  A clock lane plus 1-4 data lanes, DIFFERENTIAL, each
  lane carrying 1-2.5 Gbit/s.

  4 lanes x 2.5 Gbit/s = 10 Gbit/s on 10 wires.

PLUS A SEPARATE I2C BUS (called CCI - camera control
interface) for configuration. This split is the thing to
internalise:

  CSI-2  = pixels, one direction, very fast
  I2C    = registers, bidirectional, slow

You configure the sensor over I2C - resolution, exposure,
gain, frame rate - and it then streams pixels over CSI-2.
Two completely different buses to one chip, and bringing
up a camera means getting both right independently.
```

D-PHY's two modes

```
The physical layer switches between two electrical modes
on the same wires, and this is what makes it efficient.

HIGH-SPEED (HS) mode
  Differential, 200 mV swing around 200 mV common mode.
  Low voltage means low power and low EMI at gigabit
  rates. Used for the actual pixel burst.

LOW-POWER (LP) mode
  Single-ended, 1.2 V, both wires used independently as
  two slow signals. Used between bursts for control,
  and to signal entry into HS mode.

  LP-11  both high    = stop state, the idle condition
  LP-01, LP-00        = the HS entry sequence
  LP-10  turnaround (for bidirectional lane 0)

A FRAME LOOKS LIKE:

  LP-11 ... [HS burst: line 1] ... LP-11 ...
            [HS burst: line 2] ... LP-11 ...

The link drops to low power between every LINE. On a
battery device this matters enormously - the high-speed
drivers are only active while pixels are actually moving.

THIS IS WHY CSI-2 BRING-UP FAILS IN A CHARACTERISTIC WAY:
if the lanes never leave LP-11, the sensor is not
streaming at all - check the I2C configuration and the
sensor's clock and reset pins. If you see HS bursts but
no valid frames, the problem is packet-level: lane count,
data type, or virtual channel mismatch.
```

The packet layer

```
/* CSI-2 carries SHORT and LONG packets, distinguished by
   the data type field.                                      */

/* SHORT PACKET - 4 bytes, synchronisation only:
     Frame Start (0x00), Frame End (0x01),
     Line Start (0x02),  Line End (0x03)

   +--------+--------+--------+--------+
   | DI     | frame number    | ECC    |
   +--------+--------+--------+--------+

   LONG PACKET - carries pixel data:

   +--------+-----------------+--------+=========+--------+
   | DI     | word count      | ECC    | payload |CRC-16  |
   +--------+-----------------+--------+=========+--------+
     header: 4 bytes                     variable   2 bytes

   DI (data identifier) = virtual channel (2 bits) +
                          data type (6 bits)

   DATA TYPES you will meet:
     0x2A  RAW8      0x2B  RAW10     0x2C  RAW12
     0x1E  YUV422 8-bit
     0x24  RGB888
     0x30-0x37  user defined

   THE ECC on the header is a Hamming code that corrects one
   bit error and detects two. The header must survive - a
   corrupted word count would desynchronise the whole
   stream - so it gets stronger protection than the payload,
   which only has a CRC.

   VIRTUAL CHANNELS let several image streams share one
   physical link: a sensor sending both full-resolution and
   a downscaled preview, or two sensors through an
   aggregator. The receiver demultiplexes by VC number.

   RAW FORMATS ARE PACKED. RAW10 puts four pixels in five
   bytes:

     byte 0: P0[9:2]
     byte 1: P1[9:2]
     byte 2: P2[9:2]
     byte 3: P3[9:2]
     byte 4: P3[1:0] P2[1:0] P1[1:0] P0[1:0]

   Software that assumes two bytes per pixel gets an image
   that looks correct but with wrong colours and a
   progressive horizontal skew - a very recognisable
   symptom once you have seen it.                            */
```

THE SENSOR OUTPUTS BAYER, NOT COLOUR

Almost every image sensor has a colour filter array — one red, one blue and two green filters per 2×2 group — so each pixel measures only one colour. Turning that into RGB is *demosaicing*, and it is one stage of an image signal processor pipeline that also does black level, lens shading, white balance, denoise, gamma and sharpening. On an application processor the ISP is dedicated hardware; on a microcontroller there is usually none, which is why MCU camera work uses sensors that output YUV or RGB directly and accept the sensor's own internal processing. The video track covers the pipeline properly.

Bringing up a camera

```
/* The order matters, and each step has a distinct failure
   signature. Work through them in this sequence.         */

/* 1. POWER AND CLOCKS. Sensors need several rails in a
      documented ORDER, and an external master clock
      (XCLK/MCLK, often 24 MHz) before they respond to
      anything.                                           */
gpio_set(SENSOR_PWDN, 0);       /* release power-down      */
delay_ms(5);
mclk_start(24000000);           /* usually a timer PWM     */
delay_ms(5);
gpio_set(SENSOR_RESET, 1);      /* release reset AFTER
                                   the clock is running    */
delay_ms(20);

/* 2. I2C PROBE. Read the chip ID register. If this fails,
      nothing else can work - stop here and fix it. This
      single check separates "camera problem" from "camera
      not even present".                                  */
uint16_t id = sensor_read16(0x300A);
if (id != EXPECTED_ID) { return -ENODEV; }

/* 3. CONFIGURE. Sensor vendors supply a register list -
      often hundreds of undocumented address/value pairs.
      This is normal and you will not be able to derive it;
      start from the vendor's list for a known mode.       */
sensor_write_array(mode_1920x1080_30fps);

/* 4. RECEIVER CONFIGURATION MUST MATCH EXACTLY:
        - number of lanes
        - data type (RAW10 vs RAW12 vs YUV422)
        - virtual channel
        - line length and frame height
        - D-PHY timing (t_HS-SETTLE especially)
      A mismatch in ANY of these gives you no frames, or
      corrupt ones, with no error message beyond a receiver
      error counter.                                       */

/* 5. CHECK THE RECEIVER'S ERROR COUNTERS FIRST when
      debugging. On Linux:
        $ dmesg | grep -i csi
        $ media-ctl -p          # the pipeline topology
        $ v4l2-ctl --list-formats-ext
      ECC and CRC error counts tell you immediately whether
      the problem is electrical (errors climbing) or
      configuration (no errors, no frames).                */
```

How it shows up

Symptom	Cause
Sensor does not respond on I2C	Master clock not running, or reset released before the clock
Lanes stay in LP-11	Sensor not streaming — check I2C configuration and the mode
HS bursts present but no valid frames	Lane count, data type or virtual channel mismatch
Image skewed progressively across the frame	Line length wrong, or packed RAW format unpacked as two bytes per pixel
Colours wrong and image looks striped	RAW10/RAW12 packing not handled
Image is greyscale mosaic	Bayer data not demosaiced — there is no ISP in the path
ECC errors climbing	Electrical: lane length matching, impedance, or D-PHY timing
Works at low resolution, fails at high	Insufficient lanes or bandwidth for the pixel rate
Frames arrive but tear or duplicate	Receiver buffer bandwidth, or DMA not keeping up
Two sensors, only one works	Same virtual channel, or an I2C address collision on the control bus

Check yourself

- ✓ Compute the raw data rate for a 12 MP sensor at 30 fps and 10 bits.
- ✓ Explain why the control path and the data path are different buses.
- ✓ Name D-PHY's two electrical modes and what each is used for.
- ✓ Say what it means diagnostically if the lanes never leave LP-11.
- ✓ Distinguish short packets from long packets and give two examples of each.
- ✓ Explain why the packet header has ECC while the payload has only a CRC.
- ✓ Say what virtual channels are for.
- ✓ Describe RAW10 packing and the symptom of unpacking it wrongly.
- ✓ Explain what demosaicing is and why an MCU usually avoids needing it.
- ✓ Give the camera bring-up order and the failure signature of each step.

MIPI DSI and display interfaces

Displays are CSI-2 in reverse, with one important addition: some panels have memory and some do not, and that single fact decides whether your firmware sends a frame when something changes or sixty times a second forever.

The display interface spectrum

```
In increasing order of bandwidth and complexity:

SPI                  up to ~320x240
  A display controller with its own frame buffer. You
  send only what changed. Simple, slow, and completely
  adequate for a small UI. ILI9341, ST7789 and similar.

PARALLEL 8080/6800   up to ~800x480
  8 or 16 data lines plus control strobes. Still a
  controller with memory; just a wider path to it.
  Often driven by an MCU's FSMC/FMC memory controller,
  so writing a pixel is a store to an address.

RGB PARALLEL (DPI)   up to ~1024x600
  NO MEMORY IN THE PANEL. 16-24 data lines plus HSYNC,
  VSYNC, DE and PCLK, and you must supply every pixel of
  every frame, continuously, forever. Needs an LCD
  controller peripheral (LTDC) and a frame buffer in RAM.

MIPI DSI             1080p and beyond
  1-4 differential lanes, same D-PHY as CSI-2
  (chapter 15). Panels may or may not have memory.

LVDS / eDP           laptop-class panels
  Different physical layer, same fundamental split.

THE SPLIT THAT MATTERS MORE THAN THE WIRING:

COMMAND MODE / with GRAM
  The panel has RAM. You write a region when it changes
  and stop. The panel refreshes itself.
  -> low average power, simple firmware, ideal for a
     mostly-static UI.

VIDEO MODE / no memory
  You stream every frame at the refresh rate, with
  blanking intervals, exactly like an old CRT.
  -> constant bandwidth and power whether anything
     changes or not, but no tearing and no panel RAM cost.

A wearable with a static watch face wants command mode.
A device playing video wants video mode. Choosing the
panel decides which firmware you write.
```

Video mode timing

```
Video mode inherits CRT vocabulary, and the blanking
intervals are real time you must budget for.

|<----------------- HTOTAL ------------------>|
|<-HSA->|<-HBP->|<--- HACT --->|<-HFP->|
+-------+-------+---------------+-------+
| sync  | back  |   PIXELS      | front |
|       | porch |               | porch |
+-------+-------+---------------+-------+

Same structure vertically: VSA, VBP, VACT, VFP.

PIXEL CLOCK = HTOTAL x VTOTAL x refresh_rate

WORKED, for 800x480 at 60 Hz:
  HTOTAL = 48 + 40 + 800 + 40 = 928
  VTOTAL = 3 + 29 + 480 + 13  = 525
  PCLK   = 928 x 525 x 60 = 29.2 MHz

BANDWIDTH at 24 bits per pixel:
  29.2e6 x 24 = 701 Mbit/s
Two DSI lanes at 500 Mbit/s each covers it.

NOTE THE OVERHEAD: 928x525 = 487,200 clocks to deliver
384,000 pixels. Twenty percent of your bandwidth is
blanking. The porch values come from the PANEL DATASHEET
and are not negotiable - they are the time the panel's
internal circuitry needs.

FRAME BUFFER COST:
  800 x 480 x 3 bytes = 1.1 MB
That does not fit in any microcontroller's SRAM, which
is why RGB parallel and DSI video mode need external
SDRAM. This single number is often what forces a design
from an MCU to an application processor - or to a
command-mode panel with its own memory.
```

Talking to the panel

```
/* DSI carries both pixels and commands on the same lanes.
   DCS (Display Command Set) is the standard command
   vocabulary, and lane 0 is bidirectional so the panel can
   answer.                                                  */

/* Standard DCS commands - the same on every compliant panel */
#define DCS_ENTER_SLEEP_MODE   0x10
#define DCS_EXIT_SLEEP_MODE    0x11
#define DCS_SET_DISPLAY_OFF    0x28
#define DCS_SET_DISPLAY_ON     0x29
#define DCS_SET_COLUMN_ADDRESS 0x2A
#define DCS_SET_PAGE_ADDRESS   0x2B
#define DCS_WRITE_MEMORY_START 0x2C
#define DCS_SET_TEAR_ON        0x35

static void panel_init(void)
{
    dsi_dcs_write(DCS_EXIT_SLEEP_MODE, NULL, 0);
    delay_ms(120);              /* datasheet: mandatory     */

    /* Then the VENDOR's initialisation sequence: dozens of
       manufacturer-specific commands setting gamma curves,
       power rails and timing. Undocumented, supplied as a
       blob, and NOT derivable. Every panel needs its own,
       and the panel vendor must give you one - if they
       will not, choose another panel.                      */
    panel_vendor_init_sequence();

    dsi_dcs_write(DCS_SET_DISPLAY_ON, NULL, 0);
}

/* COMMAND MODE UPDATE - only the changed rectangle. */
void panel_blit(uint16_t x, uint16_t y, uint16_t w, uint16_t h,
                const uint16_t *pixels)
{
    uint8_t col[4] = { x >> 8, x & 0xFF,
                       (x+w-1) >> 8, (x+w-1) & 0xFF };
    uint8_t page[4] = { y >> 8, y & 0xFF,
                        (y+h-1) >> 8, (y+h-1) & 0xFF };

    dsi_dcs_write(DCS_SET_COLUMN_ADDRESS, col,  4);
    dsi_dcs_write(DCS_SET_PAGE_ADDRESS,   page, 4);
    dsi_dcs_write_memory(pixels, (size_t) w * h * 2u);
}

/* Updating a 100x20 status area costs 4 kB instead of the
   750 kB a full 800x480 frame would - a 180x saving, and
   the difference between a responsive UI and a slideshow
   on a slow link.                                          */
```

TEARING, AND THE TE SIGNAL

If you write the panel's memory while it is scanning that region out, the top of the display shows the new image and the bottom the old — a visible tear that moves. Command-mode panels provide a *tearing effect* output that pulses at the start of vertical blanking; wait for it before starting an update and the panel scans out only complete frames. It costs one pin and one interrupt. Video-mode panels avoid the problem differently, by double-buffering in the host and switching buffers during blanking.

Displays on a microcontroller

```
/* Two viable strategies, and the choice follows from the
   frame buffer arithmetic above.                          */

/* STRATEGY 1: SPI or parallel panel WITH memory.
   No frame buffer in RAM at all - draw directly into the
   panel, one region at a time.                            */
void draw_button(int x, int y, const char *label)
{
    panel_fill_rect(x, y, 100, 40, COLOUR_BLUE);
    panel_draw_text(x + 10, y + 12, label, COLOUR_WHITE);
}
/* Works on a part with 32 kB of RAM. The limit is redraw
   speed: at 40 MHz SPI, a full 320x240 16-bit refresh is
   1.5 Mbit = 38 ms. Fine for a UI, useless for animation. */

/* STRATEGY 2: RGB parallel with an LTDC and external SDRAM.
   A real frame buffer, hardware layer compositing, and
   DMA2D for accelerated fills and blits.                  */
LTDC_Layer1->CFBAR = (uint32_t) framebuffer;
DMA2D->CR = DMA2D_CR_MODE_R2M;      /* register to memory  */
DMA2D->OCOLR = 0xFF0000FF;
DMA2D->CR |= DMA2D_CR_START;        /* hardware fill       */

/* PARTIAL REFRESH IS THE KEY OPTIMISATION EITHER WAY. Track
   dirty rectangles and update only those. A UI that redraws
   the whole screen for a blinking cursor is the most common
   embedded graphics performance mistake, and the fix is
   almost always bookkeeping rather than a faster bus.

   LVGL and similar libraries do this dirty-rectangle
   tracking for you and are worth using rather than
   reimplementing.                                          */
```

How it shows up

Symptom	Cause
Panel stays black, backlight on	Vendor init sequence missing or incomplete
Image rolls or is offset	Porch timings do not match the panel datasheet
Image tears horizontally	Writing during scan-out — use the TE signal or double-buffer
Colours inverted or byte-swapped	Pixel format mismatch: RGB565 versus BGR565, or endianness
Bottom of the screen shows garbage	Frame buffer smaller than the configured resolution
UI feels sluggish	Full-screen redraws; track dirty rectangles
LTDC underrun errors	SDRAM bandwidth exhausted — reduce colour depth or refresh rate
Works at 30 Hz, fails at 60 Hz	Pixel clock or lane bandwidth exceeded
Panel needs a different init after a power cycle	Sleep-out delay too short — the 120 ms is mandatory
Cannot fit a frame buffer	Correct — use a command-mode panel with its own memory

Check yourself

✓ Name five display interfaces in order of bandwidth.

- ✓ Explain the difference between command mode and video mode.
- ✓ Say which mode suits a mostly-static UI and why.
- ✓ Compute the pixel clock for 800×480 at 60 Hz with given porches.
- ✓ Explain what fraction of bandwidth blanking consumes and why it exists.
- ✓ Compute the frame buffer size for 800×480 at 24 bits and say what it implies.
- ✓ Explain what DCS is and why a vendor init sequence is still needed.
- ✓ Describe tearing and the two ways to prevent it.
- ✓ Give the bandwidth saving from a partial update of a small region.
- ✓ Explain why dirty-rectangle tracking matters more than bus speed.

Ethernet, the MAC/PHY boundary and MDIO

Ethernet on a microcontroller is three separate things that must all work: a MAC inside the chip, a PHY outside it, and a management bus connecting them. Most bring-up problems are at one of the two boundaries, and knowing which one you are looking at is most of the diagnosis.

MAC and PHY

```
+-------------------------------------------------+
|  MICROCONTROLLER                                |
|                                                 |
|   TCP/IP stack (lwIP)                           |
|        |                                        |
|   +----+-----+                                  |
|   |   MAC    |  frames, addresses, CRC, DMA     |
|   +----+-----+                                  |
|        |                                        |
+--------|----------------+----------------------+
         | RMII/MII       | MDIO (2 wires)
         | (7 or 18 wires)|
+--------+----------------+----------------------+
|   PHY  (external chip)                          |
|   encoding, analog drive, link negotiation      |
+--------+----------------------------------------+
         |
     [magnetics]      transformer - isolation and
         |            common-mode rejection
       RJ45

THE DIVISION OF LABOUR:

MAC (in the MCU)     frame assembly, source/destination
                     addresses, CRC, collision handling,
                     DMA descriptors

PHY (external)       4B/5B or similar line coding,
                     analog line driving, auto-
                     negotiation of speed and duplex,
                     link detection

MDIO/MDC             a tiny two-wire management bus so
                     the MAC can read and write the PHY's
                     registers. Essentially I2C's job,
                     with its own protocol.

MAGNETICS            galvanic isolation to 1.5 kV, and
                     common-mode rejection. NOT optional -
                     omitting them is a real design error
                     that works on a bench and destroys
                     ports in the field.
```

MII versus RMII

```
MII    18 wires, 25 MHz clock, 4 bits per direction
RMII    7 wires, 50 MHz clock, 2 bits per direction
RGMII  12 wires, 125 MHz DDR, for gigabit

RMII is what you will use on a microcontroller: half the
pins for the same 100 Mbit/s.

RMII SIGNALS:
  REF_CLK    50 MHz, SHARED by MAC and PHY
  TXD0, TXD1
  TX_EN
  RXD0, RXD1
  CRS_DV     carrier sense / data valid

THE REF_CLK IS THE CLASSIC BRING-UP PROBLEM. Both ends
must use the SAME 50 MHz clock, and there are two valid
topologies:

  A) A 50 MHz oscillator feeds both the PHY and the MCU's
     REF_CLK input. Simple and robust.

  B) The MCU outputs 50 MHz on its MCO pin to the PHY,
     derived from its own PLL.

Topology B requires that the MCU's clock configuration
produce EXACTLY 50 MHz, and it must be running before the
PHY is released from reset. Getting this wrong gives a
PHY that never establishes a link, or a link that comes
up and passes no traffic - and neither symptom points at
the clock.

MEASURE REF_CLK WITH A SCOPE during bring-up. It is one
probe and it eliminates the most likely cause first.
```

MDIO: reading the PHY

```
/* MDIO is a 2-wire bus: MDC (clock, up to 2.5 MHz) and
   MDIO (bidirectional data). The MAC has a register pair
   that drives it for you.                                  */

static uint16_t phy_read(uint8_t phy_addr, uint8_t reg)
{
    ETH->MACMIIAR = (phy_addr << 11) | (reg << 6)
                  | ETH_MACMIIAR_CR_Div42 | ETH_MACMIIAR_MB;
    while (ETH->MACMIIAR & ETH_MACMIIAR_MB) { }   /* + timeout! */
    return (uint16_t) ETH->MACMIIDR;
}

/* THE STANDARD REGISTERS - IEEE 802.3 defines 0-15
   identically for every PHY ever made, which means this
   code works with any of them:                             */

/*  0  BMCR    control: reset, speed, duplex, autoneg
    1  BMSR    status: LINK UP, autoneg complete
    2  PHYIDR1 |  OUI and model - identifies the chip
    3  PHYIDR2 |
    4  ANAR    what we advertise
    5  ANLPAR  what the link partner advertises
   16+ vendor specific - including, annoyingly, the
       resolved speed and duplex on most PHYs           */

int phy_link_status(uint8_t addr, int *speed, int *full_duplex)
{
    /* BMSR bit 2 is LATCHING LOW: it reports "link has been
       down since the last read". Read it TWICE to get the
       current state - a genuine and very commonly missed
       detail.                                              */
    (void) phy_read(addr, 1);
    uint16_t bmsr = phy_read(addr, 1);

    if (!(bmsr & (1u << 2))) { return 0; }        /* down    */
    if (!(bmsr & (1u << 5))) { return 0; }        /* autoneg
                                                     not done */

    /* Resolved speed/duplex is vendor-specific. For the
       common LAN8742 it is register 31.                    */
    uint16_t sr = phy_read(addr, 31);
    *speed       = ((sr >> 2) & 3u) <= 1 ? 10 : 100;
    *full_duplex = (sr >> 4) & 1u;
    return 1;
}

/* FINDING THE PHY ADDRESS: it is set by strapping pins and
   is usually 0 or 1, but vendors vary. Scan for it - the
   same approach as an I2C scan (chapter 06):              */
int phy_scan(void)
{
    for (uint8_t a = 0; a < 32; a++) {
        uint16_t id = phy_read(a, 2);
        if (id != 0xFFFF && id != 0x0000) { return a; }
    }
    return -1;      /* nothing responded: check MDC, the
                       PHY's reset pin, and its supply     */
}
```

THE BRING-UP ORDER THAT ISOLATES FAULTS

Check them in this sequence and each step rules out a layer: **1.** Is REF_CLK present and 50 MHz? **2.** Does an MDIO scan find the PHY? **3.** Does the PHY report link up and auto-negotiation complete? **4.** Does the MAC receive any frames at all (check the receive descriptor count, not the IP stack)? **5.** Does a broadcast ARP appear? Only then look at lwIP. Debugging from the TCP layer downward is why Ethernet bring-up has a reputation for taking days.

Descriptors and buffers

```
/* The MAC does not have registers you write frames into.
   It walks a RING of DESCRIPTORS in memory, each pointing
   at a buffer - the same pattern as any high-throughput
   DMA engine (mcu chapter 12).                              */

typedef struct {
    volatile uint32_t status;      /* OWN bit + flags      */
    uint32_t          ctrl_len;
    uint32_t          buf1_addr;
    uint32_t          next_desc;
} eth_desc_t;

#define DESC_OWN  (1u << 31)       /* 1 = DMA owns it      */

/* THE OWNERSHIP BIT IS THE WHOLE PROTOCOL:
     OWN = 1  the DMA engine may use this descriptor
     OWN = 0  software owns it

   RX: software clears OWN after processing, handing the
       buffer back. FORGET THIS AND RECEPTION STOPS after
       exactly as many frames as you have descriptors -
       a very recognisable symptom.

   TX: software sets OWN to hand the frame over.          */

static eth_desc_t rx_desc[4] __attribute__((aligned(4)));
static uint8_t    rx_buf[4][1524] __attribute__((aligned(4)));

void eth_rx_poll(void)
{
    eth_desc_t *d = &rx_desc[rx_index];
    if (d->status & DESC_OWN) { return; }      /* DMA still
                                                  owns it   */
    uint16_t len = (uint16_t)((d->status >> 16) & 0x3FFF);
    lwip_input(rx_buf[rx_index], len - 4u);    /* strip CRC  */

    d->status = DESC_OWN;                      /* GIVE IT BACK */
    rx_index = (rx_index + 1u) & 3u;
    ETH->DMARPDR = 0;                          /* poll demand */
}

/* MEMORY PLACEMENT MATTERS, exactly as in mcu chapter 12:
   - descriptors and buffers must be in RAM the Ethernet
     DMA can reach. On STM32F7/H7 the default SRAM often is
     NOT reachable - use a specific region and place it in
     the linker script.
   - on Cortex-M7, either mark that region non-cacheable in
     the MPU, or do explicit cache maintenance around every
     descriptor access. Getting this wrong produces an
     Ethernet port that works for a few seconds and then
     stops, which is a memorably frustrating bug.          */
```

How it shows up

Symptom	Cause
MDIO scan finds nothing	No REF_CLK, PHY held in reset, or MDC divider misconfigured
PHY found but link never comes up	REF_CLK wrong frequency, magnetics or cable fault

Symptom	Cause
Link up, no frames received	RMII pin configuration, or descriptors in unreachable RAM
Receives exactly N frames then stops	OWN bit not returned to the DMA — N is your descriptor count
Works a few seconds then stops, Cortex-M7	Cache coherency on descriptors — mark the region non-cacheable
Link status flaps in software but not physically	BMSR link bit is latching low; read it twice
Works at 10 Mbit, fails at 100	Signal integrity, or a duplex mismatch from failed auto-negotiation
Ports damaged in the field	Magnetics omitted or wrongly specified
Occasional CRC errors under load	REF_CLK jitter, or clock topology B with a marginal PLL
TCP is slow but ping is fine	Descriptor count too low, or buffers being copied unnecessarily

Check yourself

- ✓ State which functions belong to the MAC and which to the PHY.
- ✓ Explain what the magnetics do and why they are not optional.
- ✓ Give the wire count and clock rate for MII and RMII.
- ✓ Describe the two valid REF_CLK topologies and the risk of each.
- ✓ Explain what MDIO is for and which registers are standardised.
- ✓ Explain why the BMSR link bit must be read twice.
- ✓ Describe how to find an unknown PHY address.
- ✓ Explain the descriptor ownership bit and the symptom of not returning it.
- ✓ Say why descriptor placement matters on an STM32H7.
- ✓ Give the five-step bring-up order and what each step rules out.

Reading a datasheet and a timing diagram

A datasheet is not a manual and is not meant to be read in order. It is a reference organised by an internal logic that nobody explains, and knowing that logic — plus how to read a timing diagram — is a skill that saves more time than any amount of coding ability.

What is in one, and the order to read it

```
THE STANDARD STRUCTURE:

 1. Features / description     marketing. Skim.
 2. Pinout and pin functions   check package variants
 3. Absolute maximum ratings   DESTRUCTION limits
 4. Recommended operating      the ranges you must
    conditions                 actually design within
 5. Electrical characteristics DC: voltages, currents
 6. Timing characteristics     AC: the numbers that
                               decide your driver
 7. Functional description     how it works
 8. Register map               what you write
 9. Application information    reference schematic
10. Package / ordering         which part to buy

THE ORDER TO ACTUALLY READ IT, first time:

1. BLOCK DIAGRAM (in section 7). Five minutes, and it
   orients everything else.
2. PIN TABLE. Which pins must be tied, which float,
   which are supplies. Note every pin marked "must be
   connected to ground" - these are usually thermal pads
   or unused supplies and omitting them is fatal.
3. RECOMMENDED OPERATING CONDITIONS. Not absolute
   maximums - those are where it BREAKS, not where it
   WORKS.
4. THE INTERFACE TIMING DIAGRAM for your bus.
5. THE REGISTER MAP, only for the registers you need.
6. APPLICATION SCHEMATIC. Copy it. The decoupling and
   the pull-ups shown there are requirements, not
   suggestions.

ABSOLUTE MAXIMUM vs RECOMMENDED, because this confusion
destroys parts:

  Absolute max VIN:     -0.3 V to VDD + 0.3 V
    Beyond this the part may be damaged. Not "may
    misbehave" - damaged, permanently, possibly slowly.

  Recommended VIH:      0.7 x VDD minimum
    Below this a logic high may not be read as high.

A 3.3 V signal into a 1.8 V part exceeds absolute maximum
by 1.2 V. It will appear to work. It will fail in
weeks.
```

Reading a timing diagram

```
A typical SPI write, with the symbols that matter:

        |<-tCSS->|                    |<-tCSH->|
CS   ---+        +--------------------+        +-------
        |________|                    |________|
                 :                    :
SCLK  ___________:__|--|__|--|__|--|__:___________
                 :  ^     ^     ^     :
                 :  |<tSU>|<tH>|     :
MOSI  XXXXXXXXXX:XX===X=====X=====XXX:XXXXXXXXXXX
                 :                    :
MISO  ---------- ZZZ==X=====X=====ZZZ ------------
                    |<tV>|

THE FIVE SYMBOLS YOU MEET EVERYWHERE:

tSU  SETUP TIME. How long data must be STABLE BEFORE the
     clock edge. YOU must guarantee this.

tH   HOLD TIME. How long data must remain stable AFTER
     the edge. YOU must guarantee this.

tV   VALID / OUTPUT DELAY. How long AFTER the edge before
     the device's output is valid. THE DEVICE imposes
     this on you, and it is what limits clock speed
     (chapter 04).

tCSS/tCSH  Chip select setup and hold, around the
     transaction.

tPD  PROPAGATION DELAY, generally.

THE ASYMMETRY IS THE KEY INSIGHT:
  - SETUP and HOLD are YOUR obligations to the device.
  - VALID DELAY is the device's obligation to you, and
    it constrains how fast you may clock.

WAVEFORM NOTATION:
  ===X===   valid data, value irrelevant
  XXXXXX    don't care / undefined
  ZZZZZZ    high impedance, nobody driving
  dashed    optional or conditional

MIN, TYP, MAX - and which one to design against:

  For times YOU must meet (setup, hold): use the MAX
    required value. Meeting the typical is not enough.
  For times the DEVICE promises (valid delay): use the
    MAX, because that is the worst case you must
    tolerate.
  TYP is for estimating average behaviour. NEVER design
    a timing budget from typical values - the part that
    fails will be the one at the limit, and there will
    be one in every thousand.
```

A worked timing check

```
/* QUESTION: can I clock this ADC at 20 MHz?

   FROM THE DATASHEET:
     tV  (SCLK falling to MISO valid)   max 25 ns
     tSU (MISO setup at the MCU)        min  5 ns
     board propagation, both ways       ~2 ns

   AT 20 MHz the period is 50 ns, so half a period - the
   time between the driving edge and the sampling edge - is
   25 ns.

   BUDGET:
     tV                     25 ns
     propagation out+back    2 ns
     MCU setup requirement   5 ns
                           -------
     total                  32 ns   needed
     available              25 ns

   DOES NOT FIT. 32 > 25.

   MAXIMUM WORKABLE CLOCK:
     half period must be >= 32 ns
     period >= 64 ns
     f <= 15.6 MHz

   So 12.5 MHz (the next prescaler step down) is the answer.

   WHAT IF I NEED 20 MHz ANYWAY? Three options, in order of
   preference:
     1. Use the MCU's "sample at the falling edge instead"
        option if it has one - some SPI peripherals allow
        delaying the sample point by half a clock, which
        doubles the available window.
     2. Shorten the traces.
     3. A faster ADC.

   THIS CALCULATION TAKES TWO MINUTES and it is the
   difference between choosing a clock rate by reasoning
   and choosing it by trying values until one works. The
   second approach leaves you at an unknown margin, and the
   failures appear in production across temperature.       */
```

THE THREE DOCUMENTS, AND WHICH ANSWERS WHAT

For a microcontroller the information is split across at least three files, and reaching for the wrong one wastes an hour: the **datasheet** holds pinout, electrical limits, timing and package — anything about a specific part number; the **reference manual** holds peripheral descriptions and register maps, shared across a whole family; the **errata sheet** holds the bugs. Read the errata before debugging anything that "should work" — silicon bugs in I2C peripherals, DMA engines and low-power modes are common, documented, and invisible unless you look.

What datasheets do not say plainly

```
THINGS THAT ARE THERE BUT EASY TO MISS:

"This pin must be left unconnected"
  Really means it. Often an internal test or regulator
  node; grounding it can damage the part.

A CONDITIONS COLUMN on every specification
  "IOL = 4 mA, VDD = 3.0 V, TA = 25 C". Your conditions
  differ, so the number differs. Check the conditions
  before trusting the value.

"Guaranteed by design" / "not tested"
  This parameter is not measured in production. Treat it
  with more caution than a tested one.

POWER SEQUENCING
  Often a small note, occasionally a diagram: "VDDIO
  must not exceed VDDCORE by more than 0.3 V during
  ramp". Violating it can latch up the part on every
  power-on, and the symptom is a board that sometimes
  does not start.

The RESET timing
  Minimum reset pulse width and minimum time after
  release before the first transaction. Both are
  routinely violated by init code that runs too soon.

FOOTNOTES UNDER THE TABLES
  Genuinely important information lives there:
  "(3) Not available in the 20-pin package."

THINGS THAT ARE NOT THERE AT ALL, and you must ask the
vendor or find out empirically:
  - the full register map, on some sensors
  - initialisation sequences (chapter 16's panel blob)
  - real power consumption in your exact use case
  - behaviour outside the specified ranges
  - how the part fails
```

How it shows up

Symptom	Cause
Part works for weeks then dies	Absolute maximum exceeded — usually an input above VDD
Works on the bench, fails in production	Designed against typical rather than worst-case timing
Works at room temperature only	Specification conditions differ from your operating range
One board in fifty does not start	Power sequencing or reset timing violated
Pin has an unexpected function	Package-variant footnote under the pin table
Peripheral behaves against the manual	Check the errata sheet before your own code
Bus fails above a certain clock	Output valid delay — do the timing budget
Measured current far above the datasheet	Different conditions: clock, temperature, or a pin loaded
Sensor needs an undocumented init blob	Normal — obtain it from the vendor
Damaged part after grounding a spare pin	"Leave unconnected" meant it

Check yourself

- ✓ Give the order to read a datasheet for the first time and why the block diagram comes first.
- ✓ Distinguish absolute maximum from recommended operating conditions.
- ✓ Define setup, hold and valid delay, and say which are your obligations.
- ✓ Explain why valid delay limits clock speed but setup time does not.
- ✓ Say which of min, typ and max to design against, for each kind of parameter.
- ✓ Work a timing budget to find the maximum clock for a given valid delay.
- ✓ Name the three documents for a microcontroller and what each answers.
- ✓ Explain what "guaranteed by design" implies.
- ✓ Give two things a datasheet often does not tell you at all.
- ✓ Explain why the conditions column matters as much as the value.

Signal integrity for firmware engineers

You will not design the board, but you will be handed bugs that live in the copper, and you need to recognise them before spending a week in the debugger. This chapter is the minimum electrical model that lets you say "this is not a software problem" with evidence.

It is the edge rate, not the clock rate

```
The intuition that misleads everyone: "this bus is only
100 kHz, so signal integrity does not apply."

IT IS THE RISE TIME THAT MATTERS, NOT THE FREQUENCY. A
100 kHz square wave with a 1 ns edge contains energy up
to hundreds of megahertz - and it is that energy which
radiates, reflects and couples.

  f_knee ~ 0.5 / t_rise

  t_rise = 1 ns   ->  f_knee = 500 MHz
  t_rise = 10 ns  ->  f_knee =  50 MHz

WHEN IS A TRACE A TRANSMISSION LINE?

  When its propagation delay exceeds about a sixth of
  the rise time.

  Signals travel at roughly 15 cm/ns on FR4.

  t_rise = 1 ns   -> critical length ~2.5 cm
  t_rise = 5 ns   -> critical length ~12 cm

So a 1 ns edge on a 5 cm trace IS a transmission line and
will reflect, whatever the clock rate. THIS IS WHY SLEW
RATE CONTROL EXISTS on GPIO pins (mcu chapter 10), and
why setting everything to maximum speed causes problems
that setting it to minimum does not.

THE FIRMWARE LEVER: you control the slew rate setting.
Use the slowest that meets timing. It costs nothing and
it removes an entire class of problem.
```

Reflections and termination

```
A signal reaching an impedance change reflects part of
its energy back.

  reflection coefficient = (Z_load - Z_line) /
                           (Z_load + Z_line)

OPEN END (Z_load infinite): coefficient = +1, the wave
reflects entirely and ADDS - overshoot, then ringing as
it bounces.

  ideal            actual
   ___              _  _
  |                | \/ \____
  |                |
__|              __|

Overshoot above VDD + 0.3 V exceeds absolute maximum
(chapter 18) and stresses the input protection diodes.
Ringing that crosses the input threshold several times
gives you MULTIPLE CLOCK EDGES from one transition -
which a counter or a shift register will faithfully
count.

THE FIRMWARE-VISIBLE SYMPTOM: an SPI device that
occasionally reads one bit too many, or a counter that
increments by two. Before assuming your code is wrong,
put a scope on the clock.

SERIES TERMINATION is the usual fix and the one you will
see on schematics: a resistor at the SOURCE, sized so
R_series + R_driver = Z_line (typically 50 ohms, so a
22-33 ohm resistor).

  driver --[33R]---------------------- receiver
           ^
      absorbs the reflection on its return

If a bus is marginal and there are footprints for series
resistors that were left at 0 ohms, fitting the right
value is often the whole fix.
```

Ground is the part nobody thinks about

```
CURRENT FLOWS IN LOOPS. The return path is as real as
the outgoing signal, and it takes the path of LEAST
INDUCTANCE - which at speed is directly under the trace,
not the shortest path on the plane.

GOOD:                    BAD:
+----------+             +----------+
|  signal  |             |  signal  |
+==========+             +==========+
|  ground  |             |   SPLIT  |  <- the return
|  plane   |             |  ______  |     current must
+----------+             +----------+     detour around

A split in the ground plane under a fast signal forces
the return current to detour, creating a large loop that
radiates and picks up noise. This is the single most
common cause of a board that fails EMC testing.

FOR FIRMWARE ENGINEERS, THE PRACTICAL VERSIONS:

1. CONNECT THE GROUNDS. Two boards linked by a UART with
   no shared ground reference do not have a defined
   signal level. This is the number one cause of
   "serial works on the desk, not in the rack".

2. SCOPE PROBE GROUNDING. The long ground lead on a
   probe is an inductive loop that ADDS ringing to what
   you measure. If you see 1 GHz ringing on a 1 MHz
   signal, suspect the probe before the board - use the
   short ground spring.

3. DECOUPLING IS A GROUND ISSUE. A 100 nF capacitor next
   to every supply pin gives switching current a short
   local loop instead of a trip across the board. When a
   chip misbehaves under load and the schematic shows
   one shared capacitor, that is a real finding.

4. CURRENT RETURNS THROUGH THE GROUND. A motor's ground
   current flowing under your I2C traces couples into
   them. "I2C fails when the motor runs" (chapter 07) is
   usually a ground-routing problem, not a filtering
   one.
```

WHAT YOU CAN ACTUALLY CHANGE FROM FIRMWARE

Four levers, and they are worth trying before escalating: **slew rate** — set every pin to the slowest that meets timing; **clock rate** — halve it and see whether the errors vanish, which localises the problem to timing or integrity immediately; **digital filters** — enable the peripheral's noise filter where it has one (I2C's DNF, CAN's sample point); and **error counters** — instrument every bus so "unreliable" becomes a number you can correlate with events like a motor starting.

Crosstalk and what it looks like in software

```
Two parallel traces couple capacitively and inductively.
A fast edge on one induces a pulse on its neighbour.

aggressor  ____|-----
               |
victim     ____/\_____   a glitch at the aggressor's edge

COUPLING FALLS OFF FAST WITH SEPARATION. The usual rule
is 3x the trace width between traces, and more for a
clock. Coupling also grows with the parallel run LENGTH -
two traces side by side for 10 cm couple far more than
for 1 cm.

RIBBON CABLES ARE THE WORST CASE: every conductor
parallel to every other, for the whole length, with no
ground plane. A ribbon carrying a clock next to an I2C
line is a reliable source of intermittent faults. The
standard fix is alternating signal and ground conductors
in the ribbon, which halves your conductor count and is
worth it.

SOFTWARE-VISIBLE SYMPTOMS OF CROSSTALK:

  - a bus that only errors when ANOTHER bus is active.
    Correlate: stop the other traffic and see if the
    errors stop. This single experiment identifies
    crosstalk faster than any measurement.

  - an interrupt that fires with no cause. An EXTI pin
    next to a switching signal will trigger on the
    neighbour's edge. If a GPIO interrupt count climbs
    when a motor or display is active, it is coupling.

  - a reset line glitching. Reset inputs are usually
    high impedance and unfiltered; a coupled pulse
    reboots the board with no crash log. If a board
    resets with no fault recorded and the reset-cause
    register says "pin reset", suspect the reset line
    rather than your firmware.
```

How it shows up

Symptom	Cause
Bus errors vanish when you halve the clock	Timing or integrity, not logic — stop debugging the code
Shift register reads one bit too many	Ringing on the clock crossing the threshold twice
Serial works on the desk, fails in the rack	No shared ground reference between the two boards
Bus A errors only when bus B is active	Crosstalk — correlate by stopping B
GPIO interrupt fires with no external event	Coupling from a neighbouring switching line
Board resets, no fault log, cause is "pin reset"	Glitch on the reset line, not a firmware crash
1 GHz ringing seen on a 1 MHz signal	Scope probe ground lead — use the spring
Chip misbehaves only under load	Inadequate decoupling near its supply pins
Failed radiated emissions testing	Slew rates too fast, or a split ground plane under a fast trace

Symptom	Cause
Intermittent faults with a ribbon cable	Crosstalk — interleave grounds or shorten the run

Check yourself

- ✓ Explain why edge rate rather than clock rate determines signal integrity.
- ✓ Compute the knee frequency for a 1 ns rise time.
- ✓ Give the critical trace length for a 5 ns edge and say what it means.
- ✓ Explain what reflects at an open-ended trace and the software-visible symptom.
- ✓ Describe series termination and how the resistor value is chosen.
- ✓ Explain where return current flows at speed and why plane splits matter.
- ✓ Give the most common cause of serial failing between two chassis.
- ✓ Describe the experiment that identifies crosstalk in one step.
- ✓ Explain why a scope can show ringing that is not really there.
- ✓ List the four things a firmware engineer can change to improve integrity.

Debugging a bus with a scope and a logic analyser

Every bus in this track eventually fails in a way that source code cannot explain. The difference between an hour and a week is knowing which instrument answers which question, and having a procedure rather than a hunch.

Which instrument

Instrument	Answers	Cannot answer
Logic analyser (~$20 clone + sigrok/PulseView)	What bytes were sent, protocol decode, timing between events, long captures	Anything about signal *shape* — it only sees above or below a threshold
Oscilloscope	Edge shape, ringing, overshoot, noise, actual voltage levels	Long captures; decoding many bytes is painful
Protocol analyser (USB, CAN)	Full protocol semantics, errors, timing, at speed	Costs real money; unnecessary for simple buses
GPIO probe pin	What your software was doing when the bus event happened	Anything about the bus itself

```
THE DECISION IS ONE QUESTION:

  "Is the DATA wrong, or is the SIGNAL wrong?"

DATA WRONG  (wrong bytes, wrong sequence, missing ACK,
             wrong address, protocol violation)
  -> LOGIC ANALYSER. It decodes, it captures for
     seconds, and a $20 one is entirely sufficient.

SIGNAL WRONG (works at low speed, intermittent, one
              board in ten, errors when a motor runs)
  -> OSCILLOSCOPE. You need to see the shape.

BUY THE LOGIC ANALYSER FIRST. An 8-channel USB clone
with PulseView decodes UART, SPI, I2C, CAN, 1-Wire and
dozens more, captures at 24 MHz, and costs less than an
hour of your time. There is no reason to debug a serial
bus without one.
```

The procedure

```
/* Work in this order. Each step rules out a layer, and
   skipping ahead is how days are lost.                    */

/* 1. IS ANYTHING HAPPENING AT ALL?
      Probe the clock. No clock means the problem is
      configuration - peripheral clock, pin alternate
      function, or the peripheral never enabled (chapter
      01). Zero point debugging protocol logic when nothing
      is being transmitted.                                */

/* 2. IS THE IDLE STATE CORRECT?
      UART   idle HIGH
      I2C    both lines HIGH (if not: no pull-ups, or a
             stuck bus - chapter 07)
      SPI    CS high, SCLK at its CPOL level
      CAN    ~2.5 V on both lines, 0 V differential

      A wrong idle state is a wiring or configuration fault
      and nothing above it can work.                       */

/* 3. IS THE TIMING RIGHT?
      Measure one bit. Not the average - one bit, with
      cursors.
        UART 115200 -> 8.68 us
        SPI 1 MHz   -> 1.00 us
        I2C 400 kHz -> 2.50 us
      A 10% error here is the whole bug (chapter 02).      */

/* 4. ARE THE LEVELS RIGHT?
      VOH should be near VDD, VOL near 0. If a "high" is
      2.0 V on a 3.3 V system, you have a pull-up fighting
      a driver, a level-shifter problem, or a short.       */

/* 5. DECODE IT.
      Now turn on protocol decoding and read the bytes.
      Compare against what your code intended to send. This
      is where you discover the address was shifted, the
      register number was wrong, or the byte order was
      reversed.                                            */

/* 6. CORRELATE WITH SOFTWARE.
      Add a GPIO probe pin toggled in your driver, captured
      on a spare analyser channel. Now you can see "the
      driver entered the ISR here, and the bus glitched
      there" on one timeline. This is the technique that
      solves the genuinely hard ones.                      */
```

Triggering is the whole skill

```
A fault that happens once an hour cannot be found by
watching. You must arm the instrument to catch it.

TRIGGER ON THE ERROR, NOT THE TRAFFIC:

I2C     trigger on a NACK. PulseView and most scopes
        support this directly, and it catches exactly
        the transaction that failed.

UART    trigger on a specific byte value, or on a
        framing error if the scope supports it.

SPI     trigger on a CS edge, then look at what came
        after.

CAN     trigger on an error frame.

THE UNIVERSAL TECHNIQUE - SOFTWARE-TRIGGERED CAPTURE:

  When your driver detects the error, toggle a GPIO.
  Trigger the analyser on that pin. You now capture
  precisely the failing event, with your own code
  deciding what counts as a failure.

    if (i2c_status & NACKF) {
        TRIGGER_PIN_HIGH();     /* arm the capture */
        TRIGGER_PIN_LOW();
        stats.nack++;
    }

  Set the analyser to capture with 90% PRE-TRIGGER, so
  you see everything that led up to the failure rather
  than what followed it. The cause is always before the
  symptom.

This one technique - your software telling the
instrument when to look - turns an intermittent fault
into a reproducible capture, and it works for every bus
in this track.
```

> **CAPTURE THE WORKING CASE FIRST**
>
> Before capturing a failure, capture a success and save it. Half of bus debugging is noticing a difference, and you cannot see a difference without a reference. It also validates your instrument setup — if you cannot capture and decode a transaction that definitely works, then a failed capture tells you nothing about the bus, only about your probe placement or threshold setting.

Recognisable pictures

```
WHAT YOU SEE                    WHAT IT MEANS

Clean edges, wrong bytes        Software: wrong register,
                                wrong address, wrong
                                byte order

Slow rounded rising edges,      Pull-up too weak, or
sharp falling edges             too much capacitance
(open-drain buses)              (chapter 07)

Ringing after each edge         Reflection; slew rate too
                                fast or missing series
                                termination (chapter 19)

Signal never reaches VDD        Pull-up fighting a driver,
                                or a level-shifter fault

Bits present but one extra      Ringing crossing the
clock counted                   threshold twice

Correct data, no ACK            Device not there,
                                unpowered, or the address
                                is shifted (chapter 06)

Everything correct, device      Timing violation: setup,
ignores it                      hold or valid delay
                                (chapter 18)

Bus idle-low when nothing       Missing pull-ups (I2C) or
is transmitting                 fail-safe bias (RS-485,
                                chapter 14)

Last byte truncated             TXE used where TC was
                                needed (chapters 01, 14)

Traffic stops after N frames    Descriptor or buffer
                                ownership not returned
                                (chapter 17)
```

How it shows up

Symptom	Cause
Analyser decodes nothing	Threshold wrong for the logic level, or ground not connected
Capture is all noise	Ground lead not attached to the board's ground
Fault never appears while watching	Trigger on the error, not the traffic
Captured the failure but not the cause	Use pre-trigger capture — the cause precedes the symptom
Ringing appears only with the probe attached	Probe ground lead inductance (chapter 19)
Signal changes when probed	Probe capacitance loading a marginal bus — you were already at the limit
Decoded bytes differ from what the code sent	Byte order, address shift, or a masking error
Everything looks correct but the device ignores it	A timing parameter, not a data problem
Cannot tell whether it is hardware or software	Add a GPIO probe and correlate on one timeline
Intermittent, cannot reproduce	Software-triggered capture on your own error detection

Check yourself

- ✓ State the one question that decides between a scope and a logic analyser.
- ✓ Give the six-step debugging procedure in order.
- ✓ Say what a missing clock signal tells you immediately.
- ✓ Give the correct idle state for each of UART, SPI, I2C and CAN.
- ✓ Give the bit time for 115200 baud and for 400 kHz I2C.
- ✓ Explain the software-triggered capture technique.
- ✓ Explain why pre-trigger capture matters.
- ✓ Say why you should capture a working transaction first.
- ✓ Interpret slow rising edges with sharp falling edges on an open-drain bus.
- ✓ Explain what it means when a signal changes as soon as you probe it.

Project: an I2C sensor driver, from datasheet to data

A complete production-quality driver for a real sensor: bus recovery, error counting, compensation arithmetic straight from the datasheet, and a state machine that never blocks. This is what the whole track has been for.

The target

```
SENSOR: Bosch BME280 — temperature, pressure, humidity.
Chosen because it is cheap, ubiquitous, well documented,
and its compensation arithmetic is genuinely non-trivial
in an instructive way.

ADDRESS: 0x76 or 0x77, selected by the SDO pin.
INTERFACE: I2C (or SPI — the register map is identical,
           which is common and worth noticing).

WHAT THE DRIVER DOES:
  - recovers a stuck bus at startup (chapter 07)
  - probes and verifies the chip ID
  - reads factory calibration
  - configures oversampling and filtering
  - reads all three measurements in ONE burst
  - applies the datasheet's compensation formulas
  - counts every error class
  - never blocks longer than one transaction timeout

WITHOUT HARDWARE: the compensation arithmetic can be
tested on a host with the datasheet's own worked example,
which Bosch provides precisely so you can validate an
implementation. That test is in the exercises and it is
worth doing first — it is the part most likely to be
subtly wrong.
```

Part 1: the register map

```
/* bme280.h - straight from section 5.3 of the datasheet. */

#define BME280_ADDR_LOW    0x76
#define BME280_ADDR_HIGH   0x77
#define BME280_CHIP_ID     0x60      /* the value, not a reg */

#define REG_ID             0xD0
#define REG_RESET          0xE0
#define REG_CALIB00        0x88      /* 26 bytes            */
#define REG_CALIB26        0xE1      /* 7 more bytes        */
#define REG_CTRL_HUM       0xF2
#define REG_STATUS         0xF3
#define REG_CTRL_MEAS      0xF4
#define REG_CONFIG         0xF5
#define REG_PRESS_MSB      0xF7      /* start of the 8-byte
                                        burst              */

/* Calibration, as the datasheet names them. Signedness is
   NOT uniform and getting one wrong gives readings that
   look plausible and drift with temperature - the worst
   kind of bug. Copy this table carefully.                 */
typedef struct {
    uint16_t T1;  int16_t T2, T3;
    uint16_t P1;  int16_t P2, P3, P4, P5, P6, P7, P8, P9;
    uint8_t  H1;  int16_t H2;  uint8_t H3;
    int16_t  H4, H5;  int8_t H6;
    int32_t  t_fine;          /* carries temperature into
                                 the pressure and humidity
                                 compensation - a shared
                                 intermediate, and the
                                 reason temperature must be
                                 compensated FIRST         */
} bme280_calib_t;

typedef struct {
    uint8_t          addr;
    bme280_calib_t   cal;
    struct {
        uint32_t nack, timeout, recover, crc_range, ok;
    } stats;
} bme280_t;
```

Part 2: probe and initialise

```
int bme280_init(bme280_t *d)
{
    /* STEP 0: recover the bus BEFORE the first transaction.
       If the MCU reset mid-read last time, SDA is stuck low
       and nothing will work (chapter 07). This costs 100 us
       and eliminates "only works after a power cycle".    */
    i2c_bus_recover();

    /* STEP 1: find it. Try both addresses rather than
       assuming - the SDO pin may be strapped either way,
       and this makes one driver work on two boards.       */
    for (uint8_t a = BME280_ADDR_LOW; a <= BME280_ADDR_HIGH; a++) {
        uint8_t id;
        if (i2c_read_regs(a, REG_ID, &id, 1) == 0 &&
            id == BME280_CHIP_ID) {
            d->addr = a;
            goto found;
        }
    }
    return -ENODEV;        /* stop here. Nothing above this
                              layer can work.              */
found:

    /* STEP 2: soft reset, then WAIT. The datasheet gives
       2 ms; poll the status register rather than trusting
       a fixed delay.                                       */
    i2c_write_reg(d->addr, REG_RESET, 0xB6);
    uint32_t deadline = g_ms + 10;
    do {
        uint8_t st;
        if (i2c_read_regs(d->addr, REG_STATUS, &st, 1) == 0 &&
            !(st & 0x01)) { break; }          /* not updating */
        if ((int32_t)(g_ms - deadline) >= 0) { return -ETIMEDOUT; }
    } while (1);

    /* STEP 3: calibration. Two non-contiguous blocks, and
       the H4/H5 fields are packed across nibble boundaries -
       a detail that is easy to get wrong and produces
       humidity readings that are wildly off.               */
    uint8_t c1[26], c2[7];
    if (i2c_read_regs(d->addr, REG_CALIB00, c1, 26) < 0) { return -EIO; }
    if (i2c_read_regs(d->addr, REG_CALIB26, c2,  7) < 0) { return -EIO; }

    d->cal.T1 = (uint16_t)(c1[0]  | (c1[1]  << 8));
    d->cal.T2 = (int16_t) (c1[2]  | (c1[3]  << 8));
    d->cal.T3 = (int16_t) (c1[4]  | (c1[5]  << 8));
    d->cal.P1 = (uint16_t)(c1[6]  | (c1[7]  << 8));
    d->cal.P2 = (int16_t) (c1[8]  | (c1[9]  << 8));
    /* ... P3-P9 likewise ... */

    d->cal.H2 = (int16_t)(c2[0] | (c2[1] << 8));
    d->cal.H3 = c2[2];
    /* THE PACKED PAIR: H4 is 12 bits split 8+4, H5 is 12
       bits split 4+8, sharing byte c2[4].                  */
    d->cal.H4 = (int16_t)((c2[3] << 4) | (c2[4] & 0x0F));
    d->cal.H5 = (int16_t)((c2[5] << 4) | (c2[4] >> 4));
    d->cal.H6 = (int8_t)  c2[6];

    /* STEP 4: configure. CTRL_HUM MUST be written BEFORE
       CTRL_MEAS - the datasheet says so, and writing them
```

```
       in the other order silently leaves humidity
       oversampling at its previous value. A footnote that
       costs an afternoon (chapter 18).                    */
    i2c_write_reg(d->addr, REG_CTRL_HUM,  0x01);  /* x1 hum   */
    i2c_write_reg(d->addr, REG_CONFIG,    0xA0);  /* 1s, IIR4 */
    i2c_write_reg(d->addr, REG_CTRL_MEAS, 0x27);  /* x1,x1,
                                                     normal   */
    return 0;
}
```

Part 3: one burst, three measurements

```
/* All eight data registers in ONE transaction. This is not
   an optimisation - it is a CORRECTNESS requirement. The
   sensor shadows its output registers during a burst, so
   reading them separately can return values from two
   different measurements: a temperature from one sample
   and a pressure from the next.

   The datasheet says so, and it is a general property of
   sensors with multi-register values. Always read related
   registers in one burst.                                  */

int bme280_read(bme280_t *d, int32_t *temp_c100,
                uint32_t *press_pa, uint32_t *hum_1024)
{
    uint8_t b[8];
    int rc = i2c_read_regs(d->addr, REG_PRESS_MSB, b, 8);
    if (rc == -ENXIO)     { d->stats.nack++;    return rc; }
    if (rc == -ETIMEDOUT) { d->stats.timeout++;
                            i2c_bus_recover();
                            d->stats.recover++;  return rc; }
    if (rc < 0)           { return rc; }

    /* 20-bit values, left-aligned in 3 bytes. */
    int32_t adc_p = (int32_t)(((uint32_t)b[0] << 12) |
                              ((uint32_t)b[1] << 4)  | (b[2] >> 4));
    int32_t adc_t = (int32_t)(((uint32_t)b[3] << 12) |
                              ((uint32_t)b[4] << 4)  | (b[5] >> 4));
    int32_t adc_h = (int32_t)(((uint32_t)b[6] << 8)  |  b[7]);

    /* 0x80000 and 0x8000 are the "measurement skipped"
       sentinels. Treating them as data gives you a
       plausible-looking wrong answer.                      */

        break;
    }
    }
}

/* FORCED MODE rather than normal mode is the right default
   for a battery device: the sensor measures once and
   returns to sleep at 0.1 uA, instead of free-running.
   Combined with the MCU sleeping between measurements
   (mcu chapter 13), the whole system draws microamps
   between samples.                                        */
```

Exercises

- **Validate the compensation on a host first.** Bosch's datasheet gives a worked example with known calibration constants and raw values. Compile the compensation functions for your PC and check them against it before touching hardware — this separates arithmetic bugs from bus bugs completely.
- **Break the bus deliberately.** Reset the MCU mid-read with a debugger. Confirm the bus is stuck, then confirm your recovery frees it.

- **Read the registers separately** instead of in one burst, then heat the sensor while changing pressure, and look for the inconsistent pairs.
- **Capture a transaction** with a logic analyser (chapter 20) and hand-decode the address, register and data against the datasheet.
- **Remove the pull-ups** and observe the edges on a scope; then fit 10 kΩ and try 400 kHz (chapter 07).
- **Port it to SPI.** The register map is identical; only the transport changes. Structure the driver so this is a 30-line change — that separation is the point.
- **Add a second sensor** at the other address and confirm both work on one bus.

How it shows up

Symptom	Cause
Chip ID read fails	Wrong address, unpowered, or a stuck bus — run recovery first
Temperature plausible, pressure wildly wrong	Compensation called out of order; `t_fine` is stale
Humidity wildly wrong	H4/H5 nibble packing decoded incorrectly
Readings drift with temperature in a way the sensor should correct	A calibration constant's signedness is wrong
Humidity oversampling has no effect	`CTRL_HUM` written after `CTRL_MEAS`
Occasional mismatched temperature and pressure	Registers read separately rather than in one burst
Reads 0x80000 sometimes	Measurement skipped or not ready — treat as a sentinel, not data
Divide-by-zero fault	Corrupt calibration data; keep the datasheet's guard
Works after power cycle only	No bus recovery at startup
Very slow on a Cortex-M0	64-bit compensation without a hardware divider — use the 32-bit variant

Check yourself

- ✓ Explain why bus recovery runs before the first transaction, not after the first failure.
- ✓ Say why the driver probes both possible addresses.
- ✓ Explain why related registers must be read in one burst.
- ✓ Explain what `t_fine` is and the ordering constraint it imposes.
- ✓ Describe the H4/H5 packing and why it is easy to get wrong.
- ✓ Say why `CTRL_HUM` must be written before `CTRL_MEAS`.
- ✓ Explain the role of the 0x80000 sentinel value.
- ✓ Justify keeping the divide-by-zero guard from the datasheet.
- ✓ Explain why forced mode suits a battery device.
- ✓ Say how you would validate the compensation arithmetic without any hardware.

TRACK

Operating systems

The OS concepts that are true of Linux, Windows and every RTOS alike — the vocabulary both driver tracks assume.

20 chapters

What an operating system is

An OS has exactly two jobs, and every feature it has is an instance of one of them. Getting this framing right makes the rest of the track — scheduling, memory, files, drivers — read as variations on a theme rather than a pile of unrelated machinery.

The two jobs

1. ABSTRACTION
Turn awkward, varied hardware into a uniform interface. A program calls `read()` and does not care whether the bytes come from an NVMe SSD, a network socket, a USB stick or a pipe. Without this, every application would need a driver for every device.

2. Arbitration
Share finite resources among competing users, safely and fairly. CPU time, memory, devices, files — all must be divided so that one program cannot starve, corrupt or spy on another.

```
Every OS subsystem is one of those two, applied to one resource:

  resource          abstraction              arbitration
  ──────────────────────────────────────────────────────────
  CPU               process / thread         scheduler
  memory            virtual address space    allocator + MMU
  storage           file, directory          permissions, quotas
  network           socket                   ports, firewall, qdisc
  devices           /dev node, handle        drivers, permissions
  time              timers, clocks           timer wheel

If you can place a feature in that table, you understand what it
is for. If you cannot, it is probably policy, not mechanism.
```

Mechanism versus policy

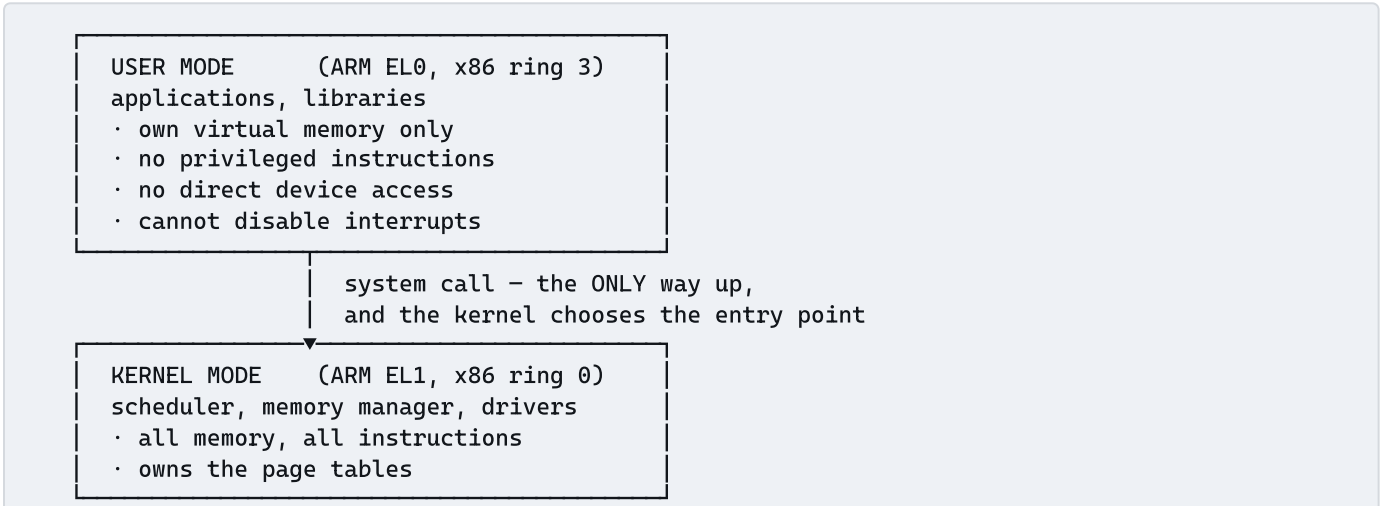
A design principle that runs through every good OS, and the reason Linux and Windows differ so much in places while doing identical things underneath.

	Mechanism	Policy
Question	*How* is it done?	*What* should be done?
Example	Context switching: save registers, swap page tables	Which thread runs next
Example	Page tables and fault handling	Which page to evict
Example	The block layer's request queue	The I/O scheduler that orders it
Changes	Rarely; it is close to hardware	Often; it is tuning and workload-dependent

Separating them is why Linux can ship several schedulers and several I/O elevators over the same core machinery, and why you can change one with a `sysctl` rather than a rebuild.

The privilege boundary

Arbitration requires enforcement, and enforcement requires that applications *cannot* bypass the OS. That needs hardware support — the exception levels of CA chapter 16 and ARM chapter 26.



> **WHY "THE OS PROTECTS YOU" IS IMPRECISE**
>
> The OS *configures* protection; the **hardware** enforces it. A kernel bug can disable it, and a system without an MMU (a Cortex-M) has no enforcement at all — which is why a wild pointer on a microcontroller can silently corrupt anything, and why RTOS "protection" is advisory unless an MPU is configured.

What an OS actually provides

Service	Abstraction offered	Chapter
Process management	Create, run, wait for and terminate programs	04, 05
Scheduling	The illusion of simultaneous execution	06, 07
Memory management	A private, large, contiguous address space	11–13
File systems	Named, persistent, hierarchical byte streams	14, 15
I/O and drivers	Uniform device interfaces	16
IPC	Safe communication between isolated programs	08
Synchronisation	Coordinated access to shared state	09, 10
Time	Clocks, timers, sleeping	17
Security	Identity, permissions, isolation	20
Networking	Sockets over protocol stacks	—

Kinds of operating system

Type	Optimises for	Examples	Typical footprint
General purpose	Throughput, fairness, broad hardware support	Linux, Windows, macOS, BSD	MBs–GBs
Real-time (RTOS)	*Predictability* — bounded worst-case latency	FreeRTOS, Zephyr, ThreadX, QNX, VxWorks	KBs–MBs
Embedded Linux	General purpose on constrained hardware	Yocto, Buildroot, Android	MBs
Hypervisor	Isolating whole OSes	KVM, Xen, Hyper-V, Hafnium	Varies
Unikernel	One application, no separation	MirageOS, Unikraft	KBs–MBs
Bare metal	No OS at all — a superloop	Cortex-M firmware	KBs

> **REAL-TIME DOES NOT MEAN FAST**
>
> It means **predictable**. An RTOS that guarantees a 50 µs worst-case interrupt latency is "real-time"; Linux with a 5 µs *average* and an occasional 5 ms outlier is not. For a general-purpose OS the metric is throughput and the average case; for an RTOS it is the *worst* case, and average performance is almost irrelevant. Design decisions follow directly: no demand paging, no unbounded allocators, priority inheritance on every lock, bounded interrupt disable times.

How the OS gets control

```
   power on
      │
   firmware / boot ROM        immutable, verifies the next stage
      │
   bootloader                 U-Boot, GRUB, UEFI
      │  loads the kernel image and a hardware description
      │  (device tree or ACPI tables)
      ▼
   kernel entry               still running on firmware's assumptions
      │  set up its own page tables, turn on the MMU,
      │  discover CPUs and memory, initialise subsystems
      ▼
   first user process         init / systemd / launchd
      │  everything after this point is scheduled normally
      ▼
   the system is "up"

Detail in os-18. The important structural point: the kernel is not
"always running". It is a library of handlers that runs when a
system call, an interrupt or a fault transfers control to it — and
otherwise the CPU is executing user code, or idle.
```

The kernel is event-driven

```
Three, and only three, ways the kernel gains control:

  1. SYSTEM CALL       user code deliberately asks          (ch. 03)
                       synchronous, on the caller's behalf

  2. INTERRUPT         a device signals asynchronously      (ch. 17)
                       unrelated to what was running

  3. EXCEPTION/FAULT   the current instruction failed       (CA ch. 16)
                       page fault, illegal instruction, alignment

  Everything the kernel does is triggered by one of these. There is
  no "kernel main loop" — except the idle task, whose entire job is
  to execute a low-power wait instruction until an interrupt arrives.

  This is why kernel code is written as short, non-blocking handlers,
  and why "what context am I in?" is the first question you ask about
  any kernel function (chapters 09 and 16).
```

Linux and Windows, same problems

Concept	Linux	Windows
Schedulable unit	`task_struct`	`KTHREAD`
Address space	`mm_struct`	Process + VAD tree
Open file	File descriptor (an `int`)	`HANDLE`
Kernel entry	`svc` / `syscall`	`svc` / `syscall`
Loadable driver	`.ko` module	`.sys` driver
Deferred work	softirq, workqueue	DPC, work item
Context constraint	"atomic context"	IRQL
Fatal error	panic / oops	Bug check (BSOD)
Uniform I/O object	Everything is a file	Everything is an object with a handle

The vocabulary differs; the problems are identical. This track teaches the concepts once so that both driver tracks are a matter of learning names rather than ideas.

What the abstraction costs

Cost	Magnitude	When it matters
System call	~50–500 ns	High-frequency I/O — hence `io_uring`, batching, vDSO
Context switch	~1–5 µs, plus cache and TLB refill	Many threads, or fine-grained switching
Page fault (minor)	~1–5 µs	First touch of each page
Page fault (major)	Milliseconds	Any real-time deadline
Scheduling jitter	Microseconds to milliseconds	Control loops, audio, motion
Memory overhead	Kernel, page tables, per-task structures	Small embedded systems

These costs explain the escape hatches that exist in every OS: `mmap` instead of `read`, `io_uring` instead of syscall-per-operation, huge pages, `mlockall()`, CPU isolation, kernel bypass (DPDK, SPDK), and ultimately choosing an RTOS or bare metal when the OS's guarantees are worth less than its overhead.

How it shows up

Symptom	Underlying OS concept
A tight loop of small reads is slow	System call overhead; batch or use `mmap`
Occasional millisecond latency spike	Major page fault, or preemption by a higher-priority task
Program cannot access a device	Arbitration: permissions on the device node
One process cannot see another's memory	Abstraction working as designed
Kernel bug takes the whole machine down	No privilege boundary *inside* the kernel
An RTOS meets deadlines that Linux misses	Worst case versus average case
Real-time task misses a deadline once an hour	Unlocked pages, or an unbounded kernel path
Firmware corrupts unrelated data	No MMU; nothing enforces isolation

Check yourself

- ✓ State the two jobs of an OS and place four subsystems into that framing.
- ✓ Distinguish mechanism from policy, with two examples.
- ✓ Name the three hardware features that make the privilege boundary enforceable.
- ✓ Explain why "real-time" means predictable, not fast, and give a design consequence.
- ✓ Name the only three ways the kernel gains control.
- ✓ Give the Windows term for four Linux concepts.
- ✓ Give approximate costs for a system call, a context switch and a major page fault.

Kernel architectures: monolithic, micro, hybrid

Where you draw the line between "in the kernel" and "outside it" determines the system's performance, its reliability and its attack surface. This is the oldest live argument in operating systems, and the answer genuinely depends on what you are building.

The question

An OS provides file systems, drivers, networking, memory management and scheduling. Which of those run in kernel mode, with full privilege and no isolation from each other — and which run as ordinary isolated processes?

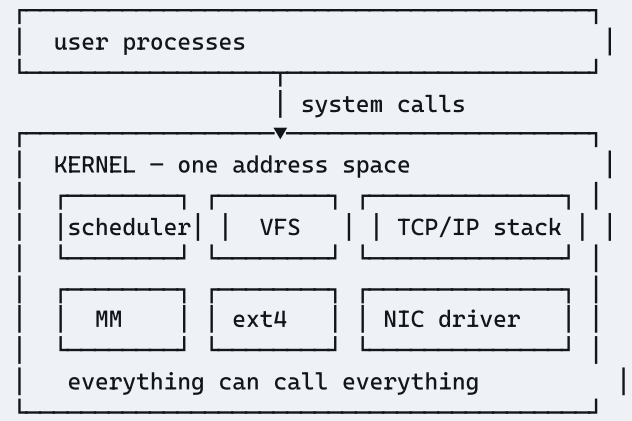
```
The trade-off, stated once:

  IN THE KERNEL              function call: ~1 ns
                             full access to everything
                             a bug is a system crash
                             a vulnerability is total compromise

  OUT OF THE KERNEL          IPC round trip: ~1–10 µs
                             isolated address space
                             a bug kills one service
                             a vulnerability is contained

  Everything below is a different answer to: how much performance
  is that isolation worth?
```

Monolithic



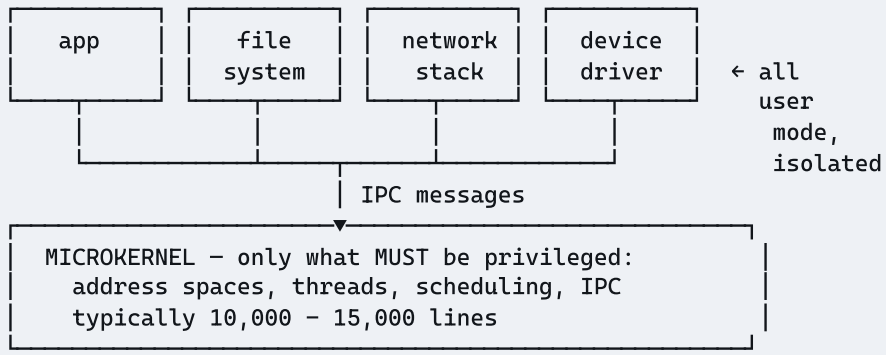
Linux, BSD, older UNIX. Loadable modules do NOT change this:
a .ko is linked into the same address space at runtime.

Advantage	Disadvantage
Subsystem calls are direct function calls — no marshalling, no context switch	Any driver bug can corrupt any kernel data
Shared data structures are cheap to access	A driver crash panics the machine
Simple to write and to reason about performance	A driver vulnerability is full system compromise
Mature, well-optimised implementations exist	Millions of lines at maximum privilege

Advantage	Disadvantage
Modules give runtime flexibility without IPC cost	No stable internal API; everything must be rebuilt together

> **WHY LINUX IS MONOLITHIC AND STAYS THAT WAY**
>
> Roughly 70% of the Linux tree is drivers, all running at EL1 with no isolation from each other. That is a deliberate trade: driver authors get direct access and full speed, and the project accepts that a bad driver can panic the system. Mitigations added over time — `lockdep`, KASAN, the driver model, and increasingly Rust for new drivers — attack the *bug rate* rather than the architecture.

Microkernel



seL4, QNX, MINIX 3, L4 family, Zircon (Fuchsia)

Advantage	Disadvantage
A driver crash kills one process; a supervisor can restart it	Every cross-component call is IPC: two context switches minimum
Trusted computing base is small enough to *formally verify* (seL4 is proved correct)	Data must be copied or shared explicitly
Components can be replaced or upgraded independently	More complex to design: everything is a protocol
Strong fault isolation and least privilege throughout	Historically 10–50% slower on I/O-heavy workloads
Natural fit for certification (DO-178C, IEC 61508)	Small ecosystem; fewer drivers exist

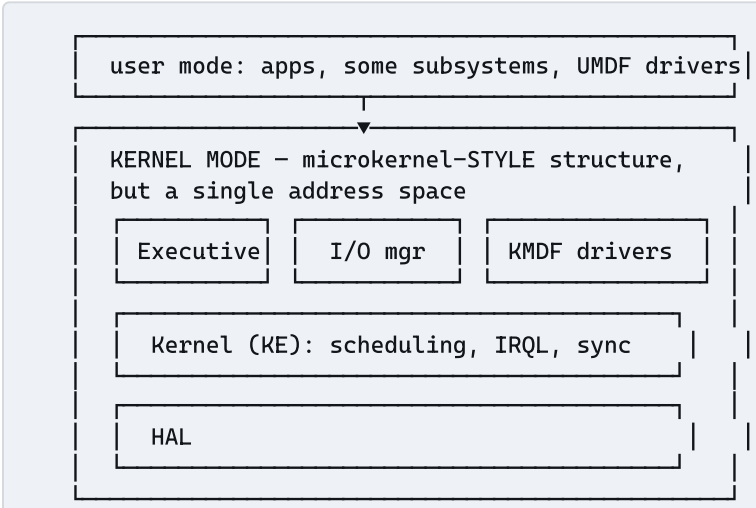
```
Why the performance gap narrowed but did not close

  1980s L3/L4 work showed IPC could be made ~20x faster than
  Mach's, by making it synchronous, register-based and avoiding
  the scheduler. Modern microkernels do a round trip in a few
  hundred nanoseconds, not microseconds.

  What still costs:
    · two address-space switches -> TLB pressure, even with ASIDs
    · cache footprint of crossing between components
    · data copies, unless shared memory is set up (which erodes
      the isolation you paid for)
    · the scheduler is now on the critical path of every I/O

  Where it wins outright: when a fault MUST be contained.
  seL4 in avionics and automotive; QNX in vehicles and medical
  devices. Isolation is the product, and the cycles are the price.
```

Hybrid



```
Windows NT, macOS/XNU (a Mach microkernel with BSD and
drivers linked into the same address space).
```

"Hybrid" mostly means: *organised* like a microkernel — layered, with defined interfaces and object abstractions — but *running* like a monolith, in one address space, for speed. Windows adds a genuine escape hatch with **UMDF**: user-mode drivers for classes of device (USB, HID, sensors) where a crash must not be fatal. That is the microkernel argument applied selectively, where the performance cost is acceptable.

Other shapes

Architecture	Idea	Used for
Exokernel	The kernel only multiplexes hardware securely; applications implement their own abstractions in libraries	Research; influenced kernel-bypass networking (DPDK) and unikernels
Unikernel	One application linked with just the OS functions it needs, in a single address space, no user/kernel split	Cloud appliances, MirageOS, Unikraft — tiny images, fast boot, minimal attack surface
Library OS	OS services as a library the application links; isolation is provided from outside	Graphene, Windows Drawbridge, WASM runtimes

Architecture	Idea	Used for
Nanokernel / separation kernel	Only spatial and temporal partitioning; everything else is a partition	Avionics (ARINC 653), mixed-criticality automotive
No kernel	A superloop plus interrupts	Cortex-M firmware (C ch. 20)

Loadable modules

```
# Linux — the module runs in the SAME address space at full privilege.
# This is convenience, not isolation.
sudo insmod driver.ko          # link into the running kernel
lsmod                          # what is loaded, and who depends on it
sudo rmmod driver              # unlink
modinfo driver.ko              # metadata, parameters, dependencies

# Windows
sc create mydrv type= kernel binPath= C:\drv.sys
sc start mydrv
pnputil /add-driver mydrv.inf /install
```

Benefit	Cost
Smaller base image; load only what the hardware needs	Symbol resolution and relocation at load time
Third-party drivers without rebuilding the kernel	A module can do anything — signing becomes essential
Development without rebooting	No stable in-kernel ABI in Linux: rebuild per version
Unload to reclaim memory	Unload races are a classic source of use-after-free

Windows *does* maintain a stable driver ABI across releases, which is why a driver from years ago often still loads. Linux deliberately does not, to force drivers upstream where they are maintained with the API. Both positions are defensible and both have real costs — this is one of the clearest philosophical differences between the two systems.

Isolating drivers without leaving the kernel

Technique	Protects against	Where
User-mode drivers	Crashes and most vulnerabilities	UMDF (Windows), FUSE, UIO/VFIO, libusb
IOMMU / SMMU	DMA from a buggy or hostile device	Both — see the security track
Memory-safe languages	Whole classes of memory bugs	Rust in Linux 6.1+, Windows drivers
eBPF	Arbitrary code — a verifier proves termination and memory safety before loading	Linux
Driver signing	Unauthorised code	Both; mandatory on Windows x64
Sanitisers and static analysis	Bugs, before shipping	KASAN, Driver Verifier, SDV

eBPF is the most interesting of these: it lets you run user-supplied code *in* the kernel while retaining safety, by proving properties statically instead of isolating at runtime. It is effectively a fourth answer to the original question.

Choosing, in practice

If you need…	Choose	Because
Broad hardware support, good throughput	Monolithic (Linux)	Ecosystem and raw performance
Certification, or provable isolation	Microkernel (seL4, QNX)	Small verifiable TCB; fault containment
Mixed criticality on one SoC	Separation kernel or hypervisor	Spatial and temporal partitioning
Hard real-time, small footprint	RTOS or bare metal	No unbounded paths; predictable
A single cloud service, minimal surface	Unikernel	No unused code, fast boot
Windows compatibility	NT hybrid	It is the platform

THE PATTERN WORTH CARRYING AWAY

Every architecture here is answering "where do I put the isolation boundary?" — and the same question recurs at every level of this site. TrustZone puts it between two worlds; the SMMU puts it in front of DMA; the MMU puts it between processes; a hypervisor puts it between kernels. The mechanism differs; the reasoning about cost versus containment is identical every time.

How it shows up

Symptom	Architectural cause
One buggy driver panics the whole machine	Monolithic: no isolation between kernel components
A driver crash only kills a service	User-mode driver (UMDF, FUSE)
Module will not load after a kernel upgrade	No stable in-kernel ABI in Linux
A Windows driver from 2015 still loads	NT maintains a stable driver ABI
Microkernel system is slower on I/O benchmarks	IPC and context switches on every operation
Filesystem in userspace is slower than in-kernel	Same reason: FUSE crosses the boundary per operation
Kernel-bypass networking is dramatically faster	Exokernel-style: removes the kernel from the data path
Use-after-free on module unload	Unload raced with in-flight work

Check yourself

- ✓ State the single trade-off that all kernel architectures are answering.
- ✓ Give two advantages and two disadvantages of a monolithic kernel.
- ✓ Explain what a microkernel keeps in the kernel and why that list is short.
- ✓ Say why microkernel IPC cost narrowed but never vanished.
- ✓ Explain in what sense Windows NT is "hybrid".
- ✓ Explain why a Linux module is not an isolation boundary.
- ✓ Give three ways to isolate drivers without moving them out of the kernel.
- ✓ Explain why Linux refuses a stable in-kernel ABI and what that buys.

The user/kernel boundary and system calls

The system call is the one door between an application and the kernel. Everything an OS offers passes through it, every argument crossing it is hostile until validated, and its cost shapes the design of every high-performance I/O interface ever built.

Why a special mechanism

A function call cannot cross the privilege boundary. If user code could simply `call` a kernel address, it could call *any* kernel address — landing in the middle of a function, skipping permission checks, with attacker-chosen register state. Isolation would be decorative.

THE THREE REQUIREMENTS

1. **Privilege escalation** must happen atomically with the control transfer.
2. **The entry point is chosen by the kernel**, not the caller. User code supplies a *number*, not an address.
3. **The kernel must be able to return** to exactly where the caller was, at its original privilege.

A synchronous exception provides all three, which is why every architecture implements system calls as a deliberate trap.

The mechanism

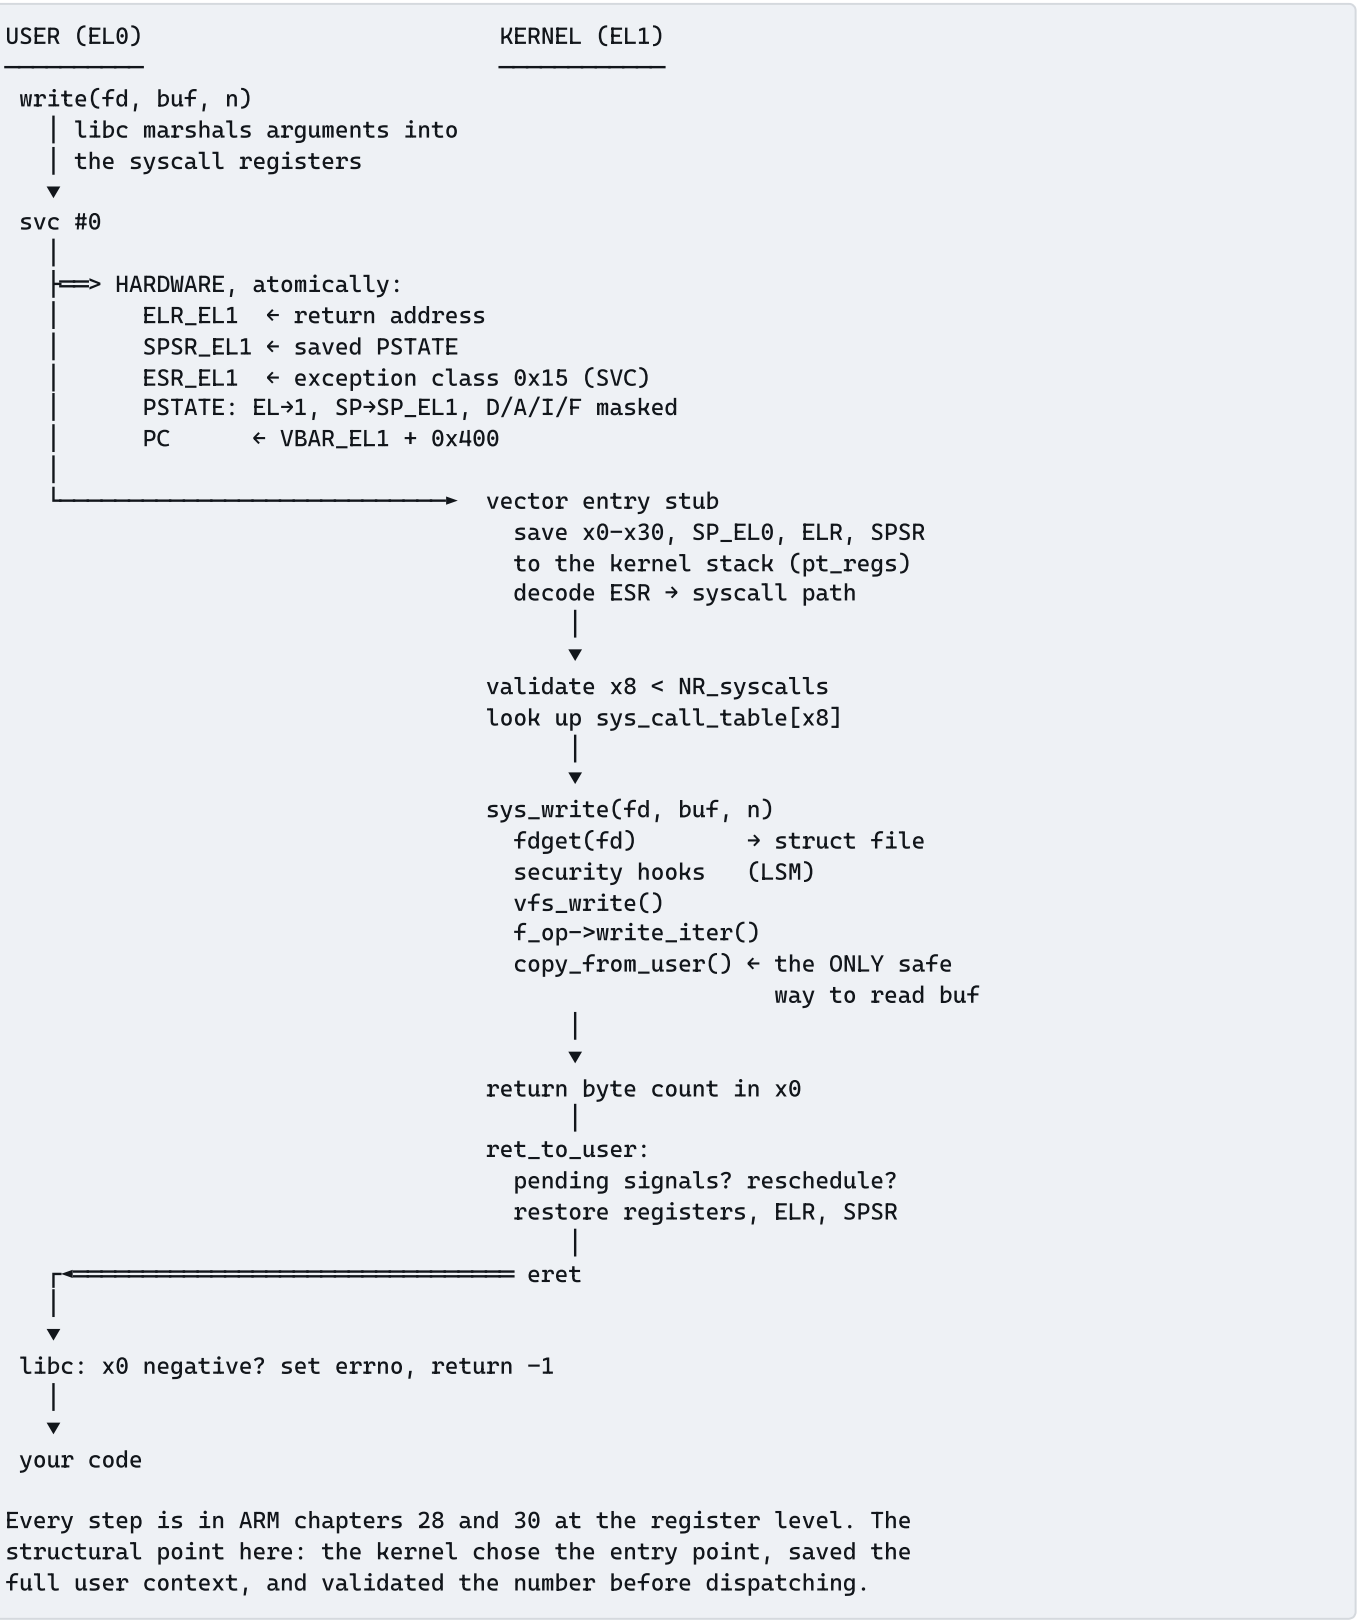
Architecture	Instruction	Number in	Arguments in	Return in
AArch64 (Linux)	`svc #0`	`x8`	`x0` – `x5`	`x0`
x86-64 (Linux)	`syscall`	`rax`	`rdi rsi rdx r10 r8 r9`	`rax`
ARM32 (Linux)	`svc #0`	`r7`	`r0` – `r5`	`r0`
RISC-V	`ecall`	`a7`	`a0` – `a5`	`a0`

THE SYSCALL ABI IS NOT THE C ABI

Note the differences: on x86-64 the fourth argument is in `r10`, not `rcx`, because the `syscall` instruction clobbers `rcx` with the return address. On AArch64 the syscall number sits in `x8`, outside the normal argument registers. Kernel entry code must know both conventions, and this is exactly the mismatch that makes hand-written syscall wrappers error-prone — use libc's.

```
/* what write(1, "hi\n", 3) compiles to on AArch64 Linux */
        mov     x0, #1                  // fd
        adr     x1, msg                 // buf
        mov     x2, #3                  // count
        mov     x8, #64                 // __NR_write
        svc     #0
        // x0 now holds the byte count, or a negative errno
```

The full round trip



Every step is in ARM chapters 28 and 30 at the register level. The structural point here: the kernel chose the entry point, saved the full user context, and validated the number before dispatching.

Validating what crosses

> **EVERY BYTE FROM USER SPACE IS HOSTILE**
> A system call argument is attacker-controlled input arriving at the highest privilege level. The kernel must assume the caller is malicious — not merely buggy — because a local user exploiting a validation gap gets kernel code execution.

```
/* NEVER dereference a user pointer directly. */
long sys_example(void __user *ubuf, size_t len)
{
        char kbuf[256];

        /* WRONG — the pointer may reference kernel memory, unmapped
           memory, or memory that another thread unmaps mid-call. */
        memcpy(kbuf, ubuf, len);

        /* RIGHT */
        if (len > sizeof kbuf)
                return -EINVAL;                 /* bound FIRST      */
        if (copy_from_user(kbuf, ubuf, len))
                return -EFAULT;                 /* returns bytes NOT copied */
        ...
}

/* copy_from_user / copy_to_user do three things you cannot skip:
     1. check the address really lies in user space
     2. install an exception fixup, so a fault returns -EFAULT
        instead of oopsing
     3. respect PAN/SMAP, the hardware feature that blocks kernel
        access to user pages outside these helpers          */
```

The five validation rules

Rule	Failure if ignored
Bound every length before using it	Kernel buffer overflow
Copy before validating, never validate in place	TOCTOU: another thread changes the value between check and use
Check every index and enum against its range	Out-of-bounds table access
Zero output structures fully before filling them	Padding bytes leak kernel stack contents to userspace
Reject unknown flags rather than ignoring them	Cannot add meanings later without breaking programs

```
/* Rule 2, the TOCTOU trap, written out */
struct req *r = (struct req __user *)arg;

if (r->len > MAX) return -EINVAL;      /* read #1 — validate */
process(r->buf, r->len);                /* read #2 — USE      */
/* Another thread in the same process can change r->len between
   the two reads. The check applied to a value that no longer
   exists. This is a real and repeatedly exploited pattern.   */

/* Correct: one copy, then validate the copy */
struct req k;
if (copy_from_user(&k, r, sizeof k)) return -EFAULT;
if (k.len > MAX) return -EINVAL;
process(k.buf, k.len);

/* Rule 4, the info leak */
struct info out;
memset(&out, 0, sizeof out);           /* padding too (C ch. 07) */
out.a = x; out.b = y;
if (copy_to_user(u, &out, sizeof out)) return -EFAULT;
```

The ABI is forever

> **"WE DO NOT BREAK USERSPACE"**
> Linus Torvalds' rule, and the reason Linux binaries from 1995 still run. A system call's number, argument layout and semantics are permanent once released. You cannot change a struct, repurpose a field, or tighten validation in a way that rejects previously-accepted input.

```
/* This is why the syscall table has entries like: */
open, openat, openat2                  /* three generations */
stat, stat64, fstatat, statx
clone, clone3
epoll_create, epoll_create1
dup, dup2, dup3

/* Each new one adds a flags argument or a size field, because the
   old one could not be extended. Designing for extension from the
   start is the lesson:                                          */

struct my_args {
        __u32 size;         /* sizeof(struct) — lets the kernel tell
                               which version the caller compiled against */
        __u32 flags;        /* reject unknown bits, so new ones are safe */
        __u64 field_a;
        __u64 field_b;
        /* new fields appended here in future versions */
};

long sys_myop(struct my_args __user *uargs, size_t usize)
{
        struct my_args a = {};

        if (usize > PAGE_SIZE) return -E2BIG;
        /* copy_struct_from_user handles version skew both ways:
           zero-fills a smaller old struct, and requires that any
           extra bytes from a newer caller are all zero.        */
        if (copy_struct_from_user(&a, sizeof a, uargs, usize))
                return -EFAULT;

        if (a.flags & ~MY_VALID_FLAGS) return -EINVAL;   /* rule 5 */
        ...
}
```

Cost, and the interfaces built to avoid it

```
A minimal syscall costs roughly 50–500 ns:

   trap and privilege change          ~20–50 cycles
   save and restore user registers    ~30–60 cycles
   table lookup and dispatch          ~10 cycles
   pipeline and branch predictor cost variable
   Spectre/Meltdown mitigations       +100–400 cycles on affected CPUs

That is 100–1000x a function call. For a program doing millions of
small operations it dominates everything else.

Four families of workaround, all worth recognising:

  BATCH        do more per call
               writev, readv, sendmmsg, io_submit

  AVOID        remove the kernel from the path entirely
               mmap (page-fault once, then plain loads/stores)
               vDSO (see below)
               DPDK, SPDK — poll the device from user space

  AMORTISE     submit many operations, collect many completions
               io_uring: shared ring buffers, often ZERO syscalls
               in steady state

  MOVE IN      run the logic in the kernel instead
               eBPF: verified user code, executed kernel-side
```

```
/* The vDSO — a small shared object the kernel maps into every
   process, containing implementations that need no privilege.  */
clock_gettime(CLOCK_MONOTONIC, &ts);
/* Reads a kernel-maintained page of timekeeping data plus the
   hardware counter, in USER MODE. No trap at all. Roughly 25 ns
   instead of 300 ns.                                           */

cat /proc/self/maps | grep vdso
LD_SHOW_AUXV=1 /bin/true | grep VDSO
```

Observing system calls

```
# trace every syscall a process makes
strace ./program
strace -c ./program              # summary: counts, time, errors
strace -f -e trace=openat,read,write ./program
strace -p 1234                   # attach to a running process

# lower overhead, system-wide
perf trace ./program
perf stat -e raw_syscalls:sys_enter ./program

# who is making the most syscalls, system-wide
sudo bpftrace -e 'tracepoint:raw_syscalls:sys_enter {
        @[comm, args->id] = count(); }'

# Windows
# Process Monitor, or Event Tracing for Windows (ETW)

# the syscall table itself
ausyscall --dump                       # numbers to names
cat /usr/include/asm-generic/unistd.h  # canonical numbering
```

> **`STRACE -C` FIRST**
> When a program is inexplicably slow, run `strace -c` before anything else. A count of two million `read()` calls of 1 byte each, or thousands of failed `stat()` calls probing for a file, diagnoses the problem in seconds — and both are extremely common.

Windows

```
Win32 is NOT the syscall layer. There are two hops:

  application
      |  CreateFile(...)                    documented, stable API
      v
  kernel32.dll / kernelbase.dll
      |  NtCreateFile(...)                  Native API
      v
  ntdll.dll
      |  mov eax, 0x55        <- syscall NUMBER, and it CHANGES
      |  syscall                 between Windows versions
      v
  === kernel ===
  KiSystemService -> SSDT lookup -> NtCreateFile

Consequences:
  · Windows' stable ABI is Win32, not the syscall interface
  · calling syscalls directly is unsupported and breaks on update
    (which is why malware does it, and why EDR products watch for it)
  · Linux is the opposite: the SYSCALL is stable and libc is a
    convenience wrapper
```

How it shows up

Symptom	Cause
Program is slow with low CPU usage	Syscall-bound; check `strace -c`
Reading a file byte-by-byte is 100× slower	One syscall per byte; buffer it
Performance dropped after a kernel security update	Spectre/Meltdown mitigations on syscall entry
Kernel oops on a bad pointer from userspace	Direct dereference instead of `copy_from_user`
Vulnerability from a length passed by the caller	Length used before being bounded
Exploit changes a value after validation	TOCTOU: validated in place instead of after copying
Kernel stack bytes appear in userspace output	Struct padding not zeroed
New kernel flag breaks an old program	Unknown flags were ignored rather than rejected
Windows software breaks after an update	Called syscalls directly instead of via Win32
`clock_gettime` is unexpectedly cheap	Served by the vDSO, no trap

Check yourself

- ✓ Give three reasons a system call cannot be an ordinary function call.
- ✓ Name the AArch64 syscall instruction and which register carries the number.
- ✓ Walk the round trip from `svc #0` to `eret`, naming what hardware saves.
- ✓ Give the five rules for validating user input, and the failure each prevents.
- ✓ Explain the TOCTOU pattern and the fix.
- ✓ Explain why `openat2` exists alongside `open`.
- ✓ Design an extensible syscall argument struct and say how version skew is handled.
- ✓ Name four techniques for reducing syscall cost, with an example of each.
- ✓ Explain why Windows' stable ABI is Win32 rather than the syscall layer.

Processes and the process control block

A process is a program plus everything the OS must remember about it. This chapter covers what that state actually is, how processes are created and destroyed, and the lifecycle bugs — zombies, orphans, fork-in-a-threaded-program — that come from getting it wrong.

What a process is

> **PROGRAM VERSUS PROCESS**
> A **program** is a file on disk: instructions and initial data. A **process** is a program in execution, together with all the state the OS maintains on its behalf. One program can back many processes; each has its own private state.

```
A process is the sum of:

  ADDRESS SPACE          its private virtual memory map
    text                 code, read-only, shared between instances
    data + bss           initialised and zeroed globals
    heap                 grows upward, via brk/mmap
    memory mappings      files, shared libraries, anonymous regions
    stack(s)             one per thread, grows downward

  EXECUTION STATE        registers, PC, stack pointer, flags
                         (per thread — see chapter 05)

  KERNEL RESOURCES       open file descriptors
                         current working directory, root directory
                         signal handlers and masks
                         timers
                         namespaces, cgroup membership

  IDENTITY               PID, PPID, UID/GID, capabilities,
                         security label (SELinux, AppArmor)

  ACCOUNTING             CPU time used, memory usage, priority,
                         start time, resource limits
```

The process control block

All of that lives in one kernel structure: `task_struct` in Linux, `EPROCESS` plus `KPROCESS` in Windows. It is the definitive answer to "what does the kernel know about this program?".

```
/* Linux: include/linux/sched.h — several hundred fields. The ones
   that matter for understanding the model:                    */

struct task_struct {
        /* ---- scheduling ---- */
        unsigned int          __state;        /* RUNNING, INTERRUPTIBLE... */
        int                   prio, static_prio, normal_prio;
        const struct sched_class *sched_class;
        struct sched_entity   se;             /* CFS/EEVDF bookkeeping */
        cpumask_t             cpus_mask;      /* affinity              */

        /* ---- memory ---- */
        struct mm_struct     *mm;             /* NULL for kernel threads */
        struct mm_struct     *active_mm;

        /* ---- identity and relationships ---- */
        pid_t                 pid, tgid;      /* thread id, THREAD GROUP id */
        struct task_struct __rcu *real_parent;
        struct list_head      children, sibling;
        const struct cred    *cred;           /* uid, gid, capabilities */

        /* ---- resources ---- */
        struct files_struct  *files;          /* fd table              */
        struct fs_struct     *fs;             /* cwd, root             */
        struct signal_struct *signal;
        struct sighand_struct *sighand;

        /* ---- kernel-side execution ---- */
        void                 *stack;          /* 8-16 KB kernel stack  */
        struct thread_struct  thread;         /* saved registers       */

        char                  comm[16];       /* the name in `ps`      */
};

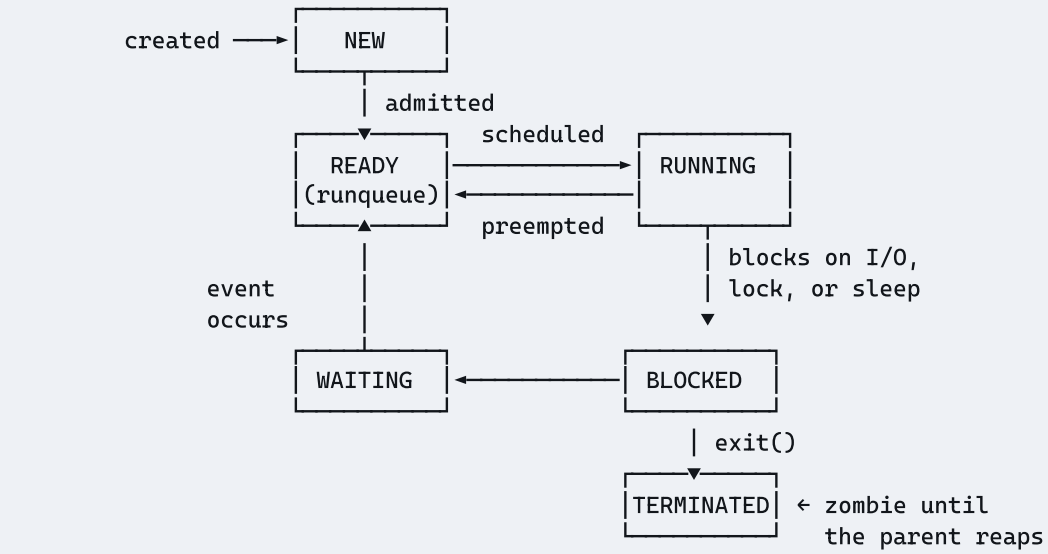
/* `current` is a macro giving the running task. On arm64 it reads
   SP_EL0, which the kernel repurposes to hold the task pointer —
   so it is a single register read, not a lookup.               */
```

THE KEY STRUCTURAL INSIGHT

In Linux there is **no separate process structure**. A process is a group of `task_struct`s sharing a `tgid`, an `mm_struct` and a `files_struct`. Threads and processes are the same object with different sharing. This is why `getpid()` returns `tgid` while `gettid()` returns `pid`, and it is the single most important thing to understand about the Linux model (chapter 05).

Windows takes the opposite approach: `EPROCESS` owns the address space and handle table, and `ETHREAD` objects belong to it. Both designs work; the Linux one is simpler internally, the Windows one maps more directly onto the conceptual model.

Process states



```
Linux state names, and what they mean in `ps`:

  R  TASK_RUNNING            running OR ready — the runqueue
  S  TASK_INTERRUPTIBLE      sleeping; a signal will wake it
  D  TASK_UNINTERRUPTIBLE    sleeping; signals will NOT wake it
                             usually blocked on disk or NFS.
                             A process stuck in D cannot be killed —
                             not even by SIGKILL. This is why
                             "unkillable process" happens.
  T  TASK_STOPPED            SIGSTOP / ptrace
  Z  EXIT_ZOMBIE             finished, awaiting reaping
  I  TASK_IDLE               idle kernel thread
```

Creating a process

Unix: fork + exec

```
pid_t pid = fork();          /* duplicate the calling process */

if (pid < 0) {
        perror("fork");                     /* failed              */
} else if (pid == 0) {
        /* CHILD: fork returns 0 here */
        execl("/bin/ls", "ls", "-l", (char *)NULL);
        _exit(127);                          /* only if exec failed */
} else {
        /* PARENT: fork returns the child's pid */
        int status;
        waitpid(pid, &status, 0);
}
```

```
Why two calls instead of one "spawn"?

  Because the gap between fork and exec is where you configure the
  child, using ORDINARY code rather than a hundred spawn() flags:

      pid = fork();
      if (pid == 0) {
              close(0);  open("input.txt", O_RDONLY);   /* redirect */
              dup2(pipefd[1], 1);                        /* pipe out */
              setuid(nobody);                            /* drop privs */
              chdir("/srv");
              setrlimit(RLIMIT_CPU, &lim);
              execv(path, argv);
      }

  That is the entire design of the Unix shell — pipes, redirection
  and job control all live in that gap. Windows' CreateProcess takes
  a large parameter block instead, and cannot express arbitrary
  setup.

Cost, and why it is not as bad as it sounds:
  fork does NOT copy memory. It marks every page COPY-ON-WRITE and
  copies page TABLES only (chapter 13). Pages are duplicated lazily,
  on first write — and exec discards the address space immediately
  anyway, so most are never copied at all.

  posix_spawn() and vfork() exist for the case where even that is
  too much; posix_spawn is the portable choice.
```

FORK() IN A THREADED PROGRAM

Only the calling thread survives into the child. Every other thread vanishes *mid-operation* — including any that held a lock. If a thread was inside `malloc` when you forked, the child's heap lock is held by a thread that does not exist, and the next allocation deadlocks forever.

Between `fork` and `exec` in a multithreaded process you may call only **async-signal-safe** functions — a short list that excludes `malloc`, `printf` and most of libc. In practice: fork, immediately exec, and use `posix_spawn()` if you can, which handles this correctly.

Windows: CreateProcess

```
STARTUPINFO si = { .cb = sizeof si };
PROCESS_INFORMATION pi;

/* one call creates and starts a NEW program — no fork equivalent */
CreateProcess(
        L"C:\\Windows\\System32\\cmd.exe",   /* image        */
        cmdline,                              /* command line */
        NULL, NULL,                           /* security     */
        TRUE,                                 /* inherit handles */
        0, NULL, NULL,
        &si, &pi);

WaitForSingleObject(pi.hProcess, INFINITE);
CloseHandle(pi.hThread);
CloseHandle(pi.hProcess);      /* handles are refcounted — close both */
```

	fork + exec	CreateProcess
Configuration	Arbitrary code between the two calls	A fixed parameter block
Cost	Two syscalls; COW page-table copy	One call, no duplication
Inheritance	Everything, then close what you do not want	Opt in, per handle
Threads	Dangerous — only the caller survives	No issue
Expressiveness	Higher: pipes, redirection, privilege drop	Lower, but safer by default

Termination, zombies and orphans

```
exit(0);       /* flushes stdio, runs atexit handlers, then _exit  */
_exit(0);      /* immediate; no cleanup — correct after a failed exec */

/* Kernel-side, exit() does:
     · close all file descriptors
     · release the address space
     · send SIGCHLD to the parent
     · re-parent any children to init (or the nearest subreaper)
     · become a ZOMBIE, keeping only the exit status  */
```

```
ZOMBIE — finished, but not yet reaped

  A dead process keeps a task_struct alive purely so the parent can
  read its exit status. It holds no memory, no fds, no CPU — but it
  does hold a PID.

  It is reaped when the parent calls wait()/waitpid(). If the parent
  never does, zombies accumulate until the PID space is exhausted
  and no process can be created system-wide.

  ps aux | grep 'Z'          <- state Z, "<defunct>"

  Fixes, in order of preference:
    · call waitpid() — ideally from a SIGCHLD handler, in a loop:
          while (waitpid(-1, &st, WNOHANG) > 0) ;
    · signal(SIGCHLD, SIG_IGN)  — the kernel reaps automatically
    · double-fork, so the grandchild is orphaned to init

ORPHAN — parent died first

  The child is re-parented to PID 1 (or the nearest process that
  called PR_SET_CHILD_SUBREAPER). init reaps continuously, so
  orphans are harmless. This is the normal way daemons detach.
```

The process tree

```
pstree -p                  # the whole hierarchy
ps -ef --forest
ps -o pid,ppid,pgid,sid,tty,stat,cmd

/* Four grouping levels, each with a purpose: */
PID      one process (in Linux, one thread group)
PGID     process group — a pipeline. Ctrl+C signals the whole group.
SID      session — a login. Has one controlling terminal.
         Detaching from it (setsid) is how a daemon is born.
Namespace  a private view of PIDs, mounts, network, users.
           This is the mechanism containers are built from.
```

```
/* Classic daemonisation, and what each step is for */
if (fork() > 0) _exit(0);      /* parent exits; child is orphaned  */
setsid();                       /* new session: no controlling tty  */
if (fork() > 0) _exit(0);      /* second fork: cannot ever reacquire
                                   a terminal                       */
chdir("/");                     /* do not pin a filesystem          */
umask(0);
close(0); close(1); close(2);   /* reopen on /dev/null              */

/* Modern systems: do NOT do this. Let systemd manage the lifecycle
   (Type=simple) and log to stdout. The double-fork dance exists to
   solve problems a service manager already solves.               */
```

Inspecting a process

```
# everything the kernel knows, as files
ls /proc/self/
cat /proc/PID/status        # state, threads, uid, memory summary
cat /proc/PID/maps          # the virtual address space
cat /proc/PID/smaps         # per-mapping RSS, PSS, dirty pages
ls  /proc/PID/fd/           # open file descriptors, as symlinks
cat /proc/PID/cmdline       # NUL-separated argv
cat /proc/PID/environ
cat /proc/PID/limits        # rlimits
cat /proc/PID/stack         # kernel stack — WHY is it in D state?
ls  /proc/PID/task/         # one directory per thread

# resource usage
ps -o pid,ppid,stat,%cpu,%mem,rss,vsz,etime,cmd -p PID
top -H -p PID               # per-thread view
/usr/bin/time -v ./program  # peak RSS, faults, context switches

# limits
ulimit -a
prlimit --pid PID
cat /sys/fs/cgroup/.../memory.max
```

DIAGNOSING AN UNKILLABLE PROCESS

A process in state **D** ignores `SIGKILL` because it is blocked in the kernel in a non-interruptible sleep. Read `/proc/PID/stack` and `/proc/PID/wchan` to see exactly which kernel function it is waiting in — almost always a storage or network filesystem call. The fix is to address the underlying I/O (a hung NFS mount, a failing disk), not the process.

Resource limits

Limit	Controls	Typical symptom when hit
`RLIMIT_NOFILE`	Open file descriptors	`EMFILE`: "too many open files" — usually an fd leak
`RLIMIT_NPROC`	Processes per user	`EAGAIN` from `fork`; often a fork bomb or leak
`RLIMIT_STACK`	Stack size	`SIGSEGV` on deep recursion
`RLIMIT_AS`	Total virtual address space	`malloc` returns NULL
`RLIMIT_CORE`	Core dump size	No core file after a crash
cgroup `memory.max`	Physical memory (containers)	OOM kill of the container
cgroup `cpu.max`	CPU bandwidth	Throttling; latency spikes

How it shows up

Symptom	Cause
Hundreds of `<defunct>` processes	Parent never calls `wait()`
"Cannot fork: resource temporarily unavailable"	PID exhaustion from zombies, or `RLIMIT_NPROC`
Process ignores `SIGKILL`	State D — uninterruptible I/O; check `/proc/PID/stack`
Child deadlocks after `fork` in a threaded program	Inherited a lock held by a thread that no longer exists
"Too many open files"	fd leak; check `ls /proc/PID/fd | wc -l`
Daemon dies when the terminal closes	Never called `setsid()`; still in the session
Child inherits an fd it should not have	Missing `O_CLOEXEC` / `FD_CLOEXEC`
Exit status is 0 despite a failure	Only the low 8 bits are returned; use the `WIFEXITED` macros
Memory usage looks doubled after `fork`	Shared COW pages counted twice; read PSS in `smaps`

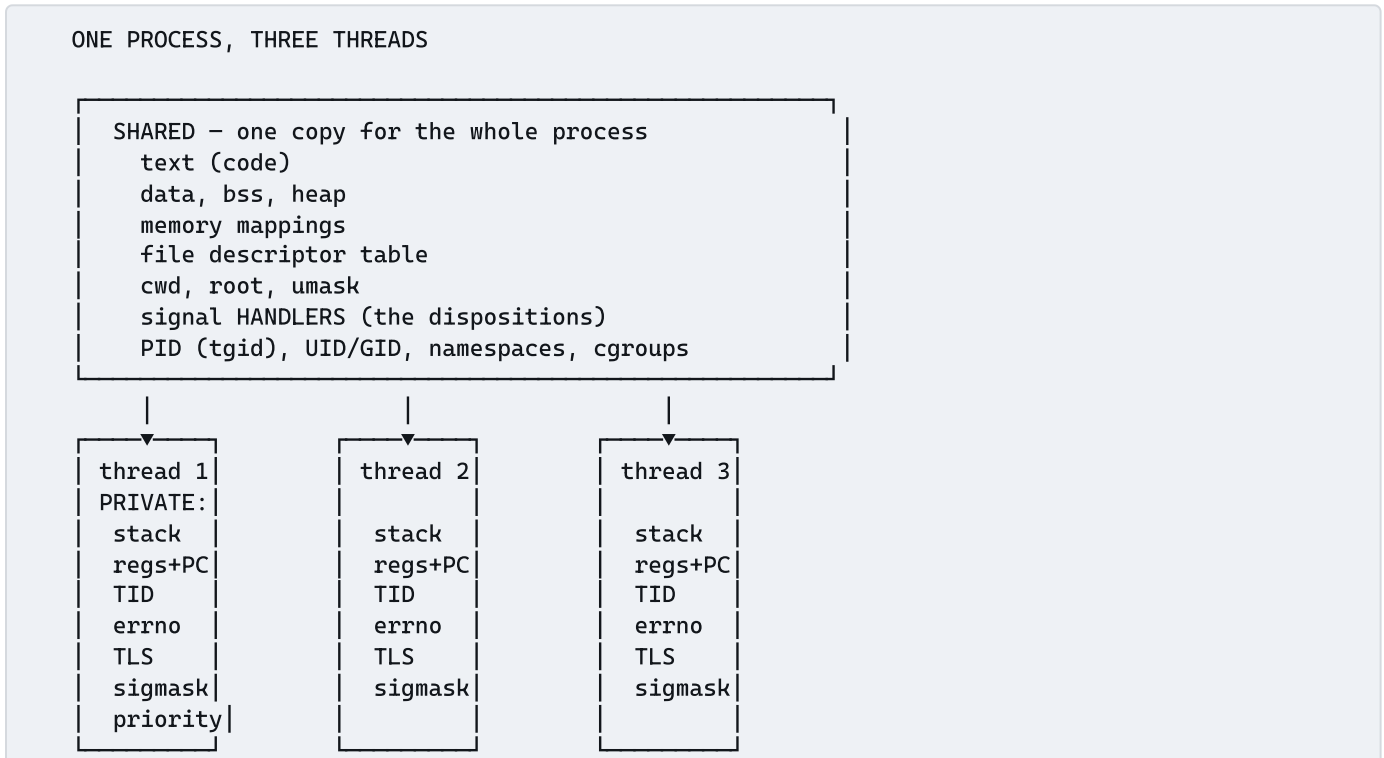
Check yourself

- ✓ Distinguish a program from a process and list four categories of process state.
- ✓ Explain why Linux has no separate process structure, and what `tgid` means.
- ✓ Name the Linux process states and explain why D-state processes cannot be killed.
- ✓ Explain what the gap between `fork` and `exec` is for, with two examples.
- ✓ Explain why `fork` is cheap despite duplicating a process.
- ✓ Explain why `fork` in a threaded program is dangerous, and the safe rule.
- ✓ Define zombie and orphan, and give two ways to prevent zombie accumulation.
- ✓ Explain what each of PID, PGID, SID and namespace groups, and what each is used for.

Threads and threading models

A thread is an independent execution context sharing an address space with its siblings. That sharing is the whole point and the whole danger: communication is free, and so is corruption.

What is shared and what is not



Note the asymmetry in signals: the HANDLER is shared, the MASK is per-thread. That is a genuine source of confusion.

THE TRADE

Threads communicate through ordinary memory — a pointer write is all it takes, at nanosecond cost. Processes must use IPC, which is safe but costs microseconds. Threads buy you cheap communication and pay for it with the entire class of data races, deadlocks and memory-ordering bugs from CA chapter 15.

The Linux model

```
/* In Linux, threads and processes are the SAME KERNEL OBJECT.
   Both are created by clone(); the flags decide what is shared. */

clone(CLONE_VM | CLONE_FS | CLONE_FILES | CLONE_SIGHAND |
      CLONE_THREAD | CLONE_SYSVSEM | CLONE_SETTLS, ...)
      /* ^ a THREAD: shares everything */

clone(SIGCHLD, ...)          /* == fork(): shares nothing */

/* So a "process" is a group of tasks with the same tgid. */
getpid()   /* returns tgid - the same for every thread */
gettid()   /* returns pid  - unique per thread          */

ls /proc/1234/task/          /* one directory per thread */
ps -L -p 1234                /* list threads             */
top -H                       /* per-thread view          */
```

> **WHY THIS DESIGN**
>
> Because the kernel needs one scheduler, one context-switch path and one wait mechanism regardless of how much is shared, the sharing is expressed as flags rather than as a separate object type. Windows takes the other approach — `EPROCESS` owns `ETHREAD`s — which matches intuition more closely at the cost of duplicating machinery.

Threading models

Model	Mapping	Property
1:1 (kernel threads)	Each user thread is one kernel thread	True parallelism; blocking is fine; context switch costs a syscall. **Linux, Windows, macOS all use this.**
N:1 (green threads)	Many user threads on one kernel thread	Very cheap switching; *one blocking call stops everything*; no multicore. Historical.
M:N	M user threads over N kernel threads	Best of both in theory; scheduler interaction is notoriously hard. Go's runtime does this well; Solaris and NPTL abandoned it.
Async / coroutines	Cooperative, one OS thread per core	No preemption, no locks needed within a task, but a blocking call stalls the whole executor

```
Why M:N mostly failed, and where it works

  The kernel scheduler and the user scheduler each make decisions
  without knowing the other's state. Classic failure: a user thread
  blocks in a syscall, taking its kernel thread with it, and the
  user scheduler cannot see that its worker vanished.

  Go succeeds because its runtime OWNS the blocking calls: every
  channel operation, network read and syscall goes through the
  runtime, which can park the goroutine and reuse the OS thread.
  That is only possible in a language with a controlled runtime.

  In C and C++ you get 1:1, and async is a library (io_uring,
  libuv, ASIO) that you must use consistently or not at all.
```

Creating threads

```
#include <pthread.h>

static void *worker(void *arg)
{
        int id = *(int *)arg;
        /* ... */
        return (void *)(intptr_t)result;
}

pthread_t t[4];
int ids[4];
for (int i = 0; i < 4; i++) {
        ids[i] = i;                     /* NOT &i - see below */
        if (pthread_create(&t[i], NULL, worker, &ids[i]) != 0)
                return -1;              /* returns errno, does NOT set it */
}
for (int i = 0; i < 4; i++) {
        void *ret;
        pthread_join(t[i], &ret);
}

/* The classic bug: passing &i, the LOOP VARIABLE. Every thread
   receives the same address, and reads whatever value it holds
   when the thread happens to run. Pass a distinct object per
   thread, or pass the value cast to intptr_t.               */
```

```
/* C11 threads - standard but thinly supported; pthreads remains
   the practical choice on POSIX.                              */
#include <threads.h>
thrd_create(&t, worker, arg);
thrd_join(t, &res);

/* Windows */
HANDLE h = CreateThread(NULL, 0, ThreadProc, param, 0, &tid);
WaitForSingleObject(h, INFINITE);
CloseHandle(h);
/* Prefer _beginthreadex in C code: it initialises the CRT's
   per-thread state (errno, strtok buffers). Raw CreateThread
   leaks that state and breaks some CRT functions.           */
```

Detached versus joinable

```
/* A joinable thread's exit status and stack are retained until
   someone joins it. Never joining leaks — the thread equivalent
   of a zombie process.                                          */

pthread_join(t, &ret);          /* wait and reclaim */

/* Or detach, if you never need the result: */
pthread_detach(t);
/* or at creation */
pthread_attr_t a;
pthread_attr_init(&a);
pthread_attr_setdetachstate(&a, PTHREAD_CREATE_DETACHED);
pthread_attr_setstacksize(&a, 256 * 1024);   /* default is 8 MB! */
pthread_create(&t, &a, worker, arg);
pthread_attr_destroy(&a);

/* Stack size matters: 8 MB of VIRTUAL address space per thread is
   fine on 64-bit, but on 32-bit it caps you at ~380 threads, and
   the guard page plus first-touch cost is real. Size it.      */
```

Thread-local storage

```
_Thread_local int counter;          /* C11              */
thread_local int counter;            /* C23 / <threads.h> */
__thread int counter;                /* GCC extension     */
__declspec(thread) int counter;      /* MSVC              */

/* Each thread gets its own instance, with static duration.
   Used for: errno, per-thread caches, random number state,
   the current transaction or request context.            */

/* Dynamic TLS, when the key is not known at compile time: */
pthread_key_t key;
pthread_key_create(&key, destructor);   /* destructor runs at thread exit */
pthread_setspecific(key, ptr);
void *p = pthread_getspecific(key);

/* Cost: a TLS access is a few instructions via a dedicated register
   (TPIDR_EL0 on AArch64). In a shared library with dynamic TLS it
   can require a function call on first access per thread.       */
```

Thread safety and reentrancy

Property	Means
Thread-safe	Correct when called concurrently from several threads — usually via internal locking
Reentrant	Correct when interrupted and called again, including from a signal handler. Stricter: implies no locks and no static state.
Async-signal-safe	Safe to call from a signal handler. Stricter still — see C ch. 16.

```
/* NOT thread-safe: returns a pointer to static storage */
char *strtok(char *s, const char *d);
struct tm *localtime(const time_t *t);
char *strerror(int e);
struct passwd *getpwnam(const char *n);

/* the _r variants take caller-supplied storage instead */
strtok_r(s, d, &saveptr);
localtime_r(t, &tm_buf);
strerror_r(e, buf, sizeof buf);
getpwnam_r(n, &pwd, buf, sizeof buf, &result);

/* Writing thread-safe code: three strategies, in order of
   preference.                                          */

/* 1. NO SHARED STATE — by far the best. Give each thread its own
      data and combine at the end.                          */
struct alignas(64) partial { long sum; };   /* padded: CA ch. 15 */
struct partial results[NTHREADS];

/* 2. IMMUTABLE SHARED STATE — read-only after construction needs
      no synchronisation at all.                            */
static const struct config *cfg;   /* set once before threads start */

/* 3. EXPLICIT SYNCHRONISATION — locks, atomics, channels.
      Necessary, but every lock is a chance to deadlock.    */
```

Signals and threads

```
/* The rules, which are unintuitive:
     · signal HANDLERS are per-PROCESS (shared)
     · signal MASKS are per-THREAD
     · a signal sent to the process is delivered to ANY ONE thread
       that has it unblocked — you do not choose which
     · pthread_kill() targets a specific thread             */

/* The standard pattern: block signals everywhere, handle them in
   one dedicated thread. This removes async-signal-safety from the
   problem entirely.                                         */
sigset_t set;
sigemptyset(&set);
sigaddset(&set, SIGINT);
sigaddset(&set, SIGTERM);
pthread_sigmask(SIG_BLOCK, &set, NULL);   /* BEFORE creating threads,
                                             so all inherit the mask */

/* ...then in one thread: */
int sig;
sigwait(&set, &sig);              /* synchronous, ordinary context —
                                     you may call anything here      */
shutdown_gracefully();

/* Linux alternative: signalfd() turns signals into a readable fd
   you can put in an epoll loop.                             */
```

Cancellation

```
pthread_cancel(t);              /* request cancellation */

/* Deferred (the default): the thread dies at the next CANCELLATION
   POINT — a blocking call such as read, write, sleep, wait.  */
pthread_setcanceltype(PTHREAD_CANCEL_DEFERRED, NULL);

/* Asynchronous: dies immediately, anywhere. Almost never usable —
   it can die holding a lock or half-way through an allocation. */
pthread_setcanceltype(PTHREAD_CANCEL_ASYNCHRONOUS, NULL);

/* Cleanup handlers run on cancellation */
pthread_cleanup_push(unlock_it, &mutex);
        /* ... critical section ... */
pthread_cleanup_pop(1);         /* 1 = also run it on normal exit */
```

PREFER COOPERATIVE SHUTDOWN

`pthread_cancel` is difficult to use correctly: every resource must have a cleanup handler, and a cancellation point can appear inside library code you did not write. In practice, use an atomic flag plus a wakeup mechanism (a pipe, an eventfd, a condition variable) and let the thread exit its own loop. Windows does not offer cancellation at all — `TerminateThread` is documented as unsafe and should never be used.

Thread pools

```
Creating a thread per unit of work does not scale:

   thread creation      ~10–100 µs and ~8 MB of virtual address space
   context switching    grows with thread count
   cache footprint      each thread evicts the others
   scheduler overhead   O(log n) or worse per switch

A POOL fixes the count and queues the work:

   [ task queue ] ──► worker 1
                  ├──► worker 2
                  ├──► worker 3
                  └──► worker 4      (typically nproc, or nproc+1)

Sizing:
   CPU-bound      ≈ number of cores
   I/O-bound      more, since most workers are blocked
   mixed          separate pools, so slow I/O cannot starve compute

Beware of the work-queue lock becoming the bottleneck — that is
what work-stealing deques solve, and why Rayon, TBB and Go's
scheduler all use per-worker queues.
```

Debugging threaded programs

```
# ThreadSanitizer — finds data races that have not yet manifested.
# The single most valuable tool here. ~5–15x slowdown.
gcc -fsanitize=thread -g prog.c && ./prog

# Helgrind / DRD — race and lock-order detection, no rebuild needed
valgrind --tool=helgrind ./prog

# gdb
info threads
thread 3
thread apply all bt          # backtrace of EVERY thread — the first
                             # thing to run on a deadlock

# what are the threads doing right now?
top -H -p PID
ps -L -o pid,tid,psr,pcpu,stat,wchan,comm -p PID
cat /proc/PID/task/TID/stack        # kernel-side, for D state

# contention
perf lock record ./prog && perf lock report
perf sched latency
```

How it shows up

Symptom	Cause
All threads get the same argument value	Passed `&i`, the shared loop variable
Adding threads makes it slower	False sharing or lock contention (CA ch. 15)
Works with 2 threads, fails with 16	A race whose window widened
Fails only on ARM, not x86	Missing barriers; TSO hid it
Memory grows with each completed thread	Joinable threads never joined
Cannot create more than ~380 threads on 32-bit	8 MB default stack exhausting address space
Signal handled by an unexpected thread	Process-directed signals go to any unblocked thread
`strtok` returns wrong results	Static state shared between threads; use `strtok_r`
Deadlock after cancelling a thread	Cancelled while holding a lock
Child process hangs after `fork`	Inherited a lock held by a thread that did not survive

Check yourself

- ✓ List what threads share and what is private, including the signal asymmetry.
- ✓ Explain why Linux uses one object for threads and processes, and what `tgid` distinguishes.
- ✓ Compare 1:1, N:1 and M:N, and say why M:N works for Go but not for C.
- ✓ Give the `&i` bug and two correct ways to pass per-thread data.
- ✓ Explain joinable versus detached and the leak that follows from confusing them.
- ✓ Distinguish thread-safe, reentrant and async-signal-safe.
- ✓ Describe the standard pattern for handling signals in a threaded program.
- ✓ Explain why `pthread_cancel` is hard to use and what to do instead.

CPU scheduling algorithms

The scheduler decides which thread runs next, and it must satisfy goals that directly contradict each other. Understanding which goal a scheduler is optimising explains every design decision it makes — and tells you which one your workload actually needs.

Goals that conflict

Goal	Definition	Conflicts with
Throughput	Work completed per second	Fairness, latency — switching costs time
Latency / response	Time from ready to running	Throughput — frequent preemption thrashes caches
Fairness	Proportional share of CPU	Priority, throughput
Priority	Important work first	Fairness — and risks starvation
Determinism	Bounded worst case	Nearly everything else
Efficiency	Low scheduler overhead itself	Sophistication of the policy

THE ONE QUESTION TO ASK

"Is this system optimising the *average* case or the *worst* case?" A general-purpose OS optimises the average — it will happily add 10 ms of jitter to gain 5% throughput. An RTOS optimises the worst case and gives up throughput without hesitation. Almost every argument about scheduler behaviour is really a disagreement about which of these the system should do.

Preemptive versus cooperative

```
COOPERATIVE           a thread runs until it yields or blocks
                      + no preemption points, so no locks needed
                        between yields — much simpler reasoning
                      + very low overhead
                      − one runaway thread hangs the system
                      − a buggy thread can never be recovered
                      used by: async runtimes, some RTOSes,
                               classic Mac OS and Windows 3.x

PREEMPTIVE            a timer interrupt can switch at any moment
                      + one thread cannot monopolise the CPU
                      + latency is bounded by the tick or better
                      − every shared structure needs synchronisation
                      − context switch cost on every switch
                      used by: every general-purpose OS

Linux preemption levels, chosen at build time:
  PREEMPT_NONE        kernel code never preempted — best throughput
  PREEMPT_VOLUNTARY   explicit reschedule points in long loops
  PREEMPT             kernel is preemptible except in critical
                      sections — the desktop default
  PREEMPT_RT          almost fully preemptible: most spinlocks
                      become sleeping mutexes and IRQ handlers
                      become threads. Latency in tens of µs,
                      at a throughput cost.
```

The classic algorithms

Algorithm	Rule	Strength	Weakness
FCFS / FIFO	First to arrive runs to completion	Trivially simple, no starvation	*Convoy effect*: one long job blocks everything behind it
SJF	Shortest job first	*Provably optimal* average wait time	Requires knowing job length; starves long jobs
SRTF	Preemptive SJF	Even better average	Same problems, plus more switching
Round robin	Each gets one time slice, cyclically	Fair, responsive, no starvation	Quantum choice is a hard trade-off
Priority	Highest priority runs	Expresses importance	Starvation; priority inversion
MLFQ	Several queues; demote CPU hogs, promote I/O-bound tasks	Approximates SJF *without* knowing job lengths	Tunable in many ways; gameable
Fair-share / CFS	Track CPU consumed; run whoever is furthest behind	Fair by construction; no heuristics to tune	Not real-time
Lottery / stride	Tickets proportional to share	Simple proportional sharing	Randomness gives poor short-term fairness

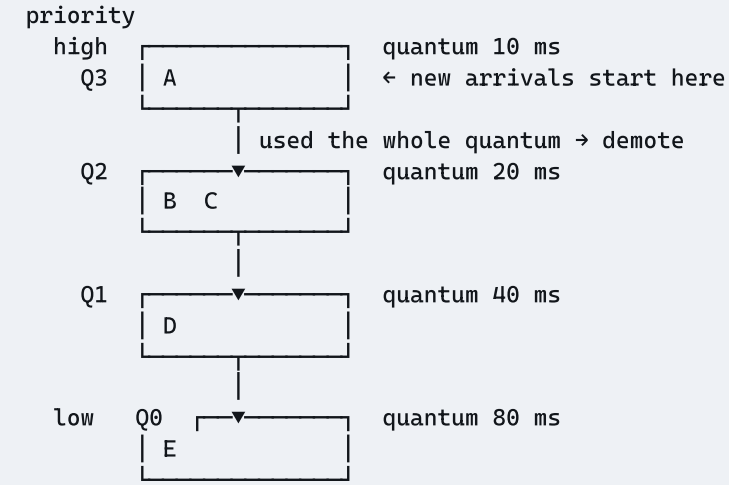
```
The quantum trade-off, made concrete

  Context switch cost ≈ 1–5 µs (plus cache and TLB refill)

    quantum 1 ms   →  overhead 0.1–0.5%   latency up to 1 ms
    quantum 10 ms  →  overhead 0.01–0.05% latency up to 10 ms
    quantum 100 µs →  overhead 1–5%       latency up to 100 µs

  Interactive work wants short quanta; batch work wants long ones.
  This is precisely why MLFQ exists: give short quanta at high
  priority to tasks that block quickly, and long quanta at low
  priority to tasks that burn their whole slice.
```

Multi-level feedback queue



```
Rules:
 1. run the highest non-empty queue, round robin within it
 2. a job that uses its full quantum is DEMOTED (it is CPU-bound)
 3. a job that blocks early stays or is PROMOTED (it is I/O-bound,
    and is probably interactive)
 4. periodically boost everything back to the top — this prevents
    starvation, and defeats gaming rule 3 by yielding just before
    the quantum expires

This infers job length from OBSERVED behaviour, which is why it
approximates SJF without an oracle. Windows and older Linux both
used variants of this.
```

Fair scheduling: CFS and EEVDF

```
/* CFS (Completely Fair Scheduler), Linux 2.6.23–6.5, replaced the
   heuristic MLFQ with a single idea:                              */

   VIRTUAL RUNTIME (vruntime) = actual runtime, weighted by nice

       vruntime += delta_exec * (NICE_0_WEIGHT / task_weight)

   · a low-nice (high-priority) task has a large weight, so its
     vruntime advances SLOWLY, so it is picked more often
   · always run the task with the SMALLEST vruntime
   · tasks are kept in a red-black tree keyed by vruntime, so
     "smallest" is O(1) to find and O(log n) to reinsert

   No heuristics, no priority boosting, no interactivity guessing —
   just: whoever has had the least CPU (weighted) runs next.

   nice values map to weights on a ~1.25x-per-step curve:
       nice  0 → weight 1024
       nice -5 → weight 3121   (~3x more CPU)
       nice  5 → weight  335   (~3x less)
       nice ±1 is roughly a 10% change in share
```

```
/* EEVDF (Earliest Eligible Virtual Deadline First) replaced CFS in
   Linux 6.6. Same fairness core, plus an explicit LATENCY term:

     · each task gets a virtual deadline based on its requested
       latency (settable per task via sched_setattr)
     · among ELIGIBLE tasks (those not ahead of their fair share),
       run the earliest deadline
     · so a task can ask for low latency WITHOUT asking for more
       CPU — which CFS could not express

   This matters for audio, games and interactive work, which want
   to be scheduled QUICKLY but not necessarily OFTEN.          */

chrt --help                      # see and set policies
nice -n 10 ./batch_job
renice -n -5 -p 1234
schedtool -n -5 -e ./program
```

Real-time scheduling

Policy	Rule	Use for
`SCHED_FIFO`	Priority 1–99. Runs until it blocks or yields. **No time slicing.**	Short, bounded, critical work
`SCHED_RR`	Same, plus round-robin among equal priorities	Several equal-priority RT tasks
`SCHED_DEADLINE`	Specify runtime, deadline and period explicitly. EDF + constant bandwidth server.	Periodic tasks with real deadlines
`SCHED_OTHER`	The fair scheduler	Everything else
`SCHED_IDLE`	Only when nothing else wants the CPU	Background scavenging

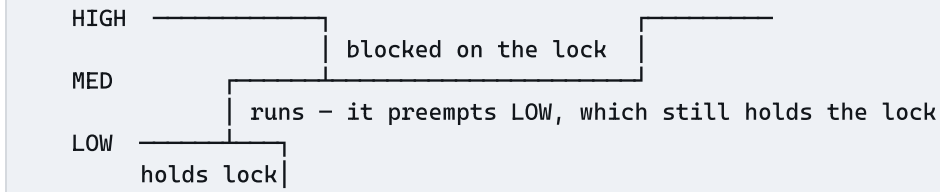
```
#include <sched.h>
struct sched_param p = { .sched_priority = 50 };
sched_setscheduler(0, SCHED_FIFO, &p);

/* SCHED_DEADLINE — say what you actually need */
struct sched_attr attr = {
        .size          = sizeof attr,
        .sched_policy  = SCHED_DEADLINE,
        .sched_runtime =  2 * 1000 * 1000,   /*  2 ms of CPU     */
        .sched_deadline = 8 * 1000 * 1000,   /*  within 8 ms     */
        .sched_period  = 10 * 1000 * 1000,   /*  every 10 ms     */
};
syscall(SYS_sched_setattr, 0, &attr, 0);
/* The kernel performs an ADMISSION TEST: if total utilisation
   would exceed capacity, the call fails rather than silently
   missing deadlines. That is what makes it genuinely real-time. */
```

A `SCHED_FIFO` INFINITE LOOP HANGS THE MACHINE

It never yields, and nothing at lower priority — including your shell — will ever run again. Protections: `sched_rt_runtime_us` reserves a slice for non-RT tasks (95% RT by default), and you should always test RT code on an isolated CPU. Reserve `SCHED_FIFO` for short, provably bounded work, and always pair it with `mlockall()` so a page fault cannot introduce unbounded delay.

Priority inversion



```
HIGH waits on LOW; MED preempts LOW; therefore MED delays HIGH
indefinitely. Priority is effectively inverted.

This is not theoretical: it nearly ended the Mars Pathfinder
mission in 1997. The fix was uploaded from Earth.

SOLUTIONS
 Priority inheritance  the lock holder temporarily inherits the
                       highest priority among its waiters.
                       → PTHREAD_PRIO_INHERIT, and RT-mutexes
                         throughout PREEMPT_RT
 Priority ceiling      the lock carries a priority; anyone taking
                       it is raised to that level immediately
 Avoid sharing         lock-free structures, or per-CPU data
```

```
pthread_mutexattr_t a;
pthread_mutexattr_init(&a);
pthread_mutexattr_setprotocol(&a, PTHREAD_PRIO_INHERIT);
pthread_mutex_init(&m, &a);
/* Costs a little on every lock and unlock. Mandatory when RT and
   non-RT threads share a mutex.                                  */
```

Multiprocessor scheduling

Concern	Mechanism
Per-CPU runqueues	Avoids one global lock. Linux has one runqueue per CPU.
Load balancing	Periodically migrate tasks between runqueues; also on wake-up and fork
Cache affinity	Prefer the CPU a task last ran on — its cache is still warm. Migration costs a full cache refill.
Scheduling domains	A hierarchy — SMT sibling → core → cluster → NUMA node — with balancing cheapest at the closest level
NUMA	Keep a task near its memory; migrating across nodes can double memory latency
Heterogeneous cores	big.LITTLE: energy-aware placement. Small tasks to LITTLE, bursty ones to big.

```
# pin to specific CPUs — essential for benchmarking and RT
taskset -c 2,3 ./program
taskset -pc 2 1234

# isolate CPUs from the general scheduler entirely (kernel cmdline)
isolcpus=2,3 nohz_full=2,3 rcu_nocbs=2,3
# then place your RT threads there with taskset. This is the
# standard recipe for low-latency work on Linux.

# NUMA placement
numactl --cpunodebind=0 --membind=0 ./program
numastat -p 1234
```

Observing the scheduler

```
# where is the time going?
vmstat 1                    # r = runnable, cs = context switches/s
pidstat -w -p PID 1         # voluntary vs involuntary switches
                            #   voluntary   = blocked on I/O or a lock
                            #   involuntary = preempted (CPU contention)

# per-task scheduler statistics
cat /proc/PID/sched         # vruntime, wait time, migrations
cat /proc/PID/status | grep -i ctxt
cat /proc/schedstat

# tracing
perf sched record ./workload && perf sched latency
perf sched timehist
trace-cmd record -e sched:'*' -- ./workload

# latency measurement for RT tuning
cyclictest -t4 -p 90 -i 200 -m -D 60
#   reports min/avg/MAX latency. The MAX is the number that matters.
```

READING THE TWO SWITCH COUNTS

High **voluntary** context switches means the task blocks a lot — it is I/O-bound, and the fix is usually fewer, larger operations. High **involuntary** switches means it is being preempted — the machine is oversubscribed, or something with higher priority keeps arriving. They call for completely different responses, and `pidstat -w` distinguishes them in one line.

How it shows up

Symptom	Cause
Occasional multi-millisecond latency spikes	Preemption, or a major page fault; use RT policy plus `mlockall`
System unresponsive but CPU is idle	Tasks blocked on I/O (D state), not on CPU
Machine hangs after starting an RT thread	`SCHED_FIFO` loop that never yields
High-priority task delayed by a low-priority one	Priority inversion; enable priority inheritance
Benchmark varies 3× between runs	Migration between big and LITTLE cores; pin with `taskset`
Throughput drops when threads exceed core count	Context-switch overhead and cache thrashing
`nice` has little effect	The task is I/O-bound; nice only allocates CPU
Performance worse after adding NUMA nodes	Memory allocated on a remote node; use `numactl`
Audio glitches under load	Latency, not throughput; needs an RT policy or EEVDF latency hint

Check yourself

- ✓ Name four scheduling goals and a pair that directly conflict.
- ✓ Explain the convoy effect and which algorithm suffers from it.
- ✓ Explain why SJF is optimal and why it cannot be implemented directly.
- ✓ Describe MLFQ's four rules and why rule 4 exists.

- ✓ Define vruntime and explain how nice values change the share.
- ✓ Say what EEVDF adds over CFS and which workloads care.
- ✓ Explain priority inversion and two mechanisms that solve it.
- ✓ Explain the difference between voluntary and involuntary context switches, and what each implies.

Context switching, step by step

The mechanism that creates the illusion of concurrency. It is conceptually simple — save one thread's state, restore another's — and the details of what counts as "state", and what it costs beyond the registers, determine the performance of the entire system.

When a switch happens

```
Only ever from inside the kernel, and only for three reasons —
matching the three ways the kernel gains control (chapter 01):

  1. THE THREAD BLOCKS            voluntary
     read() with no data ready, lock contended, sleep(), wait()
     → mark it not-runnable, pick someone else

  2. A TIMER INTERRUPT FIRES      involuntary, preemption
     the quantum expired, or a higher-priority task woke
     → the scheduler is invoked on the way out of the interrupt

  3. A THREAD BECOMES RUNNABLE    involuntary, preemption
     an interrupt completes I/O and wakes a higher-priority thread
     → preempt immediately, if the policy allows

Linux marks the current task with TIF_NEED_RESCHED rather than
switching immediately. The actual switch happens at the next safe
point — on the way back to user space, or when a preemption-disabled
region ends. That is why PREEMPT_NONE vs PREEMPT changes latency
without changing the mechanism.
```

What "context" means

State	Saved by	Cost
General-purpose registers	Software (the switch routine)	~30 stores + 30 loads
PC and stack pointer	Software	Included above
PSTATE / flags	Hardware on exception entry	Free
FP / SIMD registers	Software, usually **lazily**	512+ bytes; deferred until used
Page tables (`TTBR0`)	Software, only on *process* switch	One register write, plus TLB effects
Thread-local base (`TPIDR_EL0`)	Software	One register
Kernel stack pointer	Software	One register
Caches and TLBs	**Nobody** — they are just wrong afterwards	**The dominant cost**

THE REGISTER SAVE IS NOT THE EXPENSIVE PART

Saving and restoring 31 registers is perhaps 100 cycles. The real cost is that the new thread arrives to find the caches full of the *old* thread's data, the branch predictor trained on the old thread's branches, and possibly a cold TLB. Refilling those costs thousands of cycles and does not appear anywhere in the switch routine. This is why the measured cost of a context switch ranges from ~1 µs to ~50 µs depending entirely on working-set size.

Thread switch versus process switch

```
SAME PROCESS (thread → thread)          DIFFERENT PROCESS
  save/restore registers                  save/restore registers
  swap kernel stack                       swap kernel stack
  swap TLS register                       swap TLS register
  - page tables UNCHANGED -               SWAP TTBR0_EL1
  - TLB stays valid -                     TLB entries now belong to
  - caches stay warm-ish -                  another ASID
                                          caches likely cold

  ~1-2 µs                                 ~2-5 µs, plus a much
                                          larger refill penalty

This is the concrete reason threads are "cheaper" than processes,
and why thread pools beat process pools for fine-grained work.
```

ASIDs make process switches survivable

```
/* Without address space identifiers, changing TTBR0 would require
   flushing the entire TLB - and the new process would then take
   hundreds of TLB misses warming it back up.

   With ASIDs (ARM) / PCIDs (x86), each TLB entry is tagged with
   its owning address space. A switch changes the current ASID;
   entries from BOTH processes coexist. No flush.              */

msr     ttbr0_el1, x0        /* x0[63:48] holds the ASID */
isb

/* Kernel mappings are marked GLOBAL (nG=0), so they match under any
   ASID and survive every switch - which is why a syscall does not
   disturb the TLB at all.                                      */

/* ASIDs are a limited resource (8 or 16 bits). When they are
   exhausted the kernel rolls over the generation and DOES flush
   everything. This is rare and shows up as a periodic latency
   blip on systems with very many processes.                   */
```

> **KPTI MADE THIS WORSE**
>
> Kernel Page Table Isolation, the Meltdown mitigation, gives the kernel a *separate* page table so that kernel addresses are not mapped while user code runs. Every system call and every interrupt therefore switches address space twice. On affected CPUs this added roughly 5–30% to syscall-heavy workloads. ARM cores were mostly not vulnerable and do not pay this; most x86 cores do, unless mitigated in hardware.

The switch itself

```
/* Linux arm64, simplified from arch/arm64/kernel/entry.S.
   Only the CALLEE-SAVED registers need saving here — this runs as
   an ordinary C function call, so the caller already saved the
   volatile ones per the ABI (C chapter 11).                    */

SYM_FUNC_START(cpu_switch_to)
        /* x0 = prev task, x1 = next task */
        mov     x10, #THREAD_CPU_CONTEXT
        add     x8, x0, x10                 /* &prev->thread.cpu_context */
        mov     x9, sp

        stp     x19, x20, [x8], #16         /* save callee-saved */
        stp     x21, x22, [x8], #16
        stp     x23, x24, [x8], #16
        stp     x25, x26, [x8], #16
        stp     x27, x28, [x8], #16
        stp     x29, x9,  [x8], #16         /* FP and SP         */
        str     lr, [x8]                     /* return address    */

        add     x8, x1, x10                 /* &next->thread.cpu_context */
        ldp     x19, x20, [x8], #16         /* restore           */
        ldp     x21, x22, [x8], #16
        ldp     x23, x24, [x8], #16
        ldp     x25, x26, [x8], #16
        ldp     x27, x28, [x8], #16
        ldp     x29, x9,  [x8], #16
        ldr     lr, [x8]
        mov     sp, x9

        msr     sp_el0, x1                  /* `current` for the new task */
        ret                                  /* returns into NEXT's flow */
SYM_FUNC_END(cpu_switch_to)
```

> **THE TRICK WORTH APPRECIATING**
>
> `cpu_switch_to` is called by one thread and *returns into a different one*. The `ret` at the end jumps to the link register restored from the next task's saved context — which is wherever *that* thread last called this function. Every thread's stack is paused mid-call in the same place. A newly created thread has its saved context hand-crafted so that this `ret` lands on its entry function instead.

Lazy FPU switching

```
/* FP/SIMD state is large — 32 x 128-bit V registers, or far more
   with SVE (up to 2048 bits each). Saving it on every switch would
   dominate the cost, and most threads never touch it.        */

/* The optimisation:
     1. on switch, DISABLE FP access for the incoming thread
        (CPACR_EL1.FPEN = 0)
     2. if it never uses FP, nothing was saved or restored — free
     3. if it executes an FP instruction, a trap fires; the kernel
        then saves the previous owner's state, restores this
        thread's, enables FP, and retries the instruction     */

/* Consequences you can observe:
     · the FIRST FP instruction after a switch is expensive
     · in the kernel, FP is FORBIDDEN by default precisely because
       its state is not saved on kernel entry (C chapter 16).
       Kernel code that needs it must bracket it explicitly:  */
kernel_neon_begin();
    /* SIMD-accelerated crypto or checksum here */
kernel_neon_end();
```

Measuring the cost

```
Direct cost — the switch routine itself
    save/restore registers            ~100 cycles
    scheduler decision (EEVDF)        ~200–500 cycles
    page table swap (process switch)  ~50 cycles + barriers

Indirect cost — the part nobody counts, and the part that matters
    cold L1/L2 for the new working set   100s–1000s of cycles
    TLB refill                            100s of cycles
    branch predictor retraining           100s of cycles

  Measured end to end:
    thread ⇔ thread, tiny working set      ~1 µs
    process ⇔ process, tiny working set    ~2 µs
    process ⇔ process, 1 MB working set    ~10–50 µs

The variance IS the point: the switch has a fixed cost and a
working-set-dependent cost, and the second one dominates.
```

```
# count them
vmstat 1                        # cs column: switches per second
pidstat -w -p PID 1             # voluntary vs involuntary, per task
perf stat -e context-switches,cpu-migrations ./program
cat /proc/PID/status | grep ctxt

# see them
perf sched record ./workload && perf sched timehist
trace-cmd record -e sched:sched_switch -- ./workload

# measure the raw cost on your machine
perf bench sched pipe           # ping-pong through a pipe
perf bench sched messaging

# a rough rule: if `cs` is above ~50,000/s on a few cores, switching
# itself is a measurable fraction of your CPU budget.
```

Reducing switch cost

Technique	Effect
Fewer threads — a pool sized to core count	Removes switching that exists only because of oversubscription
Batch I/O — `io_uring`, `readv`	Fewer blocking points, so fewer voluntary switches
Async / coroutines	Switching in user space costs ~20 ns, not ~1 µs — no kernel involved
CPU pinning (`taskset`)	Prevents migration, preserves cache affinity
Longer quanta for batch work	Fewer preemptions; hurts latency
Spin briefly before blocking	Adaptive mutexes: if the lock will be free within ~1 µs, spinning is cheaper than switching twice
Busy-poll for ultra-low latency	Never sleep at all — burns a core to remove the wake-up path entirely
Huge pages	Fewer TLB entries to refill after a switch

```
/* Adaptive mutexes make the spin-versus-block decision automatically:
   spin while the lock HOLDER IS RUNNING on another CPU (it will
   likely release soon), block if the holder is descheduled (it
   will not).                                                  */

/* glibc: */
pthread_mutexattr_settype(&a, PTHREAD_MUTEX_ADAPTIVE_NP);

/* This is why uncontended and briefly-contended mutexes are
   nearly free, and heavily-contended ones are catastrophic —
   the cost cliff is exactly one context switch pair.         */
```

Context switching in an RTOS

```
/* On a Cortex-M with no MMU, a switch is far simpler and far
   faster — typically 50–200 cycles.                          */

void PendSV_Handler(void)      /* the standard RTOS switch hook */
{
        /* hardware already stacked R0–R3, R12, LR, PC, xPSR */
        __asm volatile (
        "   mrs   r0, psp            \n"   /* process stack pointer */
        "   stmdb r0!, {r4–r11}      \n"   /* save the rest         */
        "   ldr   r1, =current_tcb   \n"
        "   ldr   r2, [r1]           \n"
        "   str   r0, [r2]           \n"   /* save SP into the TCB  */
        "   bl    select_next_task   \n"
        "   ldr   r2, [r1]           \n"
        "   ldr   r0, [r2]           \n"   /* new SP                */
        "   ldmia r0!, {r4–r11}      \n"
        "   msr   psp, r0            \n"
        "   bx    lr                 \n"); /* hardware unstacks     */
}

/* Why it is so much cheaper:
     · no page tables, no TLB, no ASID
     · caches are small or absent, so little to lose
     · the hardware stacks half the registers for you
     · no scheduler tree — often a simple priority bitmap

   PendSV is used because it is the LOWEST-priority exception, so
   the switch happens only after all pending interrupts are handled.
   Switching from inside an ISR would otherwise nest badly.     */
```

How it shows up

Symptom	Cause
Throughput falls as threads exceed core count	Switching overhead and cache thrashing
Very high `cs` in `vmstat`	Oversubscription, or a lock ping-ponging between threads
High *voluntary* switches	Blocking frequently — batch the I/O
High *involuntary* switches	CPU contention — reduce thread count or pin
Latency improves dramatically after pinning	Migration was destroying cache affinity
Syscall-heavy workload slowed after a kernel update	KPTI: two address-space switches per syscall
First floating-point operation after a switch is slow	Lazy FPU restore trap
Async runtime far outperforms threads on I/O	User-space switching is ~50× cheaper
Periodic latency blip on a many-process system	ASID rollover forcing a full TLB flush
Kernel oops after using floating point in a driver	FP state not saved on kernel entry; use `kernel_neon_begin()`

Check yourself

- ✓ Name the three events that cause a context switch and which are voluntary.
- ✓ List what is saved on a switch and identify the item nobody saves.
- ✓ Explain why the register save is not the dominant cost.

- ✓ Give the difference between a thread switch and a process switch.
- ✓ Explain what ASIDs do and what happens when they run out.
- ✓ Explain lazy FPU switching and why kernel code cannot use floating point freely.
- ✓ Explain how `cpu_switch_to` can return into a different thread.
- ✓ Give four ways to reduce context-switch cost, and when each applies.

Interprocess communication

Isolation is the point of a process, so any communication must be arranged deliberately through the kernel. The mechanisms differ in throughput, latency, direction, naming and what they can carry — and choosing wrongly is the difference between microseconds and milliseconds.

The choices that matter

Question	Options	Consequence
Data or control?	Bulk bytes vs a signal or event	Shared memory vs eventfd
How much data?	Bytes vs megabytes	Copy cost decides everything
Same machine?	Local vs network	Unix sockets vs TCP
Related processes?	Parent/child vs unrelated	Anonymous pipe vs a named object
Message or stream?	Preserved boundaries vs a byte stream	Datagram vs stream socket
One-to-one or many?	Point-to-point vs multicast	Pipe vs pub/sub
Synchronisation included?	Blocking built in, or your problem	Pipes block; shared memory does not

```
Rough cost, same machine, small messages:

  shared memory + atomics    ~20–100 ns     no syscall in steady state
  futex wake                 ~1–5 µs        only when actually blocking
  pipe / socketpair          ~5–15 µs       two copies + two switches
  Unix domain socket         ~5–20 µs
  POSIX message queue        ~5–20 µs
  D-Bus / Binder             ~50–200 µs     plus marshalling
  loopback TCP               ~20–50 µs      full protocol stack

The pattern: anything that copies through the kernel costs
microseconds. Shared memory costs nanoseconds but hands you the
entire synchronisation problem in exchange.
```

Pipes

```
int fd[2];
pipe(fd);                       /* fd[0] read end, fd[1] write end */

if (fork() == 0) {
        close(fd[0]);                   /* child writes           */
        dup2(fd[1], STDOUT_FILENO);     /* stdout → pipe          */
        close(fd[1]);
        execlp("ls", "ls", NULL);
}
close(fd[1]);                           /* parent MUST close its
                                           write end, or it never
                                           sees EOF               */
char buf[4096];
ssize_t n;
while ((n = read(fd[0], buf, sizeof buf)) > 0)
        process(buf, n);
/* read returns 0 (EOF) only when ALL write ends are closed */
```

Property	Behaviour
Direction	Unidirectional. Two pipes for bidirectional, or use `socketpair()`.
Naming	Anonymous — inherited across `fork`. `mkfifo()` gives a named pipe for unrelated processes.
Boundaries	A byte stream. Two writes may be read as one. **Frame it yourself.**
Capacity	64 KB by default (`F_SETPIPE_SZ` to change). Writer blocks when full; reader blocks when empty.
Atomicity	Writes up to `PIPE_BUF` (4096) are atomic — they will not interleave with other writers.
Closed reader	Writing gives `SIGPIPE`, which kills the process by default. Almost always you want `signal(SIGPIPE, SIG_IGN)` and to handle `EPIPE`.

THE TWO PIPE BUGS EVERYONE WRITES

Forgetting to close unused ends. If the parent keeps its copy of the write end open, the reader never sees EOF and hangs forever. Every process must close every descriptor it does not use.

Assuming message boundaries. A pipe is a byte stream. If you `write()` two 100-byte messages, the reader may get 200 bytes in one `read()`, or 37 then 163. Prefix each message with a length, or use a datagram mechanism.

Sockets

```
/* Unix domain sockets: the default choice for local IPC.
   Same API as network sockets, but no protocol stack overhead. */

int sv[2];
socketpair(AF_UNIX, SOCK_STREAM, 0, sv);   /* bidirectional pipe */

/* Named, for unrelated processes */
int s = socket(AF_UNIX, SOCK_STREAM, 0);
struct sockaddr_un a = { .sun_family = AF_UNIX };
strcpy(a.sun_path, "/run/myservice.sock");
bind(s, (struct sockaddr *)&a, sizeof a);
listen(s, 16);
int c = accept(s, NULL, NULL);

/* SOCK_DGRAM preserves message boundaries;
   SOCK_SEQPACKET gives boundaries AND reliable ordering.     */
```

```
/* The killer feature: passing FILE DESCRIPTORS between processes.
   No other local IPC mechanism can do this.                    */

struct msghdr msg = {0};
char cmsgbuf[CMSG_SPACE(sizeof(int))];
msg.msg_control = cmsgbuf;
msg.msg_controllen = sizeof cmsgbuf;

struct cmsghdr *cm = CMSG_FIRSTHDR(&msg);
cm->cmsg_level = SOL_SOCKET;
cm->cmsg_type  = SCM_RIGHTS;              /* "here is an fd"      */
cm->cmsg_len   = CMSG_LEN(sizeof(int));
memcpy(CMSG_DATA(cm), &fd_to_send, sizeof(int));

sendmsg(sock, &msg, 0);

/* The receiver gets a NEW descriptor in its own table, referring
   to the same open file. This is how systemd socket activation,
   privilege separation, Wayland buffer passing and container
   runtimes all work — a privileged process opens the resource
   and hands the descriptor to an unprivileged one.
   SCM_CREDENTIALS similarly passes verified pid/uid/gid.      */
```

Shared memory

```
/* POSIX shared memory — the fastest mechanism, and the one with
   no synchronisation included.                                 */

int fd = shm_open("/myshm", O_CREAT | O_RDWR, 0600);
ftruncate(fd, SIZE);
void *p = mmap(NULL, SIZE, PROT_READ | PROT_WRITE, MAP_SHARED, fd, 0);
close(fd);                      /* the mapping keeps it alive     */
/* ... both processes now see the same physical pages ...        */
munmap(p, SIZE);
shm_unlink("/myshm");           /* remove the name                */

/* Anonymous shared memory, for related processes: */
void *p = mmap(NULL, SIZE, PROT_READ | PROT_WRITE,
               MAP_SHARED | MAP_ANONYMOUS, -1, 0);
fork();                         /* both see the same pages        */

/* memfd_create: an anonymous, sealable region you can pass by fd */
int fd = memfd_create("buf", MFD_ALLOW_SEALING);
fcntl(fd, F_ADD_SEALS, F_SEAL_SHRINK | F_SEAL_GROW);
/* Sealing lets the receiver TRUST that the sender cannot shrink
   the region underneath it — otherwise a malicious sender causes
   SIGBUS in the receiver. This is what Android and Wayland use. */
```

SHARED MEMORY GIVES YOU NO SYNCHRONISATION WHATSOEVER

You get raw memory shared between address spaces. Everything from CA chapter 15 applies in full: you need atomics with correct memory ordering, or a lock placed *in the shared region itself*. And because the peer may be malicious, you must additionally validate everything you read — a shared-memory protocol is a trust boundary.

```
/* A lock that lives in the shared region */
pthread_mutexattr_t a;
pthread_mutexattr_init(&a);
pthread_mutexattr_setpshared(&a, PTHREAD_PROCESS_SHARED);   /* essential */
pthread_mutexattr_setrobust(&a, PTHREAD_MUTEX_ROBUST);      /* see below */
pthread_mutex_init(&shared->lock, &a);

/* ROBUST matters: if the peer dies holding the lock, a normal
   mutex is stuck forever. A robust mutex returns EOWNERDEAD to
   the next acquirer, which can repair the state and call
   pthread_mutex_consistent().                                */
```

Signalling without data

Mechanism	Use	Note
`eventfd`	A counter you can `poll()`	The standard way to wake an event loop from another thread or process
`signalfd`	Signals as a readable fd	Removes async-signal-safety from the problem entirely
`timerfd`	Timers as a readable fd	Integrates cleanly with `epoll`
`futex`	Fast userspace mutex	The primitive under every Linux lock — see below
POSIX semaphores	`sem_open`, `sem_wait`	Named or in shared memory
Signals	`kill(pid, SIGUSR1)`	No payload, can be coalesced, async-safety restrictions

```
The futex, which is worth understanding once

  A mutex that never contends should cost ZERO syscalls. A mutex
  that does contend must eventually sleep, which requires the kernel.
  futex gives you both:

    lock:   atomic compare-and-swap in USER SPACE
            uncontended → done, ~20 ns, no syscall
            contended   → futex(FUTEX_WAIT) → kernel puts you to sleep

    unlock: atomic store in user space
            if waiters were recorded → futex(FUTEX_WAKE)

  The kernel is involved ONLY on contention. This is why an
  uncontended pthread_mutex_lock is nearly free and a contended
  one costs microseconds — the cliff is exactly one syscall pair.

  Every Linux mutex, condition variable, semaphore and barrier is
  built on this.
```

System V IPC

```
/* The 1983 API: message queues, semaphores and shared memory,
   named by integer keys.                                      */
key_t key = ftok("/some/path", 'A');
int shmid = shmget(key, SIZE, IPC_CREAT | 0600);
void *p = shmat(shmid, NULL, 0);

/* Avoid in new code:
     · a global integer namespace with collisions and no cleanup
     · objects PERSIST after all processes exit (ipcs / ipcrm)
     · not pollable — cannot be used with epoll
     · clumsier API

   POSIX equivalents (shm_open, mq_open, sem_open) are namespaced
   under a filesystem path, follow fd semantics, and are pollable.
   Use those.                                                  */

ipcs -a          # list leftover System V objects
ipcrm -m ID      # clean them up manually
```

Higher-level IPC

System	Built on	Adds
D-Bus	Unix sockets	Naming, method calls, signals, introspection, activation. Desktop and systemd.
Binder	A kernel driver	Android's IPC: reference-counted object passing, one-copy transfers, priority inheritance across calls
gRPC / Cap'n Proto	Sockets	Schema, serialisation, versioning, works locally or over a network
Wayland	Unix sockets + `SCM_RIGHTS`	Passes graphics buffers by fd — zero copy for pixels
io_uring	Shared memory rings	Kernel/user "IPC" with often zero syscalls in steady state
virtio	Shared memory rings	Guest ↔ host communication; the same ring design as io_uring

> **THE RECURRING DESIGN**
>
> Notice that io_uring, virtio, Binder and every high-performance IPC converge on the same structure: a **shared-memory ring buffer** with atomic head and tail indices, plus a doorbell (an eventfd, an MMIO write, a futex) used only when the peer needs waking. Bulk data by shared memory; wake-ups by syscall, as rarely as possible. Once you recognise this shape you will see it everywhere in systems design.

Choosing

```
  Need to wake an event loop?              eventfd
  Parent/child, one direction, a stream?   pipe
  Bidirectional, local, need fd passing?   Unix socket (socketpair)
  Message boundaries matter?               SOCK_SEQPACKET or datagram
  Megabytes of data?                       shared memory + a ring
  Across machines?                         TCP, or a real RPC framework
  Unrelated processes, need naming?        named socket or shm_open
  Structured API with versioning?          D-Bus, gRPC
  Absolute lowest latency?                 shared memory + busy poll

Default answer for local IPC on Linux: a Unix domain socket. It is
bidirectional, ordered, has a sane API, passes credentials and file
descriptors, works with epoll, and cleans up when the process dies.
Reach for shared memory only when you have measured that it matters.
```

Debugging IPC

```
# what is open, and connected to what
lsof -p PID
ls -l /proc/PID/fd/
ss -xp                          # Unix sockets and their peers
lsof -U

# System V leftovers
ipcs -a

# shared mappings
cat /proc/PID/maps | grep -E 'shm|SYSV|memfd'
cat /proc/PID/smaps             # Shared_Clean / Shared_Dirty per mapping

# trace the traffic
strace -e trace=read,write,sendmsg,recvmsg -p PID
sudo bpftrace -e 'tracepoint:syscalls:sys_enter_futex { @[comm] = count(); }'

# a hang: where is each side blocked?
cat /proc/PID/stack
cat /proc/PID/wchan
gdb -p PID -batch -ex 'thread apply all bt'
```

How it shows up

Symptom	Cause
Reader hangs, never gets EOF	Some process still holds the write end open
Process dies silently on write	`SIGPIPE` — the reader closed; ignore it and handle `EPIPE`
Messages arrive merged or split	Stream semantics; add length framing
Writer blocks forever	Pipe full and the reader is not consuming — a flow-control bug
Deadlock with two pipes	Both sides blocked writing while neither reads; use non-blocking + `poll`
Shared-memory data occasionally corrupt	No synchronisation or wrong memory ordering
Peer crashed and the lock is stuck	Non-robust process-shared mutex
`SIGBUS` reading shared memory	Sender truncated it; use `memfd` seals

Symptom	Cause
System V objects accumulate after restarts	They persist beyond process lifetime; use POSIX instead
Loopback TCP much slower than expected	Full protocol stack; use a Unix socket

Check yourself

- ✓ Give the seven questions that determine which IPC mechanism to use.
- ✓ Explain why a pipe reader may never see EOF, and the rule that prevents it.
- ✓ Explain why pipes do not preserve message boundaries and what to do about it.
- ✓ Describe `SCM_RIGHTS` and name two systems that depend on it.
- ✓ Say what shared memory does *not* provide, and two things you must add.
- ✓ Explain robust mutexes and the failure they address.
- ✓ Explain how a futex avoids syscalls in the uncontended case.
- ✓ Describe the ring-buffer-plus-doorbell pattern and name three systems using it.

Synchronisation primitives

Shared mutable state plus concurrency equals corruption, unless something enforces order. This chapter covers the primitives, what each one is actually for, and — the part that matters most in kernel work — which are legal in which execution context.

The problem, precisely

```
/* A shared counter, incremented by two threads. */
counter++;

/* which is really three operations (C chapter 01, CA chapter 09) */
        ldr  w1, [x0]        /* LOAD  */
        add  w1, w1, #1      /* MODIFY */
        str  w1, [x0]        /* STORE */

/* Interleaved:
     T1: load  → 5
     T2: load  → 5
     T1: add   → 6
     T2: add   → 6
     T1: store → 6
     T2: store → 6          one increment LOST                */
```

THREE PROPERTIES YOU MAY NEED, AND THEY ARE SEPARATE

- **Atomicity** — the operation completes indivisibly. Nothing observes a half-done state.
- **Mutual exclusion** — at most one thread in a region at a time.
- **Ordering** — other threads observe operations in the intended order (CA ch. 15).

Atomics give atomicity and, with the right memory order, ordering. Locks give all three. Neither is a substitute for the other, and the classic mistake is assuming that "atomic" implies "correct".

Atomic operations

```
#include <stdatomic.h>

atomic_int counter = 0;
atomic_fetch_add(&counter, 1);              /* indivisible */

/* the primitive everything else is built from */
int expected = old;
if (atomic_compare_exchange_strong(&v, &expected, desired)) {
        /* v was `old`, now it is `desired` */
} else {
        /* v was not `old`; expected now holds the actual value */
}

/* the CAS loop — the shape of every lock-free algorithm */
int old, new;
do {
        old = atomic_load(&v);
        new = f(old);                       /* any computation */
} while (!atomic_compare_exchange_weak(&v, &old, new));
/* _weak may fail spuriously but is cheaper in a loop; _strong
   does not, and is right when there is no loop.              */

/* Check what is actually lock-free on your target: */
atomic_is_lock_free(&obj);
ATOMIC_INT_LOCK_FREE            /* 2 = always, 1 = sometimes, 0 = never */
/* A "lock-free" atomic on a large struct may be implemented with a
   hidden mutex — which is a correctness surprise in a signal
   handler or an interrupt context.                            */
```

Memory order	Guarantee	Use for
`relaxed`	Atomicity only	Counters and statistics nobody synchronises on
`acquire`	Later accesses cannot move before it	Reading a flag that guards data
`release`	Earlier accesses cannot move after it	Setting a flag after writing data
`acq_rel`	Both, for read-modify-write	Lock acquire/release, reference counts that free
`seq_cst`	Plus one global total order	The safe default; the most expensive

Mutexes

```
pthread_mutex_t m = PTHREAD_MUTEX_INITIALIZER;

pthread_mutex_lock(&m);
        /* critical section */
pthread_mutex_unlock(&m);

/* Properties that matter:
     · OWNERSHIP — only the locker may unlock. This is what allows
       priority inheritance and deadlock detection.
     · SLEEPS on contention (via futex — OS chapter 08)
     · uncontended cost ~20 ns; contended cost ~1–5 µs        */

/* Types */
PTHREAD_MUTEX_NORMAL        /* self-deadlock on recursive lock   */
PTHREAD_MUTEX_ERRORCHECK    /* returns EDEADLK instead — use in
                               debug builds                      */
PTHREAD_MUTEX_RECURSIVE     /* same thread may relock. Usually a
                               design smell: it hides unclear
                               ownership of the invariant.       */
PTHREAD_MUTEX_ADAPTIVE_NP   /* spin briefly, then sleep          */
```

```
/* Always release on every path. In C, the goto ladder or the
   cleanup attribute (C chapters 11 and 14):                    */
static inline void unlock_p(pthread_mutex_t **m) { pthread_mutex_unlock(*m); }
#define LOCKED(mp) \
        pthread_mutex_t *_l __attribute__((cleanup(unlock_p))) = (mp); \
        pthread_mutex_lock(_l)

void f(void)
{
        LOCKED(&m);
        if (error) return;          /* unlocked automatically */
        ...
}                                   /* unlocked automatically */

/* Linux kernel 6.5+ has the same idea, type-safe: */
guard(mutex)(&lock);
scoped_guard(spinlock_irqsave, &lock) { ... }
```

Reader-writer locks

```
pthread_rwlock_t rw = PTHREAD_RWLOCK_INITIALIZER;

pthread_rwlock_rdlock(&rw);     /* many readers concurrently */
pthread_rwlock_unlock(&rw);

pthread_rwlock_wrlock(&rw);     /* exclusive */
pthread_rwlock_unlock(&rw);
```

READER-WRITER LOCKS ARE USUALLY SLOWER THAN YOU EXPECT

They are only a win when reads are both *frequent* and *long*. For short critical sections the extra bookkeeping — and the cache-line contention on the shared reader count, which every reader must write — often costs more than a plain mutex. They also introduce a writer-starvation policy question that the implementation answers for you, usually badly.

Measure before choosing one. If reads dominate and are short, RCU or a seqlock is almost always the better answer.

Condition variables

```
pthread_mutex_t m = PTHREAD_MUTEX_INITIALIZER;
pthread_cond_t  cv = PTHREAD_COND_INITIALIZER;
bool ready = false;

/* WAITER — note the loop, which is not optional */
pthread_mutex_lock(&m);
while (!ready)                          /* while, NEVER if */
        pthread_cond_wait(&cv, &m);     /* atomically unlocks m,
                                           sleeps, relocks on wake */
consume();
pthread_mutex_unlock(&m);

/* SIGNALLER */
pthread_mutex_lock(&m);
ready = true;
pthread_mutex_unlock(&m);
pthread_cond_signal(&cv);               /* or _broadcast for all */
```

ALWAYS `WHILE`, NEVER `IF`

Three independent reasons the predicate can be false after a wake-up:

1. **Spurious wake-ups** are explicitly permitted by POSIX and do occur.
2. **Another waiter got there first** and consumed the item — with `broadcast`, all waiters wake but only one can proceed.
3. **The condition changed again** between the signal and your reacquiring the mutex.

Using `if` produces a bug that appears under load, months later, and is nearly impossible to reproduce.

```
/* The three rules for condition variables:
     1. always associated with a mutex, and the predicate is
        protected by that mutex
     2. wait in a while loop on the predicate
     3. hold the mutex when changing the predicate

   Signal inside or outside the lock? Either is correct.
   Inside is simpler to reason about; outside avoids the waiter
   waking and immediately blocking on the mutex you still hold.
   Modern implementations optimise both cases.                */
```

Semaphores

```
#include <semaphore.h>
sem_t s;
sem_init(&s, 0, 3);             /* 0 = threads only, 3 permits */

sem_wait(&s);                   /* take a permit, or block */
        /* at most 3 threads here */
sem_post(&s);                   /* return a permit */

/* Unlike a mutex, a semaphore has NO OWNER: any thread may post.
   That makes it the right tool for:
     · limiting concurrency to N (a resource pool)
     · signalling between threads (post from one, wait in another)
     · counting available items in a producer/consumer queue

   And the wrong tool for mutual exclusion — a mutex's ownership
   is what enables priority inheritance and error checking.    */

/* sem_post IS async-signal-safe, which makes semaphores the one
   correct way to wake a thread from a signal handler.        */
```

Kernel context: the rule that dominates

> **CAN THIS CODE SLEEP?**
>
> Everything about kernel synchronisation follows from this one question. If you are in a context that cannot sleep — an interrupt handler, holding a spinlock, or above DISPATCH_LEVEL on Windows — then any primitive that might block is a bug. It will deadlock, or trigger "scheduling while atomic".

```
   Does this code need to sleep while holding the lock?
   (kmalloc(GFP_KERNEL), copy_to_user, I/O, another mutex)
        │
        ├── YES ──► MUTEX  (Linux)  /  FAST_MUTEX, ERESOURCE (Windows)
        │           process context only; never in an ISR
        │
        └── NO ───► is the data ALSO touched by an interrupt handler?
                    │
                    ├── NO ──► spin_lock()
                    │
                    └── YES ─► spin_lock_irqsave()
                               disables interrupts on THIS core, so
                               the handler cannot deadlock against you

   Special cases:
     read-mostly, rare writes    → RCU
     a simple counter or flag    → atomic_t, no lock at all
     waiting for an event        → wait_event() + wake_up()
     one-shot completion         → struct completion
     read-mostly, short reads    → seqlock
```

```
/* Linux */
spinlock_t lock;
unsigned long flags;

spin_lock_irqsave(&lock, flags);        /* save, disable, lock   */
        /* short, non-sleeping critical section ONLY */
spin_unlock_irqrestore(&lock, flags);   /* unlock, restore state */

/* Why save-and-restore rather than plain disable/enable: if
   interrupts were ALREADY disabled by an outer critical section,
   unconditionally re-enabling them at the inner unlock is a
   serious bug.                                                  */

/* Windows equivalents */
KIRQL old;
KeAcquireSpinLock(&lock, &old);          /* raises to DISPATCH_LEVEL */
KeReleaseSpinLock(&lock, old);
KeAcquireSpinLockAtDpcLevel(&lock);      /* already at DISPATCH     */
```

Linux	Windows	Sleeps?	Context
`spinlock_t`	`KSPIN_LOCK`	No	Any
`mutex`	`FAST_MUTEX`	Yes	Process only
`rw_semaphore`	`ERESOURCE`	Yes	Process only
`completion`	`KEVENT`	Yes (waiter)	Wait: process. Signal: any.
`atomic_t`	`Interlocked*`	No	Any
RCU	—	Readers: no	Any

RCU and seqlocks

```
/* RCU: Read-Copy-Update. Readers pay ZERO synchronisation cost —
   no atomics, no cache-line contention, no barriers on most
   architectures. Writers do all the work.                    */

/* reader */
rcu_read_lock();                       /* just disables preemption */
struct foo *p = rcu_dereference(gp);
if (p) use(p->field);
rcu_read_unlock();

/* writer */
struct foo *new = kmalloc(...);
*new = *old;                           /* COPY */
new->field = value;                    /* UPDATE the copy */
rcu_assign_pointer(gp, new);           /* publish, with a release */
synchronize_rcu();                     /* wait until every pre-existing
                                          reader has finished       */
kfree(old);                            /* now provably safe */

/* The insight: instead of preventing readers from seeing a torn
   update, never modify in place. Readers see either the old
   object or the new one, both consistent. Reclamation is
   deferred until no reader can hold a reference.

   Ideal for: routing tables, module lists, configuration —
   anything read constantly and updated rarely.
   Bad for: frequent writes (each one allocates and waits).   */
```

```
/* Seqlock: readers retry if a write occurred during their read.
   Very cheap reads, but readers must be side-effect free.     */

/* reader */
unsigned seq;
do {
        seq = read_seqbegin(&sl);
        a = shared.x;  b = shared.y;    /* may read a torn pair */
} while (read_seqretry(&sl, seq));      /* ...and retry if so   */

/* writer */
write_seqlock(&sl);
shared.x = 1;  shared.y = 2;
write_sequnlock(&sl);

/* Used for timekeeping: readers vastly outnumber writers and must
   never block a writer. Note readers can starve under constant
   writing, and must not have side effects since they may run
   several times.                                              */
```

Rules that prevent most bugs

Rule	Prevents
Document what each lock protects, next to its declaration	Ambiguous ownership — the root of most locking bugs
Acquire multiple locks in one global order, always	Deadlock (ch. 10)
Keep critical sections short	Contention, and latency spikes

Rule	Prevents
Never call unknown code holding a lock	Lock-order inversion via a callback
Never sleep holding a spinlock	Deadlock, "scheduling while atomic"
Never return from a function holding a lock it acquired	Unbalanced locking; use scope guards
Prefer no sharing, then immutable sharing, then locks	The whole problem class
One lock per data structure, not per function	Locks that protect nothing coherent

Finding synchronisation bugs

```
# ThreadSanitizer — finds races that have not yet manifested.
# The highest-value tool in this chapter.
gcc -fsanitize=thread -g prog.c && ./prog

# lock order and race detection without rebuilding
valgrind --tool=helgrind ./prog
valgrind --tool=drd ./prog

# contention
perf lock record ./prog && perf lock report
mutrace ./prog

# a hang: get every thread's stack
gdb -p PID -batch -ex 'thread apply all bt'

# kernel
CONFIG_PROVE_LOCKING=y          # lockdep: proves lock ORDER correctness
                                # across the whole kernel, and reports a
                                # potential deadlock the FIRST time an
                                # inconsistent order is observed —
                                # before it ever deadlocks
CONFIG_DEBUG_ATOMIC_SLEEP=y     # catches sleeping in atomic context
CONFIG_KCSAN=y                  # data race detector
```

> **LOCKDEP IS THE SINGLE BEST THING ABOUT KERNEL DEVELOPMENT**
> It builds a graph of every lock acquisition order observed at runtime and reports a cycle the first time one appears — even if the deadlock did not actually occur. A potential deadlock that would surface once a year in production becomes a splat in `dmesg` on your first test run. Always develop with it enabled.

How it shows up

Symptom	Cause
Counter is occasionally wrong	Unsynchronised read-modify-write
Works with 2 threads, fails with 16	A race whose window widened
Wakes up but the condition is false	`if` instead of `while` around `cond_wait`
Hang with all threads in `pthread_mutex_lock`	Deadlock — get all backtraces
"scheduling while atomic" / bug check 0xA	Slept in an interrupt or spinlock context
Adding a reader-writer lock made it slower	Short critical sections; the bookkeeping dominates
Performance collapses past N threads	Lock contention; the cliff is one context switch pair

Symptom	Cause
Interrupts stay disabled after unlock	Used `spin_unlock_irq` where `irqrestore` was needed
Fails on ARM, passes on x86	Missing memory ordering, hidden by TSO
Crash freeing an object another thread is reading	Missing RCU grace period or reference count

Check yourself

- ✓ Name the three properties concurrent code may need and say which primitives provide each.
- ✓ Write a CAS loop and explain `_weak` versus `_strong`.
- ✓ Give three reasons a condition-variable predicate must be rechecked in a loop.
- ✓ Explain the difference between a mutex and a semaphore, and when ownership matters.
- ✓ Give the decision procedure for choosing a kernel lock.
- ✓ Explain why `spin_lock_irqsave` saves the previous state.
- ✓ Explain how RCU makes readers free, and what writers pay instead.
- ✓ Say what lockdep proves and why it finds deadlocks that never happened.

Classic concurrency problems and deadlock

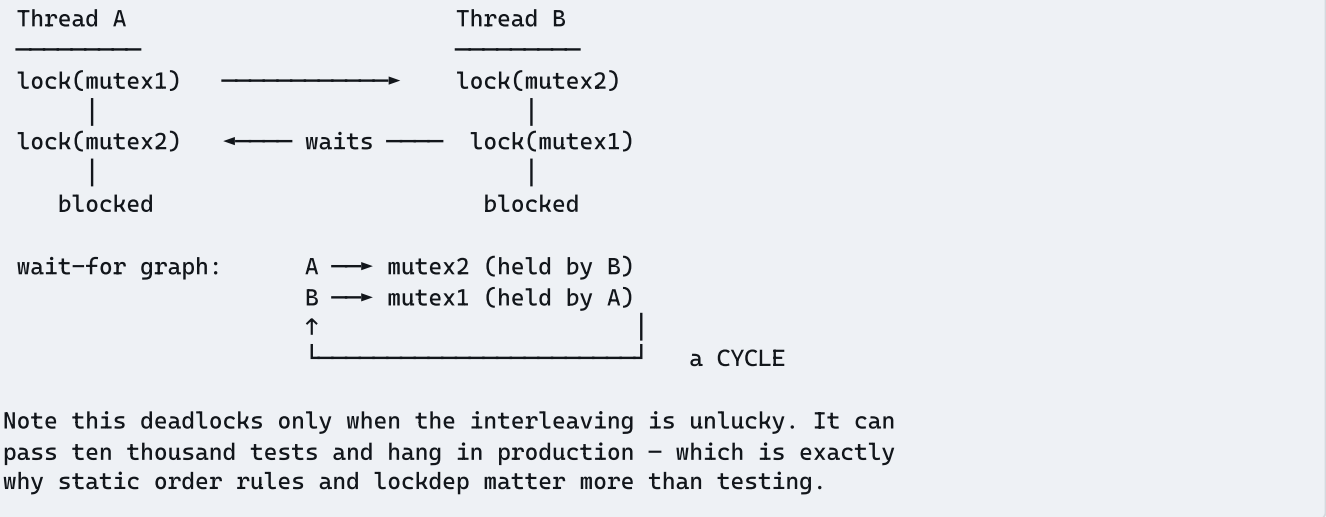
Deadlock has exactly four necessary conditions, and breaking any one of them prevents it. The classic textbook problems are not academic exercises — each is a real pattern you will meet, and each has a standard solution worth knowing by name.

The four conditions

COFFMAN'S CONDITIONS — ALL FOUR MUST HOLD SIMULTANEOUSLY

1. **Mutual exclusion** — a resource is held exclusively.
2. **Hold and wait** — a thread holds one resource while waiting for another.
3. **No preemption** — a resource cannot be forcibly taken away.
4. **Circular wait** — a cycle exists in the wait-for graph.

Break *any* one and deadlock becomes impossible. Every prevention technique below is an attack on one of these four.



```
Note this deadlocks only when the interleaving is unlucky. It can
pass ten thousand tests and hang in production — which is exactly
why static order rules and lockdep matter more than testing.
```

Breaking each condition

Attack	Technique	Practicality
Mutual exclusion	Lock-free structures, immutable data, per-thread copies	Best when applicable — removes the problem entirely
Hold and wait	Acquire all locks at once, or none. Release everything before retrying.	Often impractical: you rarely know the full set in advance
No preemption	`trylock` + back off, releasing what you hold	Workable, but risks livelock without randomised backoff
Circular wait	**A global lock order, obeyed everywhere**	**The standard solution in real systems**

```
/* LOCK ORDERING — the practical answer. Define a total order and
   document it where the locks are declared.                    */

/*
 * Lock order (acquire in this order, release in reverse):
 *      1. device->config_lock
 *      2. device->queue_lock
 *      3. buffer->lock
 */

/* When the order is dynamic — two objects of the same type — order
   by ADDRESS. Any consistent total order works.               */
void transfer(struct account *a, struct account *b, int amount)
{
        struct account *first  = (a < b) ? a : b;
        struct account *second = (a < b) ? b : a;

        if (a == b) return;             /* do not self-deadlock */

        pthread_mutex_lock(&first->lock);
        pthread_mutex_lock(&second->lock);
        a->balance -= amount;
        b->balance += amount;
        pthread_mutex_unlock(&second->lock);
        pthread_mutex_unlock(&first->lock);
}
/* Ordering by address is the standard trick; the kernel's
   double_lock_balance() and Linux's inode locking both do it.  */
```

```
/* TRYLOCK AND BACK OFF — when ordering is impossible */
for (;;) {
        pthread_mutex_lock(&m1);
        if (pthread_mutex_trylock(&m2) == 0)
                break;                          /* got both      */
        pthread_mutex_unlock(&m1);              /* release ALL   */
        usleep(rand() % 100);                    /* random backoff */
}
/* The random backoff is not optional: without it, two threads can
   repeatedly grab and release in lockstep forever — LIVELOCK.
   They are running, consuming CPU, and making no progress.    */
```

Detection and recovery

```
/* Rather than preventing deadlock, detect it and break the cycle. */

/* 1. Timeouts — crude but effective in application code */
struct timespec ts;
clock_gettime(CLOCK_REALTIME, &ts);
ts.tv_sec += 5;
if (pthread_mutex_timedlock(&m, &ts) == ETIMEDOUT) {
        release_everything();
        return -EAGAIN;                 /* retry from the top */
}

/* 2. Error-checking mutexes catch self-deadlock immediately */
pthread_mutexattr_settype(&a, PTHREAD_MUTEX_ERRORCHECK);
if (pthread_mutex_lock(&m) == EDEADLK) ...

/* 3. lockdep (kernel) — builds the lock-order graph at runtime and
      reports a cycle the FIRST time an inconsistent order is seen,
      whether or not it deadlocked. This is the gold standard.   */

/* Databases do full cycle detection in the wait-for graph and
   abort one transaction as the "victim" — which is why you must
   handle deadlock-retry errors in any transactional code.     */
```

Livelock and starvation

	Deadlock	Livelock	Starvation
Threads are	Blocked	Running	Running or blocked
CPU usage	Zero	**High**	Normal
Progress	None, ever	None, ever	Some threads progress; one never does
Cause	Circular wait	Repeated mutual back-off	Unfair scheduling or lock policy
Fix	Lock ordering	Randomised backoff, or a queue	Fair/ticket locks, aging, priority boost

```
/* Starvation from an unfair lock: a thread on the same core keeps
   reacquiring before a waiter on another core is scheduled.  */

/* A TICKET LOCK gives strict FIFO fairness: */
typedef struct { atomic_uint next, now; } ticket_lock_t;

void lock(ticket_lock_t *l) {
        unsigned my = atomic_fetch_add(&l->next, 1);
        while (atomic_load_explicit(&l->now, memory_order_acquire) != my)
                cpu_relax();
}
void unlock(ticket_lock_t *l) {
        atomic_fetch_add_explicit(&l->now, 1, memory_order_release);
}
/* Fair, but every waiter spins on the SAME cache line — the
   coherence traffic scales badly (CA chapter 15). MCS and qspinlock
   fix that by giving each waiter its own line to spin on; Linux
   uses qspinlock for exactly this reason.                    */
```

Producer–consumer

```
/* The most common real pattern: one side generates, the other
   consumes, with a bounded buffer in between.                */

#define N 16
struct item buf[N];
size_t head, tail, count;
pthread_mutex_t m = PTHREAD_MUTEX_INITIALIZER;
pthread_cond_t not_full  = PTHREAD_COND_INITIALIZER;
pthread_cond_t not_empty = PTHREAD_COND_INITIALIZER;

void produce(struct item it)
{
        pthread_mutex_lock(&m);
        while (count == N)                      /* while, not if */
                pthread_cond_wait(&not_full, &m);
        buf[head] = it;
        head = (head + 1) % N;
        count++;
        pthread_mutex_unlock(&m);
        pthread_cond_signal(&not_empty);
}

struct item consume(void)
{
        pthread_mutex_lock(&m);
        while (count == 0)
                pthread_cond_wait(&not_empty, &m);
        struct item it = buf[tail];
        tail = (tail + 1) % N;
        count--;
        pthread_mutex_unlock(&m);
        pthread_cond_signal(&not_full);
        return it;
}

/* TWO condition variables, not one. With a single cv and
   broadcast, a producer can wake another producer, which finds
   the buffer still full and sleeps again — wasted wake-ups, and
   in the signal (non-broadcast) case, a lost wake-up that hangs
   the system.                                                  */
```

Readers–writers

```
Three policies, and the trade-off is unavoidable:

  READER PREFERENCE    a new reader may enter while others read
                       → maximum read throughput
                       → WRITERS CAN STARVE indefinitely

  WRITER PREFERENCE    a waiting writer blocks new readers
                       → writers always progress
                       → readers can starve under heavy writing

  FAIR (queued)        requests served in arrival order
                       → nobody starves
                       → lower throughput than reader preference

  glibc's pthread_rwlock defaults to reader preference; the
  PTHREAD_RWLOCK_PREFER_WRITER_NONRECURSIVE_NP attribute changes it.
  Knowing which you have matters: a monitoring thread reading a
  structure in a tight loop can permanently block the writer.
```

Dining philosophers

```
   Five philosophers, five forks, each needs both neighbours' forks.

        P0
     F4    F0
   P4        P1
     F3    F1
        P2  F2  P3

  Naive: everyone picks up their LEFT fork, then their RIGHT.
  If all five do it simultaneously, each holds one fork and waits
  forever. All four Coffman conditions, in five lines of code.

  SOLUTIONS, each attacking a different condition:

  1. RESOURCE ORDERING     number the forks; always take the
                           lower-numbered one first.
                           → breaks circular wait. THE standard fix.

  2. LIMIT CONCURRENCY     a semaphore allowing only 4 diners at once.
                           → at least one can always get both forks;
                             breaks hold-and-wait in effect.

  3. ASYMMETRY             odd philosophers take left first,
                           even take right first.
                           → breaks the cycle. Same idea as (1).

  4. ATOMIC ACQUISITION    take both forks or neither, under a
                           global lock.
                           → breaks hold-and-wait. Simple, but
                             serialises everything.

  The point of the problem: it is the minimal example of resource
  ordering, and (1) is what you will actually use.
```

ABBA deadlock across layers

```
/* The dangerous version in real systems: the cycle spans two
   subsystems, and neither author can see the other's order.  */

/* Path A: filesystem operation */
lock(inode->i_mutex);
        lock(page->lock);        /* fs → mm */

/* Path B: memory reclaim */
lock(page->lock);
        lock(inode->i_mutex);    /* mm → fs */

/* Neither file's code looks wrong in isolation. This is why:
     · lock ordering must be documented GLOBALLY, not per-module
     · callbacks are dangerous: calling unknown code while holding
       a lock lets the callee acquire locks you did not expect
     · lockdep finds these, and almost nothing else does      */

/* The general rule: NEVER call into another subsystem, or into a
   caller-supplied callback, while holding a lock.            */
```

Priority inversion, again

Covered in chapter 06, but it belongs in the deadlock family: a high-priority thread is blocked indefinitely, not by a cycle but by a scheduling interaction. The fix — priority inheritance — is a property of the *lock*, which is why an RTOS mutex differs from a plain one, and why `PTHREAD_PRIO_INHERIT` exists.

Avoiding locks entirely

Guarantee	Meaning
Blocking	A suspended thread can block others indefinitely
Obstruction-free	A thread running alone completes
Lock-free	*Some* thread always makes progress — no deadlock possible
Wait-free	*Every* thread completes in bounded steps — the strongest, and rarest

```
/* A lock-free stack push */
void push(struct node *n)
{
        struct node *old;
        do {
                old = atomic_load(&head);
                n->next = old;
        } while (!atomic_compare_exchange_weak(&head, &old, n));
}

/* Pop is much harder - the ABA problem: between reading head and
   the CAS, another thread could pop A, pop B, and push A back.
   Your CAS succeeds because the pointer matches, but the list
   behind it is now wrong.

   Solutions: tagged pointers (a counter in the unused bits),
   hazard pointers, epoch-based reclamation, or RCU.

   The lesson: lock-free code is genuinely hard and easy to get
   subtly wrong. Use a reviewed library, or RCU, unless you have
   measured that lock contention is the actual bottleneck.   */
```

Debugging a hang

```
# 1. Is it deadlock or livelock? Look at CPU usage.
top -H -p PID          # 0% = deadlock;  100% = livelock or spin

# 2. Get every thread's stack. This usually answers it outright.
gdb -p PID -batch -ex 'thread apply all bt'
eu-stack -p PID
py-spy dump --pid PID              # Python
jstack PID                          # Java - reports deadlocks directly

# 3. What is each thread waiting on?
cat /proc/PID/task/*/stack          # kernel side
cat /proc/PID/task/*/wchan
ls -l /proc/PID/task/*/status | head

# 4. Reproduce it deliberately
valgrind --tool=helgrind ./prog     # lock order violations
gcc -fsanitize=thread               # races and some lock issues

# 5. Kernel
dmesg | grep -A40 'possible circular locking dependency'
# lockdep prints the exact two acquisition orders and the stacks
# that established them. It is nearly always sufficient.
```

> **THE FIRST COMMAND TO RUN ON ANY HANG**
>
> `thread apply all bt`. Two threads blocked in `pthread_mutex_lock` on different mutexes, each holding the other's, is unmistakable in the output. Most hangs are diagnosed in under a minute by that one command — before reaching for any specialised tool.

How it shows up

Symptom	Cause
Hang at 0% CPU, all threads blocked	Deadlock; get all backtraces
Hang at 100% CPU, no progress	Livelock, or spinning on a lock never released
One thread never progresses; others fine	Starvation; use a fair lock or aging
Hangs once a week under load	An order violation on a rare code path — enable lockdep or Helgrind
Hangs only after adding a callback	The callee took a lock, creating a cycle across layers
Deadlock between filesystem and memory code	Classic ABBA across subsystems
Self-deadlock on re-entering a function	Non-recursive mutex; fix the design, do not make it recursive
Writer never runs while readers are busy	Reader-preference rwlock
Lock-free stack corrupts under load	ABA problem; needs tagging or safe reclamation
Transaction aborts with "deadlock detected"	The database broke the cycle; retry the transaction

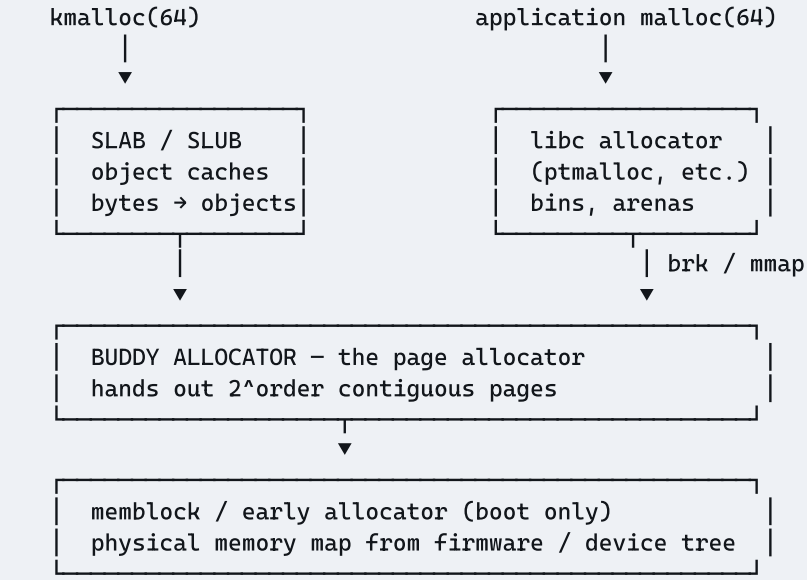
Check yourself

- ✓ State the four Coffman conditions and one way to break each.
- ✓ Explain why lock ordering is the practical solution, and how to order two objects of the same type.
- ✓ Explain why trylock-and-retry needs randomised backoff.
- ✓ Distinguish deadlock, livelock and starvation by CPU usage and cause.
- ✓ Explain why producer–consumer needs two condition variables.
- ✓ Give the three readers–writers policies and who starves under each.
- ✓ Give two solutions to dining philosophers and which condition each breaks.
- ✓ Explain ABBA deadlock across subsystems and the rule that prevents it.
- ✓ Explain the ABA problem and name two mitigations.

Physical memory management and allocators

Before virtual memory can hand out address spaces, something must track which physical pages are free. This chapter covers that layer — the page allocator, the object allocators built on it, and fragmentation, which is the problem all of them exist to fight.

The allocator stack



Each layer solves the layer above's granularity problem: the buddy allocator deals in pages, but most allocations are tens of bytes.

The buddy allocator

```
Free lists, one per ORDER, where order n means 2^n contiguous pages.

  order 0:  4 KB      order 3:  32 KB     order 6:  256 KB
  order 1:  8 KB      order 4:  64 KB     order 7:  512 KB
  order 2: 16 KB      order 5: 128 KB     ... up to order 10 (4 MB)

ALLOCATION of order 2, when only an order-4 block is free:

   order 4:  [================ 64 KB ================]
                        split
   order 3:  [====== 32 KB ======][====== 32 KB ======]
                  split                  ↑ freed to order-3 list
   order 2:  [= 16 =][= 16 =]
              return   ↑ freed to order-2 list

FREEING: when a block is released, check whether its BUDDY — the
adjacent block of the same size, found by flipping one address bit —
is also free. If so, merge them and repeat upward.

   buddy_address = block_address XOR (block_size)

That single XOR is why the scheme is fast: finding the buddy is one
arithmetic operation, not a search.

  + coalescing is automatic and cheap
  + finding a block is O(1) amortised
  - INTERNAL fragmentation: a 5-page request takes an order-3
    block (8 pages), wasting 3
  - EXTERNAL fragmentation: many scattered order-0 blocks cannot
    satisfy an order-5 request even with plenty free
```

```
# see it live
cat /proc/buddyinfo
# Node 0, zone   Normal   1024   512   256   64   16   4   1   0   0   0   0
#                         ^order0 ^1    ^2   ...                   ^order10
# Lots of low-order blocks and zeros at high orders means the memory
# is FRAGMENTED: plenty free, but no large contiguous runs.

cat /proc/pagetypeinfo     # per migrate-type breakdown
cat /proc/zoneinfo         # free pages, watermarks, per zone
```

Zones and NUMA nodes

Zone	Range	Exists because
`ZONE_DMA`	First 16 MB (x86)	Ancient ISA devices could only address 24 bits
`ZONE_DMA32`	First 4 GB	Devices with 32-bit DMA addressing
`ZONE_NORMAL`	The rest	General use
`ZONE_HIGHMEM`	Above the kernel's direct map	32-bit only; gone on 64-bit
`ZONE_MOVABLE`	Pseudo-zone	Pages that can be migrated — enables hotplug and defragmentation

```
/* Zones are why allocation can fail with memory apparently free:
   a device needing DMA32 memory cannot use pages above 4 GB.
   This is exactly what dma_set_mask() communicates.          */

/* NUMA: on multi-socket systems, memory attached to another
   socket costs 1.5-2x the latency. The allocator prefers the
   local node.                                                */
numactl --hardware              # node distances and free memory
numastat -p PID                 # where THIS process's pages live
cat /proc/PID/numa_maps
```

Slab allocators

```
The problem: kmalloc(64) from a 4 KB page allocator wastes 98%.
Plus, initialising a complex object is expensive if repeated.

The slab idea (Bonwick, 1994):
  · allocate a PAGE (or several), carve it into equal-size objects
  · keep a free list threaded through the unused objects
  · allocation = pop the list; free = push it. O(1), no search.
  · objects of one TYPE share a cache, so they stay hot in CPU cache

   ┌──────────── one slab (4 KB page) ────────────┐
   │ obj0 | obj1 | obj2 | obj3 | ... | objN | meta │
   └──┬──┴──────┬──┴──────────────────────────────┘
      └── free ──┘  a singly-linked list through free objects

Linux has had three implementations:
  SLAB   original; per-CPU and per-node queues, complex
  SLUB   the current default; simpler, better multicore scaling,
         less metadata, better debugging
  SLOB   tiny, for very small systems (removed in 6.4)
```

```
/* generic sizes - kmalloc uses power-of-two caches */
void *p = kmalloc(100, GFP_KERNEL);      /* comes from kmalloc-128,
                                            so 28 bytes are wasted */

/* a dedicated cache, when you allocate one type constantly */
static struct kmem_cache *my_cache;

my_cache = kmem_cache_create("my_objects",
                             sizeof(struct my_object),
                             0,                     /* alignment  */
                             SLAB_HWCACHE_ALIGN,    /* flags      */
                             NULL);                 /* constructor */

struct my_object *o = kmem_cache_alloc(my_cache, GFP_KERNEL);
kmem_cache_free(my_cache, o);
kmem_cache_destroy(my_cache);

/* Benefits over kmalloc: exact sizing (no power-of-two waste),
   a named entry in /proc/slabinfo for leak hunting, per-type
   locality, and optional constructors.                       */
```

```
# which caches are consuming memory?
sudo slabtop -s c              # sorted by cache size
cat /proc/slabinfo

# a steadily growing cache with no corresponding workload growth
# is a kernel memory leak, and slabtop names the object type —
# which usually identifies the subsystem immediately.
```

Fragmentation

Kind	Meaning	Mitigation
Internal	Allocated more than requested; the remainder is unusable	Size-class tuning, dedicated slab caches
External	Enough total free memory, but not contiguous	Compaction, migration, avoiding large allocations

```
External fragmentation, made concrete

   memory:  [used][free][used][free][used][free][used][free]
              4KB   4KB   4KB   4KB   4KB   4KB   4KB   4KB

   16 KB free in total. An order-2 (16 KB contiguous) request FAILS.

Linux's defences:

  MIGRATE TYPES     group pages by movability, so unmovable kernel
                    allocations do not scatter through regions that
                    would otherwise be compactable
                      MIGRATE_UNMOVABLE   kernel data, page tables
                      MIGRATE_MOVABLE     user pages, page cache
                      MIGRATE_RECLAIMABLE caches that can be dropped

  COMPACTION        physically MOVE movable pages to create
                    contiguous free runs, updating page tables and
                    reverse mappings as it goes
                      echo 1 > /proc/sys/vm/compact_memory

  CMA               reserve a region at boot that is normally used
                    for movable pages but can be reclaimed on demand
                    for large contiguous DMA buffers — cameras,
                    video codecs, GPUs

  This is why kmalloc of large sizes can fail on a long-running
  system, and why kvmalloc() exists: try kmalloc (contiguous),
  fall back to vmalloc (virtually contiguous only).           */
```

vmalloc versus kmalloc

	`kmalloc`	`vmalloc`
Physically contiguous	**Yes**	No
Virtually contiguous	Yes	Yes
Usable for DMA	**Yes**	**No**
Max practical size	A few MB, and fails under fragmentation	Large — limited by the vmalloc area
Cost	Fast	Slower: page table setup, TLB pressure
Can sleep	Depends on GFP flag	Always — never in atomic context

```
void *p = kvmalloc(size, GFP_KERNEL);   /* try kmalloc, fall back
                                           to vmalloc              */
kvfree(p);
/* Use this whenever the buffer is large and does NOT need to be
   physically contiguous. It is the right default for most
   variable-size kernel allocations.                              */
```

Reclaim and the OOM killer

```
Watermarks per zone drive reclaim:

   free pages
      |
   HIGH  ──────  above this: no reclaim needed
      |
   LOW   ──────  kswapd wakes and reclaims in the BACKGROUND
      |
   MIN   ──────  allocators reclaim SYNCHRONOUSLY (direct reclaim)
      |          - the allocating task now pays the cost, and
      |            latency spikes
      0          allocation fails → OOM killer

What gets reclaimed, cheapest first:
  1. clean page cache          just drop it, it is on disk
  2. clean anonymous pages     only if swap exists
  3. dirty page cache          must write back first
  4. dirty anonymous pages     swap out
  5. slab caches               shrinkers: dentry, inode, fs caches

  echo 3 > /proc/sys/vm/drop_caches     # drop clean caches (testing)
  vm.swappiness                          # anon vs file cache bias
  vm.min_free_kbytes                     # raise for network/RT work
                                         # to avoid direct reclaim
```

```
# when reclaim fails: the OOM killer picks a victim by oom_score
cat /proc/PID/oom_score
echo -1000 > /proc/PID/oom_score_adj    # never kill this process
dmesg | grep -A20 'Out of memory'

# In containers, the cgroup limit triggers a per-cgroup OOM long
# before the machine is out of memory:
cat /sys/fs/cgroup/.../memory.max
cat /sys/fs/cgroup/.../memory.events    # oom_kill counter
```

READING "FREE" CORRECTLY

```
free -h
#               total   used   free   shared  buff/cache  available
# Mem:            16G    4G     1G      200M        11G         11G
#                            ^^^      low, and PERFECTLY NORMAL
#                                                      ^^^
#                                          THIS is what matters

/* "free" memory is wasted memory — Linux uses everything spare for
   page cache, which it can drop instantly. Look at AVAILABLE, which
   accounts for reclaimable cache. Alarm on `free` being low is the
   single most common Linux memory misdiagnosis.                 */
```

The user-space side

```
/* malloc does not call the kernel for every allocation. */

brk / sbrk        grow the heap contiguously. Simple, but memory is
                  only returned to the OS from the TOP — one live
                  allocation at the end pins everything below it.

mmap              anonymous mappings. glibc uses this for requests
                  above MMAP_THRESHOLD (128 KB by default), and
                  returns them to the OS immediately on free.

/* Which explains a common observation: freeing a lot of memory
   sometimes reduces RSS and sometimes does not. Small allocations
   from the brk heap are recycled internally; large mmap'd ones
   go straight back.                                          */

mallopt(M_MMAP_THRESHOLD, 64*1024);
malloc_trim(0);                  /* ask glibc to return free pages */
MALLOC_ARENA_MAX=2 ./program     /* limit per-thread arenas —
                                    often cuts RSS substantially in
                                    highly threaded programs      */
```

Embedded systems

```
/* No MMU means no virtual memory, so physical fragmentation is
   permanent and unrecoverable. This is why (C chapter 14):     */

/* Static allocation — the linker proves it fits at BUILD time */
static struct session sessions[MAX_SESSIONS];

/* Fixed-size pools — O(1), no fragmentation, bounded */
static struct msg pool[64];
static uint64_t  used;

/* TLSF (Two-Level Segregated Fit) — a real-time heap with
   BOUNDED worst-case allocation time, unlike a general malloc */

/* FreeRTOS ships five heap implementations, and choosing between
   them is a real design decision:
     heap_1  allocate only, never free — safest
     heap_2  free supported, no coalescing — fragments
     heap_4  coalescing — the usual choice
     heap_5  heap_4 across multiple memory regions            */
```

How it shows up

Symptom	Cause
Allocation fails with plenty of free memory	Fragmentation, or a zone constraint (DMA32)
`kmalloc` of 1 MB fails after weeks of uptime	External fragmentation; use `kvmalloc`
Latency spikes under memory pressure	Direct reclaim; raise `vm.min_free_kbytes`
Process killed with plenty of RAM shown as cached	cgroup limit, not machine memory
"free" shows almost no free memory	Page cache — read the *available* column
A slab cache grows without bound	Kernel leak; `slabtop` names the object type

Symptom	Cause
RSS does not fall after freeing memory	brk heap cannot return non-top blocks; try `malloc_trim`
Threaded server uses far more RSS than expected	Per-thread malloc arenas; set `MALLOC_ARENA_MAX`
DMA buffer allocation fails on an embedded board	No CMA reservation, or the region is exhausted
Device fails after weeks, works after reboot	Fragmentation in a no-MMU system; use pools

Check yourself

- ✓ Draw the allocator stack and say what problem each layer solves.
- ✓ Explain buddy allocation, including how the buddy address is computed.
- ✓ Explain what `/proc/buddyinfo` tells you about fragmentation.
- ✓ Say why zones exist and give a case where allocation fails despite free memory.
- ✓ Explain the slab idea and two advantages of a dedicated cache over `kmalloc`.
- ✓ Distinguish internal from external fragmentation and name Linux's three defences against the latter.
- ✓ Give three differences between `kmalloc` and `vmalloc`.
- ✓ Explain the watermarks and why direct reclaim causes latency spikes.
- ✓ Explain why low "free" memory on Linux is normal.

Virtual memory, paging and page replacement

CA chapter 16 covered the hardware mechanism. This chapter is the software policy: which pages live in RAM, which are evicted, and how the OS makes a page fault into a feature rather than an error.

Demand paging

THE IDEA

Do not load anything until it is touched. Mark pages invalid, and let the hardware tell you — via a page fault — exactly which page a program actually needs. Programs typically use a small fraction of what they map, so this converts a large up-front cost into a series of small on-demand ones.

```
Executing a 200 MB binary

  WITHOUT demand paging: read 200 MB from disk, then start.
                         Slow to start, and most of it is never used.

  WITH demand paging:    map the file, start immediately.
                         Fault in ~2 MB of actually-executed code.

  This is also why:
    · a huge malloc() returns instantly — nothing is allocated yet
    · a program's RSS is far smaller than its VSZ
    · the first run of a program is slower than the second
      (the second finds the pages in the page cache)
```

The page fault handler

	Minor fault	Major fault
Disk I/O	None	**Yes**
Cost	~1–5 µs	~100 µs (SSD) to ~10 ms (disk)
Causes	First touch, COW, access-flag, page already in cache	Reading from a file or from swap
Acceptable in real time?	Marginal	**Never**

```
# count them
/usr/bin/time -v ./program | grep -i faults
#   Major (requiring I/O) page faults: 12
#   Minor (reclaiming a frame) page faults: 45231

ps -o min_flt,maj_flt,cmd -p PID
perf stat -e page-faults,major-faults ./program
sar -B 1                      # system-wide fault and paging rates
```

How the kernel knows what should be there

```
/* The page tables say what IS mapped. A separate structure says
   what SHOULD be mappable — that is what the fault handler
   consults.                                                    */

struct vm_area_struct {          /* one per contiguous mapping */
        unsigned long vm_start, vm_end;
        unsigned long vm_flags;          /* READ|WRITE|EXEC|SHARED */
        struct file  *vm_file;           /* backing file, or NULL
                                            for anonymous          */
        unsigned long vm_pgoff;          /* offset within the file */
        const struct vm_operations_struct *vm_ops;   /* ->fault()  */
};
/* Kept in a maple tree (formerly a red-black tree) per mm_struct,
   so "which VMA contains this address?" is O(log n).          */

/* Windows: the same idea, called a Virtual Address Descriptor. */
```

```
cat /proc/self/maps
# 5584f2a00000-5584f2a02000 r-xp 00000000 fe:01 1234  /usr/bin/cat
# 5584f2c01000-5584f2c02000 rw-p 00001000 fe:01 1234  /usr/bin/cat
# 5584f4b1e000-5584f4b3f000 rw-p 00000000 00:00 0     [heap]
# 7ffd8a3c0000-7ffd8a3e1000 rw-p 00000000 00:00 0     [stack]
#      ^start        ^end   ^perms ^offset ^dev ^inode ^backing
#                   p = private (COW),  s = shared

cat /proc/self/smaps          # per-VMA: Rss, Pss, Shared/Private,
                              # Dirty/Clean, THP usage, swap
```

Page replacement policy

When memory is full, which page is evicted? The theoretically optimal choice — the page used furthest in the future — requires knowing the future, so every real policy approximates it.

Policy	Rule	Problem
OPT / Belady	Evict the page used furthest in the future	Unimplementable; used only as a benchmark
FIFO	Evict the oldest	Ignores usage. Suffers *Belady's anomaly*: more frames can mean *more* faults.
LRU	Evict the least recently used	Good, but exact LRU needs a timestamp on every access — far too expensive in hardware
Clock / second chance	Circular scan; if the access bit is set, clear it and move on	Cheap LRU approximation. The classic implementation.

Policy	Rule	Problem
Two-list (Linux)	Active and inactive LRU lists; promotion on second reference	Resists scan pollution
LFU / ARC / MGLRU	Track frequency as well as recency	More state; better under mixed workloads

```
Linux's two-list approach, and the problem it solves

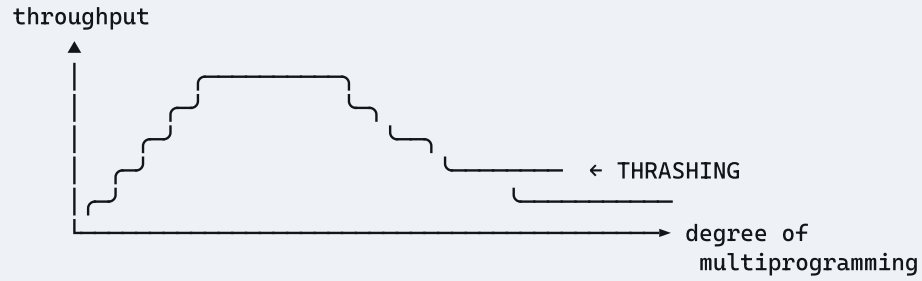
   ACTIVE list      pages referenced more than once — the working set
       ▲   │
       │   │ aging pushes down when the active list grows too large
       │   ▼
   INACTIVE list    candidates for eviction
           │
           ▼ evicted (clean: dropped; dirty: written back first)

  A page enters the INACTIVE list on first touch. It is promoted to
  ACTIVE only on a SECOND reference.

  Why: a large sequential scan — `cat bigfile`, a backup — touches
  millions of pages exactly once. With plain LRU those pages would
  evict your entire working set. With two lists they never reach
  the active list, and the working set survives. This is called
  scan resistance, and it is why `grep -r /` does not destroy your
  machine's performance for the next ten minutes.

  MGLRU (Multi-Gen LRU, Linux 6.1+) generalises this to several
  generations, with much lower overhead at scale.
```

Thrashing and the working set



```
  Beyond a point, adding processes means no process's working set
  fits. Every process faults, the disk saturates, and CPU
  utilisation COLLAPSES while the system appears maximally busy.

  The classic failure signature:
     · load average very high
     · CPU mostly in iowait
     · si/so columns in vmstat non-zero and large
     · everything, including your shell, responds in seconds

  WORKING SET: the set of pages a process has touched in the last
  T units of time. If the sum of all working sets exceeds RAM,
  thrashing is inevitable regardless of policy.

  Responses: reduce concurrency, add memory, use cgroup limits so
  one process cannot drag the system down, or enable PSI-based
  pressure handling.
```

```
# detect it
vmstat 1
#  r  b   swpd   free  buff  cache   si   so    bi    bo  cs us sy id wa
#              ^^^^                  ^^   ^^                          ^^
#   si/so = swap in/out per second. Sustained non-zero = thrashing.
#   wa    = iowait. High wa with low us/sy means waiting on disk.

# PSI — the modern, direct measure of pressure (Linux 4.20+)
cat /proc/pressure/memory
# some avg10=45.23 avg60=30.12 avg300=12.45
#      ^ % of time at least one task was stalled on memory
# This is far more actionable than free/available, and cgroup-aware.
```

Swap

Question	Answer
What is swapped?	Only **anonymous** pages. File-backed pages are simply dropped and re-read from the file.
Is swap bad?	No. Swapping *out* idle pages to make room for cache is good. Swapping *in* continuously is thrashing.
Should I disable it?	Usually not — without swap the kernel cannot evict idle anonymous memory at all, so it evicts *file* pages instead, hurting more. Do disable it for hard real-time and for latency-critical databases with their own caching.
`vm.swappiness`	0–200; the bias toward reclaiming anonymous versus file pages. Default 60. Lower means prefer dropping cache.
zram / zswap	Compressed swap in RAM. Excellent on memory-constrained devices — CPU is cheaper than I/O.

```
swapon --show
cat /proc/PID/status | grep VmSwap        # how much THIS process has swapped
smem -s swap -r                           # per-process swap usage

# real-time and latency-critical work: pin everything resident
mlockall(MCL_CURRENT | MCL_FUTURE);
# ...and check RLIMIT_MEMLOCK allows it. Without this, a single
# major fault can blow a millisecond deadline.
```

Huge pages

```
/* TLB reach (CA chapter 16): 1024 entries x 4 KB = 4 MB.
   With 2 MB pages the same TLB covers 2 GB.                  */

/* Transparent Huge Pages — automatic, no code change */
cat /sys/kernel/mm/transparent_hugepage/enabled
#   [always] madvise never
madvise(p, len, MADV_HUGEPAGE);      /* opt in, per region */

/* Explicit huge pages — reserved, guaranteed, never swapped */
echo 1024 > /proc/sys/vm/nr_hugepages
mmap(NULL, len, PROT_READ|PROT_WRITE,
     MAP_PRIVATE|MAP_ANONYMOUS|MAP_HUGETLB, -1, 0);
```

> **THP IS NOT FREE**
> Allocating a 2 MB huge page requires 2 MB of *contiguous* physical memory. Under fragmentation the kernel may enter synchronous compaction to find it, stalling the faulting process for milliseconds. Databases (MongoDB, Redis, Oracle) routinely recommend `transparent_hugepage=madvise` or `never` for exactly this reason — the latency variance is worse than the TLB benefit. Explicit `hugetlbfs` pages, reserved at boot, avoid the problem entirely.

Controlling paging from user space

```
madvise(p, len, MADV_WILLNEED);   /* prefetch: fault it in now */
madvise(p, len, MADV_DONTNEED);   /* discard: anonymous pages are
                                     freed and re-fault as ZERO   */
madvise(p, len, MADV_SEQUENTIAL); /* aggressive readahead         */
madvise(p, len, MADV_RANDOM);     /* disable readahead            */
madvise(p, len, MADV_FREE);       /* may be reclaimed lazily -
                                     faster than DONTNEED         */
madvise(p, len, MADV_HUGEPAGE);
madvise(p, len, MADV_COLD);       /* deprioritise, do not free    */

posix_fadvise(fd, off, len, POSIX_FADV_DONTNEED);   /* drop from cache */
posix_fadvise(fd, off, len, POSIX_FADV_WILLNEED);

mlock(p, len);                    /* pin: never evicted           */
mlockall(MCL_CURRENT | MCL_FUTURE);
mmap(..., MAP_POPULATE, ...);     /* prefault the whole mapping   */
```

Handling faults in user space

```
/* userfaultfd lets a user process handle its own page faults.
   The mechanism behind live VM migration, distributed shared
   memory, and CRIU checkpoint/restore.                        */

int uffd = syscall(SYS_userfaultfd, O_CLOEXEC);
/* register a region; a helper thread reads fault events from uffd
   and supplies pages with UFFDIO_COPY. The faulting thread blocks
   until the page arrives - post-copy migration in a nutshell. */
```

How it shows up

Symptom	Cause
First run slow, second run fast	Major faults on the first; page cache hits on the second
`malloc` of 10 GB succeeds instantly, crashes later	Lazy allocation plus overcommit; memory arrives on first touch
RSS far below VSZ	Normal — most mapped pages are never touched
System unresponsive, CPU mostly iowait	Thrashing; check `vmstat` si/so and PSI
Millisecond latency spike in a tight loop	Major fault; use `mlockall`
Backup job destroys database performance	Scan pollution — mitigated by two-list LRU, and by `POSIX_FADV_DONTNEED`
Random multi-millisecond stalls on a busy server	THP compaction; set `transparent_hugepage=madvise`
Disabling swap made things worse	The kernel now evicts file cache instead of idle anonymous pages

Symptom	Cause
Memory freed but RSS unchanged	`MADV_FREE` defers reclamation, or the allocator kept it
Real-time task misses a deadline hourly	An unlocked page faulted; `mlockall(MCL_FUTURE)`

Check yourself

- ✓ Explain demand paging and three observable consequences of it.
- ✓ Walk the page fault handler's decision tree and name six distinct fault causes.
- ✓ Distinguish minor from major faults by cost and cause.
- ✓ Explain what a VMA is and why the page tables alone are insufficient.
- ✓ Explain Belady's anomaly and which policy suffers it.
- ✓ Explain Linux's two-list LRU and the specific problem it solves.
- ✓ Describe thrashing, its signature in `vmstat`, and three responses.
- ✓ Explain why disabling swap can make memory pressure worse.
- ✓ Give two reasons THP can hurt latency, and the mitigation.

Memory-mapped files and copy-on-write

Two applications of the same trick: make the page tables lie, and let a fault fix things up on demand. Together they explain why `fork()` is cheap, why shared libraries cost one copy of memory system-wide, and why `mmap` is sometimes far faster than `read` and sometimes much slower.

Mapping a file into memory

```
int fd = open("data.bin", O_RDONLY);
struct stat st;
fstat(fd, &st);

void *p = mmap(NULL,            /* let the kernel choose the address */
               st.st_size,      /* length                            */
               PROT_READ,       /* protection                        */
               MAP_PRIVATE,     /* private (COW) or MAP_SHARED       */
               fd, 0);          /* file and offset (page-aligned)    */
close(fd);                      /* the MAPPING keeps the file alive  */

/* the file's bytes are now simply memory */
uint32_t magic = *(uint32_t *)p;
for (size_t i = 0; i < st.st_size; i++)
        checksum += ((uint8_t *)p)[i];

munmap(p, st.st_size);
```

```
What actually happened:

  mmap() created a VMA and returned. NO data was read.
  Every page is marked invalid in the page tables.

  The first access to each page faults:
     · kernel looks up the VMA → this is file-backed at offset N
     · finds the page in the PAGE CACHE, or reads it from disk
     · installs a PTE pointing at that page-cache page
     · retries the instruction

  Consequences:
     · the mapping is the SAME physical memory as the page cache,
       so no copy is made
     · two processes mapping the same file share those frames
     · a 100 GB file can be mapped on a machine with 8 GB of RAM
     · reading sequentially triggers readahead, exactly as read()
       would
```

The four combinations

	File-backed	Anonymous
MAP_PRIVATE	Copy-on-write view of a file. Writes are private and never reach disk. *Used for: executables, shared libraries.*	Ordinary private memory. *Used for:* `malloc` *of large blocks, thread stacks.*
MAP_SHARED	Writes go to the file and are visible to every other mapper. *Used for: databases, IPC over a file.*	Shared memory between related processes. *Used for:* `fork` *-based IPC (ch. 08).*

```
/* MAP_PRIVATE on a file is where the two ideas meet: */
void *p = mmap(NULL, len, PROT_READ | PROT_WRITE, MAP_PRIVATE, fd, 0);
p[0] = 'X';
/* The page was shared read-only with the page cache. Writing it
   triggers a COW fault: the kernel allocates a fresh frame, copies
   the contents, and remaps THIS process's PTE to the copy.
   The file on disk is untouched. Other mappers see the original. */
```

Copy-on-write

```
   BEFORE fork()
   parent PTEs ──────►  [ page A ]  [ page B ]  [ page C ]
                          rw           rw          rw

   AFTER fork() — no data copied, only page TABLES
   parent PTEs ──┐
                 ├────►  [ page A ]  [ page B ]  [ page C ]
   child  PTEs ──┘         RO,cow      RO,cow     RO,cow
                           refcount 2  refcount 2 refcount 2

   Both mappings are marked READ-ONLY, with a flag saying "this is
   COW, not genuinely read-only".

   CHILD WRITES page B
        │ write to a read-only page → PAGE FAULT
        ▼
   kernel: the VMA says writable, and the PTE says COW
        · allocate a new frame
        · copy page B into it
        · point the CHILD's PTE at the copy, mark it rw
        · decrement the original's refcount to 1
        · since only the parent now maps it, restore ITS PTE to rw
        · retry the instruction

   parent PTEs ──────►  [ page A ]  [ page B  ]  [ page C ]
                          RO,cow       rw          RO,cow
   child  PTEs ──────►  [ page A ]  [ page B' ]  [ page C ]
                          RO,cow       rw          RO,cow

  Only the pages actually written are ever duplicated. A process
  that forks and immediately execs copies almost nothing.
```

Where else COW appears

Use	How
`fork()`	The canonical case
Shared libraries	Text is shared read-only; the data segment is COW, so each process gets private globals from one on-disk copy
The zero page	All freshly allocated anonymous pages map one shared zero page read-only until written
KSM	Kernel Samepage Merging: identical pages across VMs are merged and made COW
Filesystem snapshots	btrfs, ZFS, LVM — the same idea at block granularity
Container images	overlayfs: the lower layer is shared, writes go to an upper layer

THE FORK MEMORY-ACCOUNTING CONFUSION

After `fork()`, `ps` shows both processes with the same RSS — but they share almost all of it, so the machine's real usage barely changed. RSS double-counts shared pages. Use **PSS** (Proportional Set Size), which divides each shared page's size by the number of sharers:

```
grep -H '^Pss:' /proc/*/smaps_rollup | sort -k2 -n -r | head
smem -k -s pss                    # per-process, sorted by PSS
/* PSS is the only per-process number that sums to something
   meaningful across all processes.                          */
```

Why COW is security-sensitive

```
/* Dirty COW (CVE-2016-5195) — a race between the COW fault handler
   and madvise(MADV_DONTNEED), exploitable to write to a read-only
   file mapping, giving local root on essentially every Linux
   system for nine years.

   The lesson is general: COW is a place where the page tables
   deliberately disagree with the VMA's stated permissions, and
   the window between fault and fixup is a race that must be
   handled with great care. Several later CVEs (Dirty Pipe,
   CVE-2022-0847) follow the same shape.                     */
```

mmap versus read/write

	`mmap`	`read` / `write`
Copies	Zero — you touch page-cache pages directly	One copy, cache → your buffer
Syscalls	One, then page faults	One per call
Random access	**Excellent** — just a pointer	Needs `lseek` + `read` per access
Sequential streaming	Often *slower* — fault per page	**Better** — large reads amortise everything
Small files	Setup and teardown dominate	Better
Error handling	`SIGBUS` on I/O error — hard to handle	`-EIO` return value
File growth	Must re-map; risk of `SIGBUS` past EOF	Just works
Memory pressure	Counts against the process; can be reclaimed under you	Bounded by your buffer

THE HONEST SUMMARY

`mmap` is a win for **random access to large files** and for **sharing**. It is frequently a loss for sequential streaming, because a page fault every 4 KB costs more than one `read()` of 1 MB. Linus Torvalds has made this point repeatedly, and benchmarks bear it out. Use `mmap` when you would otherwise be seeking; use `read` with a large buffer when you are streaming.

```
/* If you do use mmap, tell the kernel your access pattern */
madvise(p, len, MADV_SEQUENTIAL);   /* aggressive readahead, drop behind */
madvise(p, len, MADV_RANDOM);       /* disable readahead                 */
madvise(p, len, MADV_WILLNEED);     /* prefault now                      */
mmap(..., MAP_POPULATE, ...);       /* prefault the whole mapping        */

/* Handling SIGBUS is genuinely awkward: it fires on a truncated
   file or an I/O error, from anywhere the mapping is touched. In
   robust code, either avoid mmap for untrusted files, or install
   a handler and use siglongjmp - which is its own problem.    */
```

Zero-copy I/O

```
/* The general goal: avoid copying data through user space at all. */

/* sendfile: file → socket, entirely in the kernel */
sendfile(out_fd, in_fd, &offset, count);
/* saves two copies and two context switches versus read+write.
   This is how static web servers serve files.                */

/* splice: move data between fds via a pipe, without copying */
splice(fd_in, NULL, pipefd[1], NULL, len, SPLICE_F_MOVE);
splice(pipefd[0], NULL, fd_out, NULL, len, SPLICE_F_MOVE);

/* vmsplice: map user pages into a pipe */
/* copy_file_range: server-side copy, may be offloaded to the
   filesystem or even the storage device (reflink on btrfs/XFS) */
copy_file_range(fd_in, &off_in, fd_out, &off_out, len, 0);

/* io_uring: registered buffers plus fixed files remove even the
   per-operation syscall (OS chapter 08).                      */
```

Direct access and persistent memory

```
/* DAX: for byte-addressable persistent memory, the page cache is
   pointless - map the device's pages directly.                */
mount -o dax /dev/pmem0 /mnt

/* A store instruction now writes persistent storage. Which raises
   a genuinely new problem: ordering and durability at CPU cache
   granularity. You need explicit flushes:                     */
    dc cvap, x0        /* clean to point of persistence (ARM)   */
    clwb               /* cache line write back (x86)           */
    sfence
/* Getting this wrong gives torn, non-atomic updates that survive
   a power cut - a corruption class that did not exist before. */
```

Observing mappings

```
cat /proc/PID/maps               # all VMAs
cat /proc/PID/smaps              # per-VMA detail:
#   Rss, Pss, Shared_Clean/Dirty, Private_Clean/Dirty,
#   Referenced, Anonymous, Swap, THPeligible
cat /proc/PID/smaps_rollup       # totals — much cheaper to parse

pmap -x PID                      # readable summary
pmap -XX PID                     # everything

# is this page shared, and with whom?
sudo ./page-types -p PID         # from linux/tools/vm

# how much of the page cache does a file occupy?
vmtouch -v /path/to/file
fincore /path/to/file

# force a file out of the cache, for cold benchmarking
dd of=/path/to/file oflag=nocache conv=notrunc,fdatasync count=0
```

How it shows up

Symptom	Cause
RSS appears to double after `fork`	Shared COW pages counted twice; read PSS
`mmap` slower than `read` for streaming	One fault per page versus one large read
`SIGBUS` touching a mapping	File truncated under you, or an I/O error
Writes to a `MAP_PRIVATE` file mapping vanish	Correct — private mappings never write back
Two processes mapping the same file do not see each other's writes	Used `MAP_PRIVATE`; need `MAP_SHARED`
Memory usage grows when reading a large file	Page cache; reclaimable, not a leak
First write after `fork` is slow	COW fault plus a page copy
Shared library uses one copy of text, many of data	Text shared, data segment is COW — as designed
Data corrupted after power loss on pmem	Missing cache flush to the point of persistence
Container image uses less disk than the sum of layers	overlayfs COW at file granularity

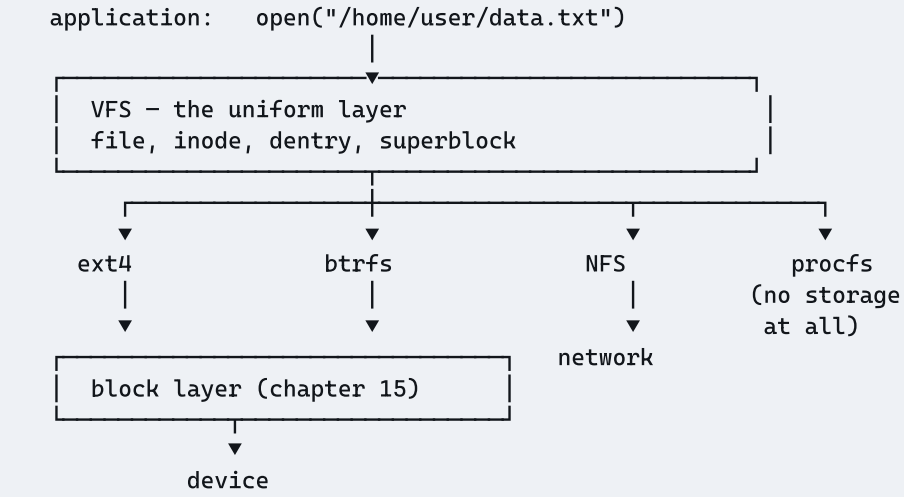
Check yourself

- ✓ Explain what `mmap` does at call time versus at first touch.
- ✓ Give the four private/shared × file/anonymous combinations and a use for each.
- ✓ Walk through a COW fault step by step, including what happens to the last sharer.
- ✓ Explain why RSS is misleading after `fork` and what to use instead.
- ✓ Name four mechanisms besides `fork` that use copy-on-write.
- ✓ Say when `mmap` beats `read` and when it does not.
- ✓ Explain why `SIGBUS` makes `mmap` error handling hard.
- ✓ Name three zero-copy mechanisms and what each avoids copying.

File systems

A filesystem turns a flat array of blocks into named, persistent, hierarchical objects — and must survive power loss halfway through any operation. That durability requirement is what makes filesystem design hard, and what every design below is really answering.

What a filesystem provides



```
The VFS is why `cat` works on a disk file, a network mount, a pipe
and /proc/cpuinfo without knowing the difference.
```

The four VFS objects

Object	Represents	Lifetime
`struct super_block`	A mounted filesystem	From mount to unmount
`struct inode`	A file's *metadata*: size, permissions, timestamps, block pointers. **Not the name.**	Cached; one per file
`struct dentry`	One path component and its inode — the name-to-inode binding	Cached aggressively (the dcache)
`struct file`	An *open* file: the current offset, mode, and the `f_op` table	Per `open()`

NAMES LIVE IN DIRECTORIES, NOT IN FILES

An inode has no name. A **directory** is a file whose contents map names to inode numbers. This single design decision explains hard links (several names, one inode), why `rename()` within a filesystem is instantaneous (it edits directory entries only), why deleting a file with an open descriptor does not free the space (the inode's link count reached zero but its *open* count did not), and why you cannot hard-link across filesystems (inode numbers are only meaningful within one).

```
ls -li                  # the leading number is the INODE number
stat file.txt           # inode, links, size, blocks, timestamps
                        # note: Links: 2 means two names for this inode

ln  file.txt hard       # another NAME for the same inode
ln -s file.txt soft     # a small file whose CONTENTS are a path

df -i                   # inode usage — a filesystem can run out of
                        # inodes while blocks remain free, which is a
                        # confusing "No space left on device" with
                        # df showing plenty of space

# a deleted-but-open file still consumes space:
lsof +L1                # files with link count 0 that are still open
ls -l /proc/PID/fd/     # shows "(deleted)"
```

On-disk layout

```
A classic UNIX-style filesystem (ext4 simplified)

  +-----------+-------------+-------------+---------------------+
  | superblock| inode bitmap| inode table |     data blocks     |
  |           | block bitmap|             |                     |
  +-----------+-------------+-------------+---------------------+

  superblock   size, block size, free counts, mount state, UUID.
               Replicated, because losing it loses everything.
  bitmaps      which inodes and blocks are free
  inode table  fixed-size records, indexed by inode number
  data blocks  file contents and directory contents

  ext4 divides all of this into BLOCK GROUPS so metadata sits near
  the data it describes, reducing seeks on rotational media.

How an inode finds its data:

  small file    12 direct block pointers            → up to 48 KB
  larger        1 single-indirect (a block of ptrs) → +4 MB
                1 double-indirect                    → +4 GB
                1 triple-indirect                    → +4 TB

  ext4 replaces most of this with EXTENTS: (start, length) pairs.
  One extent can describe 128 MB, so a large contiguous file needs
  a handful of records instead of millions of pointers.
```

Crash consistency: the real problem

```
Appending a block to a file requires THREE updates:

   1. mark the block used in the block bitmap
   2. add the block pointer to the inode
   3. update the inode's size

Power fails between any two:

   after 1 only  → a block is leaked. Wasteful, not dangerous.
   after 2 only  → the inode points at a block marked FREE.
                   It will be handed to another file. Two files now
                   share a block: SILENT CORRUPTION.
   after 3 only  → size claims data that was never written; the
                   file contains whatever was previously in that
                   block — possibly another user's data. A
                   security bug, not just a correctness one.

There is no ordering of three independent writes that is safe,
because the disk may reorder them and may not complete any of them.
Every solution below adds a mechanism to make a MULTI-BLOCK update
appear ATOMIC.
```

Approach	Mechanism	Cost	Used by
fsck	Repair inconsistencies after the fact by scanning everything	Hours on a large filesystem; may lose data	ext2, FAT
Journalling	Write intent to a log first; replay it after a crash	Metadata written twice	ext3/4, XFS, NTFS
Copy-on-write	Never overwrite; write new blocks and atomically switch the root pointer	Fragmentation; more space	btrfs, ZFS, APFS
Log-structured	The whole filesystem is an append-only log	Needs garbage collection	F2FS, NILFS, and every SSD's FTL internally
Soft updates	Carefully order writes so any prefix is consistent	Extremely intricate to implement	FFS on BSD

```
/* Journalling modes in ext4 — the trade-off made explicit */

data=journal      /* both data AND metadata to the journal first.
                     Safest, and roughly halves write throughput.  */
data=ordered      /* DEFAULT. Metadata journalled; data blocks are
                     forced to disk BEFORE the metadata that refers
                     to them commits. Prevents the "size claims
                     unwritten data" case above.                   */
data=writeback    /* metadata journalled, data unordered. Fastest;
                     after a crash a file can contain stale blocks
                     — including another file's old contents.      */

mount -o data=ordered,barrier=1 /dev/sda1 /mnt
/* barrier=1 (the default) issues cache flushes so the DEVICE does
   not reorder the journal commit ahead of the data. Turning it off
   is fast and unsafe, and is a very common cause of "journalling
   did not protect me".                                          */
```

fsync and what "written" means

```
write(fd, buf, n);      /* returns as soon as the data is in the
                           PAGE CACHE. Nothing has reached disk. */

fsync(fd);              /* force this file's data AND metadata out,
                           and flush the device's write cache      */
fdatasync(fd);          /* data plus only the metadata needed to
                           read it back — skips timestamp updates,
                           so it is measurably faster              */
sync();                 /* everything, everywhere. Returns before
                           completion on some systems.             */

/* The durable-rename idiom — the standard way to update a file
   atomically. Every step matters.                              */
fd = open("file.tmp", O_WRONLY | O_CREAT | O_TRUNC, 0644);
write(fd, data, len);
fsync(fd);                          /* 1. contents are durable    */
close(fd);
rename("file.tmp", "file");         /* 2. atomic swap of the name */
dirfd = open(".", O_RDONLY);
fsync(dirfd);                       /* 3. the RENAME is durable   */
close(dirfd);

/* Skipping step 3 is the classic bug: the rename is a directory
   metadata change, and until the directory is synced a crash can
   leave you with neither the old file nor the new one.        */
```

EVERY LAYER HAS A CACHE THAT CAN LIE

Application buffer → libc `stdio` buffer → kernel page cache → device write cache → platters or flash. `fflush()` only empties the second. `fsync()` pushes through the third and asks the fourth to flush — but consumer drives have been known to acknowledge a flush without performing one, and a virtualisation layer or a RAID controller with a non-battery-backed cache can do the same. If durability genuinely matters, test it: write, cut power, verify.

Filesystems worth knowing

Filesystem	Design	Use it for
ext4	Journalled, extents, block groups	The safe Linux default
XFS	Journalled, B+trees, allocation groups, excellent parallelism	Large files, many threads, big storage
btrfs	COW, snapshots, checksums, integrated RAID, compression	Snapshots and data integrity
ZFS	COW, checksums everywhere, pooled storage, self-healing	Data you cannot lose; licence keeps it out of the kernel
F2FS	Log-structured, flash-aware	Phones, embedded eMMC/SD
UBIFS / JFFS2	Operate on *raw NAND*, doing their own wear levelling	Embedded devices with bare flash and no FTL
SquashFS	Read-only, compressed	Firmware images, live systems, container layers
tmpfs	Page cache with no backing store	`/tmp`, `/run`, `/dev/shm`
overlayfs	Union: read-only lower + writable upper, COW per file	Containers, live images

Filesystem	Design	Use it for
FAT / exFAT	No journal, no permissions, universally supported	Interchange only — never for anything that matters
procfs / sysfs / debugfs	No storage; files are generated on read	Kernel interfaces (ch. 16)

Flash storage changes the rules

```
NAND flash cannot overwrite. It can only:
   · READ a page          (4–16 KB)
   · PROGRAM a page       (once, after erase)
   · ERASE a BLOCK        (128 KB – 4 MB) — and blocks wear out
                            after ~1,000–100,000 erase cycles

So a "write 4 KB at offset X" becomes:
   read the whole block → erase it → reprogram it with the change
   = WRITE AMPLIFICATION, and it consumes erase cycles.

TWO PLACES this is solved:

  MANAGED FLASH (SSD, eMMC, SD, UFS)
      an on-device Flash Translation Layer does log-structured
      writes, wear levelling, garbage collection and bad-block
      management, and presents a normal block device.
      → use ext4, XFS, F2FS. Issue TRIM/discard so the FTL knows
        which blocks are free:  mount -o discard, or fstrim weekly.

  RAW NAND (embedded, no FTL)
      the FILESYSTEM must do all of that itself.
      → UBI + UBIFS, or JFFS2. Using ext4 on raw NAND will destroy
        the flash and lose data.

Either way: the number of WRITES matters more than their size, and
excessive logging or a chatty database can wear out an embedded
device's flash in months.
```

Performance

```
# the dentry cache is why repeated path lookups are free
cat /proc/sys/fs/dentry-state
slabtop | grep -E 'dentry|inode'

# and why a `find /` inflates memory — it populates the dcache
echo 2 > /proc/sys/vm/drop_caches    # drop dentries and inodes

# readahead
blockdev --getra /dev/sda
posix_fadvise(fd, 0, 0, POSIX_FADV_SEQUENTIAL);

# many small files are dominated by metadata, not data
#   1 file  of 1 GB   : ~1 open, sequential reads
#   1M files of 1 KB  : ~1M opens, 1M inode reads, 1M dentry lookups
# This is why extracting a source tarball is slower than copying a
# disk image of the same size, and why build systems are IOPS-bound.

# measure
iostat -x 1
fio --name=test --rw=randread --bs=4k --numjobs=4 --size=1G
strace -c -e trace=openat,read,write,fsync ./program
```

How it shows up

Symptom	Cause
"No space left" but `df` shows free space	Inodes exhausted — check `df -i`
Deleting files does not free space	A process still holds the file open; `lsof +L1`
Data lost after power cut despite journalling	Device write cache not flushed, or barriers disabled
File exists but is full of zeros after a crash	`data=writeback`, or missing `fsync` before rename
Config file lost entirely after a crash	Renamed without syncing the directory
Extracting many small files is far slower than one big one	Metadata operations dominate; IOPS-bound
Embedded device's flash fails after months	Write amplification and no wear levelling; wrong filesystem for raw NAND
SSD slows down over time	TRIM not issued; the FTL cannot garbage collect
Hard link across filesystems fails	Inode numbers are per-filesystem
Memory usage grows during a large `find`	Dentry and inode cache — reclaimable

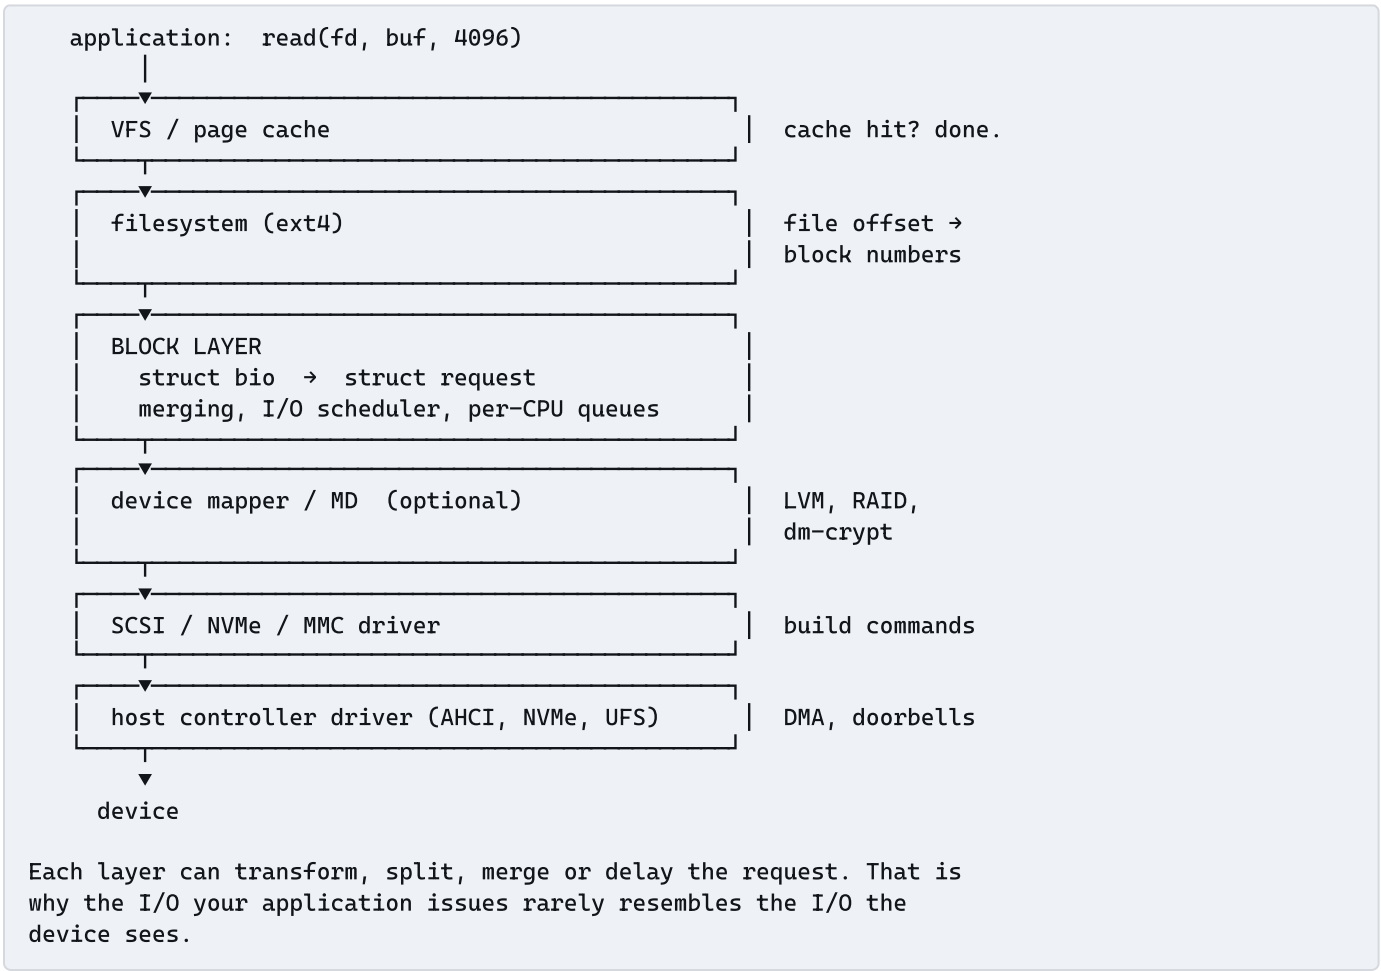
Check yourself

- ✓ Name the four VFS objects and what each represents.
- ✓ Explain why names live in directories and give three consequences.
- ✓ Describe the three-write append problem and why no ordering is safe.
- ✓ Compare journalling and copy-on-write as crash-consistency strategies.
- ✓ Explain the three ext4 journalling modes and their trade-offs.
- ✓ Write the durable-rename idiom and say what each step protects.
- ✓ Explain write amplification and the two places it can be handled.
- ✓ Say why ext4 on raw NAND is a mistake, and what to use instead.

The block layer and the storage stack

Between a filesystem's "read block 12345" and a device actually moving data sits a stack whose job is to merge, reorder, queue and account for requests. Understanding it explains most storage performance behaviour, and all storage latency surprises.

The stack



Each layer can transform, split, merge or delay the request. That is why the I/O your application issues rarely resembles the I/O the device sees.

bio and request

```
/* A `bio` is the unit of I/O submitted to the block layer: a
   target device, a starting sector, and a scatter-gather list of
   memory pages.                                                 */

struct bio {
        struct block_device *bi_bdev;
        blk_opf_t            bi_opf;      /* READ, WRITE, FLUSH,
                                             DISCARD, ZONE_APPEND */
        struct bvec_iter     bi_iter;     /* sector, size, index  */
        struct bio_vec      *bi_io_vec;   /* page, offset, len[]  */
        bio_end_io_t        *bi_end_io;   /* completion callback  */
};

/* Note the scatter-gather list: the pages need not be contiguous
   in physical memory. The device's DMA engine walks the list.
   This is why the DMA API and the SMMU matter here — see the
   security track.                                              */

/* A `request` is one or more merged bios, ready for a driver. */
```

Merging and scheduling

```
The block layer's two big optimisations:

  MERGING — adjacent requests become one
     read sectors 100-107    ┐
     read sectors 108-115    ├─► one request, sectors 100-131
     read sectors 116-123    │
     read sectors 124-131    ┘
     · front merge, back merge, or a completely new request
     · limited by max_sectors_kb and max_segments

  SORTING / SCHEDULING — reorder to suit the device
     on a rotational disk, seeking is 5-10 ms and sequential
     access is ~1000x faster, so ordering by sector is decisive.
     On an SSD, "seeking" is free and the scheduler mostly gets
     out of the way.

  This is why `iostat` often shows fewer, larger requests reaching
  the device than the application issued — and why an application
  doing 4 KB sequential writes can still achieve full bandwidth.
```

Scheduler	Idea	Use for
`none`	No reordering; straight to the device	**NVMe** — the device has thousands of queue entries and reorders better than you can
`mq-deadline`	Two sorted queues plus expiry deadlines, so nothing starves	SATA SSDs, mixed workloads, latency-sensitive work
`bfq`	Budget Fair Queueing — proportional share per process, strong interactivity	Desktops, rotational disks, containers needing fairness
`kyber`	Latency-target based; throttles to hit a goal	Fast devices with a latency SLO

```
cat /sys/block/nvme0n1/queue/scheduler
#   [none] mq-deadline kyber bfq
echo mq-deadline > /sys/block/sda/queue/scheduler

# the queue tunables that actually matter
/sys/block/X/queue/
    nr_requests          queue depth at the block layer
    read_ahead_kb        sequential prefetch (128 default)
    max_sectors_kb       largest single request
    rotational           1 = disk, 0 = SSD; affects scheduler defaults
    add_random           entropy contribution — turn off on SSDs
    nomerges             disable merging (debugging only)
    write_cache          "write back" or "write through"
```

blk-mq: why the old design broke

```
SINGLE-QUEUE (pre-2013)
   all CPUs ──► one request queue, one spinlock ──► device
   Fine at 200 IOPS. At 1,000,000 IOPS the lock IS the bottleneck,
   and every submission bounces a cache line between sockets.

MULTI-QUEUE (blk-mq)
   CPU0 ─► software queue 0 ┐
   CPU1 ─► software queue 1 ├─► hardware queue 0 ─► device
   CPU2 ─► software queue 2 ├─► hardware queue 1 ─► (NVMe has up
   CPU3 ─► software queue 3 ┘                        to 64K queues)

   · per-CPU submission: no shared lock on the fast path
   · completion interrupts are steered back to the submitting CPU,
     so the completion finds the data cache-warm
   · maps naturally onto NVMe, which was designed with the same model

  This is the same insight as per-CPU runqueues in the scheduler
  (OS chapter 06): at scale, the shared structure is the problem.
```

Device characteristics

	HDD	SATA SSD	NVMe SSD	Optane / PMEM
Random read latency	5–10 ms	~100 µs	~20–80 µs	<1 µs
Random IOPS	~100	~50–100 k	~500 k–1 M+	Millions
Sequential	100–250 MB/s	~550 MB/s	2–14 GB/s	Very high
Seek penalty	**Enormous**	None	None	None
Queue depth benefit	Small	Large	**Essential**	—
Bottleneck	Mechanics	Controller, SATA link	Sometimes the *software* stack	Software, entirely

> **THE INVERSION**
>
> On a hard disk, software overhead was irrelevant — a 10 µs kernel path next to a 10 ms seek. On NVMe the device responds in 20 µs and the kernel path can be a comparable fraction of that. This is why `io_uring`, polled I/O and SPDK exist: at these speeds the operating system itself is the thing to optimise away.

```
# polled I/O: spin instead of taking a completion interrupt.
# Burns CPU, removes interrupt and context-switch latency.
echo 1 > /sys/block/nvme0n1/queue/io_poll
# with io_uring: IORING_SETUP_IOPOLL
```

Queue depth and Little's Law

```
   throughput = queue_depth / latency          (Little's Law)

   NVMe device: 80 µs latency per operation

     QD = 1    →  1 / 80µs   =    12,500 IOPS
     QD = 32   →  32 / 80µs  =   400,000 IOPS
     QD = 128  →  128 / 80µs = 1,600,000 IOPS (until saturation)

  A single-threaded, synchronous application can NEVER exceed
  QD=1 performance, no matter how fast the device is. This is the
  single most common storage benchmarking mistake — measuring a
  million-IOPS drive with `dd` and concluding it does 12,500.

  To get depth you need: async I/O (io_uring, libaio), multiple
  threads, or readahead doing it for you.

  But depth costs LATENCY: at QD=128 each request waits behind 127
  others. Throughput and latency trade off exactly as in CA
  chapter 18.
```

```
# measure properly, with depth and parallelism
fio --name=randread --ioengine=io_uring --direct=1 \
    --rw=randread --bs=4k --iodepth=32 --numjobs=4 \
    --size=4G --runtime=60 --group_reporting

# --direct=1 bypasses the page cache. Without it you are
# benchmarking RAM, which is the second most common mistake.
```

Direct I/O

```
int fd = open("file", O_RDWR | O_DIRECT);
/* Bypasses the page cache entirely. Requires that the buffer,
   the file offset and the length are all aligned to the device's
   logical block size — usually 512 or 4096 bytes.            */

void *buf;
posix_memalign(&buf, 4096, size);      /* aligned allocation */
pread(fd, buf, 4096, offset);          /* all three aligned  */

/* Use O_DIRECT when:
     · the application has its own cache (databases)
     · the data will not be re-read, and caching it would evict
       something useful
     · you are benchmarking the device

   Do NOT use it as a general speed-up. It removes readahead and
   write coalescing, so naive sequential access gets SLOWER.  */
```

Device mapper and RAID

Target	Does
`dm-linear`	Maps a range to another device — the building block of LVM
`dm-crypt`	Transparent encryption (LUKS)
`dm-thin`	Thin provisioning and snapshots
`dm-cache`, `bcache`	Use an SSD as a cache in front of a disk
`dm-verity`	Cryptographically verified read-only device — Android Verified Boot and confidential container images depend on it
`md`	Software RAID 0/1/5/6/10

```
lsblk                          # the full stack, visually
dmsetup table                  # device mapper targets in use
cat /proc/mdstat               # RAID status and rebuild progress

/* RAID 5's write hole: a partial stripe update that is
   interrupted by power loss leaves data and parity inconsistent,
   and the inconsistency is invisible until a later rebuild
   reconstructs wrong data. Journals, battery-backed cache or a
   COW filesystem (btrfs/ZFS RAID) address it.              */
```

I/O control and isolation

```
# cgroup v2 io controller — limit or weight a container's I/O
echo "259:0 rbps=10485760 wbps=5242880 riops=1000 wiops=500" \
     > /sys/fs/cgroup/mygroup/io.max
echo "default 100" > /sys/fs/cgroup/mygroup/io.weight

# io.latency: guarantee a latency target for a priority group,
# throttling others when it is exceeded
echo "259:0 target=10000" > /sys/fs/cgroup/critical/io.latency

# per-process I/O priority (works with BFQ / CFQ-style schedulers)
ionice -c 3 -p PID             # idle class
ionice -c 2 -n 7 ./backup      # best-effort, lowest priority
```

Observing

```
iostat -xz 1
#  Device  r/s   w/s  rkB/s  wkB/s  rareq-sz  aqu-sz  r_await w_await %util
#                                             ^depth  ^latency        ^busy
#  %util is MISLEADING on SSDs: a device that can serve 32 requests
#  in parallel shows 100% "utilisation" while nearly idle. Use
#  aqu-sz and await instead.

iotop -o                        # which processes are doing I/O
pidstat -d 1

# per-request tracing
blktrace -d /dev/sda -o - | blkparse -i -
btt -i trace.bin                # latency breakdown by stage:
                                # Q2G queue→get, G2I insert,
                                # I2D issue→device, D2C device→complete
                                # This tells you WHICH LAYER is slow.

# eBPF one-liners
biolatency-bpfcc                # latency histogram
biosnoop-bpfcc                  # every I/O with process and latency
biotop-bpfcc

# where is the time going overall?
cat /proc/pressure/io           # PSI — stall percentage
```

DIAGNOSING "THE DISK IS SLOW"

Work down the stack. `iostat` `await` high but `aqu-sz` low means the *device* is slow. `aqu-sz` high means you are queueing — the device is saturated, or the scheduler is holding requests. If application latency is high but `await` is low, the problem is above the block layer: filesystem metadata, `fsync`, or the page cache. `btt` resolves this precisely by breaking one request's life into stages.

How it shows up

Symptom	Cause
NVMe benchmarks at a fraction of its rating	Queue depth 1 — synchronous single-threaded I/O
Benchmark shows impossible throughput	Hitting the page cache; use `--direct=1`
`%util` is 100% but the device is fine	`%util` is meaningless for parallel devices
`O_DIRECT` made things slower	Lost readahead and write coalescing
`O_DIRECT` returns `EINVAL`	Buffer, offset or length not block-aligned
Write latency spikes every few seconds	Writeback flushing dirty pages; tune `vm.dirty_*`
Backup job destroys interactive latency	No I/O isolation; use `ionice`, BFQ or cgroup `io.latency`
SSD gets slower over months	No TRIM; the FTL cannot garbage collect
RAID 5 array corrupt after power loss	The write hole
Random reads far slower than sequential on a disk	Seek time — the fundamental HDD characteristic

Check yourself

- ✓ Name the layers between `read()` and the device, and what each may change.
- ✓ Explain what a `bio` contains and why it is a scatter-gather list.
- ✓ Explain merging and why it matters more on rotational media.
- ✓ Say which I/O scheduler suits NVMe and why.
- ✓ Explain why blk-mq replaced the single request queue.
- ✓ Use Little's Law to explain why a synchronous program cannot saturate an NVMe drive.
- ✓ Give two legitimate uses of `O_DIRECT` and one common misuse.
- ✓ Explain why `%util` is misleading on SSDs and what to read instead.

The I/O subsystem and device drivers

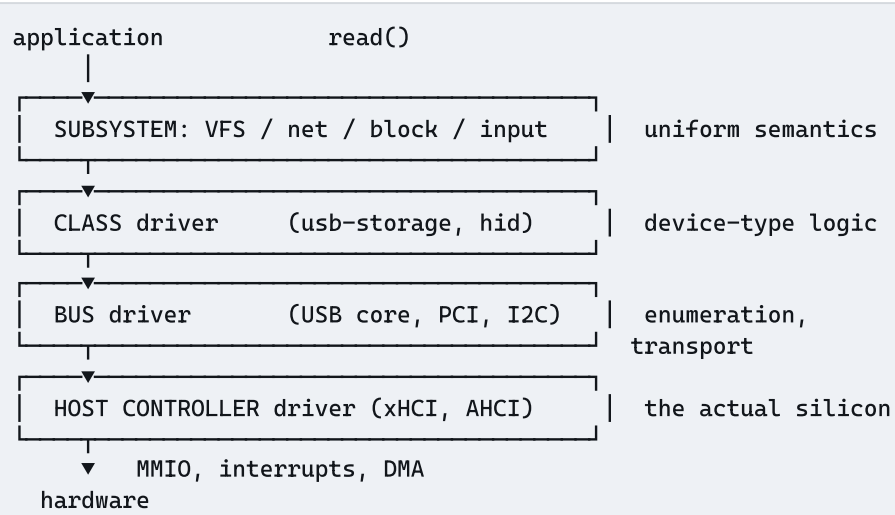
A driver is the adapter between one piece of hardware and one kernel subsystem. This chapter covers the concepts every driver model shares — device classes, the discovery and binding lifecycle, I/O models, and the layering that lets one `read()` reach a hundred different kinds of device.

What a driver actually does

TWO INTERFACES, ONE TRANSLATOR

Upward, a driver implements a **subsystem interface** — the operations a network stack, a block layer or a VFS expects. Downward, it speaks the **device's register protocol**. Everything else in a driver is lifecycle and error handling.

This is why "write a driver" is not one skill: you must know the subsystem's contract as well as the hardware's. Reading an existing driver for the same subsystem is nearly always the fastest route.



```
A USB flash drive traverses every layer: VFS → block → SCSI →
usb-storage → USB core → xHCI → the controller's registers.
Each layer is reusable, which is why adding one new USB device
usually requires no new code at all.
```

The three device classes

	Character	Block	Network
Access	Byte stream, usually sequential	Fixed-size blocks, random access	Packets
Buffered by the kernel	Usually not	Page cache	Socket buffers
Appears as	`/dev/ttyS0`	`/dev/sda`	**No `/dev` node** — `eth0`
Interface	`file_operations`	`block_device_operations` + request queue	`net_device_ops`

	Character	Block	Network
Examples	Serial, input, GPIO, sensors, your custom device	Disks, SD, NVMe	Ethernet, Wi-Fi, modems

Network devices are the odd one out: they are not files, because a packet interface does not fit `read`/`write` semantics well and because routing decisions happen above the device. Sockets are the file-like abstraction instead.

Discovery and binding

```
Two worlds, and the difference drives everything:

  DISCOVERABLE BUSES — hardware can be interrogated
      PCI:  read configuration space → vendor ID, device ID, class,
            BAR sizes and types
      USB:  request descriptors from the device
      → the bus driver enumerates, and the core matches a driver
        by ID. Hotplug works naturally.

  NON-DISCOVERABLE — you cannot ask
      on-SoC peripherals, I2C and SPI slaves.
      There is no safe way to probe address 0x40001000; a wrong
      guess can hang the bus or trigger a side effect.
      → hardware must be DESCRIBED out of band:
            device tree (embedded, ARM)
            ACPI tables (servers, x86, Windows on ARM)

This is exactly why the device tree exists, and why an embedded
Linux driver looks structurally different from a PCIe driver.
```

```
   HARDWARE SIDE                    DRIVER SIDE
   device tree node                 module loads
   or PCI enumeration               registers a driver with
        │                           its match table
        ▼                                 │
   struct device created                  ▼
   added to the bus                 struct device_driver added
        └──────────────┬──────────────────┘
                       ▼
             bus->match(dev, drv)
             compare compatible strings / vendor+device IDs
                       │
                       ▼ match
             driver->probe(dev)
             ── get resources: registers, IRQ, clocks, regulators
             ── map MMIO
             ── initialise the hardware
             ── register with the SUBSYSTEM
                       │
                       ▼
                  in service
                       │
             driver->remove(dev)   on unbind, unload, or hot-unplug
             ── quiesce hardware FIRST, then release, in reverse
```

PROBE ORDERING IS NOT GUARANTEED

Your driver may probe before the clock controller or regulator it depends on exists. Every modern driver model has an answer: Linux returns `-EPROBE_DEFER` and the core retries later; Windows' PnP manager starts devices as their dependencies become available. Never assume initialisation order, and never work around it with `late_initcall` — that is a race, not a fix.

The four resources every driver needs

Resource	Why	Failure if missing
Registers (MMIO)	To control the device	Fault, or reads of garbage
Interrupt	To learn about completions	Hangs waiting forever, or polls wastefully
Clocks	An unclocked block does not respond	Registers read as 0 or abort
Power / regulators	Same	Same

```
/* The order matters: enable clocks and power BEFORE touching any
   register. This is the single most common bring-up bug, and it
   presents identically to a wrong base address.                */

regulator_enable(vdd);
clk_prepare_enable(clk);
reset_control_deassert(rst);
/* ... only now is it safe to read the ID register ... */
id = readl(base + REG_ID);
```

The three I/O models

	Polling	Interrupt	DMA
CPU cost	100% while waiting	Per event	Near zero
Latency	Lowest, most deterministic	Interrupt entry overhead	Setup cost, amortised
Best for	Very short waits, early boot, hard real time, ultra-high-rate NICs	Most peripherals	Bulk transfer
Hazard	Wastes power; must be bounded	Storms if not cleared at the source	Coherency and address translation

```
/* Polling, done correctly — ALWAYS with a timeout */
ret = readl_poll_timeout(base + STATUS, val, val & READY, 10, 1000);
if (ret)
        return -ETIMEDOUT;      /* say so, rather than hanging */

/* Hybrid models are common in practice:
     NAPI (network)   take one interrupt, then POLL until the
                      queue drains. Interrupt latency at low
                      rates, no interrupt storm at high rates.
     Adaptive coalescing  the device delays interrupts until N
                      packets or T microseconds.               */
```

DMA from the driver's point of view

```
The three rules, which are the same on every OS:

  1. Program the device with the address the DEVICE must use —
     Linux calls it dma_addr_t, Windows calls it a logical address.
     It is NOT a virtual address and NOT necessarily a physical one:
     with an IOMMU it is an IOVA.

  2. Respect BUFFER OWNERSHIP. Between map and unmap the buffer
     belongs to the device. Touching it from the CPU without an
     explicit sync gives stale or corrupt data on non-coherent
     systems (CA chapter 15).

  3. Never DMA to stack memory or vmalloc memory. Stack buffers may
     share a cache line with unrelated data; vmalloc memory is not
     physically contiguous.

  And the reason an SMMU/IOMMU exists at all: a device issuing
  addresses bypasses the CPU's MMU entirely, so every isolation
  guarantee built with page tables has a hole in it unless
  something checks those transactions. Security track, ch. 02–07.
```

Drivers outside the kernel

Mechanism	Gives user space	Used for
UIO	Mapped registers and interrupt notification via a file descriptor	Simple custom hardware
VFIO	The same, plus IOMMU-enforced DMA isolation	Device passthrough to VMs; DPDK, SPDK
libusb	Direct USB transfers	Instruments, programmers, cameras
spidev / i2c-dev	Raw bus transactions	Prototyping, one-off sensors
gpiod	GPIO lines by fd (replaces the deprecated sysfs interface)	Scripts, tooling
FUSE	A filesystem implemented in user space	sshfs, s3fs, experimentation
UMDF (Windows)	A full driver framework in user mode	USB, HID, sensors — the recommended default

```
The trade-off (OS chapter 02, again):

  IN KERNEL       full speed, direct access, no context switches
                  a bug panics the machine
                  a vulnerability is total compromise

  IN USER SPACE   a crash kills one process
                  can use any language, any library, a debugger
                  can be restarted
                  syscall or mapping overhead per operation
                  needs an IOMMU to make DMA safe

  DPDK and SPDK take the user-space path AND remove the overhead,
  by mapping the device with VFIO and POLLING it from a dedicated
  core — no syscalls, no interrupts, no kernel in the data path.
  They trade a whole CPU core for latency and throughput.
```

Exposing a device to user space

Interface	Good for	Caution
Device node + `read` / `write`	Streams of data	Needs framing if messages have boundaries
ioctl / `DeviceIoControl`	Arbitrary commands with structured arguments	The struct is permanent ABI — design for extension
sysfs attributes	One value per file; scriptable configuration and status	It is ABI: cannot be changed once shipped
debugfs	Anything, during development	No stability guarantee — never depend on it
mmap	Zero-copy access to buffers or registers	Exposes hardware directly; validate carefully
netlink / uevents	Asynchronous notifications to user space	
A subsystem (IIO, input, v4l2, hwmon)	**Preferred.** Existing tools and libraries work immediately	Must fit the subsystem's model

> **USE AN EXISTING SUBSYSTEM IF ONE FITS**
>
> A temperature sensor registered with **hwmon** is immediately visible to `sensors`, monitoring agents and fan control. The same sensor behind a custom ioctl needs bespoke tooling forever. Before inventing an interface, search for a subsystem that already models your device class — IIO for sensors, input for buttons and touch, v4l2 for video, ALSA for audio, hwmon for monitoring, rtc, watchdog, pwm, led. This is the difference between a driver that gets merged and one that does not.

Getting removal right

```
/* Removal is where most driver bugs live, because it races with
   everything still in flight.                                    */

static void my_remove(struct device *dev)
{
        struct my_dev *d = dev_get_drvdata(dev);

        /* 1. STOP the hardware generating events, FIRST */
        writel(0, d->regs + REG_IRQ_ENABLE);
        writel(0, d->regs + REG_CTRL);

        /* 2. unregister from the subsystem, so no NEW requests
              can arrive */
        unregister_device(&d->cdev);

        /* 3. wait for in-flight work to finish */
        cancel_work_sync(&d->work);
        del_timer_sync(&d->timer);

        /* 4. release resources in reverse order of acquisition */
        clk_disable_unprepare(d->clk);
        /* devm_ resources released automatically after this   */
}

/* Get the ORDER wrong and an interrupt fires after you freed the
   structure it references — a use-after-free that only appears
   under load.                                                    */
```

```
# the single best driver test there is: bind/unbind in a loop
for i in $(seq 100); do
  echo 40010000.widget > /sys/bus/platform/drivers/mydrv/unbind
  echo 40010000.widget > /sys/bus/platform/drivers/mydrv/bind
done
dmesg | grep -iE 'kasan|use-after|warn|leak'
# Nearly every resource leak, missing-quiesce and lifetime bug
# surfaces here and almost nowhere else. Run it with KASAN on.
```

Observing the I/O subsystem

```
lspci -vv                   # PCI devices, BARs, capabilities, driver
lsusb -t                    # USB topology
ls /sys/bus/*/devices/      # everything the device model knows
ls /sys/bus/platform/drivers/mydrv/    # what bound to this driver
ls /sys/class/               # by device class

cat /proc/interrupts        # is the handler firing?
cat /proc/iomem             # who owns which physical range
cat /proc/devices           # major numbers
ls /sys/kernel/iommu_groups/*/devices/

udevadm info -a -n /dev/ttyUSB0     # every attribute, for writing rules
udevadm monitor                      # watch hotplug events live

dmesg -w                             # driver messages as they happen
```

How it shows up

Symptom	Cause
Device present but no driver bound	Match table missing the ID or compatible string
Registers read all zeros or abort	Clock or power not enabled — check this before the address
Probe fails intermittently at boot	Dependency not ready; return `-EPROBE_DEFER`
Interrupt count never increases	Wrong number, wrong trigger type, or not enabled at the device
Interrupt fires continuously	Not cleared at the source before acknowledging
DMA writes land in the wrong place	Programmed with a virtual or physical address instead of the DMA address
Crash on module unload under load	Removal order wrong; something still in flight
Works once, fails on re-bind	State not reset in probe, or leaked in remove
Custom tooling needed for a common device type	Should have used an existing subsystem
User-space driver cannot DMA safely	Needs VFIO with an IOMMU, not UIO

Check yourself

- ✓ State a driver's two interfaces and why writing one needs two kinds of knowledge.
- ✓ Give the three device classes and say why network devices have no `/dev` node.
- ✓ Explain discoverable versus described buses and why the device tree exists.
- ✓ Walk the discovery-to-probe binding flow.
- ✓ Name the four resources a driver acquires and the ordering rule between them.

- ✓ Compare polling, interrupts and DMA, and describe one hybrid model.
- ✓ Give the three DMA rules and the reason an IOMMU exists.
- ✓ Give the correct order of operations in `remove()` and the bug that wrong order causes.

Interrupts, timers and timekeeping

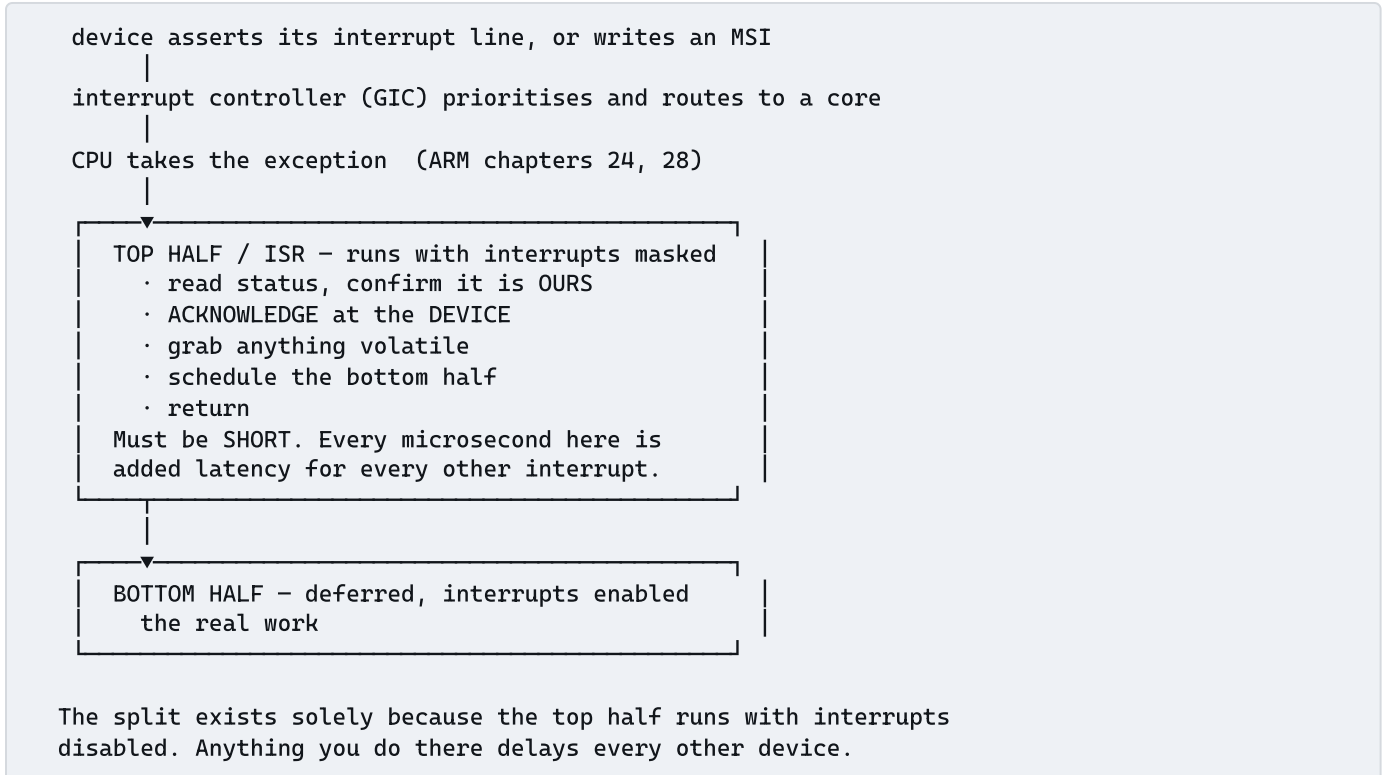
Interrupts are how hardware gets the kernel's attention, and timers are how the kernel gets its own. Both are governed by one constraint: the code that runs in interrupt context is severely restricted, and everything else about the design follows from working around that.

Interrupt context

THE RULE EVERYTHING ELSE FOLLOWS FROM

An interrupt handler runs in a *borrowed* context: on some arbitrary thread's kernel stack, with interrupts partly or fully masked, and with no task to schedule away from. Therefore it **cannot sleep**. No mutex, no `GFP_KERNEL` allocation, no `copy_to_user`, no waiting for I/O. Violating this deadlocks the machine.

Windows expresses the same constraint as **IRQL**: at DIRQL and DISPATCH_LEVEL you may not touch pageable memory or wait. Linux calls it "atomic context". The concept is identical.



Deferred work

Linux	Windows	Context	Can sleep?	Use for
softirq	—	Atomic	No	Networking, block completion. Statically defined; you will not add one.
tasklet	**DPC**	Atomic	No	Legacy in Linux (being removed); the standard mechanism on Windows
workqueue	**work item**	Process (kernel thread)	**Yes**	Anything that may block

Linux	Windows	Context	Can sleep?	Use for
threaded IRQ	—	Process (dedicated thread)	**Yes**	**The modern default** for device drivers

```
/* Threaded IRQ: a tiny hard handler plus a sleepable thread.
   This is what you should reach for first.                  */
devm_request_threaded_irq(dev, irq,
                          my_hard_isr,   /* atomic: ack, return */
                          my_thread_fn,  /* may sleep           */
                          IRQF_ONESHOT, dev_name(dev), d);

static irqreturn_t my_hard_isr(int irq, void *p)
{
        struct my_dev *d = p;
        u32 st = readl(d->regs + STATUS);

        if (!(st & IRQ_PENDING))
                return IRQ_NONE;        /* not ours — ESSENTIAL on a
                                           shared line, or the core
                                           cannot detect a stuck IRQ */
        writel(st, d->regs + STATUS);   /* W1C: clear at the SOURCE  */
        d->last_status = st;
        return IRQ_WAKE_THREAD;
}

/* PREEMPT_RT makes ALL interrupt handlers threaded by default —
   which is how it achieves bounded latency, at some throughput
   cost.                                                      */
```

THE INTERRUPT STORM

Clear the interrupt at the controller but not at the *device*, and a level-triggered line re-asserts immediately. The core does nothing but enter and leave the handler forever; the system appears hung with 100% CPU in the ISR. Always clear the condition at the source *first*, then acknowledge upward. Linux's spurious-interrupt detector will eventually disable the line and log `"nobody cared"` — which is a diagnosis, not a fix.

Edge versus level

	Level-triggered	Edge-triggered
Asserted	While the condition holds	On the transition only
Sharing	**Possible** — each handler checks and clears its own	Unsafe: two simultaneous edges register as one
Missed interrupts	Cannot be missed — the line stays asserted	**Can be lost** if masked during the edge
Failure mode	Storm, if never cleared	Silent hang, waiting for an event that already happened

```
/* The classic edge-triggered race, and the standard fix: */
static irqreturn_t isr(int irq, void *p)
{
        do {
                status = readl(STATUS);
                handle(status);
                writel(status, STATUS);        /* clear */
        } while (readl(STATUS) & PENDING);     /* RE-CHECK before
                                                  returning — a new
                                                  event may have
                                                  arrived while we
                                                  were handling      */
        return IRQ_HANDLED;
}
/* Without the loop, an event arriving between handle() and return
   produces no new edge and is lost forever. The device then waits
   for a response that never comes.                                 */
```

MSI: interrupts as memory writes

```
WIRED interrupt              MESSAGE-SIGNALLED (MSI/MSI-X, ARM LPI)
  a physical line              a WRITE to a special address
  pin-limited → shared         thousands per device, never shared
  needs "is it mine?"          the vector identifies the source
  can arrive BEFORE the DMA    arrives IN ORDER with the DMA data,
  data it announces            because it is the same bus stream

That last point is not a minor detail. With a wired interrupt, a
driver must issue a read (a "PCI posting flush") to guarantee the
DMA data has landed before it reads the buffer. With MSI the
ordering is free, which removes a subtle and common data-corruption
bug.

  cat /proc/interrupts        # PCI-MSI entries vs IO-APIC/GIC-SPI
  lspci -vv | grep -A3 MSI-X
```

Interrupt routing and affinity

```
# which CPU handles which interrupt?
cat /proc/interrupts
#            CPU0    CPU1    CPU2    CPU3
#  24:     102394       0       0       0   GICv3  35 Level  eth0

# all on CPU0 is a scalability problem. Spread them:
cat /proc/irq/24/smp_affinity_list
echo 2 > /proc/irq/24/smp_affinity_list      # pin to CPU2

# irqbalance does this automatically — and is usually wrong for
# latency-sensitive or RT workloads. Disable it and pin by hand:
systemctl stop irqbalance

# keep interrupts OFF your real-time cores entirely
# kernel cmdline: isolcpus=2,3 nohz_full=2,3 irqaffinity=0,1

# network multi-queue: one IRQ per queue, pinned per core, with RSS
# steering flows to queues. This is how a NIC scales past one core.
ethtool -l eth0
ethtool -L eth0 combined 4
```

Timer hardware

Role	Provides	ARM example
Clocksource	A monotonically increasing counter — "what time is it?"	`CNTPCT_EL0`, the architected generic timer
Clockevent	Programmable "interrupt me at time T"	`CNTP_CVAL_EL0` comparator

```
cat /sys/devices/system/clocksource/clocksource0/available_clocksource
#   arch_sys_counter        (ARM generic timer — the good one)
#   tsc hpet acpi_pm        (x86 options)

/* A good clocksource must be: monotonic, constant-rate (not
   affected by CPU frequency), synchronised across cores, and
   cheap to read. Early x86 TSC failed several of these, which is
   why HPET existed and why "unstable TSC" messages mattered.

   ARM's generic timer is architected: same behaviour on every
   implementation, readable from EL0 without a trap, which is what
   makes the vDSO clock_gettime possible (OS chapter 03).      */
```

The tick, and doing without it

```
PERIODIC TICK — the traditional design
   a timer interrupt every 1/HZ seconds (HZ = 100, 250 or 1000)
   each tick: update jiffies, run expired timers, account CPU
              time, check whether to preempt

   Simple. But it wakes the CPU 1000 times a second even when
   completely idle, preventing deep sleep states (CA chapter 20).

TICKLESS IDLE (NO_HZ_IDLE) — the default
   when a CPU goes idle, program the timer for the NEXT actual
   deadline instead of the next tick. An idle laptop can sleep
   for seconds at a time.

FULL TICKLESS (NO_HZ_FULL)
   suppress the tick even while RUNNING, if only one task is
   runnable on that CPU. Removes ~1000 interruptions per second
   from a latency-critical thread.
      kernel cmdline: nohz_full=2,3 rcu_nocbs=2,3 isolcpus=2,3
   Combined with IRQ affinity and a pinned RT thread, this is the
   standard recipe for microsecond-class latency on Linux.
```

```
/* jiffies: the tick counter. Still used, and still a trap. */
unsigned long timeout = jiffies + msecs_to_jiffies(500);

if (time_after(jiffies, timeout))       /* CORRECT              */
if (jiffies > timeout)                  /* WRONG — breaks on the
                                           32-bit wrap, which on a
                                           1000 HZ system happens
                                           every 49.7 days      */
/* time_after/time_before do signed subtraction, which is correct
   across wraparound. Use them always.                          */
```

Kernel timers

```
/* Low resolution — jiffy granularity, very cheap, batched */
struct timer_list t;
timer_setup(&t, callback, 0);
mod_timer(&t, jiffies + msecs_to_jiffies(100));
del_timer_sync(&t);            /* MUST be _sync before freeing —
                                  waits for a running callback   */

/* High resolution — nanosecond, backed by a clockevent */
struct hrtimer h;
hrtimer_init(&h, CLOCK_MONOTONIC, HRTIMER_MODE_REL);
h.function = callback;
hrtimer_start(&h, ms_to_ktime(10), HRTIMER_MODE_REL);
hrtimer_cancel(&h);

/* Short delays, no timer needed */
udelay(50);       /* BUSY-WAIT. Atomic context OK. Keep under
                     ~100 µs — you are burning a CPU.           */
usleep_range(100, 200);   /* SLEEPS. Process context only. The
                             range lets the kernel BATCH your
                             wakeup with others, saving power.  */
msleep(20);

/* Never usleep_range with a zero-width range: it defeats batching
   and wakes the CPU precisely for you alone.                   */
```

Need to wait	Use
< 10 µs	`udelay` / `ndelay` — busy-wait
10 µs – 20 ms	`usleep_range`
> 20 ms	`msleep`
Until an event	`wait_event_*` — not a timer at all
Precise, repeating	`hrtimer`
Coarse, cancellable	`timer_list`

Time in user space

```
struct timespec ts;
clock_gettime(CLOCK_MONOTONIC, &ts);      /* durations — NEVER jumps */
clock_gettime(CLOCK_REALTIME, &ts);       /* wall clock — CAN jump   */
clock_gettime(CLOCK_BOOTTIME, &ts);       /* monotonic + suspend time */

/* Served by the vDSO: no syscall, ~25 ns. */

/* precise periodic work, without drift */
struct timespec next;
clock_gettime(CLOCK_MONOTONIC, &next);
for (;;) {
        next.tv_nsec += 1000000;                /* +1 ms */
        if (next.tv_nsec >= 1000000000) { next.tv_nsec -= 1000000000; next.tv_sec++; }
        clock_nanosleep(CLOCK_MONOTONIC, TIMER_ABSTIME, &next, NULL);
        do_work();
}
/* ABSOLUTE deadlines. Sleeping for a RELATIVE 1 ms accumulates the
   work time plus wakeup jitter into permanent drift.          */

/* timerfd: a timer as a file descriptor — integrates with epoll */
int tfd = timerfd_create(CLOCK_MONOTONIC, 0);
timerfd_settime(tfd, 0, &spec, NULL);
```

NEVER MEASURE DURATIONS WITH `CLOCK_REALTIME`

NTP steps it, daylight saving changes it, an administrator can set it backwards, and a virtual machine can have it jump on migration. Durations computed from it go negative or enormous. Use `CLOCK_MONOTONIC` for anything you subtract, and `CLOCK_REALTIME` only for timestamps a human will read.

Interrupt latency

```
   device asserts
        |  ← hardware propagation, GIC arbitration
        |  ← INTERRUPTS DISABLED somewhere in the kernel  ◄── the
        |     (a spinlock, a critical section)                variable
        |  ← exception entry, register save                   part
        |  ← handler dispatch
        ▼
   your ISR's first instruction

  Total latency = hardware + longest interrupts-disabled region
                + entry cost

  The DOMINANT and most variable term is the interrupt-disabled
  time somewhere else in the kernel. This is exactly what
  PREEMPT_RT attacks: it converts most spinlocks to sleeping
  mutexes and threads the handlers, bounding that term.

  Measuring it:
     cyclictest -t4 -p 90 -i 200 -m -D 3600
     → report the MAXIMUM, not the average. The average is
       always fine; the maximum is what breaks deadlines.

     ftrace: irqsoff and preemptoff tracers find the exact
     longest region and its stack trace.
         echo irqsoff > /sys/kernel/debug/tracing/current_tracer
         cat /sys/kernel/debug/tracing/trace
```

How it shows up

Symptom	Cause
System hangs at 100% CPU in an ISR	Interrupt storm — not cleared at the device
`"irq N: nobody cared"` in dmesg	Handler returned `IRQ_HANDLED` without handling it, or a shared line with no owner
Device stops responding after high load	Lost edge-triggered interrupt; add the re-check loop
Interrupt count never increases	Wrong number, wrong trigger type, or masked at the device
All interrupts land on CPU0	No affinity spreading; the core saturates
Latency spikes only on some cores	Interrupts not steered away from the RT cores
"scheduling while atomic" / bug check 0xA	Slept in interrupt context
Timer callback runs after the structure is freed	Used `del_timer` instead of `del_timer_sync`
Periodic task drifts over hours	Relative sleeps instead of absolute deadlines
Measured duration is negative	Used `CLOCK_REALTIME`; NTP stepped it
Idle laptop has poor battery life	A periodic timer preventing deep idle (CA ch. 20)

Check yourself

- ✓ Explain why an interrupt handler cannot sleep, and name the Windows equivalent of the rule.
- ✓ Give the top-half/bottom-half split and four deferred-work mechanisms.
- ✓ Explain the interrupt storm and the ordering that prevents it.

- ✓ Compare edge and level triggering on sharing and on missed interrupts.
- ✓ Give two advantages of MSI, including the ordering property.
- ✓ Distinguish clocksource from clockevent.
- ✓ Explain tickless operation and what `nohz_full` buys.
- ✓ Explain why `jiffies > timeout` is wrong.
- ✓ Say which term dominates interrupt latency and how PREEMPT_RT addresses it.

Boot and initialisation

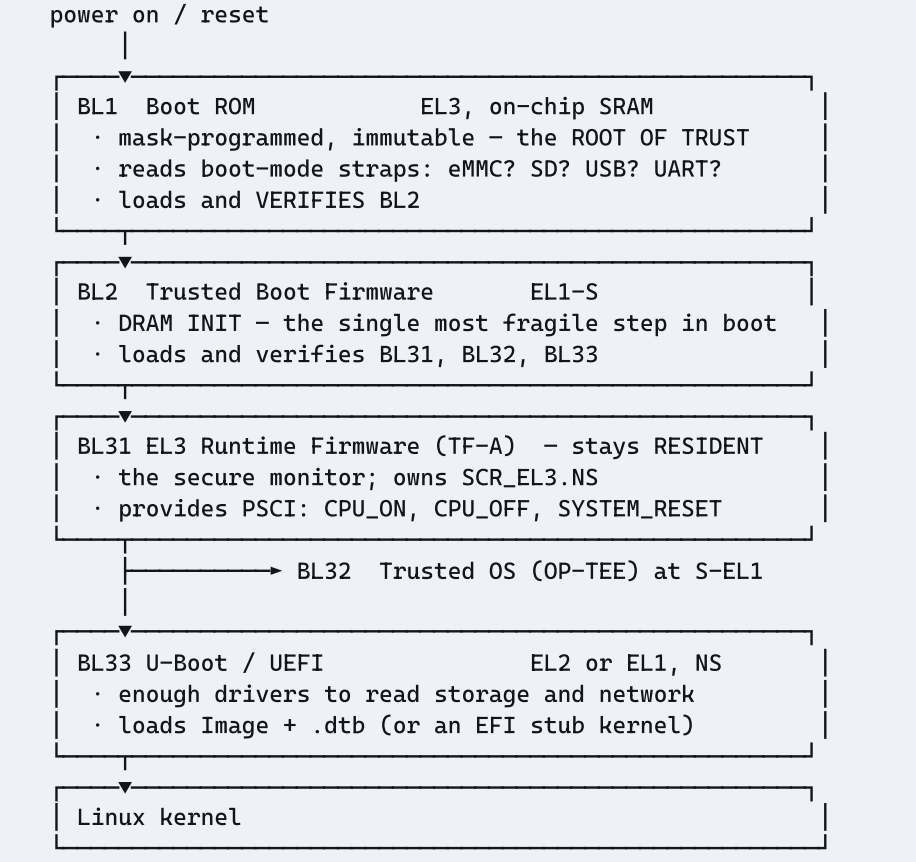
Boot is a chain of increasingly capable programs, each loading and validating the next. It is where firmware, security and the OS meet, and where bring-up problems are most opaque — because when it fails you often have no output at all.

The bootstrap problem

WHY THERE ARE SO MANY STAGES

At reset the CPU has no DRAM, no stack, no filesystem and no drivers — only a fixed address it starts executing from. Each stage exists to make the *next* one possible: on-chip ROM runs from a few kilobytes of SRAM and its only job is to initialise enough to load a slightly larger program; that program initialises DRAM so a full bootloader will fit; the bootloader has drivers enough to read a filesystem and load a kernel. Each stage is bigger and more capable because the previous one earned it the resources.

ARM64 embedded boot



The security dimension of this chain — signature verification at every arrow, anti-rollback, fuses — is the subject of the security track. Here we care about the mechanics.

The kernel's entry contract

```
/* Documented in Documentation/arch/arm64/booting.rst. The
   bootloader MUST deliver exactly this state:              */

    x0 = physical address of the flattened device tree blob
    x1 = x2 = x3 = 0                      (reserved, must be zero)

    MMU        OFF
    D-cache    OFF   (and the image must be cache-clean to PoC)
    I-cache    may be on or off
    interrupts masked at the CPU
    running at EL2 if available (preferred — enables KVM), else EL1
    all secondary CPUs parked, released via PSCI or a spin-table

/* Getting any of this wrong gives a kernel that hangs before it can
   print anything — which is why `earlycon` exists and why a serial
   console is the first thing you bring up on new hardware.     */
```

Inside the kernel

```
   head.S — arch/arm64/kernel/head.S
     · if at EL2 and not using KVM, drop to EL1
     · set up an IDENTITY map plus the initial kernel page tables
     · enable the MMU
     · BRANCH TO VIRTUAL ADDRESSES  ◄── the moment the kernel
       (__primary_switch)               starts living in its own
     · zero .bss, set up the initial stack       address space
        │
        ▼
   start_kernel()  — init/main.c
     setup_arch()        parse the DTB or ACPI, reserve memory,
                         discover CPUs, set up earlycon
     mm_init()           hand memory to the buddy allocator, slab
     sched_init()        runqueues and the idle task
     init_IRQ()          probe and initialise the GIC
     time_init()         start the generic timer
     rest_init()         create PID 1 and kthreadd, then become
                         the idle task forever
        │
        ▼
   kernel_init()  (PID 1, still in kernel mode)
     do_initcalls()      run every initcall level in order
     smp_init()          bring up secondary CPUs via PSCI CPU_ON
     mount the root filesystem
     free the initrd
     execve("/sbin/init")  ◄── PID 1 becomes a user process and
                               NEVER returns to the kernel
```

```
/* initcalls: drivers are not called explicitly. Each registers via
   a macro; the linker collects them into ordered sections.     */
early_initcall()      /* level 0 */
core_initcall()       /* 1 */
postcore_initcall()   /* 2 */
arch_initcall()       /* 3 */
subsys_initcall()     /* 4 — bus types, classes */
fs_initcall()         /* 5 */
device_initcall()     /* 6 — most drivers; module_init maps here */
late_initcall()       /* 7 */

/* Within a level, order follows LINK order, which follows the
   Makefile. Depending on that is a bug. Express real dependencies
   with -EPROBE_DEFER (OS chapter 16) instead.                 */
```

initramfs and the root filesystem

```
The chicken-and-egg problem:
   to mount the root filesystem you need its driver
   the driver is a module
   the module lives on the root filesystem

INITRAMFS solves it: a cpio archive, loaded into RAM by the
bootloader (or built into the kernel), containing exactly the
modules and tools needed to reach the real root.

   bootloader loads Image + initramfs
        |
   kernel unpacks the cpio into a tmpfs — this IS the initial root
        |
   /init runs (a shell script, or systemd)
     · load storage, RAID, LVM, crypto modules
     · assemble arrays, unlock LUKS, activate LVM
     · possibly fetch a network root
     · mount the real root at /sysroot
         |
   switch_root /sysroot /sbin/init
     · move the mounts, free the initramfs memory, exec the real init

Embedded systems often skip it entirely: build the storage driver
into the kernel and boot straight to a fixed root. Fewer moving
parts, faster boot.
```

```
# the kernel command line drives most of this
root=/dev/mmcblk0p2 rootwait rw
root=PARTUUID=abcd-1234        # stable across device renumbering
rootfstype=ext4
console=ttyAMA0,115200 earlycon
init=/bin/sh                   # emergency: skip the init system
initcall_debug                 # print every initcall and its timing
loglevel=8 ignore_loglevel

# see what you booted with
cat /proc/cmdline
```

User space boot

Init system	Model	Suits
SysV init	Numbered shell scripts, run sequentially	Historical; simple to read, slow
BusyBox init	Minimal, `/etc/inittab`	Embedded — small and predictable
systemd	Declarative units, dependency graph, parallel start, socket and bus activation	Desktops and servers; increasingly embedded
OpenRC / runit / s6	Supervision-focused, lighter	Minimal systems, containers

```
# systemd's key idea: SOCKET ACTIVATION removes ordering entirely.
# systemd creates the listening socket first, then starts the
# service lazily and passes it the fd (SCM_RIGHTS, OS chapter 08).
# Clients can connect before the service has started — their
# connections simply queue. Nothing needs to wait for anything.

systemd-analyze                # total boot time, split by phase
systemd-analyze blame          # slowest units
systemd-analyze critical-chain  # the dependency path that determined
                               # total boot time — the only one worth
                               # optimising
systemd-analyze plot > boot.svg
```

Bringing up secondary CPUs

```
/* Only CPU0 runs at reset. The others are parked. */

/* PSCI — the standard mechanism, implemented by EL3 firmware */
    SMC #0 with x0 = PSCI_CPU_ON (0xC4000003)
               x1 = target MPIDR
               x2 = entry point physical address
               x3 = context id
/* The firmware releases that core, which enters at the given
   address with the MMU off, exactly like the primary CPU did. */

/* The kernel then, per CPU:
     · set up its per-CPU page tables and stack
     · enable the MMU
     · initialise its GIC redistributor and local timer
     · calibrate, and mark itself online
     · enter the idle loop, ready for the scheduler          */

/* Older platforms used a SPIN-TABLE: secondaries poll a memory
   location written by the primary. PSCI is preferred because it
   also handles CPU_OFF, SUSPEND and SYSTEM_RESET uniformly.  */

cat /sys/devices/system/cpu/online
echo 0 > /sys/devices/system/cpu/cpu3/online     # hotplug offline
```

Fast boot

Technique	Saves
Skip the bootloader's countdown and menu	Seconds — usually the largest single win

Technique	Saves
Compile in the storage driver; drop initramfs	Hundreds of ms
Trim the kernel config aggressively	Decompression and initcall time
Choose the decompressor deliberately (LZ4 > gzip > XZ for speed)	Hundreds of ms; trades image size
`quiet` on the command line	Serial console output is astonishingly slow at 115200
Defer non-essential drivers to after userspace starts	Perceived boot time
Suspend-to-RAM or hibernate instead of a cold boot	Nearly everything
Execute-in-place (XIP) from NOR flash	The whole copy-and-decompress step

```
# find where the time actually goes
dmesg | head -50                      # timestamps are seconds since start
systemd-analyze blame
cat /proc/cmdline                      # is initcall_debug on?

# with initcall_debug, dmesg shows every initcall's duration:
dmesg | grep 'initcall' | sort -t= -k2 -rn | head -20

# a 5-second gap in dmesg timestamps is almost always a probe
# timeout — a device that is not there, or is not responding.
```

When boot fails silently

```
Work down the chain. At each step, the question is "did we get
this far?", and the answer needs SOME form of output.

  1. No bootloader output at all
       → power rails, clocks, reset, boot-mode straps, or the
         boot medium. Attach JTAG: can the probe see the core's
         IDCODE? If not, stop and fix that first.

  2. Bootloader runs, kernel produces nothing
       → almost always the console. Add `earlycon` and check that
         the device tree's chosen/stdout-path names the right UART
         at the right address.
       → or the entry contract was violated (x0 not the DTB, MMU
         left on, D-cache left on)

  3. Kernel prints, then stops at "Starting kernel..."
       → DTB wrong or absent; decompression failure; wrong load
         address; memory node describing memory that is not there

  4. Kernel boots, panics with "Unable to mount root fs"
       → the storage driver is a module and there is no initramfs,
         or `root=` names the wrong device. `rootwait` helps when
         the device appears late.

  5. Boots to a shell but a device is missing
       → the device tree node, its status property, or driver
         binding (OS chapter 16)

Tools: earlycon, `initcall_debug`, `ignore_loglevel`, a JTAG probe,
and a serial cable — which remains the single most valuable piece
of bring-up equipment.
```

How it shows up

Symptom	Cause
No output whatsoever	Console not configured; add `earlycon` and check `stdout-path`
Hangs right after "Starting kernel"	Entry contract violated, or the DTB is wrong
"Unable to mount root fs on unknown-block(0,0)"	Storage driver missing, or wrong `root=`
"Kernel panic - not syncing: No working init found"	Root mounted but `/sbin/init` is absent or not executable
Boots from SD but not eMMC	Boot-mode straps, or partition/offset differences
Random crashes under load, boots fine	Marginal DRAM timing from BL2 — test at temperature
Multi-second gap in dmesg timestamps	A probe timeout on a device that is not present
Only one CPU online	PSCI not working, or the CPU nodes in the DTB are wrong
Boot is slow with a serial console attached	Console output at 115200 dominates; add `quiet`
Works from a development board, fails on production silicon	Fuses changed the boot or security configuration

Check yourself

- ✓ Explain why boot needs multiple stages rather than one program.
- ✓ Name the ARM boot stages and what each is responsible for.
- ✓ State the ARM64 kernel entry contract and one failure caused by breaking it.
- ✓ Explain what happens between `head.S` and `start_kernel`.
- ✓ Explain the initramfs chicken-and-egg problem and how `switch_root` resolves it.
- ✓ Explain socket activation and why it removes startup ordering.
- ✓ Describe how secondary CPUs are started with PSCI.
- ✓ Give a five-step procedure for diagnosing a silent boot failure.

Real-time operating systems and latency

Real-time means *predictable*, not fast. An RTOS trades throughput, memory efficiency and flexibility for one property: a bounded worst case. This chapter covers what that bound costs, how to measure it, and when Linux can deliver it instead.

What real-time means

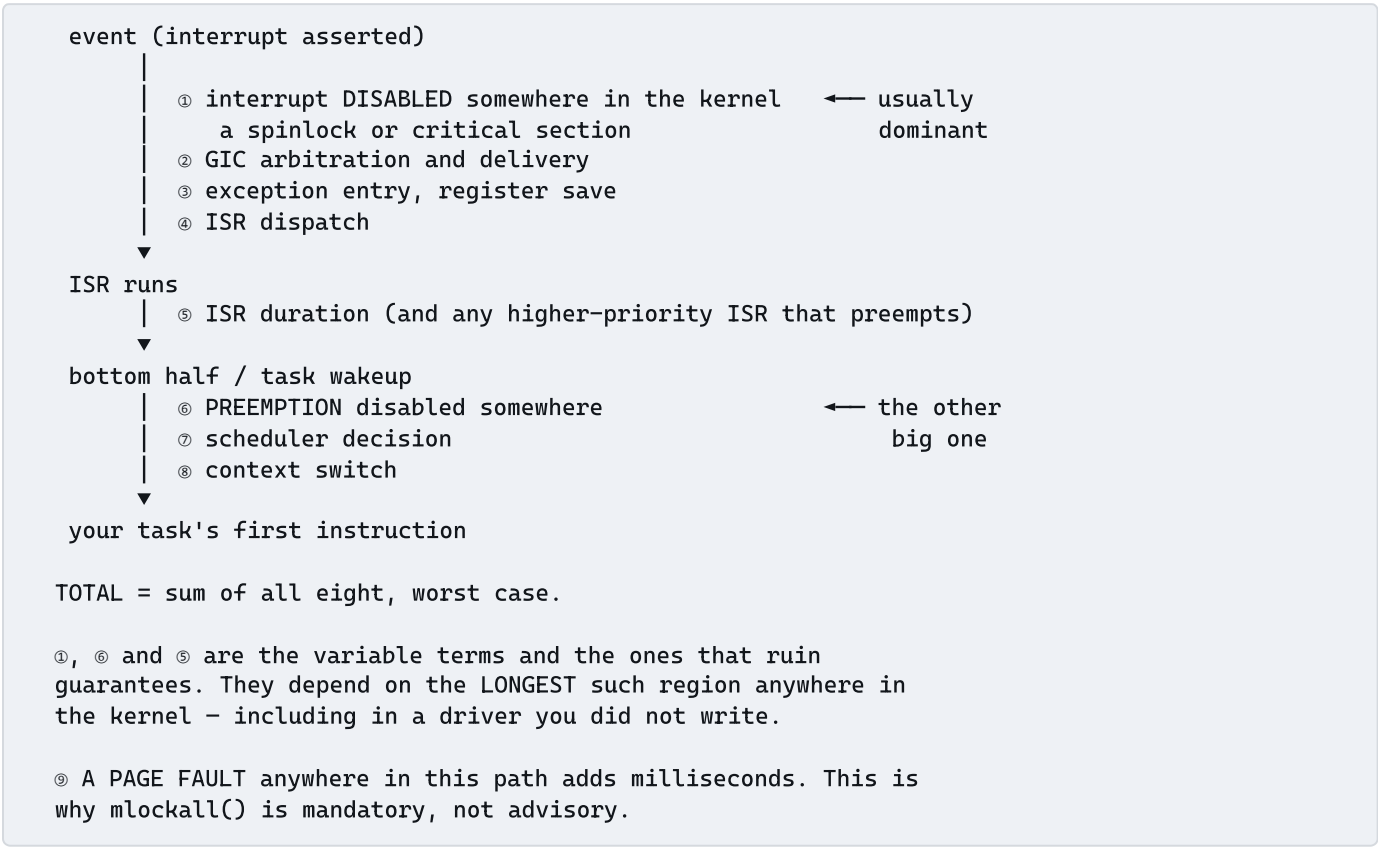
THE DISTINCTION

A system is real-time if correctness depends on *when* a result is produced, not only on the result itself. A motor controller that computes the right current 2 ms late has failed, however correct the number.

The metric is therefore the **worst case**, never the average. A system with 5 µs average latency and one 8 ms outlier per hour is *not* real-time; one with a guaranteed 200 µs bound is.

Class	Missing a deadline means	Examples
Hard	System failure. Possibly injury or loss of life.	Airbag deployment, flight control, engine timing, medical infusion
Firm	The result becomes worthless, but no damage	Video frame rendering, a missed radar sweep
Soft	Quality degrades proportionally	Audio glitches, UI stutter, VoIP jitter

Where latency comes from



How an RTOS achieves a bound

Design choice	Bounds	Costs
Strict priority preemption, no fairness	The highest-priority ready task always runs	Lower-priority tasks can starve — by design
No demand paging, often no MMU	Removes page-fault latency entirely	No isolation between tasks
Static allocation only	No allocator variance, no fragmentation	Everything sized at build time
Bounded interrupt disable regions	Term ① above	Careful hand-auditing of every critical section
Priority inheritance on every mutex	Priority inversion (ch. 06)	A few cycles per lock and unlock
O(1) scheduler — a priority bitmap	Term ⑦	Limited number of priorities
Small kernel	Few paths to audit; analysable	Few features

```
/* A typical RTOS scheduler decision, in constant time: */
static uint32_t ready_bitmap;              /* one bit per priority */

static inline int highest_ready(void)
{
        return 31 - __builtin_clz(ready_bitmap);   /* ONE instruction */
}
/* Compare with EEVDF's red-black tree walk. The RTOS gives up all
   fairness and gains a provable, tiny, constant bound.        */
```

The RTOSes you will meet

RTOS	Footprint	Character
FreeRTOS	5–10 KB	The de-facto MCU standard. Tasks, queues, semaphores, timers. MIT licensed, now maintained by AWS.
Zephyr	10–100 KB	Linux Foundation. Device-tree driven, Kconfig, extensive driver model and networking. The modern choice for new MCU work.
ThreadX / Azure RTOS	~10 KB	Safety-certified, very small, widely deployed
QNX	MBs	Microkernel, POSIX, hard real-time. Automotive infotainment and instrument clusters.
VxWorks	MBs	Aerospace and defence; long certification pedigree
RTEMS	MBs	Open source, spaceflight heritage
seL4	~10 KLOC	Formally verified microkernel with proven WCET bounds
Linux + PREEMPT_RT	MBs	Soft to firm real-time with a full OS underneath

The RTOS programming model

```
/* FreeRTOS — the shape is essentially the same in every RTOS */

void sensor_task(void *arg)
{
        TickType_t next = xTaskGetTickCount();
        for (;;) {
                read_sensor();
                process();
                /* absolute deadline — no drift accumulation */
                vTaskDelayUntil(&next, pdMS_TO_TICKS(10));
        }
}

xTaskCreate(sensor_task, "sensor",
            256,            /* stack in WORDS — sized per task */
            NULL,
            3,              /* priority: higher number = higher */
            &handle);
vTaskStartScheduler();      /* never returns */

/* ISR → task communication. Note the FromISR suffix: separate
   entry points that never block, and that request a context
   switch on return.                                          */
void UART_IRQHandler(void)
{
        BaseType_t woken = pdFALSE;
        xQueueSendFromISR(rx_queue, &byte, &woken);
        portYIELD_FROM_ISR(woken);      /* switch immediately if a
                                           higher-priority task woke */
}

/* Calling the blocking variant from an ISR is the classic RTOS
   bug: it asserts, or silently corrupts the scheduler state. */
```

PER-TASK STACKS ARE THE MEMORY PROBLEM

Every task needs its own stack, sized for its worst-case call depth *plus* any interrupt frame that can nest on it. Twenty tasks at 1 KB each is 20 KB — often more than the application's data. Undersize one and you get silent corruption of the neighbouring task's stack, which presents as impossible behaviour far from the cause.

Use `uxTaskGetStackHighWaterMark()`, enable stack-overflow checking during development, and fill stacks with a known pattern so you can measure real usage rather than guess.

Worst-case execution time

```
Hard real-time requires a PROVEN upper bound on execution time —
not a measured maximum. That is genuinely hard, because modern
hardware is designed to make the AVERAGE case fast:

  caches            a miss is 100x a hit. WCET must assume misses.
  branch prediction a mispredict costs 15+ cycles. Assume worst.
  out-of-order      timing depends on surrounding instructions
  DRAM refresh      periodic stalls outside your control
  shared buses      another master can delay you
  SMT / big.LITTLE  a sibling thread steals resources; cores differ
  DVFS              the clock itself varies

  Approaches:
    STATIC ANALYSIS   model the pipeline and caches, prove a bound
                      (aiT, Bound-T). Sound, pessimistic, expensive.
    MEASUREMENT       run many times, take the max, add margin.
                      Practical, and NOT a proof.
    HYBRID            measure segments, compose analytically.

  Simplifying for analysability is usually cheaper than analysing
  complexity: disable caches on the critical path, lock cache ways,
  use TCM/scratchpad memory, pin to one core, avoid dynamic
  dispatch, and forbid recursion and unbounded loops.
```

Will the task set meet its deadlines?

```
/* RATE MONOTONIC — static priorities, shorter period = higher
   priority. Optimal among fixed-priority schemes.            */

   Sufficient condition (Liu & Layland):
        U = Σ (Cᵢ / Tᵢ)  ≤  n(2^(1/n) − 1)

        n=1  → 1.000      n=3  → 0.780
        n=2  → 0.828      n→∞  → 0.693

   Worked example, three periodic tasks:
        T1: C=1 ms,  T=4 ms   → 0.250
        T2: C=2 ms,  T=8 ms   → 0.250
        T3: C=4 ms,  T=16 ms  → 0.250
        U = 0.75  ≤  0.780    → schedulable, guaranteed.

/* EARLIEST DEADLINE FIRST — dynamic priorities.
        schedulable iff  U ≤ 1.0
   Strictly better utilisation, but behaves badly on overload:
   under RM the low-priority tasks fail first and predictably;
   under EDF a transient overload can cause a cascade of misses.

   Linux's SCHED_DEADLINE implements EDF with a constant-bandwidth
   server and an ADMISSION TEST, so requesting more than the system
   can guarantee FAILS at setup rather than silently missing
   deadlines later (OS chapter 06).                           */
```

Real-time Linux

```
# PREEMPT_RT, merged into mainline in 6.12. What it changes:
#   · most spinlocks become sleeping rt_mutexes
#   · interrupt handlers become kernel threads by default
#   · priority inheritance everywhere
#   · bounded interrupt-disable regions throughout
#   Result: typical worst case in the tens of microseconds,
#   at roughly 10–30% throughput cost.

# The full recipe for low latency on Linux:

# 1. kernel command line — isolate cores completely
isolcpus=2,3 nohz_full=2,3 rcu_nocbs=2,3 irqaffinity=0,1 \
    intel_pstate=disable processor.max_cstate=1 idle=poll

# 2. keep interrupts off the RT cores
for i in /proc/irq/*/smp_affinity_list; do echo 0-1 > $i 2>/dev/null; done
systemctl stop irqbalance

# 3. fix the clock, disable deep idle
cpupower frequency-set -g performance

# 4. in the application
mlockall(MCL_CURRENT | MCL_FUTURE);        /* no page faults    */
sched_setscheduler(0, SCHED_FIFO, &param); /* priority 80-90    */
CPU_SET(2, &mask); sched_setaffinity(...); /* pin to an isolated core */
/* pre-fault and pre-allocate EVERYTHING before the real-time loop */

# 5. measure — the only step that proves anything
cyclictest -t2 -p 90 -a 2,3 -i 200 -m -D 24h
#   report the MAX column. Run for hours, under representative load.
```

Configuration	Typical worst-case latency
Stock desktop kernel	Milliseconds, occasionally tens
`PREEMPT` (low-latency desktop)	Hundreds of µs
`PREEMPT_RT`, tuned and isolated	10–50 µs
Bare-metal RTOS on a Cortex-M	1–10 µs
Interrupt handler alone, no OS	< 1 µs

Mixed criticality

```
Modern SoCs run real-time and general-purpose workloads together.
Four ways to combine them, in increasing order of isolation:

  1. SEPARATE CORES on one SoC (AMP)
       Cortex-A runs Linux, Cortex-M/R runs the RTOS.
       Communication via shared memory + mailbox (RPMsg, OpenAMP).
       Very common: motor control beside a Linux HMI.

  2. HYPERVISOR PARTITIONING
       Xen/Jailhouse/Hafnium gives each guest dedicated cores,
       memory and devices. Strong spatial isolation.

  3. PREEMPT_RT alone
       One kernel, RT priorities plus core isolation.
       Simplest; isolation is only as good as the kernel.

  4. DUAL KERNEL (Xenomai, RTAI)
       A tiny RT co-kernel takes interrupts FIRST and runs Linux
       as its lowest-priority task. Best Linux-hosted latency;
       a separate API and real maintenance cost.

  In all four, the hard part is shared HARDWARE: the memory
  controller, caches, the interconnect. A Linux core saturating
  DRAM bandwidth can inflate the RT core's WCET even with perfect
  logical isolation. Cache partitioning and memory bandwidth
  regulation exist for exactly this.
```

How it shows up

Symptom	Cause
Deadline missed once an hour	A page fault — `mlockall` not used, or a lazily faulted stack
Latency fine on the bench, bad in the field	Untested load path; measure under representative traffic
Occasional millisecond spike on PREEMPT_RT	A long interrupt-disabled region — find it with the `irqsoff` tracer
High-priority task delayed by a low-priority one	Priority inversion; enable priority inheritance
Adding a background job broke real-time timing	Shared memory bandwidth or cache pressure, not scheduling
RTOS task corrupts another's data	Stack overflow; check high-water marks
System hangs after raising a task's priority	A `SCHED_FIFO` loop that never yields
Timing varies 3× between runs	Migrated to a LITTLE core, or DVFS changed the clock
Works with the debugger attached, fails without	The debugger changed cache or timing behaviour
Periodic task drifts over hours	Relative delays instead of absolute deadlines

Check yourself

- ✓ Explain why real-time means predictable and why the average is irrelevant.
- ✓ Distinguish hard, firm and soft real-time with an example of each.
- ✓ Name the eight contributors to interrupt-to-task latency and the two that dominate.
- ✓ Give four RTOS design choices and what each one costs.
- ✓ Explain why `FromISR` variants exist.

- ✓ Explain why WCET analysis is hard on modern hardware, and three ways to simplify it.
- ✓ Apply the rate-monotonic bound to a three-task set.
- ✓ Give the full recipe for low-latency Linux, and the one step that proves it worked.

Virtualisation, containers and isolation

Three different answers to "run this workload without letting it interfere with that one" — with three very different isolation strengths and costs. This chapter closes the OS track by making the trade-off explicit.

The isolation spectrum

```
weaker isolation, lower cost ──────────► stronger, higher cost

  process        namespace/       VM              separate
                 container                        hardware
  ┌──────┐      ┌──────────┐    ┌──────────┐    ┌──────────┐
  │ MMU  │      │ MMU +    │    │ MMU +    │    │ physical │
  │ page │      │ kernel   │    │ 2-stage  │    │ air gap  │
  │tables│      │ namespaces│   │ + EL2    │    │          │
  └──────┘      └──────────┘    └──────────┘    └──────────┘
  shared        SHARED          own kernel      own everything
  kernel        KERNEL          shared hardware

  attack surface: the shared component
  ~30M lines      ~30M lines      ~50K lines      none
  (the kernel)    (the kernel)    (hypervisor)

The whole argument between containers and VMs is that middle row:
a container escape needs one kernel bug; a VM escape needs a
hypervisor bug, and there is far less hypervisor to get wrong.
```

Virtual machines

Type	Runs on	Examples
Type 1 (bare metal)	Directly on hardware	Xen, Hyper-V, ESXi, Jailhouse, Hafnium
Type 2 (hosted)	On a host OS	VirtualBox, VMware Workstation, QEMU/TCG
Hybrid	A host kernel module *becomes* the hypervisor	**KVM** — Linux is both host OS and Type 1 hypervisor

```
The three things a hypervisor must virtualise:

  CPU     the guest kernel expects to run privileged instructions.
          Modern hardware makes this cheap: the guest runs at EL1
          natively, and only "sensitive" operations TRAP to EL2.
          (ARM VHE, Intel VT-x, AMD-V)

  MEMORY  the guest believes it owns physical memory. A SECOND
          translation stage maps guest-physical (IPA) to real
          physical, owned by the hypervisor and unchangeable by
          the guest.
              guest VA ─[stage 1, guest]─► IPA ─[stage 2, HV]─► PA
          ARM chapter 16 covers the mechanics.

  I/O     the guest programs devices that do not exist.
          Either emulate them, paravirtualise them, or hand over
          a real one (below).
```

How a trap works

```
/* The guest kernel writes to what it believes is a UART register. */

        writel(1, uart_base + UART_CR);      /* guest, at EL1 */

/* 1. stage-1 translation: guest VA → IPA, using the guest's own
      page tables. Succeeds — the guest mapped it.
   2. stage-2 lookup of that IPA in VTTBR_EL2. The hypervisor
      deliberately left it UNMAPPED.
   3. stage-2 data abort → taken to EL2, not EL1.
   4. the hypervisor reads:
         HPFAR_EL2   the faulting IPA — which device register
         ESR_EL2.ISS ISV/SAS/SRT/WnR — size, direction, and which
                     guest register held the value
   5. it emulates the UART in software and updates its model.
   6. it advances the guest's ELR_EL2 past the faulting
      instruction and ERETs.

   The guest never knows. This is exactly how QEMU/KVM presents
   virtual hardware — and why emulated I/O is slow: every register
   access is a full world switch.                              */
```

Three ways to give a VM I/O

Approach	Mechanism	Cost	Guest needs
Full emulation	Trap every register access; emulate a real device (e1000, IDE)	Very high — a trap per access	Nothing; stock drivers work
Paravirtualisation	`virtio`: a shared-memory ring plus a doorbell	Low — batched, few exits	A virtio driver
Passthrough	Assign the real device to the guest via the IOMMU	Near zero	The real driver; the device is exclusive
SR-IOV	The device presents multiple virtual functions, one per guest	Near zero	Device support

```
virtio is the same design as io_uring and every high-performance
IPC (OS chapter 08):

   guest driver                          host / device backend
   ┌──────────────┐                      ┌──────────────────┐
   │ available    │──── shared ─────────▶│  reads requests  │
   │   ring       │     memory           │                  │
   │ used ring    │◀─────────────────────│  writes results  │
   └──────┬───────┘                      └─────────▲────────┘
          │ doorbell: ONE MMIO write               │ interrupt
          │ per BATCH, not per request             │ (or polling)
          └────────────────────────────────────────┘

  Bulk data by shared memory; exits only when the peer needs
  waking. Recognise this shape — it is the answer to nearly every
  "cross a boundary at high rate" problem in systems design.
```

PASSTHROUGH REQUIRES AN IOMMU, WITHOUT EXCEPTION

A device assigned to a guest is programmed by the guest with *guest-physical* addresses. Without an IOMMU translating and constraining its DMA, the device would write those addresses as real physical addresses — scribbling over the host or another guest. The IOMMU's stage-2 translation is what makes passthrough safe, and it is the single most important reason the SMMU exists. Covered fully in the security track.

Containers

A CONTAINER IS NOT A THING

There is no container object in the Linux kernel. A "container" is an ordinary process started with a particular combination of **namespaces** (what it can see), **cgroups** (what it can use) and **capabilities/seccomp/LSM** (what it can do). Docker and Podman are tools that assemble that combination; the kernel only sees processes.

Namespace	Isolates
`mnt`	The mount table — its own filesystem view
`pid`	Process IDs — the container's init is PID 1, and it cannot see host processes
`net`	Interfaces, routes, firewall rules, ports
`uts`	Hostname and domain name
`ipc`	System V IPC and POSIX message queues
`user`	UID/GID mapping — root inside, unprivileged outside. **The one that makes rootless containers possible.**
`cgroup`	The cgroup hierarchy view
`time`	Boot and monotonic clock offsets

```
# build one by hand — this IS a container
sudo unshare --pid --net --mount --uts --ipc --fork --mount-proc \
     chroot /path/to/rootfs /bin/sh

# inspect any process's namespaces
ls -l /proc/self/ns/
readlink /proc/1/ns/net /proc/$$/ns/net    # same link = same namespace

nsenter -t PID -n -m -p /bin/sh            # join an existing one
```

```
# cgroups v2 — the resource half
mkdir /sys/fs/cgroup/myapp
echo $$              > /sys/fs/cgroup/myapp/cgroup.procs
echo "200000 1000000" > /sys/fs/cgroup/myapp/cpu.max     # 20% of one CPU
echo 512M            > /sys/fs/cgroup/myapp/memory.max
echo "259:0 rbps=10485760" > /sys/fs/cgroup/myapp/io.max

cat /sys/fs/cgroup/myapp/memory.current
cat /sys/fs/cgroup/myapp/memory.events     # oom_kill counter
cat /sys/fs/cgroup/myapp/cpu.stat          # throttling counters
```

THE CONTAINER IS STILL USING THE HOST KERNEL

`uname -r` inside a container reports the *host's* kernel. Consequences that surprise people constantly:

- A kernel exploit escapes the container. This is the entire isolation argument against containers for untrusted workloads.
- Kernel modules, `sysctl` settings and the clock are shared or host-controlled.
- `/proc/cpuinfo` and `free` show **host** values, not the cgroup limit — which is why JVMs and thread pools historically sized themselves for 64 cores inside a 2-core container. Modern runtimes read the cgroup files; older code and hand-rolled `nproc` logic do not.

Narrowing what a container can do

```
/* Namespaces isolate what you SEE. These restrict what you can DO. */

/* 1. Capabilities — split root's power into ~40 pieces */
capsh --print
docker run --cap-drop=ALL --cap-add=NET_BIND_SERVICE ...
/* CAP_SYS_ADMIN is so broad it is effectively root — never grant it */

/* 2. seccomp — filter system calls with a BPF program */
docker run --security-opt seccomp=profile.json ...
/* Docker's default profile blocks ~44 syscalls. A tight custom
   profile is one of the highest-value hardening steps available. */

/* 3. LSM — SELinux or AppArmor mandatory access control */

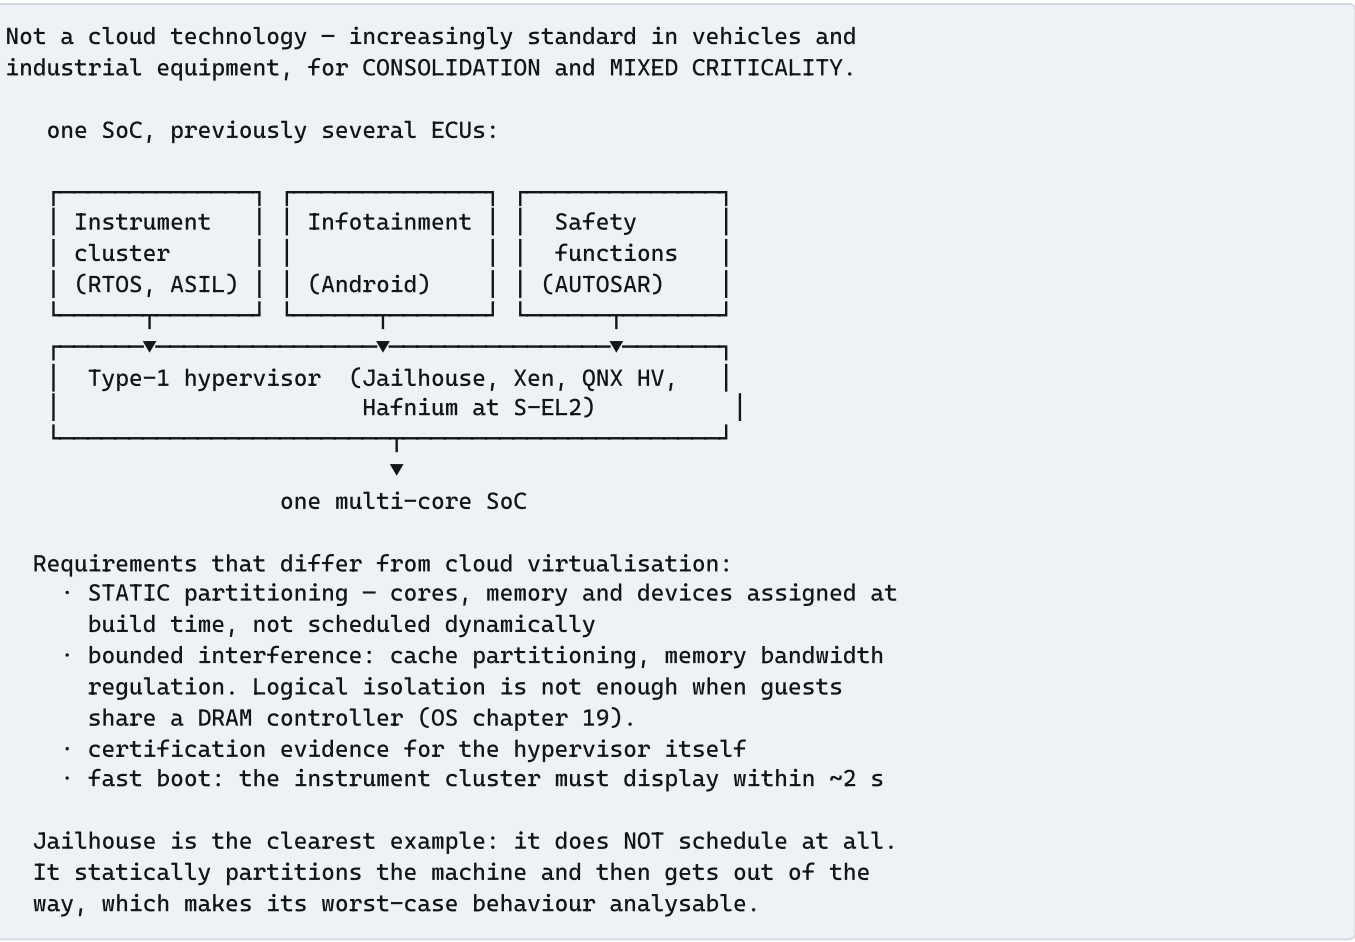
/* 4. no_new_privs — setuid binaries cannot regain privilege */
prctl(PR_SET_NO_NEW_PRIVS, 1, 0, 0, 0);

/* 5. USER NAMESPACES — root in the container maps to an
      unprivileged host UID. Even a container escape lands as
      nobody. This is the strongest single control, and what
      rootless Podman is built on.                          */
podman run --userns=keep-id ...
```

The middle ground

Technology	Idea	Trade-off
Kata Containers	Each container runs in a lightweight VM	Container UX, VM isolation; ~100 ms extra startup
Firecracker	A minimal VMM — ~50 K lines, five emulated devices	~125 ms boot, ~5 MB overhead. Powers AWS Lambda.
gVisor	A user-space kernel intercepting syscalls	Small kernel attack surface; syscall overhead and imperfect compatibility
WebAssembly	A sandboxed bytecode VM with capability-based I/O (WASI)	Microsecond startup, tiny images; a restricted programming model
Unikernel	The application linked with only the OS functions it needs	Minimal surface, fast boot; hard to debug and operate

Virtualisation in embedded systems



What each approach costs

	Process	Container	VM	Unikernel
Startup	~1 ms	~50–500 ms	~1–30 s (Firecracker ~125 ms)	~10 ms
Memory overhead	None	Negligible	Guest kernel + VMM, ~100 MB+	~1–10 MB
CPU overhead	None	Negligible	2–10%, more with emulated I/O	Low
Isolation strength	MMU only	Kernel-enforced; shared kernel	**Hardware-enforced**	Hypervisor-enforced
Different OS?	No	No — same kernel	**Yes**	N/A
Density	Thousands	Hundreds	Tens	Hundreds

How it shows up

Symptom	Cause
App sees 64 CPUs inside a 2-CPU container	`/proc/cpuinfo` is not namespaced; read the cgroup limits
Container OOM-killed with free host memory	The cgroup limit, not machine memory
Container CPU throttled at low utilisation	`cpu.max` quota exhausted within the period; check `cpu.stat`
Emulated network in a VM is very slow	Full device emulation; switch to virtio
Passthrough device fails to attach	No IOMMU enabled, or the device shares an IOMMU group
Guest crashes only under memory pressure	Host overcommit and ballooning

Symptom	Cause
`uname -r` in a container shows the host kernel	Correct — containers share the kernel
Container escape via a kernel bug	The shared-kernel trade-off; use a VM for untrusted code
RT guest misses deadlines despite dedicated cores	Shared memory bandwidth or cache; needs partitioning
Nested virtualisation is very slow	Each level multiplies trap cost

Check yourself

- ✓ Order process, container and VM isolation by strength and name the shared component in each.
- ✓ Name the three things a hypervisor must virtualise and how each is done on ARM.
- ✓ Walk through a trapped MMIO access from guest instruction to `ERET`.
- ✓ Compare emulation, paravirtualisation and passthrough on cost and guest requirements.
- ✓ Explain why passthrough requires an IOMMU.
- ✓ Explain what a container actually is in kernel terms.
- ✓ Name five namespaces and what each isolates.
- ✓ Give three consequences of containers sharing the host kernel.
- ✓ Say why embedded virtualisation favours static partitioning.

TRACK COMPLETE

That closes the operating systems track: what an OS is, kernel architectures, system calls, processes and threads, scheduling and context switching, IPC, synchronisation and deadlock, memory management and paging, filesystems and storage, the I/O subsystem, interrupts and time, boot, real-time, and virtualisation.

Next is the ARM architecture track — 35 chapters taking the concepts from computer architecture and operating systems down to the actual registers, page table descriptors, barriers and exception vectors of a real machine.

TRACK

Concurrency & multithreading

What actually happens when two things run at once: the hardware reordering underneath you, the primitives that tame it, and the bugs that only appear on the third Tuesday in production.

20 chapters

Why concurrency exists, and what it costs

Concurrency is not a feature you add for speed. It is a structural decision that buys you three specific things and charges you in a currency — correctness you can no longer verify by reading the code — that most teams underestimate until the first bug that only reproduces in production.

The three reasons, and only three

```
1. LATENCY HIDING - something is slow and not the CPU

     thread A: read from disk ................. 10 ms
     thread B: meanwhile, do actual work

   This is why servers are threaded. It has nothing to do
   with having more cores; a single core wins here too,
   because the alternative is a CPU sitting idle.

2. THROUGHPUT - the work genuinely divides

     8 cores, 8 independent chunks -> up to 8x

   This is the only reason that needs multiple cores, and
   the only one where Amdahl's law bites.

3. STRUCTURE - the problem IS concurrent

     a UI that must stay responsive while working
     a device that raises interrupts whenever it likes
     ten clients that arrive independently

   Here concurrency is not an optimisation. Modelling these
   sequentially produces worse code, not faster code.

IF YOUR REASON IS NOT ON THIS LIST, do not add threads.
"It felt like it should be faster" is not a reason, and
parallel code that is slower than the serial version is the
single most common outcome of a first attempt.
```

CONCURRENCY IS NOT PARALLELISM

Concurrency is a way to structure a program: several independent activities, whose execution may interleave. **Parallelism** is executing several things at literally the same instant, which needs hardware. A single-core machine can be highly concurrent and not at all parallel. Reasons 1 and 3 above are concurrency; reason 2 is parallelism. Confusing them is why people expect a thread pool to speed up a program that was waiting on a network socket.

What the speed-up is actually bounded by

```
/* Amdahl's law. If a fraction p of a program can be
   parallelised and the rest cannot:                        */

        speedup(N) = 1 / ( (1 - p) + p/N )

   p = 0.95, N = 8   ->  5.9x     (not 8x)
   p = 0.95, N = 32  ->  12.5x
   p = 0.95, N = INF ->  20x      <-- the ceiling, for ever

   p = 0.50, N = INF ->  2x

/* The 5% you did not parallelise caps you at 20x no matter
   how many cores you buy. And "the rest" includes things
   people forget to count:

     - process startup and teardown
     - reading the input, writing the output
     - the lock everyone contends on
     - the memory allocator
     - the one std::cout in the inner loop

   Gustafson's law is the optimistic counterpart: if you scale
   the PROBLEM with the machine rather than fixing it, the
   serial fraction shrinks in relative terms and the ceiling
   moves. Both are true. Amdahl describes making a fixed job
   faster; Gustafson describes doing a bigger job in the same
   time. Know which one you are actually doing.               */
```

The bill

Cost	What it looks like
Correctness stops being local	A function that is correct on its own can be wrong when two threads call it. You can no longer verify code by reading it in isolation, which is the single biggest cost and the hardest to price
Bugs become non-deterministic	A race that fires once in 10^8 iterations appears weekly in production and never on your laptop. "Cannot reproduce" becomes a normal state
Tests stop proving things	A passing test means "this interleaving worked", not "the code is correct". See chapter 20 for what to do instead
Memory traffic multiplies	Two threads writing near each other can be *slower* than one thread doing all the work — false sharing
Synchronisation is not free	An uncontended mutex is ~20 ns; a contended one that sleeps is ~1–10 µs. Lock a mutex per element of a million-element loop and you have written something slower than the serial version by an order of magnitude
Latency gets a tail	Average throughput improves; the 99.9th percentile gets worse, because now there is queueing and there are lock convoys
Debugging tools stop helping	A breakpoint changes the timing and the bug goes away. `printf` is a memory barrier and a syscall

```
/* Rough costs on a modern out-of-order core. Ratios, not
   measurements - benchmark your own platform.              */

  an L1 cache hit ........................   ~1 ns
  an uncontended atomic increment ........   ~5-20 ns
  an uncontended mutex lock + unlock .....   ~20 ns
  a cache line bouncing between two cores ..  ~50-200 ns
  a contended mutex that must sleep ......   ~1-10 us
  a thread context switch ................   ~1-5 us
  creating a thread ......................   ~10-100 us
  a condition-variable wake-up ...........   ~5-50 us

/* The two lines worth memorising:

   * creating a thread costs about as much as 10,000 mutex
     operations. This is why thread POOLS exist (chapter 17).

   * moving a cache line between cores costs more than a
     hundred arithmetic operations. This is why data layout
     decides parallel performance more often than algorithm
     choice does (chapter 16).                               */
```

THE MOST COMMON FIRST MISTAKE

Taking a loop, splitting it across eight threads, and finding it runs slower. Almost always one of three causes: the threads are contending on a shared counter or allocator; they are writing to adjacent memory and bouncing a cache line; or the work per item is smaller than the synchronisation cost. All three are covered later in this track, and all three are invisible in the source code.

The models you will meet

Model	Idea	Where it wins
Shared memory + locks	Threads see the same memory; mutexes keep them out of each other's way	The default in C, C++, Java, Rust. Fast, and the easiest to get subtly wrong
Message passing	No shared state; send values down channels	Go, Erlang, Rust channels. Whole bug classes vanish; copying costs
Event loop	One thread, a queue of callbacks, never block	Node.js, embedded superloops, GUI toolkits. No data races by construction; one slow callback stalls everything
async/await	Cooperative tasks that yield at explicit points	Rust, C#, Python. Millions of concurrent waits on a few threads (chapter 18)
Data parallel	One operation over a large array, split automatically	SIMD, OpenMP, GPUs. See the GPU track
Interrupt-driven	Hardware preempts you at any instruction	Every embedded system, whether you chose it or not

THE EMBEDDED CASE IS NOT OPTIONAL

Even a bare-metal program with no threads is concurrent: an interrupt can fire between any two instructions, and the handler shares memory with the code it interrupted. Everything in this track about races, atomicity and memory ordering applies, minus the scheduler. If you have ever written `volatile` hoping it would fix something, chapters 11 and 12 are for you.

Why it is hard, specifically

```
Two threads run this. `counter` starts at 0.

    counter = counter + 1;

One line. It compiles to three operations:

    LDR  w0, [counter]      // read
    ADD  w0, w0, #1         // modify
    STR  w0, [counter]      // write

An interleaving that loses an increment:

  thread A          thread B          counter
  --------          --------          -------
  LDR  -> 0                              0
                    LDR  -> 0            0
  ADD  -> 1                              0
                    ADD  -> 1            0
  STR                                    1
                    STR                  1     <-- should be 2

Now note three things that make this worse than it looks:

1. This interleaving is RARE. The window is nanoseconds.
   Your test passes ten million times and fails in
   production.

2. The compiler may keep `counter` in a register across the
   whole loop, so the write happens ONCE, at the end.

3. The hardware may reorder your loads and stores relative
   to other variables entirely (chapter 12).

Points 2 and 3 mean you cannot reason about concurrency by
reading the source at all. You are reasoning about a
contract between you, the compiler and the CPU - and that
contract is the memory model.
```

Rules that survive contact with real systems

1. **Do not share what you can copy.** The cheapest synchronisation is the kind you deleted. Give each thread its own data and merge at the end.

2. **Do not communicate by sharing memory; share memory by communicating.** Go's slogan, and it is right far more often than shared-mutable-state advocates admit.

3. **Immutable data needs no locks.** If nothing writes after publication, every reader is safe for free.

4. **One lock, one clearly named invariant.** If you cannot state in a sentence what a lock protects, nobody can use it correctly, including you in six months.

5. **Measure before and after.** Parallel code that is not faster is strictly worse than serial code, and you will not know which you have without a number.

6. **Prefer coarse locking first.** One big lock that is correct beats fine-grained locking that is subtly wrong. Make it correct, measure, then split only what the profile demands.

What this track assumes and what it adds

The operating systems track already introduced threads, synchronisation primitives and deadlock as OS concepts. The C++ and Rust tracks cover their respective language models. This track is the practitioner's version: what the hardware really does, which primitive to reach for and why, the failure modes that only appear under load, and how to find them deliberately rather than by waiting.

How it shows up

Symptom	Cause
Parallel version is slower than serial	Contention, false sharing, or work per item smaller than the sync cost
Speed-up plateaus at 4x on 32 cores	Amdahl — the serial fraction, often the allocator or the I/O
Works on your laptop, fails on the server	More cores, different timing, a wider window for the race
Fails only in release builds	The optimiser hoisted a load out of a loop that had no barrier
Adding a `printf` makes it work	The syscall is a barrier and a scheduling point — the bug is real and you have just hidden it
Average latency improved, p99 got much worse	Queueing and lock convoys
A counter is slightly wrong under load	Non-atomic read-modify-write
Hangs once a week with no CPU usage	Deadlock (chapter 14)
Hangs once a week at 100% CPU	Livelock, or a spin that never yields

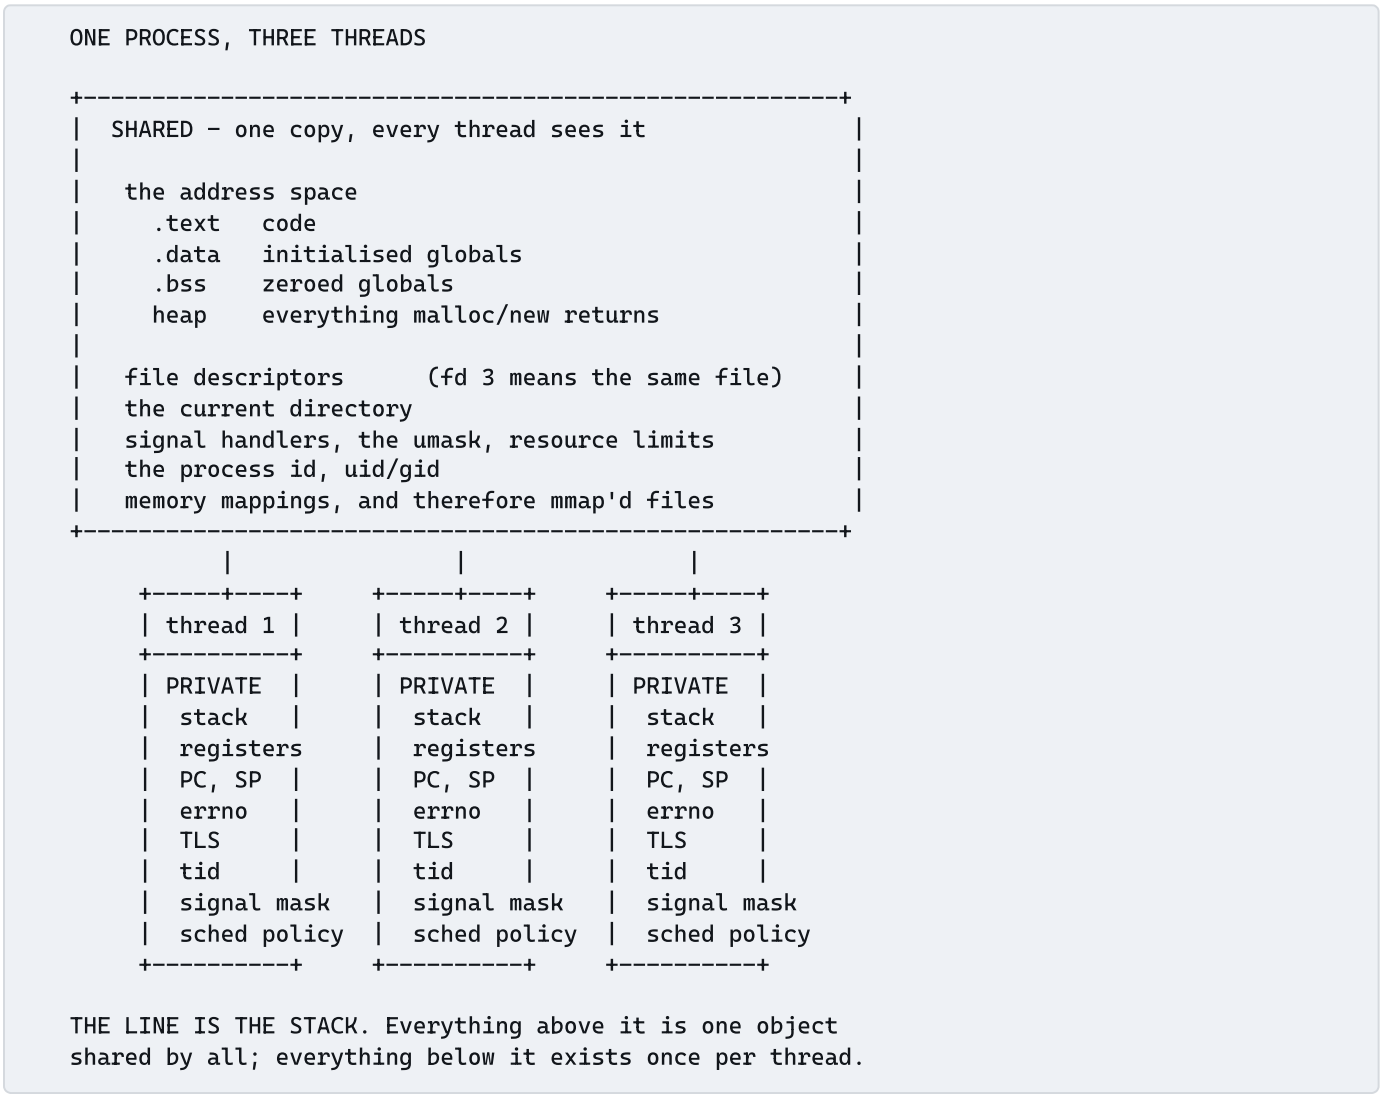
Check yourself

- ✓ Give the three legitimate reasons to introduce concurrency, and a real example of each.
- ✓ Distinguish concurrency from parallelism and say which one a single-core machine can offer.
- ✓ State Amdahl's law and compute the ceiling for `p = 0.9`.
- ✓ Name three costs of concurrency that do not appear in a profiler.
- ✓ Order these by cost: thread creation, uncontended mutex, cache-line transfer, atomic increment.
- ✓ Explain why creating a thread per work item is usually wrong.
- ✓ Show the interleaving that loses an increment, and name two further reasons source-level reasoning fails.
- ✓ Name four concurrency models and one system that uses each.
- ✓ Explain why a bare-metal program with interrupts is concurrent.
- ✓ State the six rules, and say which one you would break first under deadline pressure — and what it would cost.

Threads, and exactly what they share

Every concurrency bug is ultimately a disagreement about what is shared. This chapter draws the line precisely — what one thread can see of another's state, what it cannot, and the handful of per-thread things people assume are private and are not.

The picture



"PRIVATE" MEANS "NOT SHARED BY DEFAULT", NOT "UNREACHABLE"

A thread's stack is ordinary memory in the same address space. Pass a pointer to a local variable to another thread and it can read and write it — there is no hardware boundary. Stack-private is a *convention* the compiler relies on, not a protection. Which is why returning a pointer to a local, or handing one to a thread that outlives the frame, is a use-after-free with extra steps.

The things people get wrong

Thing	Shared or private?	Why it surprises people
`errno`	**Private**	It looks like a global. It is a macro expanding to `(*__errno_location())`, which is thread-local. This was fixed decades ago and people still expect the old behaviour
File descriptors	**Shared**	Including the *file offset*. Two threads doing `read()` on the same fd interleave and each gets part of the data. Use `pread` / `pwrite`
The heap	**Shared**	Which is why `malloc` must be thread-safe, and why it is often a contention point (chapter 16)
Signal handlers	**Shared** (the disposition)	But the signal *mask* is per-thread, and which thread receives a process-directed signal is unspecified
The current working directory	**Shared**	One thread calling `chdir()` changes every other thread's relative paths, mid-operation
The FPU / SIMD registers	**Private**	Saved and restored per thread — but on some embedded targets only if the kernel was built to do so
`static` locals in a function	**Shared**	The classic accidental global. `static char buf[256]` inside a helper makes that helper unusable concurrently
Anything returning a pointer to internal state	**Shared**	`strtok`, `asctime`, `gethostbyname`… the `_r` suffix exists for exactly this reason
C++ function-local `static` init	Shared, but **thread-safe since C++11**	The compiler emits a guard. It is safe, and it is also a hidden lock in your hot path

```
/* The static-buffer bug, which every codebase has once. */

const char *format_id(int id)
{
        static char buf[32];              /* SHARED. Disaster. */
        snprintf(buf, sizeof buf, "id-%d", id);
        return buf;
}

/* Two threads:
     A: format_id(1)  -> writes "id-1"
     B: format_id(2)  -> overwrites with "id-2"
     A: prints buf    -> "id-2"

   No crash. No sanitiser hit unless you look for it. Just
   quietly wrong output, occasionally, under load.

   THREE FIXES, in order of preference:                     */

/* 1. Caller owns the buffer. Boring, obvious, always right. */
void format_id_r(int id, char *out, size_t n)
{
        snprintf(out, n, "id-%d", id);
}

/* 2. Thread-local storage. Works, but the lifetime rules are
      now subtle and each thread pays for the buffer.        */
const char *format_id_tls(int id)
{
        static _Thread_local char buf[32];   /* C11          */
        snprintf(buf, sizeof buf, "id-%d", id);
        return buf;
}

/* 3. Allocate and make the caller free it. Correct, and now
      you have an allocation in a hot path.                  */
```

Thread-local storage

```
/* One name, one variable per thread, resolved at access. */

  C11         _Thread_local int depth;
  C++11       thread_local int depth;
  GCC/Clang   __thread int depth;          /* older, faster,
                                              no destructors */
  POSIX       pthread_key_create(&key, dtor);
              pthread_setspecific(key, p);
              pthread_getspecific(key);
  Windows     __declspec(thread) int depth;
              TlsAlloc/TlsGetValue/TlsSetValue

/* WHAT IT IS FOR

     per-thread scratch buffers
     per-thread random-number state
     a "current transaction" or "current request" pointer
     recursion depth counters, logging context
     per-thread allocator caches - this is how modern mallocs
       avoid a global lock

   WHAT IT COSTS

     * access is not free: often a register read plus an
       offset, sometimes a function call (__tls_get_addr) for
       dynamically loaded modules
     * every thread pays the memory, even threads that never
       touch it
     * destructors run at thread exit - but NOT if the thread
       is killed, and not for the main thread on some
       platforms
     * it is invisible shared-nothing state, which makes code
       hard to reason about and impossible to move between
       threads

   THE TRAP: thread_local in a THREAD POOL is per-WORKER, not
   per-TASK. Task 1 leaves state behind that task 2 sees, and
   the two tasks are unrelated. If you use TLS for request
   context in a pool, you must clear it on every task
   boundary (chapter 17).                                  */
```

STACK SIZE IS A REAL CONSTRAINT, AND THE DEFAULT IS NOT WHAT YOU THINK

Linux gives a pthread 8 MB by default (`ulimit -s`), Windows gives 1 MB reserved, and an RTOS gives you whatever you asked for — often 512 bytes. Spawn a thousand threads on Linux and you have reserved 8 GB of address space; it is virtual and mostly unbacked, but on a 32-bit target it is fatal. Meanwhile a deep recursion or a large local array on an embedded target silently runs off the end of a small stack and corrupts whatever is next in RAM. Set it deliberately with `pthread_attr_setstacksize`.

What "shared" means for the compiler

```
/* Sharing is not just about which memory two threads can
   reach. It is about what the COMPILER is allowed to assume.

   In single-threaded code the compiler may assume nothing
   else changes memory. That assumption is what makes
   optimisation possible - and it is exactly wrong under
   concurrency.                                          */

int flag = 0;

void waiter(void)
{
        while (!flag)          /* the compiler sees no writes  */
                ;              /* to `flag` in this loop, so   */
        do_work();             /* it may hoist the load OUT:   */
}

/*     if (!flag) for (;;) ;    <- an infinite loop, legally  */

/* `volatile` stops that hoist, and does NOTHING ELSE:
     - it does not make the access atomic
     - it does not order it against other accesses
     - it does not stop the CPU reordering

   volatile is for memory-mapped registers and for variables
   changed by a signal handler on the SAME thread. It is not a
   concurrency tool, and treating it as one is the second most
   common mistake in this whole track.

   The right answer is an atomic with an ordering:           */

#include <stdatomic.h>
atomic_int flag = 0;

void waiter(void)
{
        while (!atomic_load_explicit(&flag, memory_order_acquire))
                ;
        do_work();       /* now guaranteed to see the writes
                            the setter made before storing    */
}

/* Chapters 11 and 12 are entirely about that last guarantee. */
```

Threads below user space

```
The same word means different things at different levels.

USER THREAD (pthread, std::thread, HANDLE)
  scheduled by the kernel, has a kernel task behind it.
  On Linux, 1:1 - one pthread is one task_struct.

KERNEL THREAD (kthread)
  lives entirely in the kernel, no user address space.
  Workqueues, kswapd, ksoftirqd (Linux chapter 14).

INTERRUPT CONTEXT
  not a thread at all. Cannot sleep, cannot take a mutex,
  borrowed the stack of whatever it interrupted. Everything
  in this track applies, but only the primitives that do
  not sleep are legal - spinlocks, atomics.

HARDWARE THREAD (SMT / hyperthreading)
  two architectural register sets sharing one core's
  execution units. To software it is two CPUs; to the cache
  it is one. Two "parallel" threads on one core's siblings
  share L1 and can contend invisibly.

FIBER / COROUTINE / GREEN THREAD
  scheduled in USER SPACE, no kernel involvement. Cheap to
  switch, cannot use more than one core by itself, and a
  blocking syscall stalls every one of them (chapter 18).

Knowing which of these you have decides which primitives
are legal. Taking a sleeping mutex in interrupt context is
not slow - it is a kernel bug that panics.
```

How it shows up

Symptom	Cause
A function returns another thread's data	A `static` buffer inside it
Two threads reading one file each get half the data	Shared fd, shared offset — use `pread`
Relative paths break intermittently	Another thread called `chdir`
A signal is handled by the wrong thread	Process-directed signals go to any thread that has not masked them
Stack corruption on an embedded target	Default thread stack far smaller than the locals in use
Address space exhausted with a few thousand threads	8 MB reserved per thread on a 32-bit build
Request context leaks between unrelated requests	`thread_local` in a thread pool, not cleared per task
A polling loop never exits in release builds	Non-atomic flag; the load was hoisted out of the loop
`volatile` "fixed" a race, then it came back	It never fixed it — it changed the timing
Kernel panic taking a mutex in an interrupt	Sleeping primitive in non-sleepable context

Check yourself

- ✓ List what threads in one process share and what is per-thread, from memory.
- ✓ Explain why a thread's stack is "private" but not protected.

- ✓ Say whether `errno` is shared, and how that is implemented.
- ✓ Explain what goes wrong when two threads `read()` the same descriptor.
- ✓ Find the `static` buffer bug in a function and give three fixes, ranked.
- ✓ Give three good uses for thread-local storage and one trap it creates in a thread pool.
- ✓ State the default thread stack size on Linux and on Windows, and why it matters at scale.
- ✓ Explain precisely what `volatile` does and what it does not.
- ✓ Show why a non-atomic polling loop can become an infinite loop after optimisation.
- ✓ Distinguish a user thread, a kernel thread, interrupt context, an SMT sibling and a coroutine, and say which synchronisation primitives are legal in each.

Creating, joining and cancelling threads

Starting a thread is three lines in any language. Ending one correctly is where the bodies are buried: lifetimes that outlive the data they point at, detached threads still running during static destruction, and cancellation, which is almost always the wrong tool.

The same idea, four spellings

```
/* POSIX */
#include <pthread.h>

static void *worker(void *arg)
{
        int id = *(int *)arg;
        printf("worker %d\n", id);
        return (void *)(intptr_t)(id * 2);      /* the result  */
}

int main(void)
{
        pthread_t t;
        int id = 7;

        /* &id is a pointer to a LOCAL. Safe only because we
           join before main's frame goes away. See below.     */
        if (pthread_create(&t, NULL, worker, &id) != 0)
                return 1;      /* returns errno, does NOT set it */

        void *ret;
        pthread_join(t, &ret);
        printf("result %d\n", (int)(intptr_t)ret);
        return 0;
}
```

```
// C++11 and later - the same thing, with types and RAII
#include <thread>
#include <future>

int worker(int id) { return id * 2; }

int main()
{
    std::thread t(worker, 7);   // arguments are COPIED by value
    t.join();                   // or t.detach() - one or the
                                // other, or std::terminate

    // When you want a result, do not hand-roll it:
    std::future<int> f = std::async(std::launch::async, worker, 7);
    int result = f.get();       // blocks, and rethrows any
                                // exception the worker threw
}

// std::jthread (C++20) joins in its destructor and carries a
// stop_token. It is what std::thread should have been.
#include <stop_token>
std::jthread jt([](std::stop_token st) {
    while (!st.stop_requested()) { /* work */ }
});
// no join needed: the destructor requests stop, then joins.
```

```
// Rust - the lifetime problem solved by the type system
use std::thread;

let data = vec![1, 2, 3];
let h = thread::spawn(move || {          // `move` transfers
    data.iter().sum::<i32>()             // ownership in
});                                      // -- no dangling
let total: i32 = h.join().unwrap();      // possible

// Borrowing across threads needs a SCOPE, which guarantees
// the threads end before the borrow does (Rust 1.63+):
let v = vec![1, 2, 3];
thread::scope(|s| {
    s.spawn(|| println!("{:?}", &v));    // borrow is fine:
    s.spawn(|| println!("{}", v.len())); // scope joins all
});                                      // before returning
```

```
/* Windows */
#include <windows.h>
#include <process.h>

static unsigned __stdcall worker(void *arg)
{
        return (unsigned)(uintptr_t)arg * 2;
}

int main(void)
{
        /* _beginthreadex, NOT CreateThread, for anything that
           touches the CRT: it allocates the per-thread CRT
           state that errno, strtok and friends need.         */
        uintptr_t h = _beginthreadex(NULL, 0, worker,
                                     (void *)(uintptr_t)7, 0, NULL);
        WaitForSingleObject((HANDLE)h, INFINITE);

        DWORD code = 0;
        GetExitCodeThread((HANDLE)h, &code);
        CloseHandle((HANDLE)h);        /* a HANDLE is a resource;
                                          leaking it leaks the
                                          thread object          */
        return 0;
}
```

JOIN OR DETACH — THERE IS NO THIRD OPTION

Every thread you create holds resources until someone collects it. `join` waits and collects; `detach` says "collect yourself when you finish". Do neither and you leak a thread control block per thread, which on a long-running server is a slow death. C++ chose to make this loud: `~std::thread` on a joinable thread calls `std::terminate`, deliberately, so the bug is a crash rather than a leak.

The lifetime bug

```
THE MISTAKE

  void start(void)
  {
          int id = 7;                     // on start's stack
          pthread_t t;
          pthread_create(&t, NULL, worker, &id);
          pthread_detach(t);
  }                                       // frame destroyed
                                          // HERE
  worker() now reads &id -> whatever the next call put there

The window is tiny and the value is often still correct,
which is what makes it survive testing.

THREE FIXES

1. JOIN before the frame ends.
     pthread_join(t, NULL);   // id is alive until here

2. HEAP-ALLOCATE the argument, worker frees it.
     struct arg *a = malloc(sizeof *a);
     a->id = 7;
     pthread_create(&t, NULL, worker, a);
     // worker: ... free(a);
     // and if pthread_create FAILS, free it yourself

3. PASS BY VALUE where the API allows.
     pthread_create takes void*, so you can smuggle an int:
     pthread_create(&t, NULL, worker, (void *)(intptr_t)7);
     Legal, ugly, and it does not scale past one small value.

C++ picks fix 3 by default - std::thread COPIES its
arguments - which is why passing a reference needs the
explicit std::ref(), and why doing so reintroduces the bug.

Rust picks fix 1 and 2 and makes the compiler check, which
is the entire point of `move` and thread::scope.
```

Cancellation, and why you should not

```
/* POSIX cancellation exists. Almost every use of it is wrong. */

    pthread_cancel(t);          /* politely ask                */

/* What actually happens depends on two per-thread settings:

     PTHREAD_CANCEL_DEFERRED   (default)
       the thread dies at the next CANCELLATION POINT - a list
       of ~100 functions including read, write, sleep, wait,
       printf, malloc-sometimes. Between them it is immune.

     PTHREAD_CANCEL_ASYNCHRONOUS
       the thread dies at literally any instruction. Which
       means it can die holding a mutex, halfway through a
       malloc, with a file half-written. Almost nothing is
       async-cancel-safe. Do not use this.

   Even deferred cancellation leaves you needing cleanup
   handlers for every resource:                              */

static void *worker(void *arg)
{
        char *buf = malloc(1024);
        pthread_cleanup_push(free, buf);       /* runs on cancel */

        pthread_mutex_lock(&m);
        pthread_cleanup_push(unlock_helper, &m);

        read(fd, buf, 1024);                   /* cancellation
                                                  point         */
        pthread_cleanup_pop(1);                /* unlock         */
        pthread_cleanup_pop(1);                /* free           */
        return NULL;
}

/* And in C++ this is worse than it looks: on glibc, cancellation
   is implemented by throwing a special exception through your
   frames. A `catch (...)` that does not rethrow swallows it and
   the thread refuses to die.                                    */
```

USE A STOP FLAG INSTEAD. ALWAYS.

Cooperative cancellation is simpler, portable, testable and correct: an atomic flag the worker checks at points *it* chooses, so it is never interrupted mid-invariant. Every modern design does this — `std::stop_token`, Rust channels, Go's `context`, .NET's `CancellationToken`. The only thing `pthread_cancel` gives you is the ability to interrupt a blocking syscall, and the right answer there is a self-pipe, an `eventfd`, or a timeout.

```
/* The pattern to use, in full. */

struct worker {
        atomic_bool     stop;
        int             wake_fd[2];   /* self-pipe            */
        pthread_t       tid;
};

static void *run(void *arg)
{
        struct worker *w = arg;
        struct pollfd fds[2] = {
                { .fd = w->sock,        .events = POLLIN },
                { .fd = w->wake_fd[0],  .events = POLLIN },
        };

        while (!atomic_load_explicit(&w->stop, memory_order_relaxed)) {
                if (poll(fds, 2, -1) < 0) {
                        if (errno == EINTR) continue;
                        break;
                }
                if (fds[1].revents)      /* woken to stop      */
                        break;
                handle(w->sock);         /* never interrupted
                                            mid-operation       */
        }
        cleanup(w);                      /* ordinary code, no
                                            cleanup handlers    */
        return NULL;
}

void worker_stop(struct worker *w)
{
        atomic_store_explicit(&w->stop, true, memory_order_relaxed);
        write(w->wake_fd[1], "x", 1);    /* break the poll     */
        pthread_join(w->tid, NULL);      /* and WAIT for it    */
}

/* The join at the end is not optional. "I set the flag" is not
   "it has stopped", and shutting down while a worker still
   touches your data is the commonest shutdown crash there is. */
```

Shutdown order

```
The rule: a thread must not outlive anything it points at.

BAD, and extremely common:

  main() returns
    -> static destructors run
    -> a detached worker wakes up
    -> touches a logger that no longer exists
    -> crash during exit, in a stack trace that makes no
       sense because the frames are gone

THE ORDER THAT WORKS

  1. tell every worker to stop        (set flags, wake them)
  2. JOIN every worker                (now none are running)
  3. tear down what they used         (queues, loggers, pools)
  4. return from main

Steps 1 and 2 are separate for a reason: signalling all of
them before joining any of them means shutdown takes as long
as the slowest worker, not the sum of all of them.

AND NOTE: detached threads cannot be joined, so a design
with detached threads has NO correct shutdown. That is the
real argument against detach - not the leak.
```

How it shows up

Symptom	Cause
Worker sees a garbage argument, occasionally	Pointer to a caller's local; the frame is gone
`std::terminate` at a scope exit	A joinable `std::thread` destroyed
Thread count grows until the process dies	Threads neither joined nor detached
`pthread_create` returns 11 (EAGAIN)	Out of threads or address space — check `ulimit -u` and the stack size
Crash during process exit, in destructor code	A detached thread still running past static destruction
Cancelled thread never dies	It never reaches a cancellation point, or a `catch(...)` swallowed the unwind
Deadlock after cancelling a thread	It died holding a mutex
`errno` or `strtok` misbehaves on Windows	`CreateThread` instead of `_beginthreadex` — no CRT state
Shutdown takes N × the worker timeout	Signalling and joining one worker at a time instead of all, then all
Handle leak on Windows	`CloseHandle` not called on the thread handle

Check yourself

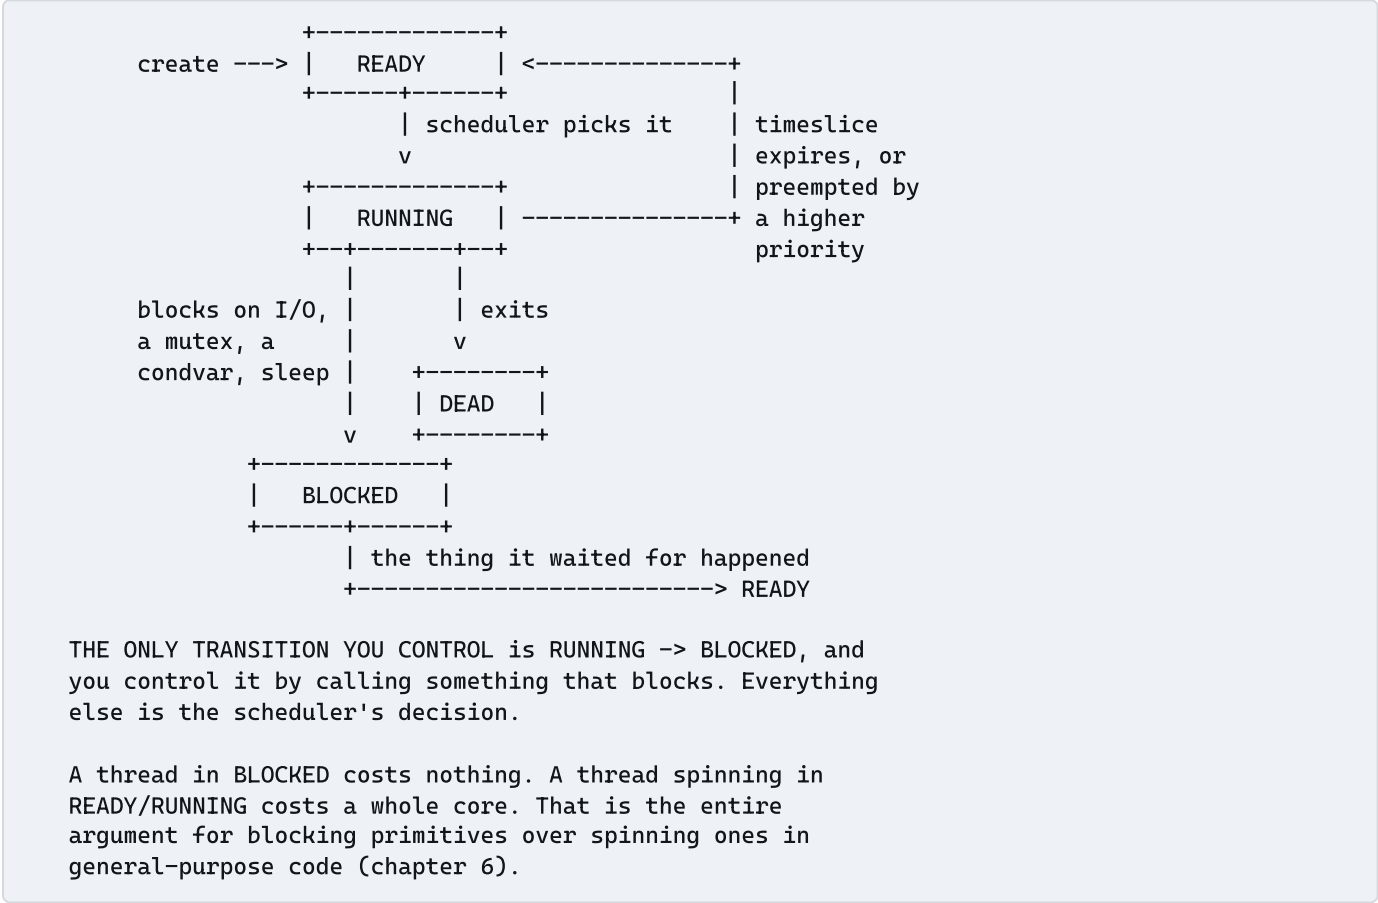
- ✓ Write thread creation and join in POSIX, C++ and Rust from memory.
- ✓ Explain why every thread must be joined or detached, and what C++ does if you do neither.
- ✓ Show the argument-lifetime bug and give three fixes, saying which language picks which.
- ✓ Explain what `std::jthread` adds over `std::thread`.
- ✓ Say why `_beginthreadex` is preferred to `CreateThread`.

- ✓ Describe deferred versus asynchronous cancellation and why the latter is unusable.
- ✓ Write the stop-flag-plus-self-pipe pattern and say why the join at the end is required.
- ✓ Give the four-step shutdown order and explain why signalling and joining are separate phases.
- ✓ Explain why a design built on detached threads has no correct shutdown.

How the scheduler decides who runs

You do not control when your threads run. Understanding the policy that does — and the four or five knobs you are actually allowed to turn — is the difference between tuning a system and superstitiously adding `sleep(0)` until the symptom moves.

The state machine



Policies you can actually choose

Policy	Behaviour	Use it when
`SCHED_OTHER` / CFS	Fair-share by weight. Every runnable thread makes progress; `nice` adjusts the share	Default. Almost always right
`SCHED_FIFO`	Real-time. Runs until it blocks or yields. A higher-priority FIFO thread preempts instantly and **never** gives the CPU back on its own	Hard deadlines, and only with a bounded work loop
`SCHED_RR`	FIFO plus a timeslice among equal priorities	Several equal-priority real-time threads
`SCHED_DEADLINE`	You declare (runtime, deadline, period); the kernel admits you or refuses	Periodic real-time work where you can state the budget
`SCHED_IDLE`	Runs only when nothing else wants the CPU	Background scrubbing, prefetch
`SCHED_BATCH`	CFS, but assumed non-interactive; fewer preemptions	Long compute jobs where throughput beats latency

```
/* Setting a real-time policy. Needs CAP_SYS_NICE or root, and
   a rlimit (RLIMIT_RTPRIO) that allows it.                    */

#include <pthread.h>
#include <sched.h>

int make_realtime(pthread_t t, int prio)
{
        struct sched_param p = { .sched_priority = prio };
        /* prio 1..99 for FIFO/RR; higher number = higher
           priority, the opposite of `nice`.                  */
        return pthread_setschedparam(t, SCHED_FIFO, &p);
}

/* THE FOOTGUN, and it is a big one:

   A SCHED_FIFO thread that busy-loops on a single-core system
   locks the machine. Nothing else - not your shell, not the
   watchdog - will ever run. Linux ships a safety valve:

     /proc/sys/kernel/sched_rt_runtime_us  = 950000
     /proc/sys/kernel/sched_rt_period_us   = 1000000

   which caps all real-time threads at 95% of each second so
   you can still get a shell. Turn that off (set runtime to -1)
   only if you are certain, and keep a serial console.

   THE RULE FOR SCHED_FIFO: the loop body must be bounded and
   must end in a blocking call. If it can spin, it will.     */
```

PRIORITY IS NOT URGENCY

Raising a thread's priority does not make it faster; it makes it *starve everything below it*. On a loaded system that is usually how you turn a latency problem into an unresponsive machine. Before reaching for priorities, check whether the thread is actually runnable — a thread blocked on I/O gains nothing from being important. And a high-priority thread that takes a lock a low-priority thread holds gets priority inversion, which is worse than the original problem.

Affinity, and why the scheduler moves you

```
/* By default a thread may run on any CPU, and the scheduler
   WILL move it to balance load. That migration costs you:
   cold L1, cold L2, cold TLB, and possibly a different NUMA
   node from your memory.                                    */

#define _GNU_SOURCE
#include <sched.h>

void pin_to(int cpu)
{
        cpu_set_t set;
        CPU_ZERO(&set);
        CPU_SET(cpu, &set);
        sched_setaffinity(0, sizeof set, &set);   /* 0 = self  */
}

# From the shell:
$ taskset -c 2,3 ./myapp          # start pinned
$ taskset -cp 2 1234              # pin a running thread
$ numactl --cpunodebind=0 --membind=0 ./myapp

# See where threads actually ran:
$ ps -eLo pid,tid,psr,comm | grep myapp
$ perf stat -e migrations,context-switches ./myapp

/* WHEN PINNING HELPS
     - real-time threads that must not be migrated
     - one thread per core, no oversubscription, cache-heavy
     - NUMA: keeping a thread on the node holding its memory
     - isolating a latency-critical thread with isolcpus /
       nohz_full so the kernel stops interrupting it

   WHEN IT HURTS
     - you pinned two hot threads to SMT siblings of one core
       and they now fight over one L1
     - you pinned everything and the scheduler can no longer
       balance a load you did not predict
     - a pinned thread blocks and its core idles while another
       core has a run queue three deep

   Measure. Pinning is one of the few tuning knobs that is
   just as likely to hurt as help.                           */
```

Yielding, sleeping, and spinning

```
/* Four ways to give up the CPU, and only two are usually right. */

  sched_yield()           "I am still ready; run someone else."
                          Under CFS this often means the
                          scheduler picks YOU again immediately,
                          because you still have the most
                          credit. As a synchronisation tool it
                          is a coin flip. Legitimate use: a
                          spin-wait's back-off path, and little
                          else.

  nanosleep(1ms)          Genuinely blocks. Precise to the
                          timer resolution, which under CFS
                          means "at least 1ms, possibly 4ms".
                          Fine for polling something slow.
                          Terrible inside a lock.

  a blocking wait         futex / condvar / poll. The thread
                          leaves the run queue entirely and is
                          woken by the event itself. THIS IS
                          THE RIGHT ANSWER for waiting on
                          another thread.

  a spin loop             Burns a core to save a few hundred
                          nanoseconds of wake-up latency. Right
                          only when the wait is provably shorter
                          than a context switch (~1-5 us), and
                          only with a pause instruction:

                              while (locked)
                                      __builtin_ia32_pause();  /* x86 */
                              /* or on ARM: */
                              __asm__ volatile("yield");
                              /* or WFE, which actually sleeps
                                 the core until an event       */

/* The pause/yield hint matters more than it looks: it stops
   the core speculating down the loop, frees the SMT sibling's
   execution units, and cuts the power draw of the spin by a
   large factor.                                              */
```

> **THE SCHEDULER IS NOT YOUR SYNCHRONISATION PRIMITIVE**
> Code that works because "thread A is higher priority so it runs first" is not synchronised; it is lucky. Add a core, change a kernel version, run under a hypervisor where your vCPU is descheduled (virtualisation chapter 8), and the assumption evaporates. If order matters, express it with a primitive that guarantees it.

Watching it happen

```
# Is my thread running, blocked, or fighting for a core?
$ ps -eLo pid,tid,stat,psr,pcpu,comm | grep myapp
#   R = running/ready   S = interruptible sleep
#   D = uninterruptible (usually disk)   T = stopped

# How often is it being switched out, and voluntarily?
$ cat /proc/$(pidof myapp)/status | grep ctxt_switches
voluntary_ctxt_switches:     4821    # it blocked - good
nonvoluntary_ctxt_switches:  91024   # it was preempted - it
                                     # wants more CPU than it
                                     # is getting

# Where did the time actually go?
$ perf sched record -- ./myapp
$ perf sched latency --sort max
# per-task: runtime, number of switches, and worst-case delay
# between "became runnable" and "actually ran"

# Scheduling latency for a real-time thread:
$ cyclictest -t1 -p 80 -i 1000 -l 100000 -m
T: 0 (1234) P:80 I:1000 C: 100000 Min: 8 Act: 12 Avg: 14 Max: 71

# A high nonvoluntary count plus high `perf sched latency` max
# means oversubscription: you have more runnable threads than
# cores. No amount of priority tuning fixes that - reduce the
# thread count.
```

How it shows up

Symptom	Cause
Machine locks up entirely	A `SCHED_FIFO` thread spinning, with the RT throttle disabled
Raising priority made latency worse	Priority inversion, or starving the thread that produces the work
Huge `nonvoluntary_ctxt_switches`	More runnable threads than cores
Throughput drops when you add threads	Oversubscription plus cache thrash from migration
Latency spikes every few hundred milliseconds	Migration, or a timer tick on a core you did not isolate
Pinning made it slower	Two hot threads on SMT siblings sharing one L1
`sched_yield` loop burns a core and never progresses	CFS re-picks the yielding thread; it is not a handoff
Works on bare metal, misses deadlines in a VM	The vCPU is a thread on the host and gets descheduled
`pthread_setschedparam` returns EPERM	No `CAP_SYS_NICE`, or `RLIMIT_RTPRIO` is zero
Timing changes completely under a debugger	The debugger is a scheduling event; the original timing was never guaranteed

Check yourself

- ✓ Draw the thread state machine and say which transition you control.
- ✓ Explain why a blocked thread is free and a spinning one is not.
- ✓ Name four scheduling policies and when each is appropriate.

- ✓ Explain what the RT throttle protects you from and why disabling it is dangerous.
- ✓ State the rule a `SCHED_FIFO` loop body must obey.
- ✓ Give two cases where pinning helps and two where it hurts.
- ✓ Explain why `sched_yield` is unreliable as a synchronisation mechanism.
- ✓ Say when a spin loop is justified, and what instruction belongs in it.
- ✓ Interpret a high `nonvoluntary_ctxt_switches` count.
- ✓ Explain why "higher priority so it runs first" is not synchronisation.

Race conditions and data races

Two different bugs share one word. A *data race* is undefined behaviour and a tool can find it. A *race condition* is a logic error that no tool can find, because the code is doing exactly what you wrote. Telling them apart tells you which of the two entirely different fixes you need.

The two bugs

```
DATA RACE - a language-level violation

  two threads access the same memory location
  at least one writes
  they are not ordered by any synchronisation

  -> UNDEFINED BEHAVIOUR in C, C++ and Rust-with-unsafe.
     Not "you get one value or the other". The compiler
     was allowed to assume this never happens, so it may
     have optimised on that assumption.

  FOUND BY: ThreadSanitizer, Helgrind, the Go race
            detector, Rust's type system at compile time.
  FIXED BY: a lock, an atomic, or not sharing.

RACE CONDITION - a logic error about ordering

  the program's correctness depends on which of several
  legal orderings actually happens.

  -> WELL-DEFINED BEHAVIOUR. Every individual operation is
     properly synchronised. The SEQUENCE is wrong.

  FOUND BY: thinking, review, stress tests, and production.
  FIXED BY: making the composite operation atomic, or
            removing the assumption about order.

EVERY DATA RACE IS A RACE CONDITION.
NOT EVERY RACE CONDITION IS A DATA RACE.

And the second kind is the one that survives to production,
precisely because your tools said the code was clean.
```

```
/* A DATA RACE. TSan finds this in seconds. */

int counter;                            /* plain int          */

void *worker(void *_) {
        for (int i = 0; i < 100000; i++)
                counter++;              /* unsynchronised RMW  */
        return NULL;
}
/* Fix: make it atomic, or hold a lock. */

/* A RACE CONDITION with NO data race. TSan says nothing. */

std::mutex m;
std::map<std::string, int> cache;

int get_or_create(const std::string &k)
{
        {   std::lock_guard<std::mutex> g(m);
            auto it = cache.find(k);
            if (it != cache.end())
                    return it->second;      /* properly locked  */
        }                                   /* LOCK RELEASED    */

        int v = expensive_compute(k);       /* slow, unlocked   */

        {   std::lock_guard<std::mutex> g(m);
            cache[k] = v;                   /* properly locked  */
            return v;
        }
}

/* Every access to `cache` is under the mutex. No data race.
   But two threads calling get_or_create("x") simultaneously
   both miss, both compute, and both insert. If
   expensive_compute has a side effect - allocating an id,
   opening a connection, charging a card - you have just done
   it twice.

   THE BUG IS THE GAP between the two locked regions. */
```

> **THE TEST: COULD AN ADVERSARY SCHEDULE THIS?**
> Imagine an adversary who chooses when every thread is preempted, at instruction granularity, with full knowledge of your code. Would the program still be correct? Not "is it likely" — the window in the example above is milliseconds wide, and under load it is hit constantly. Any reasoning of the form "the chance of that is tiny" is a bug you have decided not to fix.

The shapes races take

Shape	Example	Fix
Check-then-act	`if (!exists(f)) create(f);`	One atomic operation: `O_CREAT|O_EXCL`, `try_emplace`, compare-and-swap
Read-modify-write	`x = x + 1`	An atomic RMW, or a lock
Lost update	Two threads read a record, both edit, both save	Optimistic concurrency: a version number checked on write

Shape	Example	Fix
Time-of-check to time-of-use	`access()` then `open()`	Never re-resolve; use the handle you already checked. A security bug, not just a correctness one
Publication race	Set a pointer, then initialise the object	Initialise fully, then publish with a release store (chapter 12)
Iterator invalidation	One thread iterates while another inserts	Hold the lock for the whole iteration, or copy, or use a concurrent container
Lifetime race	Thread B uses an object thread A is destroying	Shared ownership (`shared_ptr` , refcount) or a join before teardown
Lazy init	Double-checked locking, written by hand	`std::call_once` , a function-local `static` , or an acquire/release pair done properly

Double-checked locking, the canonical wrong answer

```
/* THE BROKEN VERSION. Published in books for a decade. */

Singleton *instance;                    /* plain pointer      */
std::mutex m;

Singleton *get(void)
{
        if (!instance) {                /* 1. unsynchronised
                                              read            */
                std::lock_guard<std::mutex> g(m);
                if (!instance)
                        instance = new Singleton();   /* 2. */
        }
        return instance;
}

/* TWO independent defects:

   (a) Line 1 reads `instance` with no synchronisation while
       line 2 writes it. That is a DATA RACE: undefined
       behaviour, full stop.

   (b) Even if the read were somehow fine, `new Singleton()`
       is three steps:
              allocate
              construct
              assign to instance
       and nothing forces that order. A compiler or CPU may
       publish the pointer BEFORE the constructor has run.
       Another thread sees non-null, returns it, and uses a
       half-built object.

   Defect (b) is why this is famous: the code looks right, the
   bug is invisible in the source, and it appears only on
   weakly-ordered hardware like ARM - so it ships from an x86
   developer's laptop and fails on the phone.               */

/* CORRECT, and simplest: */
Singleton &get(void)
{
        static Singleton instance;   /* C++11 guarantees this
                                        is thread-safe and
                                        initialised exactly
                                        once                  */
        return instance;
}

/* CORRECT, when you need the pointer form: */
std::atomic<Singleton *> instance{nullptr};
std::mutex m;

Singleton *get(void)
{
        Singleton *p = instance.load(std::memory_order_acquire);
        if (!p) {
                std::lock_guard<std::mutex> g(m);
                p = instance.load(std::memory_order_relaxed);
                if (!p) {
                        p = new Singleton();
```

```
                        /* release: everything the constructor
                           wrote is visible to any thread that
                           acquires this pointer.             */
                        instance.store(p, std::memory_order_release);
                }
        }
        return p;
}
```

Finding them on purpose

```
# ThreadSanitizer - finds DATA races, not race conditions.
# Roughly 5-15x slower, 5-10x more memory. Worth every cycle.
$ gcc -fsanitize=thread -g -O1 app.c -o app
$ ./app
WARNING: ThreadSanitizer: data race (pid=4211)
  Write of size 4 at 0x5586f4a0 by thread T2:
    #0 worker app.c:12
  Previous read of size 4 at 0x5586f4a0 by thread T1:
    #0 worker app.c:12
  Location is global 'counter' of size 4

# It only reports races it OBSERVES. Code paths not executed
# are not checked, so run it against your real workload.

$ valgrind --tool=helgrind ./app       # slower, no rebuild
$ go test -race ./...                  # built in
$ cargo +nightly build -Z sanitizer=thread

# For RACE CONDITIONS, no tool. What actually works:
#   * run with more threads than cores, so preemption is
#     constant rather than rare
#   * inject delays at suspicious points and see what breaks
#   * stress in a loop for hours; log the interleaving
#   * model-check the protocol (TLA+, Spin) if it is critical

# Widening the window deliberately - the cheapest technique
# in this whole chapter:
        auto it = cache.find(k);
        if (it != cache.end()) return it->second;
+       std::this_thread::sleep_for(std::chrono::milliseconds(50));
        int v = expensive_compute(k);
# If the bug is a gap between two locked regions, a sleep in
# the gap turns "once a week" into "every single time".
```

> **A CLEAN TSAN RUN IS NOT A CLEAN PROGRAM**
>
> ThreadSanitizer proves the absence of data races *on the paths it executed*. It says nothing about race conditions, nothing about paths you did not run, and nothing about ordering bugs across processes or against hardware. Treat it as a lint that catches an important, mechanical class of bug — not as a proof.

How it shows up

Symptom	Cause
A counter is slightly low under load	Non-atomic read-modify-write; increments lost
A cached value is computed twice	Check-then-act with an unlocked gap

Symptom	Cause
A user is charged twice	The same gap, with a side effect in it
Crash using a freshly published object	Publication race — the pointer was visible before the constructor finished
Fails on ARM, never on x86	Weaker memory ordering exposes a publication or reordering bug
Fails only with optimisation on	The compiler exploited the undefined behaviour a data race permitted
Iterator crash in a container that is "locked"	The lock was released between obtaining the iterator and using it
Use-after-free during shutdown	Lifetime race — no join before teardown
A file is created twice, or a symlink attack succeeds	TOCTOU between check and use
TSan is clean and the bug persists	It is a race condition, not a data race — different bug, different fix

Check yourself

- ✓ Define a data race and a race condition precisely, and say which tools find which.
- ✓ Explain why a data race is undefined behaviour rather than "you get one of two values".
- ✓ Write a race condition that contains no data race.
- ✓ State the adversarial-scheduler test and apply it to a piece of your own code.
- ✓ Name six shapes races take and give the fix for each.
- ✓ Give both defects in hand-written double-checked locking.
- ✓ Explain why the double-checked locking bug ships from x86 and fails on ARM.
- ✓ Write the two correct forms of lazy initialisation in C++.
- ✓ Explain what a clean ThreadSanitizer run does and does not prove.
- ✓ Describe the delay-injection technique and why it is so effective on gap bugs.

Mutual exclusion from first principles

Before you can use a mutex well you have to know what one is made of. This chapter builds mutual exclusion up from nothing — the software-only algorithms that almost work, the hardware instruction that makes it possible, and the futex trick that makes it fast.

What we are trying to buy

```
A correct mutual-exclusion protocol needs four properties.
Dropping any one of them is a real bug with a real name.

1. MUTUAL EXCLUSION
     at most one thread in the critical section at a time.
     Without it: the thing you were trying to prevent.

2. PROGRESS  (deadlock freedom)
     if nobody is in the critical section and somebody
     wants in, somebody gets in.
     Without it: deadlock (chapter 14).

3. BOUNDED WAITING  (starvation freedom)
     a thread that wants in gets in after a bounded number
     of other entries.
     Without it: starvation - a thread waits for ever
     while others take turns ahead of it.

4. NO ASSUMPTIONS ABOUT SPEED
     correctness must not depend on relative thread speeds,
     core counts, or the scheduler.
     Without it: works on your laptop.

Note what is NOT on the list: fairness in the FIFO sense,
and performance. Most real mutexes deliberately give up
strict fairness to go faster (see barging, below).
```

Software-only: interesting, and not what you use

```
/* PETERSON'S ALGORITHM - two threads, no special instruction.
   Correct on a sequentially consistent machine.            */

atomic_bool want[2] = { false, false };
atomic_int  turn    = 0;

void lock(int me)
{
        int other = 1 - me;
        want[me] = true;        /* I want in                  */
        turn = other;           /* but you go first           */
        while (want[other] && turn == other)
                ;               /* spin                       */
}

void unlock(int me) { want[me] = false; }

/* WHY IT WORKS: the `turn` write is a deliberate deference.
   If both threads arrive together, both set turn, and the
   LAST write wins - so exactly one of them sees turn pointing
   away from itself and proceeds.

   WHY YOU WILL NEVER USE IT:

   1. It is for exactly two threads. Extending it (Lamport's
      bakery algorithm) needs O(n) storage and O(n) scanning
      per acquisition.

   2. It spins. Every waiter burns a core.

   3. THE REAL KILLER: it is only correct under sequential
      consistency, and no real CPU provides that. On ARM or
      x86 the store to `want[me]` and the load of
      `want[other]` can be reordered, and both threads enter.
      Making it correct needs full barriers in both places -
      at which point you are paying more than a real mutex
      costs.

   It is on the exam because it proves mutual exclusion is
   possible without hardware help. It is not in your code
   because hardware help is cheaper.                        */
```

The instruction that changes everything

```
/* What we need is one indivisible read-modify-write. Every
   architecture provides one; they differ in shape.        */

/* x86: exchange, with an implicit lock prefix. */
        xchg    eax, [lock]        ; atomically swap

/* x86: compare-and-swap, the general form. */
        lock cmpxchg [ptr], ebx    ; if [ptr]==eax, [ptr]=ebx

/* ARM: LOAD-LINKED / STORE-CONDITIONAL. No single atomic RMW -
   instead a pair, where the store FAILS if anyone touched the
   line in between.                                          */
retry:  ldaxr   w1, [x0]           ; load-acquire exclusive
        cmp     w1, #0
        b.ne    retry              ; already locked, spin
        mov     w2, #1
        stlxr   w3, w2, [x0]       ; store-release exclusive
        cbnz    w3, retry          ; w3 != 0 means we lost the
                                   ; reservation - try again

/* ARMv8.1-A LSE adds true single-instruction atomics, which
   scale far better under contention because they can be done
   at the point of coherency instead of bouncing the line:   */
        swpal   w1, w2, [x0]       ; swap
        casal   w1, w2, [x0]       ; compare-and-swap
        ldaddal w1, w2, [x0]       ; atomic add

/* In C, you write none of this: */
        while (atomic_exchange_explicit(&lock, 1,
                                        memory_order_acquire))
                ;                          /* spin lock       */
        /* critical section */
        atomic_store_explicit(&lock, 0, memory_order_release);
```

> **WHY ACQUIRE AND RELEASE, SPECIFICALLY**
>
> The lock is not just about exclusion — it is about *visibility*. Acquiring with `memory_order_acquire` guarantees that everything the previous holder did before releasing is visible to you afterwards. Releasing with `memory_order_release` guarantees your writes are visible to the next acquirer. A "mutex" that excluded correctly but gave no ordering guarantee would still let you read stale data. Chapter 12 is this idea in full.

A spinlock, properly written

```
/* The naive version, and why each fix matters. */

/* v1: correct, and terrible under contention. */
void lock_v1(atomic_flag *l) {
        while (atomic_flag_test_and_set_explicit(l, memory_order_acquire))
                ;
}
/* Every waiter hammers the cache line with an atomic RMW.
   With 16 waiters the line ping-pongs 16 ways and the HOLDER
   cannot even write its own data. Contention makes it slower
   the more threads you add.                                  */

/* v2: test-and-test-and-set. Spin on a plain LOAD, which can
   sit in the local cache in Shared state and generate no bus
   traffic at all. Only attempt the expensive RMW when it
   looks free.                                                */
void lock_v2(atomic_bool *l) {
        for (;;) {
                if (!atomic_exchange_explicit(l, true,
                                              memory_order_acquire))
                        return;
                while (atomic_load_explicit(l, memory_order_relaxed))
                        cpu_relax();          /* pause / yield  */
        }
}

/* v3: add back-off, so the thundering herd on release does not
   all collide at once. */
void lock_v3(atomic_bool *l) {
        unsigned backoff = 1;
        for (;;) {
                if (!atomic_exchange_explicit(l, true,
                                              memory_order_acquire))
                        return;
                while (atomic_load_explicit(l, memory_order_relaxed)) {
                        for (unsigned i = 0; i < backoff; i++)
                                cpu_relax();
                        if (backoff < 1024) backoff *= 2;
                }
        }
}

/* v4: give up and sleep, because spinning past a few hundred
   cycles is worse than a context switch. That is a MUTEX. */

/* And note none of v1-v3 is FAIR: a thread that just released
   can immediately re-acquire while an older waiter is still
   backing off. A TICKET LOCK fixes that:                     */

struct ticket { atomic_uint next, now_serving; };

void ticket_lock(struct ticket *t) {
        unsigned me = atomic_fetch_add_explicit(&t->next, 1,
                                        memory_order_relaxed);
        while (atomic_load_explicit(&t->now_serving,
                                    memory_order_acquire) != me)
                cpu_relax();
}
void ticket_unlock(struct ticket *t) {
        atomic_fetch_add_explicit(&t->now_serving, 1,
```

```
                                    memory_order_release);
}
/* Strict FIFO, and every waiter still spins on one shared
   line. MCS and CLH locks fix that too by giving each waiter
   its own line to spin on - which is what the kernel uses for
   contended spinlocks.                                      */
```

> **NEVER SPIN WHERE YOU CAN BE PREEMPTED**
> A spinlock assumes the holder is *running* and will release shortly. If the holder is descheduled — because you are in user space, or in a VM whose vCPU was taken away (virtualisation chapter 8) — every waiter burns a full timeslice waiting for a thread that cannot run. This is lock-holder preemption, and it is why spinlocks belong in the kernel with preemption disabled, not in application code.

The futex: spin a little, then sleep

```
   A real mutex wants both: no syscall in the fast path, and
   no spinning in the slow one. Linux's futex gives exactly
   that by making the KERNEL involved only on contention.

   state: 0 = free, 1 = locked, 2 = locked and someone waits

   LOCK
     CAS 0 -> 1 succeeds?          done. NO SYSCALL AT ALL.
                                   This is the common case and
                                   it costs ~20 ns.
     otherwise:
       spin briefly (adaptive)
       still locked?
         set state to 2  ("I am going to sleep")
         futex(FUTEX_WAIT, addr, 2)
           kernel: "is *addr still 2? then queue me and sleep"
           - the recheck inside the kernel is what closes the
             race between deciding to sleep and sleeping

   UNLOCK
     if state was 1:  store 0.     NO SYSCALL.
     if state was 2:  store 0, then
                      futex(FUTEX_WAKE, addr, 1)

   THE WHOLE TRICK is that "2" records the existence of
   waiters, so the unlock path knows whether a syscall is
   needed. An uncontended mutex never enters the kernel in
   either direction.

   Windows: WaitOnAddress / WakeByAddressSingle.
   macOS:   __ulock_wait / os_unfair_lock.
   Same idea everywhere.
```

How it shows up

Symptom	Cause
Hand-rolled lock works on x86, fails on ARM	Missing barriers; the algorithm assumed sequential consistency
Spinlock gets slower as threads are added	Test-and-set hammering one cache line — needs test-and-test-and-set
One thread never acquires while others cycle	Barging; the lock is unfair. Use a ticket lock

Symptom	Cause
A core is pinned at 100% doing nothing	Spinning on a lock whose holder is descheduled
Latency spikes to whole milliseconds	Lock-holder preemption, or spinning past the point where sleeping was cheaper
Reading stale data despite holding the lock	Lock implemented with relaxed atomics — exclusion without ordering
Wake-up is missed and a thread sleeps for ever	The check-then-sleep race; futex's in-kernel recheck exists to prevent exactly this
Performance collapses at exactly N threads	N is the point where the contended path starts entering the kernel

Check yourself

- ✓ State the four properties a mutual-exclusion protocol must have, and name the bug you get without each.
- ✓ Explain how Peterson's algorithm achieves exclusion, and the three reasons it is unusable.
- ✓ Name the atomic primitive on x86 and the ARM equivalent, and say why LL/SC can fail spuriously.
- ✓ Explain what LSE atomics improve over LL/SC under contention.
- ✓ Explain why a lock needs acquire and release semantics, not just exclusion.
- ✓ Improve a naive test-and-set spinlock twice and justify each change.
- ✓ Write a ticket lock and say what it fixes and what it does not.
- ✓ Explain lock-holder preemption and why spinlocks are a kernel construct.
- ✓ Describe the three futex states and say why the "2" state exists.
- ✓ Explain what the kernel-side recheck in `FUTEX_WAIT` prevents.

Mutexes in practice

The primitive is simple; using it well is a set of habits. What a lock protects, how long you hold it, whether you can take two, and never — under any circumstances — releasing it by hand on an error path.

A lock protects an invariant, not a variable

```
THE QUESTION THAT PREVENTS MOST LOCK BUGS

  "What is true when this lock is not held?"

If you cannot answer in one sentence, the lock is
decoration.

BAD: "m protects `count`."
     Then what protects the relationship between `count`
     and the buffer it counts? Two locks, two invariants,
     and a window between them.

GOOD: "m protects the queue: `head`, `tail`, `count` and
       the elements between head and tail are mutually
       consistent whenever m is not held."

Now every rule follows from the sentence:
  - you may not read `count` without m, because the
    invariant only holds while m is unheld and you are
    observing it mid-update otherwise
  - you must restore ALL of it before unlocking
  - a function that returns a pointer INTO the queue has
    leaked the invariant past the lock, and is wrong

WRITE THE SENTENCE IN A COMMENT NEXT TO THE LOCK. It is the
single highest-value comment in concurrent code, and the
one people never write.
```

```
/* What that looks like in a header. */

struct queue {
        /* @lock protects every field below it: head, tail and
         * count are mutually consistent, and elements
         * [head, tail) are initialised, whenever @lock is not
         * held. Callers must not retain pointers to elements
         * after releasing @lock.
         */
        pthread_mutex_t lock;
        struct item    *head, *tail;
        size_t          count;
};

/* The kernel writes this as a lockdep-checkable annotation;
   C++ has an analyser attribute for it:                    */

class Queue {
    std::mutex m_;
    size_t     count_ GUARDED_BY(m_);      /* clang thread
                                              safety analysis */
public:
    size_t size() { std::lock_guard<std::mutex> g(m_);
                    return count_; }
};
/* -Wthread-safety turns "read count_ without m_" into a
   COMPILE ERROR. It is underused and nearly free.          */
```

Never unlock by hand

```
/* THE BUG, in every codebase that uses manual unlock. */

int process(struct queue *q, int x)
{
        pthread_mutex_lock(&q->lock);

        if (x < 0)
                return -EINVAL;              /* LOCK LEAKED   */

        if (q->count == 0) {
                pthread_mutex_unlock(&q->lock);
                return -EAGAIN;              /* fine, for now */
        }

        do_work(q);                          /* if this throws
                                                or longjmps:
                                                LOCK LEAKED   */
        pthread_mutex_unlock(&q->lock);
        return 0;
}
/* Someone adds a fourth early return in six months, and the
   process deadlocks the next time that path is taken.      */

/* C++: RAII. The destructor cannot be forgotten and runs on
   exceptions too. */
int process(Queue &q, int x)
{
        std::lock_guard<std::mutex> g(q.m);   /* one line     */
        if (x < 0)      return -EINVAL;       /* unlocked      */
        if (q.empty())  return -EAGAIN;       /* unlocked      */
        do_work(q);                           /* throws? still
                                                 unlocked      */
        return 0;
}
/* std::scoped_lock (C++17) is the same and takes N mutexes
   deadlock-free. Prefer it: std::lock_guard has no advantage. */

/* Rust: the data is INSIDE the mutex, so there is no way to
   touch it without locking, and the guard unlocks on drop. */
let q = Mutex::new(Queue::new());
{
    let mut g = q.lock().unwrap();
    g.push(item);
}   // unlocked here, always

/* C, with GCC/Clang: */
static inline void unlock_p(pthread_mutex_t **m) {
        pthread_mutex_unlock(*m);
}
#define LOCKED(mtx) \
        pthread_mutex_t *__l __attribute__((cleanup(unlock_p))) \
                = &(mtx); pthread_mutex_lock(__l)

int process(struct queue *q, int x)
{
        LOCKED(q->lock);
        if (x < 0) return -EINVAL;      /* unlocked correctly */
        ...
}
```

RUST'S REAL CONTRIBUTION

Other languages give you a lock and a separate piece of data and trust you to pair them. Rust makes `Mutex<T>` *own* the `T`, so accessing the data without holding the lock is not a bug you might make — it is code that does not compile. That single design choice removes the entire "forgot to take the lock" category, which is most of this chapter.

Which mutex

Kind	What it adds	Cost
Normal / fast	Nothing. Undefined behaviour if you relock or unlock someone else's	Cheapest. The default
Error-checking	Returns `EDEADLK` on self-relock, `EPERM` on foreign unlock	A branch. Use in debug builds
Recursive	The owner may lock it again; counts	An owner field and a counter — and see the warning below
Timed	`pthread_mutex_timedlock`, `try_lock_for`	Nothing extra when uncontended
Robust	If the owner dies, the next locker gets `EOWNERDEAD` and may recover	Only for shared-memory IPC mutexes
Priority-inheriting	Boosts the holder to the highest waiter's priority	Essential for real-time (chapter 15)
Adaptive	Spins briefly before sleeping	Great for short critical sections, wasteful for long ones
Shared / process-shared	Lives in shared memory across processes	Must be robust, or a crash wedges everyone

RECURSIVE MUTEXES ARE A DESIGN SMELL

They exist so that a function holding a lock can call another function that takes the same lock. That situation means you do not know your own locking structure. The real cost is that the invariant is only guaranteed at the *outermost* unlock — so the inner function sees the data mid-update and cannot tell. The fix is to split each public function into a locking wrapper and an unlocked `_locked` worker, which also documents which is which.

```
/* The pattern that removes the need for recursion. */

static void queue_push_locked(struct queue *q, struct item *i)
{
        /* caller MUST hold q->lock. Name says so. */
        ...
}

void queue_push(struct queue *q, struct item *i)
{
        LOCKED(q->lock);
        queue_push_locked(q, i);
}

void queue_push_many(struct queue *q, struct item **v, size_t n)
{
        LOCKED(q->lock);                    /* taken ONCE     */
        for (size_t k = 0; k < n; k++)
                queue_push_locked(q, v[k]);
}
```

How much to protect, and for how long

```
/* TOO COARSE: one lock for everything.
   Correct, simple, and it serialises your whole program. */

/* TOO FINE: a lock per element.
   More memory than the data, more time in locking than in
   work, and now you can deadlock by taking two. */

/* HOLD TIME is usually the bigger lever than granularity: */

/* BAD - I/O inside the critical section. */
{
        std::lock_guard<std::mutex> g(m);
        auto v = cache[k];
        write_to_disk(v);            /* 10 ms, holding the lock,
                                        blocking every other
                                        thread                 */
}

/* GOOD - copy out, then work. */
Value v;
{
        std::lock_guard<std::mutex> g(m);
        v = cache[k];                /* microseconds          */
}
write_to_disk(v);                    /* nobody is blocked     */

/* THE RULES

   1. Never call into unknown code while holding a lock. A
      callback, a virtual function, an allocator or a logger
      may take another lock and deadlock you (chapter 14).
   2. Never do I/O or sleep while holding a lock.
   3. Never allocate while holding a hot lock if you can
      avoid it - malloc has its own locks.
   4. Copy small things out and release; do not hold a lock
      across expensive work.
   5. If the critical section is one atomic-sized update, use
      an atomic instead (chapter 11).                        */
```

Measuring contention

```
# Is the lock actually contended, or are you guessing?

$ perf lock record ./app && perf lock report
 Name   acquired  contended  avg wait    max wait   total wait
 &q->lock  184291      41082   1.42 us   9.81 ms     58.3 ms

$ perf stat -e 'syscalls:sys_enter_futex' -p $(pidof app)
# a large futex count means real contention: the fast path is
# not being taken

# In the kernel:
$ echo 1 > /proc/sys/kernel/lock_stat
$ cat /proc/lock_stat

# The number that matters is CONTENDED / ACQUIRED. Below a few
# percent, leave it alone. Above ten percent, either shrink
# the critical section or split the lock - and measure again,
# because splitting a lock often just moves the queue.
```

How it shows up

Symptom	Cause
Deadlock on an uncommon error path	Manual unlock missed on an early return
Deadlock after an exception	Manual unlock skipped by the unwind — use RAII
Data corruption despite "everything is locked"	Two locks, two invariants, and a gap between them
A getter returns a torn value	Read without the lock because "it is just one field"
Crash using a pointer obtained under a lock	The invariant escaped the critical section
Throughput collapses under load	Long hold times — usually I/O or allocation inside the lock
Deadlock when a callback fires	Unknown code called while holding a lock
Works, then deadlocks after a refactor adds a call	A recursive-mutex design that was hiding the structure
`EDEADLK` from `pthread_mutex_lock`	Self-relock on an error-checking mutex — a real bug it just caught for you
Everything hangs after a process crashes	Process-shared mutex that was not robust

Check yourself

- ✓ State the sentence that should be written next to every lock, and write one for a real structure.
- ✓ Show the manual-unlock bug and give the fix in C, C++ and Rust.
- ✓ Explain what Rust's `Mutex<T>` makes impossible that other languages permit.
- ✓ Name six kinds of mutex and what each adds.
- ✓ Explain why recursive mutexes are a design smell and give the refactor that removes them.
- ✓ Give five rules about what must never happen inside a critical section.
- ✓ Explain why hold time usually matters more than lock granularity.
- ✓ Measure lock contention and say what ratio would make you act.
- ✓ Explain why splitting a contended lock sometimes changes nothing.

Condition variables and waiting for a state

A mutex answers "may I touch this?". A condition variable answers "has it become what I need yet?" — without burning a core asking. It is the primitive people most often get wrong, and every mistake comes from forgetting that the condition variable itself holds no state at all.

The problem it solves

```
You want: "wait until the queue is non-empty."

ATTEMPT 1 - spin
    while (queue_empty(q))
            ;
  Burns a core. On one core, may never progress.

ATTEMPT 2 - spin with a lock
    for (;;) {
            lock(m);
            if (!queue_empty(q)) break;
            unlock(m);
    }
  Burns a core AND hammers the lock, so the producer
  cannot get in to add anything.

ATTEMPT 3 - poll with a sleep
    for (;;) {
            lock(m);
            if (!queue_empty(q)) break;
            unlock(m);
            sleep_ms(1);
    }
  Works. Adds up to 1 ms of latency to every item and wakes
  up pointlessly all night. This is what people ship when
  they do not know about condition variables.

WHAT YOU ACTUALLY WANT
    lock(m);
    while (queue_empty(q))
            cond_wait(cv, m);      /* atomically: unlock m,
                                      sleep, and relock m
                                      on wake              */
    take_item(q);
    unlock(m);

Zero CPU while waiting, and wake-up latency measured in
microseconds.
```

THE ATOMICITY THAT MAKES IT WORK

`cond_wait` must release the mutex and begin waiting *as one indivisible step*. If there were any gap, a producer could add an item and signal in that gap — and the consumer would then go to sleep waiting for an event that already happened, for ever. This is the **lost wake-up**, and avoiding it is the entire reason the API takes the mutex as an argument rather than you unlocking it yourself.

The three rules

```
/* RULE 1: ALWAYS wait in a loop, never an if. */

        lock(m);
        while (!condition)          /* while, not if           */
                cond_wait(cv, m);
        /* condition is true here */
        unlock(m);

/* Three separate reasons, any one of which is sufficient:

   (a) SPURIOUS WAKE-UPS. POSIX explicitly permits cond_wait
       to return without any signal at all. This is not a bug
       in the implementation; it is licensed by the standard
       so that implementations can be fast (and it genuinely
       happens on signal delivery).

   (b) BARGING. Between the signaller's signal and your
       actually running, a THIRD thread may acquire the mutex
       and consume the item. You wake up, the queue is empty
       again. Most implementations are not FIFO handoff.

   (c) BROADCAST. If the signaller uses broadcast, every
       waiter wakes but only some can proceed.

   A codegen or review rule of "cond_wait is only ever called
   inside a while loop testing the predicate" catches almost
   every condition-variable bug there is.                    */

/* RULE 2: hold the mutex when you change the predicate. */

        lock(m);
        queue_push(q, item);        /* change the state ...    */
        unlock(m);
        cond_signal(cv);            /* ... then signal         */

/* Signalling inside or outside the lock are both correct.
   Outside avoids the waiter waking straight into a locked
   mutex ("hurry up and wait"), which some implementations
   optimise anyway. Inside is required if the condition
   variable or the predicate might be destroyed by a woken
   waiter - which is a real hazard on shutdown.

   THE THING THAT IS NEVER CORRECT is changing the predicate
   WITHOUT the mutex and then signalling: the waiter may test
   the predicate between your write and your signal, and
   sleep for ever.                                           */

/* RULE 3: one condition variable per predicate. */

/* WRONG - one cv for two different conditions */
        while (queue_full(q))  cond_wait(cv, m);   /* producer */
        while (queue_empty(q)) cond_wait(cv, m);   /* consumer */
/* signal() may wake a producer when you meant a consumer, and
   the woken thread goes straight back to sleep, having
   consumed the signal. Deadlock with a full queue.
```

```
   Either use TWO condition variables, or use broadcast and
   accept the thundering herd.                              */
```

The bounded buffer, written properly

```
/* The canonical example, and a good template. */

#define CAP 256

struct bbuf {
        pthread_mutex_t m;
        pthread_cond_t  not_empty;      /* two predicates,     */
        pthread_cond_t  not_full;       /* two variables       */
        void           *slot[CAP];
        size_t          head, tail, count;
        bool            closed;         /* for clean shutdown  */
};

int bbuf_put(struct bbuf *b, void *item)
{
        pthread_mutex_lock(&b->m);

        while (b->count == CAP && !b->closed)
                pthread_cond_wait(&b->not_full, &b->m);

        if (b->closed) {                        /* shutdown path */
                pthread_mutex_unlock(&b->m);
                return -EPIPE;
        }

        b->slot[b->tail] = item;
        b->tail = (b->tail + 1) % CAP;
        b->count++;
        pthread_mutex_unlock(&b->m);

        pthread_cond_signal(&b->not_empty);    /* exactly one
                                                  consumer can
                                                  proceed       */
        return 0;
}

void *bbuf_get(struct bbuf *b)
{
        pthread_mutex_lock(&b->m);

        while (b->count == 0 && !b->closed)
                pthread_cond_wait(&b->not_empty, &b->m);

        if (b->count == 0) {                    /* closed, empty */
                pthread_mutex_unlock(&b->m);
                return NULL;
        }

        void *item = b->slot[b->head];
        b->head = (b->head + 1) % CAP;
        b->count--;
        pthread_mutex_unlock(&b->m);

        pthread_cond_signal(&b->not_full);
        return item;
}

/* Shutdown. Note the BROADCAST: every waiter, on both
   variables, must be released - and `closed` is part of every
   predicate above precisely so they can be.                */
```

```
void bbuf_close(struct bbuf *b)
{
        pthread_mutex_lock(&b->m);
        b->closed = true;
        pthread_mutex_unlock(&b->m);
        pthread_cond_broadcast(&b->not_empty);
        pthread_cond_broadcast(&b->not_full);
}
```

```
// C++, where the predicate overload removes the loop from
// your code but not from the semantics.
#include <condition_variable>

std::mutex m;
std::condition_variable cv;
std::queue<int> q;
bool closed = false;

void producer(int v) {
    { std::lock_guard<std::mutex> g(m); q.push(v); }
    cv.notify_one();
}

std::optional<int> consumer() {
    std::unique_lock<std::mutex> lk(m);      // unique_lock, not
                                             // lock_guard: wait
                                             // must unlock it
    cv.wait(lk, [&]{ return !q.empty() || closed; });
    //           ^ this IS the while loop, written once
    if (q.empty()) return std::nullopt;
    int v = q.front(); q.pop();
    return v;
}

// With a timeout - note wait_for returns the predicate's value,
// so you can tell timeout from success without a second check:
if (!cv.wait_for(lk, std::chrono::seconds(5),
                 [&]{ return !q.empty(); }))
        return timeout();
```

> **`WAIT` NEEDS `UNIQUE_LOCK`, AND THAT IS NOT ARBITRARY**
>
> `std::lock_guard` cannot unlock; `cv.wait` must. That is why the type differs, and why the compiler stops you. Similarly, waiting on a condition variable with a `recursive_mutex` locked twice releases it only once — so you sleep still holding it, and nobody can ever signal you. Another reason recursive mutexes cause trouble.

Signal or broadcast

	`signal` / `notify_one`	`broadcast` / `notify_all`
Wakes	One waiter (unspecified which)	Every waiter
Correct when	Every waiter waits for the same predicate and one item satisfies exactly one	Waiters have different predicates, or one event satisfies many
Cost	One wake-up	N wake-ups, N−1 of which relock, re-test and sleep again — the thundering herd
Risk	Waking the wrong waiter if predicates differ, losing the signal	Only performance

The safe default when unsure is `broadcast`: it is never *incorrect*, only slower. Use `signal` when you can state, in one sentence, that every waiter on this variable is waiting for exactly the same thing and one event satisfies exactly one of them.

How it shows up

Symptom	Cause
Consumer proceeds with an empty queue	`if` instead of `while` — spurious wake-up or barging
Everything hangs, no CPU used	Lost wake-up: the predicate was changed without the mutex, or signalled before any waiter existed
Hangs only under load	One condition variable serving two predicates; a signal woke the wrong kind of waiter
Hangs on shutdown	Waiters still blocked; needs a `closed` flag in every predicate plus a broadcast
Latency spikes with many consumers	Thundering herd from `broadcast`
Sleeps for ever holding the mutex	Waiting with a recursive mutex locked more than once
Works, but one core sits at 100%	Someone replaced the wait with a polling loop
Crash inside `cond_signal` at shutdown	A woken waiter destroyed the condition variable while the signaller was still inside it — signal under the lock
Occasional 1 ms latency per item	A poll-and-sleep loop, not a condition variable

Check yourself

- ✓ Explain what a condition variable adds over a mutex, and why it holds no state itself.
- ✓ Explain the atomic unlock-and-wait, and the bug that exists without it.
- ✓ Give three independent reasons the wait must be in a `while` loop.
- ✓ State what must be true when you change a predicate, and the failure when it is not.
- ✓ Explain why one condition variable per predicate matters, with the deadlock it prevents.
- ✓ Write a bounded buffer with clean shutdown from memory.
- ✓ Say why `cv.wait` requires `unique_lock` rather than `lock_guard`.
- ✓ Give the rule for choosing `signal` over `broadcast`.
- ✓ Explain the risk of signalling outside the lock during shutdown.

Semaphores, barriers and latches

Three primitives that are not mutexes. A semaphore counts permits; a latch is a one-shot gate; a barrier is a rendezvous. Reaching for the right one turns several pages of condition-variable code into a line, and reaching for the wrong one produces the most durable deadlocks in this track.

Semaphores: counting permits

```
A semaphore is an integer with two atomic operations and a
waiting rule.

  wait / P / acquire / down
      if count > 0:  count--,  proceed
      else:          block until someone posts

  post / V / release / up
      count++,  wake one waiter if any

THREE DISTINCT USES, and they look nothing alike:

1. COUNTING A RESOURCE    initial = N
     N identical things (connections, buffers, slots).
     wait = take one, post = give one back.

2. SIGNALLING             initial = 0
     "an event happened". Producer posts, consumer waits.
     The count IS the number of pending events, so unlike a
     condition variable a semaphore REMEMBERS a post that
     arrives before anyone waits. No lost wake-ups.

3. MUTUAL EXCLUSION       initial = 1
     A "binary semaphore". Works, and you should not:
     it has no owner, so no priority inheritance, no
     deadlock detection, no error checking, and anyone may
     post a semaphore they never waited on.

THE KEY DIFFERENCE FROM A CONDITION VARIABLE:
  a condvar is stateless and a signal to nobody is lost.
  a semaphore is stateful and a post to nobody is stored.
That single property decides which one your problem wants.
```

```
/* POSIX */
#include <semaphore.h>

sem_t slots;
sem_init(&slots, 0 /* not process-shared */, 8 /* permits */);

sem_wait(&slots);        /* take one, blocking            */
sem_trywait(&slots);     /* or fail with EAGAIN           */
sem_timedwait(&slots, &abs_timeout);
/* ... use the resource ... */
sem_post(&slots);        /* give it back                  */

/* sem_post is ASYNC-SIGNAL-SAFE - almost uniquely among
   synchronisation primitives. It is the only correct way to
   wake a thread from a signal handler.                    */

/* C++20 */
#include <semaphore>
std::counting_semaphore<8> slots{8};
std::binary_semaphore     signal{0};

slots.acquire();
slots.release();
if (slots.try_acquire_for(std::chrono::milliseconds(10))) { ... }

/* Windows */
HANDLE s = CreateSemaphore(NULL, 8, 8, NULL);
WaitForSingleObject(s, INFINITE);
ReleaseSemaphore(s, 1, NULL);
```

THE RULE THAT CATCHES MOST SEMAPHORE BUGS

Wrap it. A raw `sem_wait` / `sem_post` pair scattered across a function has exactly the problem manual `unlock` has, plus no owner to blame. Use a RAII guard, and make the semaphore private to the type that owns the resource it counts — never a global that any code may post.

```
/* Semaphore as a connection pool - use 1, the good one. */

class Pool {
    std::counting_semaphore<> permits_;
    std::mutex                m_;
    std::vector<Conn>         free_;
public:
    explicit Pool(int n) : permits_(n) { /* fill free_ */ }

    class Lease {                       /* RAII, so a throw or
                                           an early return
                                           cannot leak a permit */
        Pool *p_; Conn c_;
    public:
        Lease(Pool *p, Conn c) : p_(p), c_(std::move(c)) {}
        ~Lease() { if (p_) p_->give_back(std::move(c_)); }
        Lease(Lease&& o) : p_(o.p_), c_(std::move(o.c_))
                           { o.p_ = nullptr; }
        Conn &get() { return c_; }
    };

    Lease take() {
        permits_.acquire();             /* blocks if all N are
                                           out - THIS is the
                                           backpressure         */
        std::lock_guard<std::mutex> g(m_);
        Conn c = std::move(free_.back());
        free_.pop_back();
        return Lease(this, std::move(c));
    }
private:
    void give_back(Conn c) {
        { std::lock_guard<std::mutex> g(m_); free_.push_back(std::move(c)); }
        permits_.release();             /* release AFTER the
                                           object is back in
                                           the list             */
    }
};
```

Latches: a gate that opens once

```
/* A latch counts DOWN to zero and then stays open for ever.
   Single use. Nobody resets it.                              */

#include <latch>                        /* C++20             */

std::latch ready(3);                    /* three participants */

/* worker */
        do_setup();
        ready.count_down();             /* "I am ready"        */
        ready.wait();                   /* wait for the others */
        /* all three are past setup here */

/* or, from a coordinator that does not participate: */
        ready.wait();                   /* until all 3 counted */

/* arrive_and_wait() is count_down() + wait() in one call.  */

/* USES
     - start N workers, wait until all have initialised
     - fan out N requests, wait for all N to complete
     - hold workers at a starting line for a benchmark

   Before C++20, or in C, it is a counter plus a condvar: */

struct latch {
        pthread_mutex_t m;
        pthread_cond_t  cv;
        unsigned        n;
};
void latch_count_down(struct latch *l) {
        pthread_mutex_lock(&l->m);
        if (l->n > 0 && --l->n == 0)
                pthread_cond_broadcast(&l->cv);   /* broadcast:
                                                     everyone is
                                                     released    */
        pthread_mutex_unlock(&l->m);
}
void latch_wait(struct latch *l) {
        pthread_mutex_lock(&l->m);
        while (l->n > 0)
                pthread_cond_wait(&l->cv, &l->m);
        pthread_mutex_unlock(&l->m);
}
```

Barriers: a rendezvous, repeatedly

```
/* A barrier is a REUSABLE latch. Every participant waits
   until all arrive; then all are released and the barrier
   resets for the next round.                                */

#include <barrier>                      /* C++20             */

std::barrier sync(4, [] {               /* completion function:
        swap_buffers();                    runs ONCE per phase,
        ++generation;                      by one thread, while
});                                        all others wait    */

void worker(int id) {
        for (int step = 0; step < 1000; step++) {
                compute_my_share(id);
                sync.arrive_and_wait();     /* phase boundary  */
                /* every thread's writes from this phase are
                   visible to every thread in the next one    */
        }
}

/* pthread barriers, the same thing: */
pthread_barrier_t b;
pthread_barrier_init(&b, NULL, 4);
int r = pthread_barrier_wait(&b);
if (r == PTHREAD_BARRIER_SERIAL_THREAD) {
        /* exactly ONE thread gets this - do the once-per-phase
           work here */
}

/* WHAT BARRIERS ARE FOR: bulk-synchronous parallelism.
   Iterative solvers, physics steps, image filters, any
   "everyone computes, then everyone exchanges" loop.

   THE COST: every phase runs at the speed of the SLOWEST
   participant. With 16 threads and one that is 10% slow,
   you lose 10% of all 16. Load imbalance is the whole game.

   THE DEADLOCK: if any participant leaves early - returns,
   throws, hits an error path - every other thread waits for
   ever. arrive_and_drop() exists for exactly this, and code
   that can throw between arrivals needs it.               */
```

> **THE THREE WAYS BARRIERS DEADLOCK**
>
> **1.** A participant exits the loop early on an error and never arrives again. **2.** The count does not match the number of threads — off by one, or a thread that failed to start. **3.** Two barriers used in different orders by different threads. All three present identically: everything hangs, no CPU used, and a stack dump shows every thread in `barrier_wait`.

Choosing

You want to...	Use
Protect data from concurrent access	**Mutex** — it has an owner
Wait for a state to become true	**Condition variable**

You want to…	Use
Limit concurrency to N	**Counting semaphore**
Signal from an interrupt or signal handler	**Semaphore** — the only async-signal-safe one
Wake a thread for an event that may arrive first	**Semaphore**, which stores the post
Wait for N things to finish, once	**Latch**
Synchronise phases of a loop, repeatedly	**Barrier**
Run something exactly once	`call_once` / `pthread_once`
Deliver a single value to a single waiter	`future` / `promise`

How it shows up

Symptom	Cause
Pool exhausts and never recovers	A permit leaked on an error path — needs RAII
More than N concurrent users of an N-permit resource	Somebody posted without waiting; a semaphore has no owner to stop them
Real-time thread misses deadlines behind a binary semaphore	No priority inheritance — use a mutex (chapter 15)
Everything hangs at a barrier	Wrong participant count, or one thread left early
Barrier phase takes as long as the slowest thread every time	Working as designed — fix load balance, not the barrier
Latch never opens	Fewer `count_down` calls than the initial count, often an early return
Deadlock on shutdown with waiters on a semaphore	Semaphores have no "close" — post N times or use a different primitive
Signal handler deadlocks the process	It took a mutex or signalled a condvar; only `sem_post` is safe there
Counter drifts over days	Unbalanced wait/post, usually one path that returns without releasing

Check yourself

- ✓ Define a semaphore's two operations and give the three distinct uses.
- ✓ State the key difference between a semaphore and a condition variable, and when it decides the choice.
- ✓ Explain why a binary semaphore is a poor mutex — give three specific losses.
- ✓ Say why `sem_post` is the only safe wake-up from a signal handler.
- ✓ Write a permit-leaking bug and fix it with RAII.
- ✓ Distinguish a latch from a barrier in one sentence.
- ✓ Explain what a barrier's completion function is for.
- ✓ Give the three ways a barrier deadlocks and how each presents.
- ✓ Explain why a barrier makes every phase run at the slowest participant's speed.
- ✓ Pick the right primitive for six of the situations in the table without looking.

Reader-writer locks, seqlocks and RCU

Most shared data is read far more often than it is written. Three primitives exploit that, each trading a different thing away — and the first one, the obvious one, is usually the worst of the three.

Reader-writer locks, and why they disappoint

```
/* The idea: many readers OR one writer. */

pthread_rwlock_t l = PTHREAD_RWLOCK_INITIALIZER;

pthread_rwlock_rdlock(&l);      /* shared                    */
        read_things();
pthread_rwlock_unlock(&l);

pthread_rwlock_wrlock(&l);      /* exclusive                 */
        write_things();
pthread_rwlock_unlock(&l);

/* C++17: */
std::shared_mutex m;
{ std::shared_lock  g(m);  read_things();  }   /* many         */
{ std::unique_lock  g(m);  write_things(); }   /* one          */

/* WHY IT OFTEN LOSES TO A PLAIN MUTEX:

   1. Taking a read lock is a WRITE to the lock's state - the
      reader count. So every reader dirties the same cache
      line, and 16 readers "reading in parallel" bounce one
      line 16 ways. Under load a shared_mutex read lock can be
      SLOWER than an exclusive mutex, because a mutex at least
      only bounces the line once per holder.

   2. It is bigger and its uncontended path is longer: more
      state to update, more branches.

   3. Fairness is a policy you did not choose. Reader-preferring
      implementations starve writers indefinitely under a steady
      read load. Writer-preferring ones make readers queue
      behind a writer that has not started yet.

   4. There is no atomic upgrade. read -> write means unlock,
      relock, and RE-VALIDATE everything you read, because the
      world changed in the gap. Implementations that offer
      upgrade usually deadlock if two readers try at once.

   USE IT WHEN: read critical sections are LONG (microseconds,
   not nanoseconds) and writes are genuinely rare. Below that,
   measure against a plain mutex before believing it helps. */
```

THE RULE OF THUMB

If the read critical section is shorter than about a microsecond, a plain mutex usually wins. The reader-writer lock only starts paying when the work under the read lock is long enough to dwarf the cost of the reader-count update — and by then you should ask whether you could copy the data out under a mutex instead.

Seqlocks: readers that never write

```
The insight: let readers do NOTHING to shared state, and
detect afterwards whether they were interfered with.

A counter, incremented on entry and exit of every write.

  even  = stable
  odd   = a write is in progress

WRITER                          READER
  seq++            (odd)        do {
  write the data                    s1 = seq;
  seq++            (even)           if (s1 & 1) continue;
                                    ... read the data ...
                                    s2 = seq;
                                  } while (s1 != s2);

If seq changed, or was odd, the read was torn - so retry.

WHAT YOU GAIN
  readers issue ZERO writes. No cache line is dirtied, so
  N readers genuinely scale. This is why Linux uses it for
  the system time (gettimeofday) - read constantly by every
  core, written once per tick.

WHAT YOU GIVE UP
  * readers may retry, so a reader can starve under a
    constant write load
  * the data being read MUST be safe to read while torn -
    no pointer chasing, no unbounded loops on a value that
    might be garbage mid-write
  * writers still need a mutex among themselves; a seqlock
    does not order writers
  * it is not a general-purpose lock. It suits small,
    fixed-size, self-contained records.
```

```
/* A seqlock in C11 atomics. */

typedef struct { atomic_uint seq; struct data d; pthread_mutex_t wm; } seqlock;

void seq_write(seqlock *l, const struct data *src)
{
        pthread_mutex_lock(&l->wm);            /* writers only */
        atomic_fetch_add_explicit(&l->seq, 1, memory_order_relaxed);
        atomic_thread_fence(memory_order_release);   /* odd BEFORE
                                                        the data */
        l->d = *src;
        atomic_thread_fence(memory_order_release);   /* data BEFORE
                                                        even     */
        atomic_fetch_add_explicit(&l->seq, 1, memory_order_relaxed);
        pthread_mutex_unlock(&l->wm);
}

struct data seq_read(seqlock *l)
{
        struct data out;
        unsigned s1, s2;
        do {
                s1 = atomic_load_explicit(&l->seq, memory_order_acquire);
                if (s1 & 1u)
                        continue;              /* write in flight */
                out = l->d;                    /* may be torn     */
                atomic_thread_fence(memory_order_acquire);
                s2 = atomic_load_explicit(&l->seq, memory_order_relaxed);
        } while (s1 != s2);
        return out;
}

/* Note: strictly, reading l->d while a writer writes it is a
   data race by the letter of the C standard, and TSan will say
   so. Real implementations use atomic loads per field or
   compiler-specific escape hatches. This is one of the few
   places where the model and the practice diverge, and the
   kernel's read_seqcount_begin/retry is the reference. */
```

RCU: readers that do not even check

```
Read-Copy-Update. The most extreme point on the curve:
readers pay LITERALLY NOTHING - no atomic, no branch, in
the classic kernel build not a single instruction.

THE IDEA
  Never modify data in place. Instead:
    1. COPY the object
    2. modify the copy
    3. publish the new pointer atomically
    4. WAIT until every reader that might still hold the
       old pointer has finished
    5. free the old one

Step 4 is the whole trick, and it is called the GRACE
PERIOD.

  writer:  new = copy(old)
           modify(new)
           rcu_assign_pointer(p, new)     ; release store
           synchronize_rcu()              ; wait for readers
           kfree(old)

  reader:  rcu_read_lock()                ; often a no-op
           q = rcu_dereference(p)
           use(q)                         ; q stays valid
           rcu_read_unlock()              ; often a no-op

HOW THE GRACE PERIOD IS DETECTED
  In the kernel's classic RCU, a reader may not sleep or be
  preempted inside a read-side section. So once every CPU
  has passed through a context switch, no reader from
  before the update can still be running. That is a
  QUIESCENT STATE, and observing one per CPU ends the
  grace period. No reference counts, no atomics, no
  communication from readers at all.

THE COSTS
  * writers are expensive and must wait, possibly
    milliseconds
  * memory is freed late, so usage spikes under write load
  * readers may see stale data - RCU gives you a consistent
    SNAPSHOT, not the latest value
  * read sections have hard rules (no sleeping in classic
    RCU) that the compiler cannot check

WHERE IT WINS: routing tables, module lists, security
policy, the dcache - anything read on every operation by
every core and updated rarely.
```

```
/* Userspace RCU (liburcu) - the same API outside the kernel. */
#include <urcu.h>

struct config *global_cfg;

/* reader - the hot path */
void handle_request(void)
{
        rcu_read_lock();
        struct config *c = rcu_dereference(global_cfg);
        use(c->timeout, c->retries);
        rcu_read_unlock();
}

/* writer - rare */
void update_config(int timeout)
{
        struct config *old, *new = malloc(sizeof *new);

        pthread_mutex_lock(&writer_lock);      /* writers still
                                                  serialise      */
        old = global_cfg;
        *new = *old;                           /* COPY           */
        new->timeout = timeout;                /* UPDATE         */
        rcu_assign_pointer(global_cfg, new);   /* PUBLISH        */
        pthread_mutex_unlock(&writer_lock);

        synchronize_rcu();                     /* WAIT           */
        free(old);                             /* now safe       */
}

/* call_rcu(&old->head, free_cb) defers the free instead of
   blocking the writer - what you use when the writer is on a
   latency-sensitive path.                                    */
```

Choosing

	Mutex	RW lock	Seqlock	RCU
Reader cost	One atomic	One atomic, contended	Two plain loads	≈ nothing
Readers scale?	No	Poorly	Yes	Perfectly
Writer cost	Low	Low	Low	High — grace period
Readers can starve?	No	Possible	**Yes**, under write load	No
Readers see	Latest	Latest	Latest, or retry	A recent snapshot
Read section may sleep	Yes	Yes	No	No (classic RCU)
Memory freed	Immediately	Immediately	Immediately	Late
Good for	Almost everything	Long reads, rare writes	Small fixed records	Pointer-published structures read by every core

> **TRY THE BORING ANSWER FIRST**
> The order to reach for these is: plain mutex → copy the data out under a mutex → RW lock → seqlock → RCU. Each step buys read scalability and costs correctness margin. Most code that reaches for RCU would have been fine copying a small struct under a mutex, and would have been far easier to review. Move down the list only when a profile says the read path is the bottleneck.

How it shows up

Symptom	Cause
RW lock is slower than the mutex it replaced	Short read sections; the reader-count line is the bottleneck
Writers never get in	Reader-preferring RW lock under continuous read load
Deadlock upgrading read to write	Two readers both trying to upgrade
Stale data after a documented update	RCU is working as designed — readers see a snapshot
Memory usage spikes under write load	RCU frees late; use `call_rcu` and rate-limit writers
Reader crashes dereferencing a freed pointer	Missing `rcu_read_lock`, or the writer freed before the grace period
Kernel hang in `synchronize_rcu`	A read-side section that slept or never ended
Seqlock reader spins for ever	Writers never stop; the reader is starved
Seqlock reader crashes	It followed a pointer read from torn data
TSan reports a race on a seqlock	Genuine, by the letter of the standard — this is a known model/practice gap

Check yourself

- ✓ Explain why taking a read lock is a write, and what that costs.
- ✓ Give four reasons a reader-writer lock can lose to a plain mutex.
- ✓ Explain why there is no safe atomic read-to-write upgrade.
- ✓ Describe the seqlock protocol and say what readers give up.
- ✓ Explain why seqlock data must be safe to read while torn.
- ✓ State the five steps of an RCU update and name the one that is the trick.
- ✓ Explain how a grace period is detected without readers signalling anything.
- ✓ Give three costs of RCU.
- ✓ Order the four primitives by reader cost and by review difficulty.
- ✓ Say which primitive you would use for a routing table, for the system clock, and for a config struct read once per request.

Atomic operations and the CAS loop

An atomic operation is one that no other thread can observe half-finished. That is a smaller guarantee than people assume — it says nothing about *ordering*, and it does not compose. Both of those gaps are where the bugs live.

What atomic buys, and what it does not

```
ATOMIC GIVES YOU

  indivisibility   no thread sees a half-written value.
                   No torn reads, no lost read-modify-write.

  a defined value  the result is one of the values some
                   thread actually wrote - never a mixture.

ATOMIC DOES NOT GIVE YOU

  ordering         unless you ask. atomic_fetch_add with
                   memory_order_relaxed orders NOTHING
                   around it (chapter 12).

  composition      two atomic operations are not one atomic
                   operation:

                       if (atomic_load(&a) == 0)     // 1
                               atomic_store(&b, 1);  // 2

                   anything can happen between 1 and 2.
                   This is the check-then-act race with
                   extra syntax.

  atomicity of the SURROUNDING LOGIC. An atomic counter
  that is correct tells you nothing about the invariant it
  was counting.

THE ONE OPERATION THAT COMPOSES is compare-and-swap, because
it folds the check and the act into a single indivisible
step. Everything lock-free is built out of it.
```

The operation set

```
#include <stdatomic.h>                /* C11                   */

atomic_int   counter = 0;
atomic_bool  flag    = false;
_Atomic(struct point) pt;             /* may be lock-free or
                                         not - see below      */

/* LOAD / STORE - indivisible, but nothing more by default. */
        int v = atomic_load(&counter);
        atomic_store(&counter, 42);

/* READ-MODIFY-WRITE - the useful ones. Each returns the OLD
   value, which is what makes them composable into algorithms. */
        old = atomic_fetch_add(&counter,  1);
        old = atomic_fetch_sub(&counter,  1);
        old = atomic_fetch_or (&flags, MASK);
        old = atomic_fetch_and(&flags, ~MASK);
        old = atomic_fetch_xor(&flags, MASK);
        old = atomic_exchange (&ptr, newptr);

/* COMPARE-AND-SWAP - the universal primitive. */
        bool ok = atomic_compare_exchange_strong(&p, &expected, desired);
        /* if (*p == expected) { *p = desired; return true; }
           else                { expected = *p; return false; }

           NOTE: `expected` is updated on failure. That is not
           a wart - it saves you a reload in the retry loop.  */

/* C++ is the same set, spelled as methods: */
        std::atomic<int> c{0};
        c.fetch_add(1, std::memory_order_relaxed);
        c.compare_exchange_weak(exp, des);

/* Rust: */
        use std::sync::atomic::{AtomicUsize, Ordering};
        let c = AtomicUsize::new(0);
        c.fetch_add(1, Ordering::Relaxed);
        c.compare_exchange_weak(exp, des, Ordering::AcqRel,
                                Ordering::Relaxed)
```

> **`STRONG` VERSUS `WEAK`**
> `compare_exchange_weak` may fail *spuriously* — return false even when the value matched. That sounds useless until you remember ARM's LL/SC (chapter 6): the store-exclusive fails if anything touched the cache line, including an unrelated access. The weak form maps to one LL/SC attempt; the strong form has to add a retry loop inside. **Use `weak` inside a loop you were writing anyway; use `strong` when a single attempt must be conclusive.** On x86 they compile identically.

The CAS loop

```
/* The shape of every lock-free update. Learn it once. */

        T old = atomic_load_explicit(&obj, memory_order_relaxed);
        T new;
        do {
                new = compute_new_from(old);     /* pure! */
        } while (!atomic_compare_exchange_weak_explicit(
                        &obj, &old, new,
                        memory_order_acq_rel,    /* on success */
                        memory_order_relaxed));  /* on failure */

/* WHY IT IS CORRECT: the CAS only succeeds if `obj` is still
   `old` - i.e. nobody changed it while you were computing.
   If someone did, `old` is refreshed with the current value
   and you recompute. Progress is guaranteed for the system
   (someone always wins) but not for any given thread.

   THREE RULES FOR THE BODY:

   1. compute_new_from() MUST be pure and cheap. It runs again
      on every failure. Anything with a side effect - logging,
      allocating, incrementing another counter - happens
      multiple times.

   2. It must not be able to loop for ever. Under heavy
      contention a thread can lose repeatedly; if that matters,
      add back-off, or use a lock.

   3. Do NOT reload `old` yourself at the top of the loop.
      compare_exchange already wrote the current value into it.
      Reloading opens a window and is a common source of
      subtle livelock.                                        */

/* A worked example: atomically clamp-and-add. */
int add_clamped(atomic_int *c, int delta, int max)
{
        int old = atomic_load_explicit(c, memory_order_relaxed);
        int new;
        do {
                if (old >= max)
                        return -1;               /* full        */
                new = old + delta;
                if (new > max) new = max;
        } while (!atomic_compare_exchange_weak_explicit(
                        c, &old, new,
                        memory_order_acq_rel, memory_order_relaxed));
        return new;
}
/* You cannot write that with fetch_add. This is exactly the
   class of problem CAS exists for: a read-modify-write whose
   "modify" involves a decision.                           */
```

Is it actually lock-free?

```
/* An "atomic" type is not necessarily implemented in hardware.
   If the type is too big, the compiler emits a hidden LOCK. */

        _Atomic(struct { long a, b, c; }) big;   /* 24 bytes    */

        printf("%d\n", atomic_is_lock_free(&big));   /* 0       */

/* C++ has the compile-time version, which is what you want in
   a static_assert: */
        static_assert(std::atomic<MyType>::is_always_lock_free,
                      "this type needs a hidden mutex");

/* WHAT IS LOCK-FREE, TYPICALLY

     1, 2, 4, 8 bytes         yes, everywhere
     16 bytes                 x86-64: yes, via CMPXCHG16B
                              ARM64:  yes, via LDXP/STXP or
                                      CASP (LSE)
                              but often only if you compile
                              with -mcx16 / -march=armv8.1-a
     anything larger          NO - a lock table, keyed by
                              address, inside libatomic

   WHY IT MATTERS

     * a hidden lock is not async-signal-safe, so your
       "atomic" is illegal in a signal handler
     * it is not usable across processes in shared memory:
       the lock table is per-process, so two processes
       "atomically" updating the same shared struct do not
       exclude each other AT ALL
     * performance falls off a cliff you cannot see in the
       source

   Check it. Once, in a static_assert, and never worry again. */
```

> **`VOLATILE` IS STILL NOT ATOMIC**
>
> Worth repeating from chapter 2 because it is the most durable misconception in this field. `volatile` stops the compiler caching a value in a register. It does not make the access indivisible, does not stop the CPU reordering, and does not give any ordering guarantee. On MSVC with `/volatile:ms` it happens to add acquire/release semantics — which is why code written for Windows breaks when ported, and why `/volatile:iso` exists.

What atomics are actually for

Use	Operation	Ordering usually needed
Statistics counters	`fetch_add`	`relaxed` — nobody makes a decision on the value
Reference counts, increment	`fetch_add`	`relaxed` — you already hold a reference
Reference counts, decrement	`fetch_sub`	`acq_rel`, or release plus an acquire fence before destroying
A "stop" flag	`store` / `load`	`relaxed` is usually fine; `release` / `acquire` if data goes with it
Publishing a pointer	`store`	**`release`**, always (chapter 12)

Use	Operation	Ordering usually needed
Sequence numbers, ID allocation	`fetch_add`	`relaxed`
Spinlock acquire / release	`exchange` / `store`	`acquire` / `release`
Lock-free stack, queue	`compare_exchange`	`acq_rel`
One-time initialisation	`compare_exchange`	`acq_rel`, or just use `call_once`

```
/* The reference-count idiom, written correctly. It is the
   most common real use of non-trivial ordering.           */

void ref_get(struct obj *o)
{
        /* relaxed: we already hold a reference, so the object
           cannot die under us, and no data is being published */
        atomic_fetch_add_explicit(&o->refs, 1, memory_order_relaxed);
}

void ref_put(struct obj *o)
{
        if (atomic_fetch_sub_explicit(&o->refs, 1,
                                      memory_order_release) == 1) {
                /* We dropped the last reference. The release
                   above published OUR writes. Now we must
                   ACQUIRE everyone else's before we destroy,
                   or we may free memory whose last write we
                   never saw.                                  */
                atomic_thread_fence(memory_order_acquire);
                destroy(o);
        }
}
/* This exact pattern is in the C++ standard's shared_ptr
   discussion, in Boost, and in the Linux kernel's kref. If you
   find yourself writing a refcount by hand, copy it exactly. */
```

How it shows up

Symptom	Cause
Counter is correct but the logic around it is not	Two atomic operations treated as one — use CAS
CAS loop performs a side effect several times	An impure body; it re-runs on every failure
CAS loop spins for ever under load	No back-off; a thread keeps losing. Livelock
CAS never succeeds	`expected` reloaded manually at the top of the loop, or `weak` used where a single conclusive attempt was needed
"Atomic" struct is slow and not signal-safe	Too large — `libatomic` is using a hidden lock
Two processes corrupt a shared atomic struct	Same cause: the hidden lock table is per-process
Works on x86, breaks on ARM	Relaxed ordering that x86's strong model was hiding
Use-after-free on the last `put`	Missing acquire fence before destroy in the refcount
Works with MSVC, breaks with GCC	Relied on `/volatile:ms` giving acquire/release semantics

Symptom	Cause
Link error on `__atomic_load_16`	16-byte atomics without `-mcx16` / `-latomic`

Check yourself

- ✓ State exactly what atomicity guarantees and the two things it does not.
- ✓ Show why two atomic operations are not one, with a concrete race.
- ✓ Explain why compare-and-swap is the primitive everything lock-free is built from.
- ✓ Write the CAS loop from memory and give the three rules for its body.
- ✓ Explain why `expected` is updated on failure and why reloading it manually is a bug.
- ✓ Distinguish `compare_exchange_weak` from `strong`, and relate it to LL/SC.
- ✓ Explain how an "atomic" type can contain a hidden lock and give two consequences.
- ✓ Say why `volatile` is not a substitute, including the MSVC caveat.
- ✓ Write the reference-count get/put pair with correct orderings and justify each.
- ✓ Give the right memory order for a statistics counter and for publishing a pointer, with reasons.

Memory ordering and happens-before

Your program's memory operations do not happen in the order you wrote them. The compiler reorders, the CPU reorders, and the cache system makes writes visible to different cores at different times. A memory model is the contract that says which of those reorderings you are allowed to notice — and *happens-before* is the only relation in it that matters.

Three layers of reordering

```
YOU WROTE                  WHAT ACTUALLY RUNS

  a = 1;                     the COMPILER may:
  b = 2;                       reorder independent stores
  x = c;                       keep a value in a register
                               delete a "redundant" load
                               hoist a load out of a loop
                               merge two stores into one

                             the CPU may:
                               execute out of order
                               speculate past a branch
                               buffer stores and drain later
                               prefetch loads early

                             the MEMORY SYSTEM may:
                               make your store visible to
                               core 2 before core 3 sees it

NONE of this is a bug. All of it is required for
performance, and all of it is invisible in single-threaded
code because each layer preserves the illusion for the
thread doing the work.

Concurrency is where the illusion leaks - and the memory
model is the exact specification of how much it may leak.
```

Architecture	Reordering allowed	Practical effect
Sequential consistency	None	The mental model everyone has. No real CPU provides it
x86-64 (TSO)	Store→Load only	Strong. Most sloppy code accidentally works, which is why it ships
ARM64	Almost anything	Weak. The same code fails, and this is where your bug is discovered
RISC-V (RVWMO)	Almost anything	Weak, similar to ARM
POWER	Anything, plus non-multi-copy-atomic	Weakest in common use

Happens-before is the whole model

```
The C, C++, Rust, Java and Go memory models all say the
same thing:

  If A happens-before B, then B sees A's effects.
  If neither happens-before the other AND one is a write,
  that is a DATA RACE - undefined behaviour.

HOW YOU ESTABLISH HAPPENS-BEFORE - and there are only four
ways:

1. PROGRAM ORDER, within one thread.
     a = 1; b = 2;      -> a=1 happens-before b=2
     (as OBSERVED by that thread. Others may disagree.)

2. RELEASE / ACQUIRE on the same variable.
     thread A:  ... writes ...
                atomic_store(&flag, 1, release);
     thread B:  while (!atomic_load(&flag, acquire)) ;
                ... reads ...
     -> everything before A's store happens-before
        everything after B's load. THIS IS THE ONE YOU USE.

3. THREAD CREATION AND JOIN.
     everything before pthread_create happens-before the
     new thread's first instruction.
     everything in a thread happens-before pthread_join
     returns.

4. MUTEX UNLOCK / LOCK on the same mutex.
     which is just case 2 with nicer syntax - unlock is a
     release, lock is an acquire.

TRANSITIVITY: happens-before chains. If A hb B and B hb C
then A hb C. That is what makes a mutex work across three
threads.

AND NOTHING ELSE ESTABLISHES IT. Not "thread B started
later". Not "the sleep was long enough". Not "it is only
one byte".
```

The six orderings

```
/* From weakest to strongest. */

memory_order_relaxed
        Atomicity only. No ordering with anything.
        USE FOR: counters nobody makes decisions on, and the
        increment side of a refcount.
        DO NOT USE FOR: publishing anything.

memory_order_acquire        (loads, and RMW)
        Nothing after this in program order may be reordered
        BEFORE it. Pairs with a release on the same variable
        to give you everything the releaser wrote.
        THINK: "I am picking up the data."

memory_order_release        (stores, and RMW)
        Nothing before this in program order may be reordered
        AFTER it.
        THINK: "I am handing over the data."

memory_order_acq_rel        (RMW only)
        Both. For a read-modify-write that both consumes and
        publishes - a CAS in a lock-free stack, a refcount
        decrement.

memory_order_seq_cst        (the default)
        Acquire+release PLUS a single total order that ALL
        seq_cst operations agree on, across all variables.
        The only one that gives you the naive mental model.
        Costs a full barrier (DMB ISH on ARM, MFENCE-ish on
        x86 for stores).

memory_order_consume
        Intended as a cheaper acquire for pointer chasing.
        Every real compiler promotes it to acquire because
        the specification is unimplementable as written.
        DO NOT USE IT. It is being deprecated.
```

> **THE DEFAULT IS `SEQ_CST`, AND THAT IS THE RIGHT DEFAULT**
>
> Write `atomic_load(&x)` and you get sequential consistency. It is the slowest ordering and the only one that behaves the way you expect. **Start there.** Weaken an ordering only when a profile shows the barrier costs you and you can write down the happens-before chain that still holds. Code littered with `relaxed` written by someone who could not articulate why is the least reviewable code in existence.

The publication pattern

```
/* This is 90% of the memory ordering you will ever need. */

struct config *cfg;                     /* the payload         */
atomic_bool ready = false;

/* PUBLISHER */
void publish(void)
{
        struct config *c = malloc(sizeof *c);
        c->timeout = 30;                /* (1) */
        c->retries = 3;                 /* (2) */
        cfg = c;                        /* (3) */

        atomic_store_explicit(&ready, true, memory_order_release);
        /* RELEASE: (1),(2),(3) cannot move after this line, and
           are guaranteed visible to anyone who ACQUIRES `ready`
           and sees true.                                        */
}

/* CONSUMER */
void consume(void)
{
        if (atomic_load_explicit(&ready, memory_order_acquire)) {
                /* ACQUIRE: nothing below may move above. Having
                   seen `true`, we are guaranteed to see (1),(2)
                   and (3).                                     */
                use(cfg->timeout, cfg->retries);   /* safe      */
        }
}

/* WHAT GOES WRONG WITH relaxed

        atomic_store_explicit(&ready, true, memory_order_relaxed);

   The store to `ready` may become visible BEFORE the stores to
   c->timeout, c->retries, or even before `cfg` itself. The
   consumer sees ready==true, dereferences a pointer that is
   still null or points at uninitialised memory, and crashes.

   ON x86 this almost never happens, because TSO does not
   reorder store-store. ON ARM it happens immediately. That
   asymmetry is why this bug reaches production: it is written
   on a laptop and found on a phone.                          */
```

The one x86 also gets wrong

```
/* Store-Load is reordered even on x86. This is Dekker's
   pattern, and it is the classic demonstration.            */

atomic_int x = 0, y = 0;
int r1, r2;

/* thread A */              /* thread B */
x = 1;                      y = 1;
r1 = y;                     r2 = x;

/* CAN r1 == 0 && r2 == 0 ?

   With sequential consistency: NO. Someone stored first, and
   the other thread must see it.

   In reality: YES, on every real CPU including x86.

   Both stores sit in their core's store buffer. Both loads
   read from L1, which has not seen the other core's store
   yet. Both read 0.

   This is the ONLY reordering x86 permits, and it is enough
   to break hand-rolled synchronisation. It is why
   seq_cst STORES are expensive on x86 - the compiler must
   emit an MFENCE or use XCHG to drain the store buffer.

   THE FIX: use seq_cst on both (the default), or insert
   atomic_thread_fence(memory_order_seq_cst) between the store
   and the load in each thread.                              */
```

What it compiles to

```
/* ARM64 - the orderings map to distinct instructions, which
   is why the choice actually costs something.              */

  relaxed load        LDR   x0, [x1]
  acquire load        LDAR  x0, [x1]          ; load-acquire
  seq_cst load        LDAR  x0, [x1]          ; same

  relaxed store       STR   x0, [x1]
  release store       STLR  x0, [x1]          ; store-release
  seq_cst store       STLR  x0, [x1]          ; same
                      (with -moutline-atomics or older targets
                       you may instead see DMB ISH + STR)

  fence(acquire)      DMB ISHLD
  fence(release)      DMB ISH
  fence(seq_cst)      DMB ISH

  relaxed fetch_add   LDXR/ADD/STXR loop, or LDADD  (LSE)
  acq_rel fetch_add   LDAXR/ADD/STLXR,   or LDADDAL (LSE)

/* x86-64 - almost everything is free, which is the trap. */

  relaxed load        MOV
  acquire load        MOV                     ; free!
  seq_cst load        MOV                     ; free!

  relaxed store       MOV
  release store       MOV                     ; free!
  seq_cst store       XCHG  (or MOV + MFENCE) ; NOT free

/* Read that x86 column again. Acquire and release cost
   NOTHING on x86 - so code that omits them behaves
   identically. The bug is not merely hidden; it is
   unobservable, on that machine, for ever.                */
```

> **TEST ON WEAK HARDWARE, OR YOU HAVE NOT TESTED**
> An arm64 machine — a Raspberry Pi, an Apple Silicon Mac, a Graviton instance — will surface ordering bugs that x86 physically cannot exhibit. If your product ships on ARM and your CI is x86-only, your CI is not testing the memory model at all. Add one weak-ordered runner; it is the highest-value CI change a concurrent codebase can make.

How it shows up

Symptom	Cause
Crash dereferencing a just-published pointer	Relaxed store where a release was needed
Reader sees the flag but stale data	Missing acquire on the reader side
Works on x86, fails on ARM/Apple Silicon	Store-store or load-load reordering that TSO forbids
Fails only at -O2	The compiler hoisted a non-atomic load out of a loop
Both threads take the "other one went first" branch	Store-Load reordering — needs `seq_cst` or a fence
Adding a `printf` fixes it	The syscall is a full barrier
Use-after-free on the last refcount drop	Release on the decrement without the acquire fence before destroy

Symptom	Cause
Performance regression after "fixing" ordering	Every operation promoted to `seq_cst`; on ARM each store became an `STLR` or a `DMB`
Code using `memory_order_consume` behaves as acquire	Correct — every compiler promotes it

Check yourself

- ✓ Name the three layers that reorder your memory operations and give an example of each.
- ✓ State the happens-before rule and the four ways to establish it.
- ✓ Explain why transitivity of happens-before is what makes a mutex work.
- ✓ List the six memory orderings and say what each guarantees.
- ✓ Say which ordering is the default and why that is the right default.
- ✓ Write the publication pattern with correct orderings and explain what breaks with `relaxed`.
- ✓ Explain why the publication bug ships from x86 and fails on ARM.
- ✓ Give the Dekker example and say why both threads can read zero even on x86.
- ✓ Say what an acquire load and a release store compile to on ARM64 and on x86-64.
- ✓ Explain why acquire/release being free on x86 makes the bug worse, not better.

Lock-free and wait-free data structures

Lock-free does not mean fast, and it does not mean easy. It means one specific progress guarantee, bought with a memory-reclamation problem that has no cheap solution. This chapter is mostly about why you should not write these, and what to do when you must.

The guarantees, precisely

```
BLOCKING (a mutex)
  If the thread holding the lock is descheduled, killed, or
  page-faults, NOBODY makes progress.

OBSTRUCTION-FREE
  A thread makes progress if it runs alone for long enough.
  Weakest useful guarantee; rarely used on its own.

LOCK-FREE
  At least ONE thread makes progress, always.
  Individual threads may starve indefinitely.
  -> the system never stalls because a thread was
     descheduled at a bad moment.

WAIT-FREE
  EVERY thread completes in a BOUNDED number of steps,
  regardless of what other threads do.
  -> no starvation, and a hard latency bound.
  -> almost always slower in the common case, because
     bounding the worst case costs work in every case.

WHAT THIS BUYS YOU, and it is narrower than the marketing:

  * immunity to lock-holder preemption. Matters enormously
    in a hypervisor guest (virtualisation chapter 8) or a
    system with mixed priorities.
  * usable from an interrupt handler or a signal handler,
    where you cannot take a sleeping lock.
  * no deadlock, ever - there is no lock to order.
  * a real worst-case bound (wait-free only), which is why
    hard real-time cares.

WHAT IT DOES NOT BUY

  * throughput. Under contention a lock-free structure
    does the same cache-line bouncing a spinlock does, and
    often more, because losers retry.
  * simplicity. See the rest of this chapter.
```

THE HONEST RECOMMENDATION

Use a mutex. If profiling proves the lock is the bottleneck, first try: sharding the data, per-thread accumulation with a merge, a read-mostly structure (chapter 10), or an off-the-shelf concurrent container. Write a lock-free structure yourself only if none of those fit and you have a memory-reclamation scheme, a weak-hardware test rig, and a reviewer who has done it before. This is not conservatism — published, peer-reviewed lock-free algorithms have shipped with bugs found years later.

A lock-free stack, and its famous bug

```
/* The Treiber stack. Four lines, and one of them is wrong. */

struct node { struct node *next; void *val; };
_Atomic(struct node *) top;

void push(void *v)
{
        struct node *n = malloc(sizeof *n);
        n->val = v;
        n->next = atomic_load_explicit(&top, memory_order_relaxed);
        while (!atomic_compare_exchange_weak_explicit(
                        &top, &n->next, n,
                        memory_order_release,      /* publish n */
                        memory_order_relaxed))
                ;                                  /* n->next was
                                                      refreshed  */
}

void *pop(void)
{
        struct node *t = atomic_load_explicit(&top, memory_order_acquire);
        while (t && !atomic_compare_exchange_weak_explicit(
                        &top, &t, t->next,
                        memory_order_acquire, memory_order_acquire))
                ;
        if (!t) return NULL;
        void *v = t->val;
        free(t);                    /* <-- THE BUG IS HERE      */
        return v;
}
```

```
   THE ABA PROBLEM

   stack:  A -> B -> C

   thread 1: reads top = A, reads A->next = B.
             about to CAS(top, A, B)...
             ...and is preempted here.

   thread 2: pop() -> gets A, frees it
             pop() -> gets B, frees it
             push(X)
             push(A)      <-- malloc RETURNS THE SAME ADDRESS

   stack:  A -> X -> C          (B is freed!)

   thread 1: resumes. CAS(top, A, B) - top IS still A, so the
             CAS SUCCEEDS.

   stack:  B -> ???             B is freed memory.

   The value was A, then changed, then became A again. The CAS
   cannot tell. Hence A-B-A.

   AND NOTE the second bug hiding in the same window: thread 1
   read `t->next` from a node thread 2 already freed. That is
   a use-after-free even before the ABA fires.
```

The real problem: when can you free?

```
/* "Is any other thread still looking at this node?" has no
   cheap answer, and every solution is a whole subsystem.    */

/* 1. TAGGED POINTERS - fixes ABA, not use-after-free.
      Pack a counter beside the pointer and CAS both at once. */

struct tagged { struct node *ptr; uintptr_t tag; };
_Atomic(struct tagged) top;          /* needs 128-bit CAS:
                                        CMPXCHG16B / CASP     */
/* Every store increments tag, so A-with-tag-7 never equals
   A-with-tag-9. Cheap and effective - but a reader can still
   dereference a node that was freed between its load and its
   CAS. Only sufficient if nodes are never actually freed
   (a free list you own).                                     */

/* 2. HAZARD POINTERS - each thread publishes what it is
      looking at; the reclaimer checks before freeing.       */

_Atomic(struct node *) hazard[MAX_THREADS];

void *pop(void)
{
        struct node *t;
        do {
                t = atomic_load(&top);
                if (!t) return NULL;
                atomic_store(&hazard[my_id], t);   /* announce  */
                if (atomic_load(&top) != t)        /* re-verify */
                        continue;                  /* it moved  */
        } while (!atomic_compare_exchange_weak(&top, &t, t->next));

        atomic_store(&hazard[my_id], NULL);
        retire(t);          /* deferred: free only when no
                               hazard[] entry points at it      */
        return t->val;
}
/* Bounded memory, O(threads) scan per reclaim, and a store +
   fence on every read. C++26 has std::hazard_pointer. */

/* 3. EPOCH-BASED RECLAMATION - readers announce an epoch;
      memory from epoch N is freed once every thread has been
      seen in epoch N+2. This is crossbeam's approach in Rust,
      and it is essentially userspace RCU (chapter 10).
      Cheaper reads than hazard pointers, unbounded memory if
      a thread stalls inside a critical section.             */

/* 4. NEVER FREE - a preallocated pool and a free list.
      The only approach that is genuinely simple, and the one
      real-time systems actually use. Bounded, predictable,
      and it turns the problem into capacity planning.       */

/* 5. A GARBAGE COLLECTOR - which is why lock-free structures
      are dramatically easier in Java, Go and C#. The hardest
      part of the problem is already solved for you.         */
```

RECLAMATION IS THE WHOLE DIFFICULTY

Every lock-free algorithm you read in a paper assumes garbage collection, or waves at "a safe memory reclamation scheme". That hand-wave is 80% of the implementation work and essentially all of the bugs. If you are evaluating a lock-free library, the first question is not "is the algorithm correct" — it is "which reclamation scheme, and what happens when a thread stalls inside a read".

The one you should actually write

```
/* A single-producer single-consumer ring buffer. Lock-free,
   wait-free, no reclamation problem, ~30 lines, and it covers
   a large fraction of real use cases: an audio callback, an
   ISR to a worker, a logging thread.

   It works because with exactly one producer and one consumer,
   each index has exactly one writer.                          */

#define CAP 1024                    /* power of two           */

struct spsc {
        void       *slot[CAP];
        alignas(64) atomic_size_t head;   /* consumer writes   */
        alignas(64) atomic_size_t tail;   /* producer writes   */
        /* alignas(64) keeps them on separate cache lines -
           without it the two threads fight over one line and
           the whole thing runs at a fraction of the speed
           (chapter 16).                                       */
};

bool spsc_push(struct spsc *q, void *v)
{
        size_t t = atomic_load_explicit(&q->tail, memory_order_relaxed);
        size_t h = atomic_load_explicit(&q->head, memory_order_acquire);
        if (t - h == CAP)
                return false;                   /* full        */

        q->slot[t & (CAP - 1)] = v;             /* write data  */
        atomic_store_explicit(&q->tail, t + 1,
                              memory_order_release);  /* publish */
        return true;
}

bool spsc_pop(struct spsc *q, void **out)
{
        size_t h = atomic_load_explicit(&q->head, memory_order_relaxed);
        size_t t = atomic_load_explicit(&q->tail, memory_order_acquire);
        if (h == t)
                return false;                   /* empty       */

        *out = q->slot[h & (CAP - 1)];
        atomic_store_explicit(&q->head, h + 1,
                              memory_order_release);
        return true;
}

/* Note the indices MONOTONICALLY INCREASE and are masked only
   on use. That is what makes full and empty distinguishable
   without wasting a slot, and unsigned wraparound is
   well-defined so it is correct for ever.                     */
```

How it shows up

Symptom	Cause
Rare corruption in a lock-free stack	ABA — a node was freed and reallocated at the same address
Use-after-free reading `t->next`	No reclamation scheme; the node was freed between the load and the CAS
Memory grows without bound	Epoch reclamation with a thread stalled inside a critical section
Lock-free version slower than the mutex	Contention causes retries; losers redo the work
SPSC queue is 10x slower than expected	Head and tail on the same cache line — needs `alignas(64)`
Works on x86, corrupts on ARM	Missing acquire/release; TSO was hiding it
One thread starves for seconds	Lock-free guarantees system progress, not per-thread — use wait-free if that matters
Link error on 128-bit CAS	Tagged pointers without `-mcx16` or `-march=armv8.1-a`
Queue reports full when it is empty	Indices masked before comparison instead of on use

Check yourself

- ✓ Define blocking, lock-free and wait-free in terms of progress guarantees.
- ✓ Give three things lock-free genuinely buys and two it does not.
- ✓ Walk through the ABA sequence step by step.
- ✓ Identify the second bug that occurs in the same window as ABA.
- ✓ Name five reclamation approaches and the cost of each.
- ✓ Explain why lock-free structures are far easier in Java or Go.
- ✓ Write an SPSC ring buffer with correct orderings from memory.
- ✓ Explain why the SPSC queue has no reclamation problem.
- ✓ Say why the indices increase monotonically and are masked only on use.
- ✓ Explain the `alignas(64)` and what happens without it.

Deadlock, livelock and starvation

Three ways for a program to stop making progress, distinguishable in about ten seconds if you know what to look at. Deadlock is also the one concurrency bug with a complete, mechanical prevention strategy — which is why it is inexcusable in new code.

The four conditions

```
Coffman's conditions. Deadlock requires ALL FOUR.
Break any one and it cannot happen.

1. MUTUAL EXCLUSION
     the resource cannot be shared.
     Break it: use immutable data, or copies, or a
     lock-free structure. Often impossible.

2. HOLD AND WAIT
     a thread holds one resource while requesting another.
     Break it: take all locks at once (std::scoped_lock),
     or take none and retry.

3. NO PREEMPTION
     a resource cannot be taken away from its holder.
     Break it: try_lock with a timeout, and back off.

4. CIRCULAR WAIT
     a cycle in the "waits for" graph.
     Break it: a GLOBAL LOCK ORDER.
     <-- THIS IS THE ONE YOU BREAK. Always.

Condition 4 is the practical target because it costs
nothing at runtime, needs no error path, and can be
checked mechanically.
```

```
/* THE CANONICAL DEADLOCK */

void transfer(Account &from, Account &to, int amount)
{
        std::lock_guard<std::mutex> g1(from.m);   /* A then B */
        std::lock_guard<std::mutex> g2(to.m);
        from.balance -= amount;
        to.balance   += amount;
}

/* thread 1: transfer(alice, bob, 100)   locks alice, wants bob
   thread 2: transfer(bob, alice, 50)    locks bob,  wants alice
   -> a cycle. Both wait for ever.                          */

/* FIX 1: a global order. Any total order will do, as long as
   everyone uses the same one. Address works and needs no
   extra state.                                             */
void transfer(Account &from, Account &to, int amount)
{
        Account *a = &from, *b = &to;
        if (a > b) std::swap(a, b);          /* ORDER BY ADDRESS */

        std::lock_guard<std::mutex> g1(a->m);
        std::lock_guard<std::mutex> g2(b->m);
        from.balance -= amount;
        to.balance   += amount;
}
/* Careful: transfer(x, x) now locks the same mutex twice.
   Guard it: if (&from == &to) return; */

/* FIX 2: let the library do it. std::scoped_lock takes N
   mutexes with a deadlock-avoidance algorithm (repeated
   try_lock with back-off).                                 */
void transfer(Account &from, Account &to, int amount)
{
        std::scoped_lock g(from.m, to.m);    /* C++17, safe in
                                                any order       */
        from.balance -= amount;
        to.balance   += amount;
}
/* This is the right default. std::lock() is the C++11 form. */
```

WRITE THE LOCK ORDER DOWN

Not in a wiki — in a header, next to the locks, as a numbered list. "Locks are acquired in this order: (1) `registry.m`, (2) `account.m`, (3) `logger.m`. Never take a lower-numbered lock while holding a higher-numbered one." That comment is checkable in review and by tooling. A lock order that exists only in people's heads has already been violated somewhere.

The deadlocks you did not write

```
/* The cycle is rarely two mutexes in one function. It is
   almost always a call you did not know took a lock.       */

/* 1. THE CALLBACK. */
void Subject::notify() {
        std::lock_guard g(m_);
        for (auto *o : observers_)
                o->on_event();     /* unknown code. It may call
                                      back into US and try to
                                      take m_. Or take ITS lock,
                                      while another thread does
                                      the reverse.             */
}
/* FIX: copy the observer list under the lock, release, then
   call. Or dispatch onto a queue.                          */
void Subject::notify() {
        std::vector<Observer *> copy;
        { std::lock_guard g(m_); copy = observers_; }
        for (auto *o : copy) o->on_event();     /* unlocked    */
}

/* 2. THE ALLOCATOR. malloc takes locks. Allocating inside
      your lock creates an order between your lock and the
      allocator's - and the allocator is taken by everything. */

/* 3. THE LOGGER. Same shape, and worse because logging is
      added to error paths, which is where lock state is
      already unusual.                                       */

/* 4. RECURSION THROUGH A LIBRARY. You call into a framework
      holding your lock; it calls your callback on another
      path that takes the same lock.                         */

/* 5. FORK. In a multithreaded process, fork() gives the child
      ONE thread and a copy of every mutex - including ones
      that were locked by threads that do not exist in the
      child. The child deadlocks on the first malloc.
      This is why POSIX says only async-signal-safe functions
      are legal between fork and exec, and why
      pthread_atfork exists.                                 */

/* 6. SIGNAL HANDLERS. A handler that takes a lock the
      interrupted thread already holds deadlocks that thread
      against itself.                                        */
```

Telling the three apart

	Deadlock	Livelock	Starvation
CPU usage	**Zero**	**100%**	Normal
Progress	None, ever	None, but busy	Some threads progress, one does not
Threads are	Blocked in a wait	Running, retrying	Runnable but never chosen
Typical cause	Circular wait	Mutual back-off, or a CAS loop that always loses	Unfair lock, priority, or a hot producer
Recovers alone?	Never	Sometimes, with randomised back-off	Sometimes, when load drops

```
# Deadlock: attach and look. Every thread will be in a wait.
$ gdb -p $(pidof app)
(gdb) thread apply all bt
Thread 3: __lll_lock_wait () ... at accounts.cpp:41
Thread 2: __lll_lock_wait () ... at accounts.cpp:41
# Two threads, same line, both waiting. That is your cycle.

$ eu-stack -p $(pidof app)            # lighter than gdb
$ py-spy dump --pid $(pidof app)      # Python
$ jstack $(pidof java)                # Java PRINTS the cycle:
#   "Found one Java-level deadlock"

# Live detection - use it in every debug build:
$ valgrind --tool=helgrind ./app
==1234== Thread #2: lock order "0x5a1000 before 0x5a1040" violated

# The kernel's version, and the best of them:
$ echo 1 > /proc/sys/kernel/lock_stat      # with CONFIG_LOCKDEP
# lockdep learns the lock order from observed acquisitions and
# reports a POTENTIAL inversion the first time it sees one -
# even if the deadlock never actually happens. That is the
# property you want: it finds the bug on the run where it did
# NOT deadlock.

# In C++, the same idea, free:
$ clang++ -Wthread-safety -Wthread-safety-analysis ...
# with GUARDED_BY / ACQUIRED_BEFORE annotations.
```

TIMEOUTS ARE A DIAGNOSTIC, NOT A FIX

`try_lock_for(5s)` converts a hang into an error you can log — genuinely useful, and it makes production survivable. It does not remove the cycle. Code that retries after a timeout can livelock instead, and code that gives up leaves the invariant half-updated. Use timeouts to detect and report; fix the order.

Livelock and starvation

```
/* LIVELOCK: everyone is polite, nobody progresses. */

bool transfer(Account &a, Account &b) {
        while (true) {
                std::unique_lock la(a.m);
                std::unique_lock lb(b.m, std::try_to_lock);
                if (lb.owns_lock()) { do_it(); return true; }
                /* release both and retry - no deadlock ... */
        }   /* ... but two threads can retry in lockstep for
               ever, each releasing just as the other tries.  */
}
/* FIX: randomised exponential back-off, so the two threads
   desynchronise. This is precisely why Ethernet uses it. */
                std::this_thread::sleep_for(
                        std::chrono::microseconds(rand() % (1 << n)));

/* STARVATION: progress happens, but not for you. */

/* Causes:
     - a reader-preferring RW lock and continuous readers
       (chapter 10)
     - an unfair mutex where a barging thread re-acquires
       before the queued waiter is scheduled
     - priority: a SCHED_FIFO thread starving everything below
     - a CAS loop where one thread always loses to a faster
       core, or to a core with better cache locality

   Fixes: ticket locks, fair queueing, priority ageing, or
   accepting it and measuring the p99.9 rather than the mean. */
```

The rules that prevent all of this

1. **Define a global lock order and document it in the header.** Break circular wait and the other three conditions do not matter.
2. **Take multiple locks with `scoped_lock`,** never by hand.
3. **Never call unknown code while holding a lock.** No callbacks, no virtual calls, no allocation in hot paths, no logging.
4. **Never hold a lock across I/O or a sleep.**
5. **Prefer one coarse lock** until a profile forces you to split it. Two locks are more than twice the risk of one.
6. **Run lockdep, Helgrind or `-Wthread-safety` in CI.** All three find inversions on runs that did not hang.
7. **Add timeouts in production** so a hang becomes a logged error with a stack, not a mystery.

How it shows up

Symptom	Cause
Hang, zero CPU, two threads on the same lock line	Classic circular wait
Hang, 100% CPU	Livelock, or a CAS loop that never wins

Symptom	Cause
One request in a thousand takes 30 seconds	Starvation under an unfair lock
Deadlock only when logging is enabled	The logger's lock introduced a new order
Deadlock only under memory pressure	An allocation inside a lock, and the allocator took its own
Child process hangs after `fork`	A mutex copied in a locked state; only the forking thread survived
Hang inside a signal handler	The handler took a lock the interrupted thread held
Deadlock appears after adding an observer	A callback invoked under the lock
Works for months, deadlocks after a refactor	Two call paths now acquire in opposite orders
Helgrind reports an inversion that never hangs	Correct and valuable — it found a latent cycle

Check yourself

- ✓ State the four Coffman conditions and say which one you break in practice, and why that one.
- ✓ Write the classic transfer deadlock and give two distinct fixes.
- ✓ Explain the edge case in ordering by address and how to guard it.
- ✓ Give six ways a lock gets taken that you did not write.
- ✓ Explain why `fork` in a multithreaded process is dangerous.
- ✓ Distinguish deadlock, livelock and starvation by CPU usage and thread state.
- ✓ Describe how lockdep finds a deadlock on a run that did not deadlock.
- ✓ Explain why a timeout is a diagnostic rather than a fix.
- ✓ Explain why livelock needs randomised back-off specifically.
- ✓ List the seven prevention rules and identify which two you currently violate.

Priority inversion and real-time concurrency

A high-priority thread blocked behind a low-priority one is not a scheduling curiosity; it is the failure that put Mars Pathfinder into a reset loop on another planet. This chapter covers the mechanism, the two standard fixes, and what "real-time" actually demands of concurrent code.

The mechanism

```
Three threads. H high, M medium, L low. H and L share a
mutex; M shares nothing.

time -->

L    [--lock--][ running ]
M                        [======== running, forever =======]
H              [wants the lock ... blocked ... blocked ....]

1. L takes the mutex and starts work.
2. H becomes runnable, preempts L, and blocks on the mutex.
3. L is runnable again - but M, which is higher priority
   than L, preempts it.
4. L never runs, so it never releases the mutex, so H never
   runs.

H is now effectively running at L's priority, and is
blocked by M - a thread it outranks and shares nothing
with. That is UNBOUNDED PRIORITY INVERSION: the delay has
no upper bound, because any number of medium-priority
threads can keep arriving.

BOUNDED inversion - H waiting while L finishes its critical
section - is unavoidable and fine. You bound it by keeping
critical sections short. It is the UNBOUNDED case, caused
by a third thread, that must be designed out.
```

MARS PATHFINDER, 1997

The lander began resetting on the Martian surface. A high-priority bus-management task shared a mutex with a low-priority meteorological task; a medium-priority communications task preempted the low one, the high-priority task missed its deadline, and the watchdog rebooted the spacecraft. The fix was uploaded from Earth: enable priority inheritance on that mutex — a flag that VxWorks supported and that had been left off.

The two protocols

```
/* PRIORITY INHERITANCE (PI)
   While L holds a mutex that H wants, L runs at H's priority.
   As soon as it releases, it drops back.                    */

pthread_mutexattr_t a;
pthread_mutexattr_init(&a);
pthread_mutexattr_setprotocol(&a, PTHREAD_PRIO_INHERIT);
pthread_mutex_init(&m, &a);

/*   L    [--lock--][boosted to H's priority][unlock]
     M                                      [ runs ]
     H              [blocked][----------------------][runs]

   M can no longer preempt L, because L is temporarily as
   important as H. The inversion is now BOUNDED by the length
   of L's critical section.

   Cost: the scheduler must track the boost, and inheritance
   is TRANSITIVE - if L is itself blocked on a mutex held by
   K, K gets boosted too. Chains are handled but cost more.

   This is the default choice, and what Linux's PREEMPT_RT,
   VxWorks and QNX use.                                      */

/* PRIORITY CEILING (PCP / immediate ceiling)
   Every mutex is given a CEILING: the priority of the
   highest-priority thread that will ever take it. Any thread
   that acquires it is immediately raised to the ceiling.   */

pthread_mutexattr_setprotocol(&a, PTHREAD_PRIO_PROTECT);
pthread_mutexattr_setprioceiling(&a, 80);

/*   Advantages over inheritance:
       * no boost tracking at runtime - the raise is
         unconditional and cheap
       * prevents DEADLOCK among ceiling-protected mutexes,
         provably, because a thread can only ever block on a
         mutex whose ceiling exceeds its current priority
       * better worst-case analysis for certification

     Disadvantages:
       * you must know every user of every mutex in advance,
         and keep the ceilings correct as the code changes
       * a low-priority thread is boosted even when no
         high-priority thread wants the lock - it "wastes"
         priority

   Use PCP in certified systems where the thread set is fixed
   and analysed. Use PI everywhere else.                     */
```

> **ONLY MUTEXES CAN DO THIS**
>
> Priority inheritance requires an **owner**. A semaphore has none — anyone may post it — so there is nobody to boost. The same applies to condition variables, barriers, and hand-rolled spinlocks. If you are using a binary semaphore as a mutex in a real-time system (chapter 9), you have no protection against unbounded inversion. This is the single strongest argument for using a real mutex.

What real-time actually requires

```
"Real-time" does not mean fast. It means BOUNDED.
A system with a guaranteed 10 ms response is real-time.
One that is usually 10 us and occasionally 200 ms is not.

THE THINGS THAT MUST BE BOUNDED

1. every critical section          measurable, short
2. priority inversion              PI or PCP mutexes
3. memory allocation               PREALLOCATE. malloc has
                                   unbounded worst case and
                                   its own locks
4. page faults                     mlockall(MCL_CURRENT |
                                   MCL_FUTURE) - a demand
                                   page fault is milliseconds
5. interrupt latency               threaded IRQs, or a small
                                   bounded top half
6. the scheduler itself            SCHED_FIFO/RR/DEADLINE,
                                   not CFS
7. lock acquisition                fair (ticket/FIFO) locks,
                                   or no locks at all
8. cache and TLB behaviour         pinning, and sometimes
                                   cache partitioning

MISS ANY ONE and the system has an unbounded tail, however
good the other seven are. This is why real-time work feels
like removing things rather than adding them.
```

```
/* The standard preamble for a real-time thread on Linux. */

#include <sched.h>
#include <sys/mman.h>
#include <malloc.h>

void rt_setup(void)
{
        /* 1. Never be swapped or demand-paged. */
        mlockall(MCL_CURRENT | MCL_FUTURE);

        /* 2. Stop the allocator returning memory to the OS and
              having to fault it back in. */
        mallopt(M_TRIM_THRESHOLD, -1);
        mallopt(M_MMAP_MAX, 0);

        /* 3. Touch the whole stack now, so no fault later. */
        char scratch[512 * 1024];
        memset(scratch, 0, sizeof scratch);

        /* 4. Real-time policy. */
        struct sched_param p = { .sched_priority = 80 };
        pthread_setschedparam(pthread_self(), SCHED_FIFO, &p);

        /* 5. Pin, and use a core isolated with isolcpus and
              nohz_full so the kernel stops interrupting it. */
        cpu_set_t s; CPU_ZERO(&s); CPU_SET(3, &s);
        sched_setaffinity(0, sizeof s, &s);
}

/* And a PI mutex for anything shared with a lower-priority
   thread: */
pthread_mutexattr_t a;
pthread_mutexattr_init(&a);
pthread_mutexattr_setprotocol(&a, PTHREAD_PRIO_INHERIT);
pthread_mutex_init(&shared_lock, &a);

/* THEN MEASURE, because every one of those steps is a claim: */
$ cyclictest -t1 -p80 -a3 -i200 -m -n -l 10000000
T: 0 (1234) P:80 I:200 C:10000000 Min:2 Act:3 Avg:3 Max:14
/* Max is the number that matters. Run it for hours, under
   load, with the real workload running. A Max that grows the
   longer you run means something is unbounded.             */
```

Inversion outside the scheduler

```
/* The same shape appears wherever a queue is shared. */

  A LOCK CONVOY
    Many threads pass one lock in strict FIFO order. Each
    releases, the next is woken, but the releaser immediately
    tries again and now queues at the back. Throughput
    collapses to one handoff per context switch (~µs) even
    though the critical section is nanoseconds.
    FIX: barging (unfair) locks, or shard the data.

  THE THUNDERING HERD
    N threads woken for one item; N-1 immediately sleep again.
    FIX: signal instead of broadcast (chapter 8), or a queue
    per worker.

  I/O PRIORITY INVERSION
    A high-priority thread blocks on a page from a file whose
    read was queued behind a low-priority thread's bulk copy.
    FIX: ionice, cgroup I/O weights, or read ahead.

  MEMORY ALLOCATOR INVERSION
    Your RT thread calls malloc, which takes the arena lock a
    low-priority thread holds while the allocator does an
    mmap. Unbounded, and invisible in your source.
    FIX: preallocate. This is why RT code has pools.

  In every case the pattern is: a scarce serialised resource,
  and a scheduling policy that does not know about it.      */
```

How it shows up

Symptom	Cause
High-priority thread misses deadlines under load	Unbounded priority inversion — enable `PTHREAD_PRIO_INHERIT`
Watchdog resets the system intermittently	The Pathfinder failure, exactly
Raising a thread's priority made latency worse	It now blocks on a lock held by something it outranks
Latency fine in test, terrible in production	Medium-priority load absent in test is the third thread in the inversion
Occasional millisecond spikes in an RT loop	A page fault, a `malloc`, or a migration — one of the eight bounds is missing
Binary semaphore gives no protection	Semaphores have no owner, so no inheritance
Throughput collapses at a specific thread count	A lock convoy
`cyclictest` Max grows the longer you run	Something is unbounded; the average is irrelevant
Works on bare metal, misses deadlines in a VM	The vCPU is descheduled by the host (virtualisation chapter 8)
`pthread_mutexattr_setprotocol` returns ENOTSUP	The platform has no PI mutexes — a design constraint you must plan around

Check yourself

- ✓ Draw the three-thread inversion and say which thread causes the unbounded part.
- ✓ Distinguish bounded from unbounded inversion and say which is acceptable.

- ✓ Explain priority inheritance and what "transitive" means for it.
- ✓ Explain priority ceiling, and give one advantage and one disadvantage over inheritance.
- ✓ Explain why a semaphore cannot offer either protocol.
- ✓ Define real-time in one sentence without using the word "fast".
- ✓ List the eight things that must be bounded, and name what breaks each.
- ✓ Write the real-time thread preamble and justify every step.
- ✓ Explain what `cyclictest`'s Max tells you that Avg does not.
- ✓ Describe a lock convoy and how it differs from ordinary contention.

Cache effects: false sharing and contention

The most common reason parallel code is slower than serial code has nothing to do with locks or algorithms. It is that two cores are fighting over one 64-byte line of memory that they do not even logically share — and nothing in the source code shows it.

Why a cache line is the unit of everything

```
Coherence protocols operate on CACHE LINES, not variables.
A line is 64 bytes on x86 and most ARM (128 on Apple
Silicon's performance cores, which catches people out).

MESI, simplified. Each line, in each core's cache, is in
one of four states:

  M odified   I have it, it is dirty, nobody else has it
  E xclusive  I have it, it is clean, nobody else has it
  S hared     several caches have it, all clean
  I nvalid    I do not have it

THE RULE THAT COSTS YOU:
  to WRITE a line, a core must own it EXCLUSIVELY.
  So every write must INVALIDATE every other copy.

TWO CORES READING the same line:
  both in S. No traffic at all after the first fetch.
  Reads scale perfectly.

TWO CORES WRITING the same line, alternately:
  core 1 writes -> must invalidate core 2's copy
  core 2 writes -> must invalidate core 1's copy
  ... the line PING-PONGS between them.

  Each transfer costs 50-200 cycles on the same die, and
  far more across sockets. Do it in a tight loop and the
  two cores together are slower than one core alone.
```

False sharing

```
/* TRUE sharing: two threads use the same variable. The cost
   is inherent - you asked for it.

   FALSE sharing: two threads use DIFFERENT variables that
   happen to sit in the same cache line. The cost is pure
   accident, and pure waste.                                */

struct counters {
        long a;          /* thread 0 increments this  */
        long b;          /* thread 1 increments this  */
};                       /* 16 bytes: ONE cache line  */

/* Threads 0 and 1 touch nothing in common. Logically there is
   no sharing at all. But every increment of `a` invalidates
   the line holding `b`, so thread 1 must re-fetch it - and
   vice versa, millions of times per second.

   Measured effect: commonly 5-20x slower than the same code
   with the fields separated. On a 2-socket machine, worse. */

/* THE FIX: pad to a cache line. */

#define CACHELINE 64

struct counters {
        alignas(CACHELINE) long a;
        alignas(CACHELINE) long b;
};                       /* 128 bytes, two lines, zero
                            interference                    */

/* C++17 gives you the portable constants: */
#include <new>
struct counters {
        alignas(std::hardware_destructive_interference_size) long a;
        alignas(std::hardware_destructive_interference_size) long b;
};
/* hardware_destructive_interference_size  = keep apart
   hardware_constructive_interference_size = keep together   */

/* Linux kernel: */
        struct foo {
                int a;
                ____cacheline_aligned int b;
        };
/* Or the whole-struct form, for per-CPU data:              */
        DEFINE_PER_CPU_ALIGNED(struct stats, my_stats);
```

> **THE DIAGNOSTIC QUESTION**
> "Do two threads write to memory within 64 bytes of each other?" If yes, and it is in a hot loop, that is almost certainly your problem. Note it is *within 64 bytes*, not *the same variable* — adjacent array elements, adjacent struct members, and two objects from the same allocation batch all qualify.

Where it hides

```
/* 1. AN ARRAY INDEXED BY THREAD ID - the classic. */
long results[NUM_THREADS];            /* 8 threads = 64 bytes
                                         = ONE line. Every
                                         thread fights every
                                         other thread.        */
/* FIX: */
struct padded { alignas(64) long v; };
struct padded results[NUM_THREADS];

/* 2. A LOCK NEXT TO THE DATA IT PROTECTS. */
struct node {
        pthread_mutex_t lock;
        int             data;         /* same line as the lock */
};
/* Waiters spinning on the lock word invalidate the line, so
   the HOLDER - who is trying to work on `data` - keeps losing
   its cache line to the very threads waiting for it. Separate
   them, or accept it for cold locks.                         */

/* 3. HEAD AND TAIL OF A QUEUE. Producer writes tail, consumer
      writes head. Adjacent -> every push fights every pop.
      This is why the SPSC queue in chapter 13 has
      alignas(64) on both.                                    */

/* 4. REFERENCE COUNTS INSIDE SHARED OBJECTS. Many readers
      touching an object they only READ still write its
      refcount, so a "read-only" workload writes constantly.
      This is a large part of why shared_ptr copies are
      expensive, and why RCU (chapter 10) is worth the
      complexity for read-mostly data.                        */

/* 5. FALSE SHARING YOU INHERITED. Two unrelated globals the
      linker placed adjacently. Two objects malloc returned
      from the same 64-byte chunk. A vector<bool> where
      "different" elements are bits of one byte.              */

/* 6. std::atomic MEMBERS IN A STRUCT. Atomics make the
      invalidation explicit and frequent - false sharing
      between two atomics is the worst case of all.           */
```

Measuring it

```
# The definitive counter on x86: HITM - a cache hit in a
# MODIFIED line in ANOTHER core's cache. That is the ping-pong.

$ perf c2c record ./app
$ perf c2c report --stdio
# Shared Data Cache Line Table
#  Total  Tot  ----- LLC Load Hitm -----
#  Rmt  Lcl   Hitm    Total  Lcl  Rmt   Data address
#  ...  ...   82.4%    1621  1338  283   0x55d4a2f01840
#
#   ----- Offset ---  Code address   Symbol
#         0x0            worker+0x24  results[tid]++
#         0x8            worker+0x24  results[tid]++
#
# TWO DIFFERENT OFFSETS in ONE line, both hot, both written.
# That is false sharing, named and located.

# Cheaper first check:
$ perf stat -e cache-misses,cache-references,\
LLC-load-misses,LLC-store-misses ./app

# On ARM, the equivalent counters vary by implementation:
$ perf list | grep -i 'snoop\|coheren'

# THE ZERO-TOOL TEST, and it is a good one:
#   pad the suspect structure to 64 bytes and re-run.
#   If it gets dramatically faster, you found it.
#   If nothing changes, it was not false sharing - stop
#   guessing and go back to the profiler.
```

Designing for it

```
/* THE GENERAL PRINCIPLE: separate by WRITER, not by meaning. */

/* BAD: grouped by what the fields mean. */
struct connection {
        int             fd;             /* read by all       */
        atomic_long     bytes_in;       /* written by reader */
        atomic_long     bytes_out;      /* written by writer */
        atomic_int      refs;           /* written by all    */
        struct sockaddr peer;           /* read by all       */
};

/* GOOD: grouped by who writes them. */
struct connection {
        /* immutable after construction - shared freely, and
           never invalidated. Put it first and it stays hot. */
        int             fd;
        struct sockaddr peer;

        alignas(64) atomic_long bytes_in;    /* reader thread */
        alignas(64) atomic_long bytes_out;   /* writer thread */
        alignas(64) atomic_int  refs;        /* everyone      */
};

/* AND THE BETTER ANSWER: do not share the counters at all. */

struct stats { alignas(64) long n, bytes; };
struct stats per_thread[NUM_THREADS];

void record(int tid, long b) {          /* no atomics, no
        per_thread[tid].n++;               contention, plain
        per_thread[tid].bytes += b;        increments        */
}

long total_n(void) {                    /* pay once, when you
        long t = 0;                        actually need it   */
        for (int i = 0; i < NUM_THREADS; i++)
                t += per_thread[i].n;
        return t;
}
/* Sharding beats optimising the shared case. A per-thread
   counter with a periodic merge is faster than the cleverest
   atomic, because it generates no coherence traffic at all. */
```

> **DO NOT PAD EVERYTHING**
>
> Padding costs memory and cache capacity. A struct padded from 24 to 128 bytes means five times fewer fit in L2, and a traversal that was cache-friendly becomes cache-hostile. Pad only fields that are *written by different threads in a hot loop*. Everything else benefits from being packed — `hardware_constructive_interference_size` exists to say "keep these together" for exactly that reason.

How it shows up

Symptom	Cause
Parallel version slower than serial, no locks involved	False sharing
Scaling is negative past 2–4 threads	A line ping-ponging between more and more cores

Symptom	Cause
Adding a field to a struct halved throughput	It pushed two hot fields into one line, or shifted alignment
Performance changes with unrelated code edits	The linker moved two globals into the same line
Much worse on a 2-socket machine	Cross-socket coherence traffic is far more expensive
Worse on Apple Silicon than expected	128-byte lines; 64-byte padding is not enough
Atomic counter is the hottest line in `perf c2c`	True sharing — shard it instead
A "read-only" workload generates write traffic	Reference counts, or a shared iterator
Padding made it slower	You padded a cold structure and destroyed its cache density
Lock holder is starved by its own waiters	Lock word in the same line as the protected data

Check yourself

- ✓ Explain why writing requires exclusive ownership of a line, and what that costs.
- ✓ Distinguish true from false sharing with an example of each.
- ✓ Explain why `long results[8]` indexed by thread id is a performance disaster.
- ✓ Name six places false sharing hides.
- ✓ Give the two C++17 interference-size constants and say what each is for.
- ✓ Describe what `perf c2c` shows and what "two offsets in one line" means.
- ✓ Give the zero-tool test for false sharing and how to interpret both outcomes.
- ✓ Restructure a struct to group by writer rather than by meaning.
- ✓ Explain why sharding beats optimising the shared counter.
- ✓ Say when padding is wrong, and what it costs.

Thread pools, work queues and work stealing

Creating a thread costs about as much as ten thousand mutex operations, so you create them once and feed them work. That single decision brings its own set of problems: how many threads, what happens when the queue fills, and the deadlock that every pool eventually hits.

The shape

```
    submit(task) ---> +---------------------------+
                      |      TASK QUEUE           |
                      +---------------------------+
                         |        |        |
                      +--v--+  +--v--+  +--v--+
                      | W 0 |  | W 1 |  | W 2 |    N workers,
                      +-----+  +-----+  +-----+    created once

    Each worker:
         for (;;) {
                 task = queue.pop();     /* blocks when empty  */
                 if (!task) break;       /* shutdown sentinel  */
                 task();
         }

    WHAT THE POOL BUYS
      * thread creation cost paid once, not per task
      * a bound on concurrency - N threads, not N-thousand
      * a natural place to apply backpressure
      * warm caches: a worker keeps running the same code

    WHAT IT COSTS
      * the queue is a contention point
      * a blocking task occupies a worker doing nothing
      * thread-local state now belongs to the WORKER, not the
        task (chapter 2)
      * and the deadlock in the "recursion" section below
```

How many threads

```
/* THE ONLY TWO RULES YOU NEED */

/* CPU-BOUND work: N = number of cores.
   More threads do not create more CPU; they add context
   switches and cache pressure. */
        unsigned n = std::thread::hardware_concurrency();
        /* subtract one if the main thread also works */

/* I/O-BOUND work: N = cores / (1 - blocked_fraction)
   A thread blocked 90% of the time uses 10% of a core, so
   you need ~10x more threads to keep the cores busy. */

        /* measured: each task spends 45 ms waiting, 5 ms
           computing -> blocked_fraction = 0.9
           8 cores / (1 - 0.9) = 80 threads               */

/* AND THE REAL ADVICE: if the answer is "80 threads", you
   probably want async I/O and a small pool instead
   (chapter 18). Eighty stacks is 640 MB of reserved address
   space and eighty things for the scheduler to consider. */

/* MIXED WORKLOADS: use SEPARATE POOLS, sized differently.
   One CPU pool of `cores` threads, one I/O pool of many.
   A single pool sized for I/O will thrash on CPU work; sized
   for CPU it will stall on I/O.                           */

/* MEASURE, do not calculate:
     * are all workers busy?         -> add threads
     * are cores idle with work queued?  -> workers are
                                           blocking
     * is throughput flat but latency rising? -> the queue is
                                           growing; you are
                                           past capacity     */
```

A pool, complete

```
#include <thread>
#include <mutex>
#include <condition_variable>
#include <deque>
#include <functional>
#include <future>
#include <vector>

class ThreadPool {
public:
    explicit ThreadPool(unsigned n, size_t max_queue = 4096)
        : max_(max_queue)
    {
        for (unsigned i = 0; i < n; i++)
            workers_.emplace_back([this] { run(); });
    }

    ~ThreadPool() { shutdown(); }

    /* Returns a future, so the caller can wait for a result -
       and, crucially, so an exception in the task surfaces at
       get() instead of calling std::terminate. */
    template <class F>
    auto submit(F f) -> std::future<decltype(f())>
    {
        using R = decltype(f());
        auto task = std::make_shared<std::packaged_task<R()>>(
                        std::move(f));
        auto fut = task->get_future();
        {
            std::unique_lock<std::mutex> lk(m_);

            /* BACKPRESSURE. An unbounded queue is not a
               feature - it converts "too slow" into "out of
               memory", much later, somewhere else. */
            not_full_.wait(lk, [this] {
                    return q_.size() < max_ || stop_; });
            if (stop_) throw std::runtime_error("pool stopped");

            q_.emplace_back([task] { (*task)(); });
        }
        not_empty_.notify_one();
        return fut;
    }

    void shutdown()
    {
        { std::lock_guard<std::mutex> g(m_);
          if (stop_) return;
          stop_ = true; }
        not_empty_.notify_all();      /* release every waiter  */
        not_full_.notify_all();
        for (auto &t : workers_)      /* THEN join. Signal all,
            if (t.joinable()) t.join();  then join all
                                         (chapter 3).          */
        workers_.clear();
    }

private:
    void run()
```

```
    {
        for (;;) {
            std::function<void()> task;
            {
                std::unique_lock<std::mutex> lk(m_);
                not_empty_.wait(lk, [this] {
                        return !q_.empty() || stop_; });
                if (q_.empty()) return;     /* stopping, drained */
                task = std::move(q_.front());
                q_.pop_front();
            }
            not_full_.notify_one();

            /* A task that throws must not kill the worker, or
               the pool silently shrinks to zero and everything
               hangs. packaged_task captures the exception into
               the future; this catch is the belt to that
               braces. */
            try { task(); }
            catch (...) { /* log it */ }
        }
    }

    std::mutex                          m_;
    std::condition_variable             not_empty_, not_full_;
    std::deque<std::function<void()>> q_;
    std::vector<std::thread>            workers_;
    size_t                              max_;
    bool                                stop_ = false;
};
```

THE DEADLOCK EVERY POOL EVENTUALLY HITS

A task submits another task to the *same* pool and waits for it. With N workers, N such tasks occupy every worker, and the sub-tasks they are waiting for can never be scheduled. The pool is full of threads waiting for work that cannot start. It works fine in testing with one request and deadlocks under load.

```
/* THE DEADLOCK */
pool.submit([&] {
        auto f = pool.submit([] { return part_two(); });
        return part_one() + f.get();     /* <-- waits, holding
                                               a worker            */
});

/* FIXES, in order of preference:

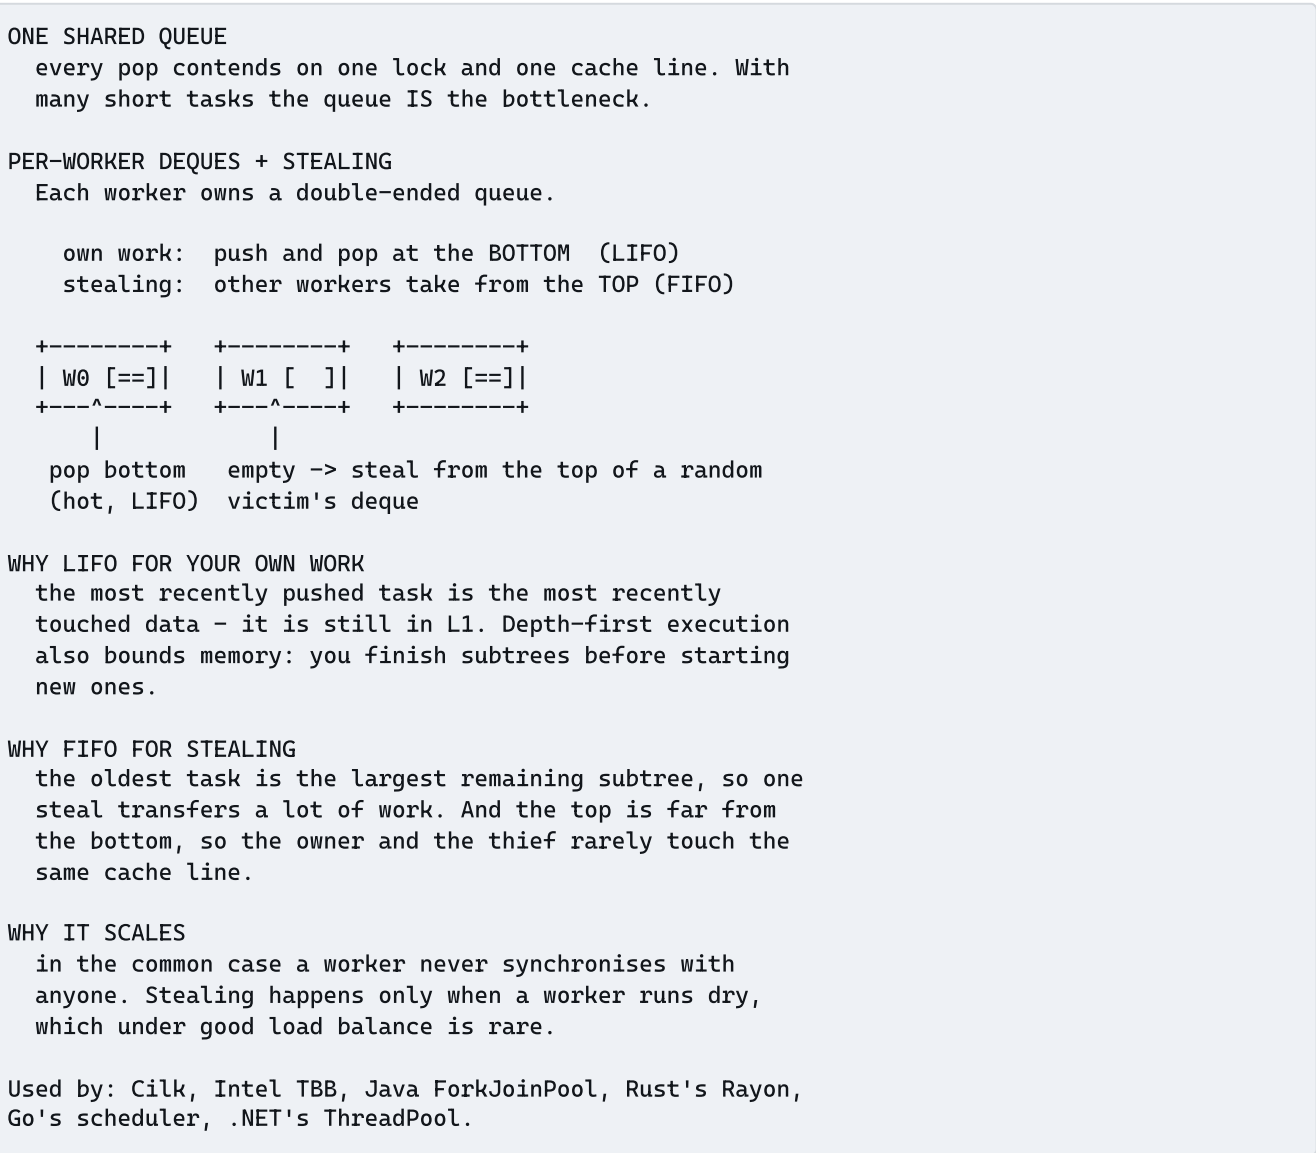
   1. DO NOT BLOCK IN A TASK. Restructure so the continuation
      is itself a task, triggered by completion. This is what
      async/await and future.then() are for (chapter 18).

   2. SEPARATE POOLS. Parent tasks in pool A, children in
      pool B. The cycle is broken because they are different
      resources - the same reasoning as lock ordering.

   3. HELP WHILE WAITING. The waiting thread runs queued tasks
      instead of blocking. This is what work-stealing runtimes
      (TBB, Rayon, Go, .NET) do, and it is why they tolerate
      nested parallelism. Note it changes the semantics: your
      task can now be re-entered on the same thread.

   4. AN UNBOUNDED POOL that grows when all workers block.
      .NET's injection heuristic. Effective, and it makes
      thread counts unpredictable.                          */
```

Work stealing



> **THREAD-LOCAL STATE BELONGS TO THE WORKER, NOT THE TASK**
> A `thread_local` holding "the current request id" is set by task 1 and still there when unrelated task 2 runs on the same worker. With work stealing it is worse: a task can migrate mid-tree, so even "the same task" may see different thread-local state. Either clear it at every task boundary, or pass context explicitly. This is a common source of logs attributing work to the wrong request.

How it shows up

Symptom	Cause
Pool hangs under load, fine in tests	Nested submit-and-wait exhausting the workers
Pool silently stops processing	A task threw and killed its worker; repeat until zero remain
Memory grows until the process dies	Unbounded queue absorbing a permanent overload
Cores idle with a long queue	Workers blocked on I/O — wrong pool size, or wrong model
Throughput flat, latency climbing	Past capacity; the queue is the delay
Queue lock is the hottest thing in the profile	Tasks too small — batch them, or use work stealing

Symptom	Cause
Log lines attributed to the wrong request	`thread_local` context not cleared between tasks
Shutdown hangs	Workers blocked in `wait` with no stop flag in the predicate
Adding threads made it slower	Context switching and cache pressure past the core count
Deadlock only with work stealing enabled	A task was re-entered on a thread already inside it

Check yourself

- ✓ Give three things a pool buys and three it costs.
- ✓ Size a pool for CPU-bound and for I/O-bound work, and say when the I/O answer means you want async instead.
- ✓ Explain why an unbounded task queue is a bug, not a feature.
- ✓ Explain what happens when a task throws, and two places to catch it.
- ✓ Describe the nested-submit deadlock and give four fixes in order of preference.
- ✓ Explain why work stealing uses LIFO locally and FIFO for thieves.
- ✓ Explain why work stealing scales when a single shared queue does not.
- ✓ Say why `thread_local` is dangerous in a pool, and worse with stealing.
- ✓ Write the shutdown sequence and explain the order of its steps.

Asynchronous models: events, coroutines, async/await

A thread blocked on a socket costs a megabyte of stack and a scheduler slot to do nothing. Asynchronous models remove that cost by making waiting explicit — and charge you in a different currency: your code turns inside out, and the function colour problem arrives.

The problem with a thread per connection

```
10,000 concurrent connections, one thread each:

  10,000 x 8 MB reserved stack   = 80 GB of address space
  10,000 kernel task structures
  a run queue the scheduler must reason about
  context switches whenever any of them wakes

Most of those threads are doing NOTHING - waiting for a
packet. The work is tiny; the waiting is everything.

THE ASYNC ALTERNATIVE

  one thread (or a few), and a readiness list:

    for (;;) {
            events = wait_for_readiness(all_fds);
            for (e : events)
                    handle(e);      /* never blocks */
    }

  10,000 connections =  ~10,000 small state objects,
  a few hundred bytes each, and one thread.

THE TRADE

  you may NEVER BLOCK inside a handler. One blocking call -
  a DNS lookup, a disk read, a mutex - stalls every other
  connection on that thread. In a threaded model it stalls
  only itself.

  That single rule is what makes async both fast and
  hostile to write.
```

Readiness versus completion

	Readiness (`epoll`, `kqueue`)	**Completion (`io_uring`, IOCP)**
Kernel tells you	"you can read now"	"your read is done, here is the data"
You then	Call `read()`, which returns immediately	Nothing — the buffer is already filled
Syscalls per operation	Two: wait, then read	Can be zero — submit and reap in batches
Buffers	Allocated when the data arrives	Must be committed *before*, and pinned until completion
Regular files	**Does not work** — a file is always "ready", so `read()` blocks anyway	Works properly

	Readiness (`epoll` , `kqueue`)	Completion (`io_uring` , IOCP)
Where	Linux, BSD, macOS	Windows (IOCP) since the 1990s, Linux (`io_uring`) since 5.1

```
/* The readiness loop, which is what most async runtimes wrap. */

int ep = epoll_create1(0);

struct epoll_event ev = {
        .events = EPOLLIN | EPOLLET,     /* edge-triggered     */
        .data.ptr = conn,
};
epoll_ctl(ep, EPOLL_CTL_ADD, conn->fd, &ev);

for (;;) {
        struct epoll_event out[64];
        int n = epoll_wait(ep, out, 64, -1);
        for (int i = 0; i < n; i++)
                handle(out[i].data.ptr);
}

/* LEVEL vs EDGE triggered - the classic epoll bug:

     LEVEL (default): reports while data remains. Forgiving.
     EDGE  (EPOLLET): reports only on a CHANGE. Fewer wake-ups,
                      and you MUST read until EAGAIN or you
                      will never be told again - the connection
                      simply goes silent and stays silent.

   With EPOLLET the loop is:
        while ((n = read(fd, buf, sizeof buf)) > 0) consume();
        if (n < 0 && errno != EAGAIN) error();

   Forget the loop and you get a hang that appears only when a
   message spans two reads.                                    */
```

Callbacks, and why they became coroutines

```
/* CALLBACK STYLE - the control flow is inside out. */

read_async(sock, buf, [](int n) {
        parse_async(buf, n, [](Request r) {
                db_query_async(r, [](Row row) {
                        render_async(row, [](string html) {
                                write_async(sock, html, [](int) {
                                        /* five levels deep, and
                                           now try adding error
                                           handling to each   */
                                });
                        });
                });
        });
});

/* PROBLEMS
     * error handling at every level, or errors vanish
     * no try/catch, no RAII scope - the stack is gone by the
       time the callback runs
     * lifetimes are manual: who owns `buf` across five
       callbacks? Use-after-free is the default outcome
     * a loop becomes a recursive callback chain
     * debugging: the stack trace shows the event loop, not
       how you got there                                    */

/* ASYNC/AWAIT - the same machine, written as straight code. */

async Task<void> serve(Socket sock) {
        try {
                auto n    = co_await read_async(sock, buf);
                auto req  = parse(buf, n);
                auto row  = co_await db_query_async(req);
                auto html = render(row);
                co_await write_async(sock, html);
        } catch (const IoError &e) {          /* works again    */
                log(e);
        }
}   /* destructors run. RAII works. Loops are loops. */

/* WHAT THE COMPILER DOES: splits the function at every await
   into a state machine, and heap-allocates the locals that
   live across a suspension point. `co_await` is "return to
   the caller, and resume here when the awaited thing
   completes".                                             */
```

STACKLESS VERSUS STACKFUL

Stackless coroutines (C++20, Rust, C#, JavaScript) store only the variables that survive a suspension — tens of bytes, and the compiler computes the size. You can only suspend inside a coroutine, which is why `await` is contagious. **Stackful** coroutines and goroutines get a real (growable) stack, so any function can yield — no colouring — at the cost of kilobytes each and a runtime that manages stacks. Go chose stackful; almost everyone else chose stackless.

The function colour problem

```
/* An async function can only be awaited from an async
   function. So async spreads up the call graph until it
   reaches main.                                          */

        int compute(int x);                    /* "red"  - sync */
        async Task<int> fetch(int x);          /* "blue" - async */

        /* calling fetch from compute: impossible without
           blocking, which defeats the purpose             */

/* CONSEQUENCES

   1. TWO ECOSYSTEMS. Rust has `Read` and `AsyncRead`,
      `Mutex` and `tokio::Mutex`. Python has requests and
      aiohttp. Libraries get written twice.

   2. THE BRIDGE IS DANGEROUS. block_on() from inside an async
      context deadlocks the executor - the thread that would
      run the future is the one blocked waiting for it.

   3. sleep() IS A BUG. std::thread::sleep in an async task
      blocks the whole executor thread and every other task on
      it. Every runtime ships its own: tokio::time::sleep.

   4. A LOCK HELD ACROSS AN AWAIT is held for an unbounded
      time, and in a work-stealing executor may be released
      on a different thread than took it - which is undefined
      for many mutex implementations.

   THE RULE: never hold a std mutex across an await. Either
   scope it so it is released first, or use the runtime's
   async-aware mutex.                                     */

        /* WRONG */
        let g = mutex.lock().unwrap();
        let v = fetch().await;              /* held across await */

        /* RIGHT */
        let v = fetch().await;
        { let mut g = mutex.lock().unwrap(); *g = v; }

        /* OR, when you genuinely must hold it: */
        let mut g = async_mutex.lock().await;
        let v = fetch().await;              /* fine: this mutex
                                               yields properly  */
```

Choosing a model

Model	Concurrency ceiling	Use when
Thread per task	Thousands	Simple, CPU-bound, or moderate concurrency. Still the right default for most programs
Thread pool	Thousands of tasks, N threads	Bounded CPU work (chapter 17)
Event loop + callbacks	Hundreds of thousands	You have no coroutine support. Expect the pyramid

Model	Concurrency ceiling	Use when
async/await	Hundreds of thousands	High-concurrency I/O in a language that supports it well
Goroutines / green threads	Millions	You can choose the language. No colouring, blocking calls are handled by the runtime
Virtual threads (Java 21)	Millions	Existing blocking code, made scalable without rewriting it — the most interesting recent development here

> **ASYNC IS FOR I/O CONCURRENCY, NOT FOR SPEED**
>
> An async runtime does not make anything compute faster; it removes the cost of *waiting*. If your bottleneck is CPU, async adds state-machine overhead and buys nothing — you want a thread pool. If your bottleneck is ten thousand idle sockets, async is transformative. Diagnosing which you have, before rewriting, saves a great deal of regret.

How it shows up

Symptom	Cause
One slow request stalls every other connection	A blocking call inside a handler
A connection goes silent and never recovers	Edge-triggered epoll without reading to `EAGAIN`
Deadlock calling `block_on` inside a task	Blocking the executor thread that would run the future
Everything stops for exactly one second	`thread::sleep` instead of the runtime's sleep
Panic or UB unlocking a mutex	Held across an `await`, released on a different thread
Use-after-free in a callback	A buffer whose owner returned before the callback ran
Memory grows with connection count faster than expected	Large futures — a big local held across an await is stored in the state machine
Stack traces show only the event loop	Inherent to callbacks; async/await restores useful traces
Async rewrite made it slower	The workload was CPU-bound
Works on Linux, poor on Windows	A readiness design ported to a completion-based OS

Check yourself

- ✓ Compute the address space cost of 10,000 threads and explain why async avoids it.
- ✓ State the one rule an event-loop handler must never break.
- ✓ Distinguish readiness from completion notification and give an OS for each.
- ✓ Explain why `epoll` does not work for regular files.
- ✓ Describe the edge-triggered bug and the loop that prevents it.
- ✓ Give four problems with callback style that async/await fixes.
- ✓ Explain stackless versus stackful coroutines and which languages chose which.
- ✓ Define the function colour problem and give three consequences.
- ✓ Explain why holding a standard mutex across an `await` is wrong.
- ✓ Say when async is the wrong tool, and what to use instead.

Parallel patterns and how to decompose work

Almost every parallel program is one of six shapes. Recognising which one you have tells you where the synchronisation goes, what the scaling limit is, and — usually — that you can avoid sharing altogether.

The six

```
1. EMBARRASSINGLY PARALLEL / MAP
     f(x) for every x, independently.
     NO shared state, NO synchronisation, linear scaling
     until you hit memory bandwidth.
     -> image filters, hashing files, per-request work.

2. REDUCE
     combine N values into one with an associative op.
     Tree-shaped: log N depth, and the only sync is at the
     joins.
     -> sum, max, count, histogram merge.

3. MAP-REDUCE (scatter-gather)
     map, then reduce. The overwhelmingly common shape.
     -> "count word frequencies", "sum per customer".

4. PIPELINE
     stage1 -> stage2 -> stage3, each on its own thread,
     items flowing through.
     Throughput = the SLOWEST stage. Latency = the sum.
     -> decode -> filter -> encode; parse -> plan -> exec.

5. FORK-JOIN / DIVIDE AND CONQUER
     split, recurse in parallel, combine. Naturally
     matches work stealing (chapter 17).
     -> quicksort, mergesort, tree traversal, FFT.

6. PRODUCER-CONSUMER
     decouple rates with a queue. Not really about speed -
     about smoothing bursts and isolating failure.
     -> logging, request queues, sensor to processor.

AND THE ONE THAT IS NOT A PATTERN:
   "put a mutex around the shared thing and run it on
   8 threads". That is not a decomposition, it is a hope.
```

Map, and the mistake in it

```
/* THE OBVIOUS VERSION - and why it is slow. */

std::atomic<long> total{0};

parallel_for(0, n, [&](int i) {
        total += expensive(data[i]);     /* EVERY iteration
                                            writes one atomic  */
});
/* All threads hammer one cache line. Often SLOWER than the
   serial loop (chapter 16).                                   */

/* THE FIX: privatise, then combine. Once. */

struct alignas(64) Partial { long v = 0; };
std::vector<Partial> partial(nthreads);

parallel_for_chunked(0, n, [&](int lo, int hi, int tid) {
        long local = 0;                  /* a REGISTER, not
                                            even memory        */
        for (int i = lo; i < hi; i++)
                local += expensive(data[i]);
        partial[tid].v = local;          /* ONE write, ever    */
});
long total = 0;
for (auto &p : partial) total += p.v;    /* nthreads adds      */

/* The pattern, in one line: ACCUMULATE PRIVATELY, MERGE ONCE.
   It applies to counters, histograms, string builders, output
   buffers, allocators, random number generators - anything
   where the combine is associative.                          */

/* And the libraries already do it: */
        std::reduce(std::execution::par, v.begin(), v.end(), 0L);
        v.par_iter().map(expensive).sum::<i64>();      // Rayon
        #pragma omp parallel for reduction(+:total)    // OpenMP
```

GRANULARITY IS THE SINGLE BIGGEST LEVER

Too fine and scheduling overhead dominates: a task that takes 100 ns cannot pay for a 1 µs enqueue. Too coarse and the tail dominates: 8 chunks on 8 cores means one slow chunk leaves 7 cores idle. The usual sweet spot is **tasks of roughly 10–100 µs**, and **4–8× more chunks than cores** so the scheduler can balance. Both numbers are worth measuring rather than trusting.

Pipelines

```
/* Three stages, bounded queues between them. */

BoundedQueue<Raw>     q1(64);
BoundedQueue<Decoded> q2(64);

std::thread reader([&] {
        Raw r;
        while (read_next(&r)) q1.push(r);
        q1.close();                       /* propagate the end  */
});
std::thread decoder([&] {
        Raw r;
        while (q1.pop(&r)) q2.push(decode(r));
        q2.close();
});
std::thread writer([&] {
        Decoded d;
        while (q2.pop(&d)) write_out(d);
});

/* THE PROPERTIES

   throughput = 1 / (slowest stage time)
        adding threads to the FAST stages changes nothing.
        Find the slow stage and parallelise THAT - a pipeline
        where stage 2 is the bottleneck becomes
        stage1 -> [stage2 x 4] -> stage3.

   latency = sum of all stages + queueing
        a pipeline makes throughput better and latency WORSE.
        If you care about latency, this is the wrong pattern.

   BOUNDED queues are mandatory
        an unbounded queue between a fast producer and a slow
        consumer converts backpressure into memory exhaustion,
        far away from the cause.

   CLOSING must propagate
        each stage closes its output when its input closes and
        it has drained. Miss one and shutdown hangs -
        the commonest pipeline bug.

   ORDER is not preserved once you widen a stage.
        If output order matters you need sequence numbers and
        a reorder buffer at the end, which is real work.     */
```

Fork-join

```
/* Parallel mergesort, with the two details that matter. */

void psort(int *a, int n, int depth)
{
        /* DETAIL 1: a cutoff. Below it, go serial. Without
           this you create a task per ELEMENT and spend all
           your time scheduling. */
        if (n < 4096) { std::sort(a, a + n); return; }

        /* DETAIL 2: bound the depth, or the task count
           explodes. depth 0 means "no more forking". */
        int mid = n / 2;
        if (depth > 0) {
                auto left = std::async(std::launch::async,
                                       [&]{ psort(a, mid, depth-1); });
                psort(a + mid, n - mid, depth - 1);
                left.get();                    /* join */
        } else {
                psort(a, mid, 0);
                psort(a + mid, n - mid, 0);
        }
        std::inplace_merge(a, a + mid, a + n);
}
/* call with depth = log2(hardware_concurrency) + 1 */

/* WITH A WORK-STEALING RUNTIME you can skip the depth bound -
   that is exactly what stealing is for. Rayon: */
        fn psort(a: &mut [i32]) {
            if a.len() < 4096 { a.sort(); return; }
            let mid = a.len() / 2;
            let (l, r) = a.split_at_mut(mid);
            rayon::join(|| psort(l), || psort(r));   /* steals  */
            merge(l, r);
        }
/* rayon::join is nearly free when nobody steals - it pushes
   the right half and runs the left inline. The cutoff is
   still needed; the depth bound is not.                    */
```

Choosing a decomposition

```
THREE WAYS TO CUT A PROBLEM

BY DATA        each thread gets a slice of the data and
               runs the same code.
               + scales with data size
               + easy to balance
               - needs the data to be splittable
               -> the default. Try this first.

BY TASK        each thread runs different code.
               + suits heterogeneous work
               - scales to the NUMBER OF TASKS, not cores
               - balancing is manual and usually wrong
               -> pipelines, and GUI-plus-worker.

BY PIPELINE    each thread is a stage.
               + good for streaming, bounded memory
               - throughput capped by the slowest stage
               - latency increases

THE QUESTIONS THAT PICK ONE

  Is the work uniform?        yes -> data
  Is there a natural stream?  yes -> pipeline
  Is the work heterogeneous?  yes -> task
  Does order matter?          if yes, avoid widening stages
  Is state shared?            if yes, can you privatise it?
                              (usually yes - do that first)
```

LOAD IMBALANCE BEATS ALMOST EVERY OTHER INEFFICIENCY

Eight chunks on eight cores where one chunk takes twice as long means seven cores idle for half the run — a 43% loss, invisible in any lock profile. Fix it with more, smaller chunks plus dynamic scheduling (`schedule(dynamic)` in OpenMP, work stealing elsewhere) rather than by trying to predict chunk costs. Static partitioning is only right when every item genuinely costs the same.

How it shows up

Symptom	Cause
Parallel map slower than serial	Shared accumulator — privatise and merge
Speed-up stops at 2–3× on 16 cores	Load imbalance, or memory bandwidth saturation
Most time in the scheduler	Tasks too small; raise the cutoff
Cores idle at the end of every phase	Too few chunks; use 4–8× the core count
Adding threads to a pipeline changes nothing	You widened a stage that was not the bottleneck
Pipeline consumes all memory	Unbounded queue absorbing a rate mismatch
Pipeline hangs at shutdown	Close not propagated through every stage
Output order scrambled after optimising	A widened stage; needs sequence numbers
Fork-join creates millions of tasks	No cutoff, or no depth bound without work stealing
Scales on one machine, not on the bigger one	NUMA — threads on one node, memory on another

Check yourself

- ✓ Name the six patterns and give a real workload for each.
- ✓ Explain why a shared atomic accumulator in a parallel map is usually a mistake.
- ✓ State the privatise-and-merge rule and list five things it applies to.
- ✓ Give the two granularity failure modes and the rough numbers that avoid both.
- ✓ State how pipeline throughput and latency are each determined.
- ✓ Explain why bounded queues are mandatory in a pipeline.
- ✓ Explain why close must propagate, and what happens if it does not.
- ✓ Give the two details a fork-join implementation needs, and say which one work stealing removes.
- ✓ Compare data, task and pipeline decomposition and say which to try first.
- ✓ Quantify the cost of one chunk in eight taking twice as long.

Finding concurrency bugs on purpose

A test that passes tells you one interleaving worked. The discipline that finds concurrency bugs is not better luck — it is making the rare interleaving common, on hardware that permits it, with tools that see what your eyes cannot.

The method

```
FIRST: WHICH BUG IS IT?  Ten seconds of observation saves
an afternoon.

  hung, 0% CPU           -> deadlock (chapter 14)
  hung, 100% CPU         -> livelock, or a spin/CAS loop
  wrong answer, no crash -> race condition or lost update
  crash in random places -> data race, or use-after-free
  one thread never runs  -> starvation
  slow, not wrong        -> contention or false sharing
  fine alone, wrong in
    parallel             -> shared state you forgot about

THEN, IN THIS ORDER:

1. Make it reproduce more often   (this chapter)
2. Run a sanitiser                (finds data races)
3. Read the code for the invariant, not the syntax
4. Only then, attach a debugger

Reaching for gdb first is the classic mistake: a breakpoint
changes the timing, and the bug you were chasing stops
happening.
```

Making it reproduce

```
# 1. MORE THREADS THAN CORES. Forces constant preemption,
#    so the interleavings you never see become normal.
$ ./app --threads=64          # on 8 cores

# 2. PIN EVERYTHING TO ONE CORE. Removes true parallelism and
#    maximises preemption at arbitrary instructions. Finds a
#    completely different set of bugs from (1) - run both.
$ taskset -c 0 ./app

# 3. RUN ON WEAK HARDWARE. An arm64 box exhibits reorderings
#    x86 physically cannot (chapter 12). If you ship on ARM
#    and test on x86, you are not testing the memory model.

# 4. SLOW DOWN THE SUSPECT WINDOW. The single highest-value
#    technique in this chapter:
      auto it = cache.find(k);
      if (it != cache.end()) return it->second;
+     std::this_thread::sleep_for(std::chrono::milliseconds(50));
      auto v = compute(k);
#    A gap bug that happened once a week now happens every
#    time. Delete the sleep once you have the fix.

# 5. RANDOMISE SCHEDULING. Inject a yield at every
#    synchronisation point, under a flag:
      #ifdef FUZZ_SCHED
      #define SYNC_POINT() do { if (rand() % 4 == 0) \
                                std::this_thread::yield(); } while (0)
      #else
      #define SYNC_POINT() ((void)0)
      #endif

# 6. STRESS IN A LOOP, and record the seed.
$ for i in $(seq 1 100000); do ./test --seed=$i || \
      { echo "FAILED seed=$i"; break; }; done

# 7. RUN UNDER LOAD. Many races need a competitor:
$ stress-ng --cpu 8 --vm 2 & ./app
```

> **PIN TO ONE CORE *AND* OVERSUBSCRIBE — THEY FIND DIFFERENT BUGS**
>
> One core with many threads gives you frequent, arbitrary preemption: it finds check-then-act gaps, lost updates and non-reentrant code. Many cores give you true simultaneity and memory reordering: it finds publication bugs, false sharing and missing barriers. A bug found by one is often invisible to the other, so a stress suite should do both.

The tools

Tool	Finds	Cost
`-fsanitize=thread`	Data races, and lock-order inversions	5–15× slower, 5–10× memory
`-fsanitize=address`	Use-after-free, overflow — often the visible symptom of a race	~2× slower
`valgrind --tool=helgrind`	Races and lock-order violations, no rebuild	20–50× slower
`valgrind --tool=drd`	Similar, better on some patterns, lower memory	Similar

Tool	Finds	Cost
`-Wthread-safety` (clang)	Missing locks — **at compile time**	Free. Needs annotations
Kernel lockdep	Potential deadlocks on runs that did not deadlock	Debug kernel only
`perf c2c`	False sharing, by address and line	Low
`perf lock`	Contention: which lock, how long	Low
rr	**Deterministic record and replay** — reverse-execute a captured failure	~2×, x86 only
TLA+ / Spin	Design-level protocol bugs, exhaustively	Your time; finds bugs no test can

```
# ThreadSanitizer, in practice.
$ g++ -fsanitize=thread -g -O1 -fno-omit-frame-pointer app.cpp
$ TSAN_OPTIONS="halt_on_error=1 history_size=7" ./app

WARNING: ThreadSanitizer: data race (pid=4211)
  Write of size 8 at 0x7b0400000f00 by thread T2:
    #0 Cache::insert(...) cache.cpp:88
    #1 worker(...) main.cpp:41
  Previous read of size 8 at 0x7b0400000f00 by thread T1:
    #0 Cache::lookup(...) cache.cpp:62
  Location is heap block of size 96 allocated by main thread
  Mutexes locked by thread T2: M12 (cache.cpp:20)
  Mutexes locked by thread T1: (none)      <-- THE ANSWER

# That last pair of lines is what you read first: one side
# held the mutex, the other did not.

# rr, when a bug is rare but you caught it once:
$ rr record ./app
$ rr replay
(rr) continue                 # runs to the crash, identically
(rr) reverse-continue         # run BACKWARDS to the previous
(rr) watch -l ptr             # write to that address
# Deterministic replay of a race is close to magic: the
# recording contains the exact interleaving that failed.
```

SANITISERS DO NOT COMPOSE, AND THEY MISS RACE CONDITIONS

TSan and ASan cannot be enabled together — build twice. TSan needs the *whole* program instrumented; an uninstrumented third-party library produces false negatives and sometimes false positives. And most importantly: TSan finds **data races**, not **race conditions** (chapter 5). A clean TSan run on properly-locked code that has a gap between two critical sections proves nothing at all.

Designing so the bug cannot happen

```
/* Cheaper than any tool in the table above. */

/* 1. DON'T SHARE. Per-thread state merged at the end
      (chapter 19). No sharing, no race, nothing to test.

   2. IMMUTABLE AFTER PUBLICATION. Build fully, publish with a
      release store, never mutate. Readers need no lock at all.

   3. OWNERSHIP, NOT LOCKING. One thread owns each object;
      others send messages. Rust enforces this; in C++ you can
      approximate it with move-only types and a queue.

   4. MAKE ILLEGAL STATES UNREPRESENTABLE. Put the data inside
      the mutex so there is no way to touch it unlocked -
      Rust's Mutex<T>, or in C++:                              */

template <class T>
class Guarded {
    std::mutex m_;
    T          v_;
public:
    template <class F>
    auto with(F f) -> decltype(f(v_)) {
        std::lock_guard<std::mutex> g(m_);
        return f(v_);                /* the ONLY way in       */
    }
};
Guarded<std::map<int,int>> cache;
cache.with([&](auto &m) { m[k] = v; });
/* You cannot forget the lock, because there is no accessor
   that does not take it. The whole class of bug is gone.    */

/* 5. ANNOTATE, and let the compiler check.                  */
class Cache {
    std::mutex m_;
    std::map<int,int> data_ GUARDED_BY(m_);
    int hits_ GUARDED_BY(m_);
public:
    int hits() { return hits_; }   /* -Wthread-safety: ERROR,
                                      reading hits_ without m_ */
};

/* 6. ONE INVARIANT PER LOCK, written down (chapter 7).      */
```

What to run in CI

```
# The realistic set, in cost order. Even the first three
# catch most of it.

  every commit:
    -Wthread-safety                       free, compile time
    unit tests under TSan                 slow but bounded
    unit tests with threads=4x cores      finds gap bugs

  nightly:
    the full suite under TSan and under ASan (separate runs)
    the full suite pinned to one core
    the full suite on an ARM64 runner      <-- the highest-value
                                               single addition
    a stress soak, several hours, seeds logged

  before a release:
    Helgrind on the critical paths
    a load test measuring p99.9, not the mean

# And record every intermittent failure with its seed and its
# machine. Three occurrences of "flaky test" with the same
# stack is not flakiness; it is a bug with a low reproduction
# rate, and it will reach production at scale.
```

> **NEVER MARK A CONCURRENCY TEST FLAKY**
>
> A test that fails once in fifty runs is telling you the truth about a bug that will happen once in fifty thousand production requests — which, at a thousand requests a second, is once a minute. Retrying the test until it passes converts a caught bug into a shipped one. Quarantine it if you must ship, but track it as a defect, not as noise.

How it shows up

Symptom	What to do
"Cannot reproduce"	Oversubscribe, pin to one core, add a sleep in the suspect gap
Fails in CI, never locally	Different core count or a slower machine — widening the window
Fails only in release builds	The optimiser exploited undefined behaviour a data race permitted
Disappears under the debugger	Timing changed. Use logging or `rr` instead
Disappears when you add a `printf`	The syscall is a barrier — you moved the bug, not fixed it
TSan clean, bug persists	It is a race condition, not a data race
TSan reports a race in a third-party library	Uninstrumented code, or a genuine bug — `suppressions` file, then investigate
Only fails on arm64	A memory-ordering bug x86 cannot exhibit
Only fails at high load	Contention widens every window; also check queue bounds
Test marked flaky six months ago	Look at it. It is almost certainly your production incident

Check yourself

- ✓ Classify a hung program by CPU usage and say what each case means.

- ✓ Give the four-step order for attacking a concurrency bug, and why the debugger is last.
- ✓ Name seven ways to make a rare interleaving common.
- ✓ Explain why pinning to one core and oversubscribing find different bugs.
- ✓ Read a TSan report and identify the two lines that matter most.
- ✓ State three limits of ThreadSanitizer.
- ✓ Explain what `rr` gives you that a debugger cannot.
- ✓ Write a `Guarded<T>` wrapper and explain which bug class it deletes.
- ✓ Give the CI set you would actually run, and name the single highest-value addition.
- ✓ Explain why a flaky concurrency test is a production incident in waiting.

TRACK

Compilers & toolchain

What happens between your source file and a running instruction — and why the optimiser sometimes deletes your code.

16 chapters

What a compiler is and its phases

Between your source file and a running instruction there are about a dozen distinct transformations. Knowing which one is responsible for a given behaviour is what lets you answer "why did it do that?" instead of guessing.

The pipeline

```
   hello.c
      |
      v
   PREPROCESSOR              #include, #define, #if
      |                      -> a single translation unit
      v  hello.i
   LEXER                     characters -> TOKENS
      |                      (chapter 02)
      v
   PARSER                    tokens -> a PARSE TREE
      |                      (chapter 03)
      v
   SEMANTIC ANALYSIS         types, scopes, name resolution
      |                      -> an annotated AST (chapter 04)
      v
   IR GENERATION             AST -> an INTERMEDIATE
      |                      REPRESENTATION (chapter 05)
      v
   ===== THE MIDDLE END: machine-independent =====
      |
   OPTIMISATION PASSES       constant folding, dead code,
      |                      inlining, loop transforms
      |                      (chapters 06-07)
      v
   ===== THE BACK END: machine-specific =====
      |
   INSTRUCTION SELECTION     IR -> target instructions
      |                      (chapter 08)
      v
   SCHEDULING                reorder for the pipeline
      |
      v
   REGISTER ALLOCATION       virtual -> physical registers
      |                      (chapter 09)
      v
   ASSEMBLY EMISSION
      |
      v  hello.s
   ASSEMBLER                 text -> an OBJECT FILE
      |                      (chapter 11)
      v  hello.o
   LINKER                    objects + libraries -> an
      |                      executable (chapter 12)
      v  a.out
   LOADER                    map it, relocate, resolve
                             (chapter 13)

   THE SPLIT THAT MATTERS: front end (language-specific),
   middle end (neither), back end (target-specific). It is why
   GCC supports many languages on many targets with N+M
   components rather than N*M.
```

Watching each phase

```
# --- Preprocessor only ---
    gcc -E hello.c -o hello.i
    ; expands includes and macros. When a macro misbehaves,
    ; look here FIRST - the answer is always visible.
    gcc -E -P hello.c | less     ; -P drops line markers

# --- Tokens ---
    gcc -E -dD hello.c           ; with all macro definitions
    clang -cc1 -dump-tokens hello.c

# --- The parse tree / AST ---
    clang -Xclang -ast-dump -fsyntax-only hello.c
    gcc -fdump-tree-original-raw hello.c

# --- The IR ---
    clang -S -emit-llvm hello.c -o hello.ll   ; LLVM IR
    gcc -fdump-tree-all hello.c               ; GIMPLE, every
                                              ; pass
    gcc -fdump-rtl-all hello.c                ; RTL

# --- Assembly ---
    gcc -S hello.c -o hello.s
    gcc -S -O2 -fverbose-asm hello.c          ; with comments

# --- Object file ---
    gcc -c hello.c -o hello.o
    objdump -d hello.o
    readelf -a hello.o

# --- The whole thing, with every step shown ---
    gcc -v hello.c
    ; prints the actual cc1, as and ld command lines - which
    ; is how you find out what flags your build system is
    ; really passing.

# THE SINGLE MOST USEFUL TOOL for this whole track:
    https://godbolt.org        (Compiler Explorer)
# Source on the left, assembly on the right, colour-matched,
# for any compiler and any target including aarch64. Open it
# now and keep it open while reading these chapters.
```

> **COMPILER EXPLORER CHANGES HOW YOU LEARN THIS**
> Every claim in this track is checkable in about ten seconds: paste the code, pick `armv8-a clang` or `aarch64 gcc`, set `-O2`, and read the output. Do that rather than believing the text — including when the text is right, because the habit is what makes the knowledge stick.

Front end, middle end, back end

	Front end	Middle end	Back end
Knows about	The *language*	Neither	The *target*
Input	Source text	IR	IR
Output	IR	Better IR	Machine code
Errors from here	Syntax, type errors	Rarely any	"Cannot allocate register"

	Front end	Middle end	Back end
GCC	c, c++, fortran, go, d…	GIMPLE passes	x86, aarch64, riscv…
LLVM	clang, rustc, swift…	LLVM IR passes	LLVM backends

```
/* WHY THE SPLIT PAYS: LLVM has one optimiser. Rust, Swift,
   Julia, Zig, clang and a dozen others all feed it LLVM IR
   and inherit every optimisation anyone writes.

   AND WHY IT LEAKS: the middle end optimises the IR under the
   assumption that the source program has NO UNDEFINED
   BEHAVIOUR. That assumption is what makes aggressive
   optimisation legal, and it is why UB has effects that look
   insane at the source level (chapter 15).                */
```

GCC and LLVM

```
/* You will use both. The differences that matter in
   practice:                                              */

   GCC
     · the default for the Linux kernel and most embedded
       Linux toolchains
     · GIMPLE (tree-based) then RTL (low-level) IR
     · a monolithic program
     · often marginally better code on some targets,
       especially with -O2 on ARM
     · inline assembly and __attribute__ syntax are the de
       facto standard that Clang copies

   LLVM/CLANG
     · a LIBRARY, so tools are built on it: clangd, clang-tidy,
       clang-format, sanitizers, static analysers
     · LLVM IR: typed, SSA, human-readable, stable enough to
       write tools against
     · far better diagnostics - error messages that point at
       the right thing
     · the sanitizers (ASan, UBSan, TSan, MSan) originate here
     · what Rust, Swift and Zig use

/* IN EMBEDDED WORK you will typically compile the kernel and
   the BSP with GCC (because that is what the vendor
   supports), and use Clang's tooling - clangd for navigation,
   clang-tidy and the sanitizers for analysis - alongside it.
   The Linux kernel now builds with either.

   AND FOR LEARNING: read Clang's LLVM IR output. It is far
   more legible than GIMPLE and the optimisation passes are
   individually observable.                               */
```

Optimisation levels

Flag	Does	Use for
`-O0`	Nothing. Every variable in memory, code matches source line for line	Debugging. **The kernel will not build with it**
`-O1`	Cheap optimisations, fast compile	Rarely chosen deliberately

Flag	Does	Use for
`-O2`	The standard. Inlining, vectorisation, most passes	**Almost everything**
`-O3`	`-O2` plus aggressive inlining and vectorisation	Measured hot paths; can be *slower* from cache pressure
`-Os`	Optimise for size	Flash-constrained microcontrollers
`-Oz`	Size above all (Clang)	Extremely tight parts
`-Og`	Optimise, but keep debugging usable	Debug builds of code that must run at speed
`-Ofast`	`-O3` plus **unsafe maths**	Almost never — it breaks IEEE 754 (CA ch. 03)

```
/* WHY -O0 IS NOT "SAFE":

   · the kernel REQUIRES optimisation. Inline assembly
     constraints, __builtin_constant_p, and many macros only
     work when constants fold. Linux does not build at -O0.
   · unoptimised code is 3–10x slower and much larger, which
     on an embedded target may not fit or may miss deadlines.
   · a BUG THAT ONLY APPEARS AT -O2 is usually undefined
     behaviour in your code (chapter 15), not a compiler bug.
     Turning optimisation off hides it; it does not fix it.

/* THE RIGHT DEBUG BUILD is -Og -g, or -O2 -g with the
   understanding that variables may be optimised out. Modern
   DWARF and gdb handle -O2 far better than they used to
   (chapter 14).                                          */
```

Flags worth knowing

```
# --- Warnings: turn them on, all of them ---
    -Wall -Wextra              ; the baseline. Not optional.
    -Werror                    ; in CI
    -Wshadow                   ; a shadowed variable is
                               ; almost always a bug
    -Wconversion               ; implicit narrowing
    -Wsign-conversion
    -Wcast-align               ; important on ARM
    -Wpointer-arith
    -Wvla                      ; variable-length arrays
    -Wframe-larger-than=1024   ; stack usage (Linux ch. 02)
    -Wstack-usage=1024

# --- Standards ---
    -std=c11 / -std=gnu11 / -std=c17
    -pedantic                  ; reject GNU extensions

# --- Code generation ---
    -fno-strict-aliasing       ; the kernel uses this; see
                               ; chapter 15
    -fno-common
    -fstack-protector-strong
    -fno-omit-frame-pointer    ; makes profiling and
                               ; backtraces work
    -ffunction-sections -fdata-sections
        + -Wl,--gc-sections    ; drop unused code at link time
                               ; (chapter 12)
    -flto                      ; link-time optimisation

# --- Target selection, ARM ---
    -march=armv8-a+crc+crypto
    -mtune=cortex-a53
    -mcpu=cortex-a53+crc       ; sets both
    -mgeneral-regs-only        ; no FP/SIMD - REQUIRED for
                               ; kernel code (Linux ch. 02)

# --- Freestanding, for firmware ---
    -ffreestanding -nostdlib -nostdinc
    -fno-builtin

# --- Diagnostics about what the optimiser did ---
    -fopt-info-vec             ; which loops vectorised
    -fopt-info-vec-missed      ; and which did NOT, with the
                               ; reason (chapter 07)
    -fopt-info-inline
    clang: -Rpass=.* -Rpass-missed=.* -Rpass-analysis=.*
```

Translation units and the build

```
   foo.c  bar.c  baz.c
     |      |      |
     |  each compiled SEPARATELY, knowing nothing about the
     |  others - this is the C model
     v      v      v
   foo.o  bar.o  baz.o
     \      |      /
      \     |     /
       LINKER  +  libc.a, libm.so
          |
          v
       a.out

  CONSEQUENCES OF SEPARATE COMPILATION:

    · the compiler cannot inline across files, or prove
      anything about a function it has not seen
      -> which is why `static` matters: a static function has
         no external callers, so the compiler may inline it,
         specialise it, or delete it entirely
      -> and why LTO exists (chapter 12): defer optimisation
         to link time, when everything IS visible

    · a declaration mismatch between files is NOT caught by
      the compiler - only by the linker, and only sometimes
      -> which is what header files are for, and why a
         function should be declared in exactly one header
         that both the definition and the callers include

    · build times scale with the number of translation units
      times the size of the headers each pulls in
      -> which is why include hygiene matters on large
         projects, and why C++ modules were invented
```

How it shows up

Symptom	Which phase
"expected ';' before..."	Parser — but the cause is often a bad macro; check `-E`
A macro expands wrongly	Preprocessor — `gcc -E` shows the truth
"incompatible pointer types"	Semantic analysis
Code works at `-O0`, breaks at `-O2`	Almost always UB in your code (ch. 15)
A variable "optimised out" in gdb	Register allocation — build with `-Og`
"undefined reference to ..."	Linker — the symbol was never defined (ch. 12)
"multiple definition of ..."	Linker — defined in two objects
Runs on the host, crashes on target	Wrong `-march`, or an alignment assumption
Binary far larger than expected	No `--gc-sections`, or debug info not stripped
A loop did not vectorise	`-fopt-info-vec-missed` names the reason
Illegal instruction on target	`-march` allowed something the CPU lacks

Check yourself

- ✓ Name every phase from source to running instruction, in order.
- ✓ Explain the front/middle/back-end split and what it buys.
- ✓ Dump the output of five different phases for one source file.
- ✓ Use Compiler Explorer to check a claim about generated code.
- ✓ Say when to prefer GCC and when Clang, in embedded work.
- ✓ Explain why the kernel cannot be built at `-O0`.
- ✓ Explain why a bug appearing only at `-O2` is usually yours.
- ✓ List ten warning flags and what each catches.
- ✓ Explain what separate compilation prevents the compiler from doing, and what `static` and LTO recover.
- ✓ Attribute ten error messages to the phase that produced them.

Lexical analysis

Turning a stream of characters into a stream of tokens. The simplest phase of a compiler, and the one whose rules produce the most surprising error messages when you break them.

What a token is

```
SOURCE:      int count = x + 42;   /* a comment */

TOKENS:
   KEYWORD      "int"
   IDENTIFIER   "count"
   PUNCTUATOR   "="
   IDENTIFIER   "x"
   PUNCTUATOR   "+"
   NUMBER       "42"        value 42, type int
   PUNCTUATOR   ";"
   (the comment is discarded, replaced by one space)

EACH TOKEN CARRIES:
   a KIND
   the TEXT (its "spelling")
   a SOURCE LOCATION - file, line, column
   for literals, a computed VALUE and TYPE

THE SOURCE LOCATION is why error messages can point at the
right character, and why it must be preserved all the way
through the front end. A compiler that loses it produces
the "error somewhere in this file" diagnostics that older
toolchains were notorious for.

C's TOKEN CATEGORIES (C11 6.4):
   keywords          int, if, while, _Atomic, ...
   identifiers       count, printf, _my_var
   constants         42, 0x2A, 3.14, 'c', 1e-9
   string literals   "hello"
   punctuators       + - * / = == { } [ ] ; ...
   header names      <stdio.h>  (only after #include)
```

The maximal munch rule

```
/* THE RULE: at each point, take the LONGEST sequence of
   characters that forms a valid token. Greedily, without
   looking at whether the result makes sense.              */

        x+++y

/* Munched maximally: */
        x  ++  +  y        -> (x++) + y
/* NOT: */
        x  +  ++y

/* AND THE FAMOUS ONE: */
        a = b //*divide*/c;
             ^^
/* `//` starts a line comment in C99 and later, so this is: */
        a = b;
/* In C89, where // was not a comment, it was: */
        a = b / c;
/* The same source, two meanings, decided by the standard
   version. Real code was broken by this transition.      */

/* THE DIVISION TRAP: */
        int x = a /*p;      /* `/*` opens a comment! */
/* intended: a divided by *p. Write it as: */
        int x = a / *p;
        int x = a / (*p);

/* AND IN C++ BEFORE C++11: */
        vector<vector<int>> v;
                        ^^
/* `>>` munched as the right-shift operator, not two closing
   angle brackets. You had to write `> >`. C++11 special-cased
   it - which tells you the rule is a genuine design tension,
   not a curiosity.                                        */

/* THE PRACTICAL LESSON: whitespace is not decoration. When an
   expression parses strangely, add spaces between operators
   and look again.                                          */
```

The translation phases

```
C defines EIGHT translation phases, in order (C11 5.1.1.2).
Knowing them explains several otherwise baffling behaviours:

  1. Map physical characters to the source character set.
     Replace trigraphs (??= for #). Removed in C23.

  2. DELETE backslash-newline pairs - LINE SPLICING.
     Happens BEFORE tokenising, which is why:

         int x = 1; \
         int y = 2;

     is one line, and why a stray space AFTER the backslash
     breaks a macro continuation with a confusing error.

  3. Decompose into PREPROCESSING TOKENS and whitespace.
     Each comment becomes one space.

  4. Execute PREPROCESSING DIRECTIVES and expand macros.
     #include files are processed recursively through phases
     1-4.

  5. Convert escape sequences in character and string
     literals.

  6. CONCATENATE ADJACENT STRING LITERALS:
         "hello" " " "world"   ->   "hello world"
     which is why this works:
         #define PREFIX "app: "
         puts(PREFIX "started");

  7. Convert preprocessing tokens to TOKENS. Syntax and
     semantic analysis. -> a translation unit

  8. Resolve external references. LINK. -> a program

  PHASES 1-6 ARE THE PREPROCESSOR. Phase 7 is the compiler
  proper. Phase 8 is the linker (chapter 12).

  THE CONSEQUENCE PEOPLE MEET: the preprocessor operates on
  PREPROCESSING TOKENS, which are not quite tokens. A number
  like 0x1p+3 is one pp-number even though it would not be a
  valid integer, which is why some macro tricks work and
  others produce "invalid suffix" errors.
```

The hard cases

```
/* --- 1. IS IT A TYPE OR A VARIABLE? --------------------- */
       foo * bar;
/* This is EITHER:
     a declaration: `bar` is a pointer to `foo`
     an expression: `foo` multiplied by `bar`
   depending on whether `foo` is a typedef name.

   THE LEXER CANNOT KNOW. It must ask the symbol table, which
   is built by the parser. This is "the lexer hack": C
   compilers feed type information BACKWARDS from the parser
   to the lexer, so it can emit TYPEDEF_NAME or IDENTIFIER.

   This is why C's grammar is not context-free, and why
   `typedef` makes C genuinely harder to parse than languages
   that spell declarations differently.                    */

/* --- 2. NUMERIC LITERALS -------------------------------- */
       42          int
       42u         unsigned
       42l  42L    long
       42ull       unsigned long long
       0x2A        hex
       052         OCTAL - leading zero! A classic bug:
                   permissions written as 0644 are octal
                   (correct), but a zero-padded decimal like
                   0100 is 64, not 100.
       0b101010    binary - a GNU extension, standard in C23
       1'000'000   digit separators (C++14, C23)
       3.14        double
       3.14f       float
       1e-9        double
       0x1.8p3     hex float: 1.5 * 2^3 = 12.0

/* --- 3. CHARACTER AND STRING ESCAPES -------------------- */
       '\n' '\t' '\\' '\'' '\0'
       '\x41'      hex - CONSUMES AS MANY HEX DIGITS AS IT
                   CAN, so "\x41BC" is ONE character with
                   value 0x41BC (implementation-defined
                   overflow), not 'A' followed by "BC".
                   Write "\x41" "BC" instead.
       '\101'      octal - exactly up to three digits
       u8"..."     UTF-8

/* alternative spellings of [ ] { } # ## for keyboards
   lacking those characters. Still in the standard. They very
   occasionally surprise someone using `<:` in a template
   argument.                                               */
```

> **THE OCTAL TRAP IS A REAL EMBEDDED BUG**
>
> `#define TIMEOUT_MS 0100` is 64, not 100. It appears in configuration constants, in zero-padded register values copied from a datasheet table, and in permission masks where octal *was* intended but the reader does not realise. Never zero-pad a decimal constant, and when you do mean octal, use `0o` (C23) or a comment.

Writing one

```
/* Lexers are simple enough to write by hand, and most
   production compilers do - it is faster and gives better
   error messages than a generated one.                    */

typedef enum {
        TOK_EOF, TOK_IDENT, TOK_NUMBER, TOK_STRING,
        TOK_PLUS, TOK_MINUS, TOK_STAR, TOK_SLASH,
        TOK_LPAREN, TOK_RPAREN, TOK_SEMI, TOK_EQ, TOK_EQEQ,
        TOK_KEYWORD_IF, TOK_KEYWORD_WHILE, /* ... */
} TokenKind;

typedef struct {
        TokenKind kind;
        const char *start;      /* into the source buffer */
        size_t      length;
        int         line, column;
        union { long ival; double dval; };
} Token;

static Token next_token(Lexer *lx)
{
        skip_whitespace_and_comments(lx);

        if (at_end(lx))
                return make(lx, TOK_EOF);

        char c = advance(lx);

        /* identifiers and keywords */
        if (isalpha(c) || c == '_') {
                while (isalnum(peek(lx)) || peek(lx) == '_')
                        advance(lx);
                /* look it up in a keyword table - a perfect
                   hash, or just a sorted bsearch           */
                return make_ident_or_keyword(lx);
        }

        /* numbers */
        if (isdigit(c))
                return scan_number(lx);

        /* strings */
        if (c == '"')
                return scan_string(lx);

        /* MAXIMAL MUNCH on operators: check the longest
           first                                            */
        switch (c) {
        case '=':
                if (match(lx, '=')) return make(lx, TOK_EQEQ);
                return make(lx, TOK_EQ);
        case '+': return make(lx, TOK_PLUS);
        case '(': return make(lx, TOK_LPAREN);
        ...
        }

        return error_token(lx, "unexpected character");
}

/* NOTE `start` and `length` POINT INTO THE SOURCE rather than
```

```
   copying the text. That is how real compilers avoid
   allocating a string per token, and it is why the source
   buffer must outlive the tokens.

   THE OTHER PRODUCTION DETAIL: a keyword is just an
   identifier whose spelling is in a table. Do not write a
   separate scanner for each.                              */
```

Generated lexers

```
/* flex / lex - a regular expression per token kind: */

                          return TOK_NUMBER; }
"=="                    { return TOK_EQEQ; }
"="                     { return TOK_EQ; }
"+"                     { return TOK_PLUS; }
.                       { return TOK_ERROR; }
%%

/* flex compiles these into a DFA - a state machine that
   consumes one character per step, in constant time. That is
   why lexing is linear and fast.

   THE RULE ORDER MATTERS: flex prefers the longest match, and
   among equal-length matches, the rule listed FIRST. So
   keywords must come before the identifier rule, or every
   keyword lexes as an identifier.

/* WHEN TO USE A GENERATOR: prototypes, small languages,
   configuration file parsers. For a production compiler,
   hand-written wins on error messages, on incremental
   re-lexing for an IDE, and on the context sensitivity C
   needs anyway.                                           */
```

How it shows up

Symptom	Cause
"unterminated comment"	A `/*` inside what you meant as division — `a / *p`
Half the file vanishes	An unclosed comment swallowing to the next `*/`
Macro continuation breaks	Whitespace after the backslash — line splicing is phase 2
Constant is smaller than written	Leading zero — it is octal
"invalid suffix on integer constant"	Token pasting produced something that is not a valid number
`x+++y` parses unexpectedly	Maximal munch — add spaces
String escape consumes too much	`\x` is greedy — split the literal
"expected ';' before '*'"	A typedef name the compiler does not know about — a missing include
Two adjacent strings merge unexpectedly	Phase 6 concatenation, often from a macro

Symptom	Cause
Error points at the wrong line	Line splicing or a macro moved things — check `gcc -E`

Check yourself

- ✓ Tokenise a line of C by hand, including the source locations.
- ✓ State the maximal munch rule and give three cases where it surprises.
- ✓ List C's eight translation phases and say which are the preprocessor's.
- ✓ Explain why line splicing happens before tokenising, and the bug that follows.
- ✓ Explain string literal concatenation and one place it is useful.
- ✓ Explain the lexer hack and why C's grammar is not context-free.
- ✓ Decode six numeric literal forms, including the octal trap.
- ✓ Explain why `"\x41BC"` is not what you expect.
- ✓ Write a hand-rolled lexer for a small expression language.
- ✓ Explain why flex rule order matters for keywords.

Grammars and parsing

Turning a flat stream of tokens into a tree that reflects the structure of the program. This is where operator precedence comes from, why C's declaration syntax is famously awkward, and how a compiler decides what your code means.

Grammars

```
A GRAMMAR is a set of rules that generate a language. Written
in BNF or EBNF:

   expr    -> expr '+' term
            | expr '-' term
            | term

   term    -> term '*' factor
            | term '/' factor
            | factor

   factor  -> NUMBER
            | IDENT
            | '(' expr ')'

  TERMINALS are tokens: '+', NUMBER, IDENT.
  NON-TERMINALS are the named rules: expr, term, factor.

  THE STRUCTURE ENCODES PRECEDENCE. Because `term` appears
  inside `expr`, multiplication binds tighter than addition:
  the only way to derive `1 + 2 * 3` is with `2 * 3` as one
  term. Precedence is not a table bolted on afterwards - it is
  the SHAPE of the grammar.

  AND ASSOCIATIVITY comes from the recursion side:

     expr -> expr '+' term      LEFT recursive  -> left assoc
                                (a+b)+c
     expr -> term '+' expr      RIGHT recursive -> right assoc
                                a+(b+c)

  So `a - b - c` means `(a-b)-c` because the grammar is
  left-recursive, and `a = b = c` means `a = (b = c)` because
  assignment's rule is right-recursive.
```

Ambiguity

```
/* A grammar is AMBIGUOUS if some input has more than one
   parse tree. The classic:                                  */

        stmt -> 'if' '(' expr ')' stmt
              | 'if' '(' expr ')' stmt 'else' stmt
              | ...

        if (a) if (b) x(); else y();

/* Two readings:
     if (a) { if (b) x(); else y(); }     <-- the rule
     if (a) { if (b) x(); } else y();

   THE DANGLING ELSE. Every C-family language resolves it the
   same way: an `else` binds to the NEAREST unmatched `if`.
   That is a disambiguation rule imposed on top of an
   ambiguous grammar, not something the grammar itself
   expresses.

   AND IT IS WHY braces are worth writing even for
   single statements - not because the rule is unclear, but
   because the reader has to apply it.                       */

/* THE OTHER AMBIGUITY C HAS: the typedef problem
   (chapter 02).                                              */
        (foo)(bar);
/* a cast of `bar` to type `foo`, or a call of function `foo`
   with argument `bar`? Only the symbol table knows.         */

/* AND C++ ADDS the "most vexing parse": */
        Widget w(Gadget());
/* Declares a FUNCTION `w` taking a pointer-to-function
   returning Gadget, and returning Widget. Almost never what
   was meant. C++11's brace initialisation exists partly to
   escape it:                                                */
        Widget w{Gadget{}};
```

Recursive descent

```
/* One function per grammar rule. Readable, debuggable, gives
   excellent error messages - which is why GCC, Clang and most
   production compilers use it despite the theory favouring
   generated parsers.                                        */

        case TOK_LT: case TOK_GT:
        case TOK_LE: case TOK_GE:     return 7;
        case TOK_SHL: case TOK_SHR:   return 8;
        case TOK_PLUS: case TOK_MINUS: return 9;
        case TOK_STAR: case TOK_SLASH:
        case TOK_PERCENT:              return 10;
        default: return 0;      /* not a binary operator */
        }
}

static Node *parse_binary(Parser *p, int min_prec)
{
        Node *left = parse_unary(p);

        for (;;) {
                int prec = precedence_of(peek(p).kind);

                if (prec == 0 || prec < min_prec)
                        break;

                Token op = advance(p);

                /* LEFT associative: the right operand may only
                   contain operators of HIGHER precedence, so
                   pass prec + 1.
                   For a RIGHT associative operator, pass prec
                   instead.                                    */
                Node *right = parse_binary(p, prec + 1);

                left = make_binary(left, op, right);
        }
        return left;
}

        /* the whole expression grammar: */
        Node *e = parse_binary(p, 1);

/* ONE FUNCTION, one table. Adding an operator is a table
   entry. This is what most modern hand-written parsers use,
   and it is worth understanding because the `prec + 1` versus
   `prec` distinction is exactly where associativity lives. */
```

PRECEDENCE AND ASSOCIATIVITY ARE GRAMMAR, NOT CONVENTION

When you wonder why `a & b == c` means `a & (b == c)` — a genuine C wart that has caused real bugs — the answer is that `==` sits at a higher precedence level than `&` in the grammar C inherited from B. It is not a rule someone can change; it is the shape of the language. Parenthesise bitwise operators.

LR parsing and generators

```
/* The other family: BOTTOM-UP. Instead of predicting which
   rule applies, shift tokens onto a stack and REDUCE when the
   top of the stack matches a rule's right-hand side.       */

   Parsing `1 + 2 * 3`:

     stack                  input          action
     (empty)                1 + 2 * 3      shift
     1                      + 2 * 3        reduce factor
     factor                 + 2 * 3        reduce term
     term                   + 2 * 3        reduce expr
     expr                   + 2 * 3        shift
     expr +                 2 * 3          shift
     expr + 2               * 3            reduce factor,term
     expr + term            * 3            SHIFT (not reduce!)
     expr + term *          3              shift
     expr + term * 3        (end)          reduce factor
     expr + term * factor   (end)          reduce term
     expr + term            (end)          reduce expr
     expr                   (end)          ACCEPT

   THE INTERESTING STEP is `expr + term` with `*` next: the
   parser could reduce `expr + term` to `expr`, or shift the
   `*`. It shifts, because `*` binds tighter. That decision -
   SHIFT/REDUCE - is what a precedence declaration resolves in
   a generator.

/* yacc / bison: */
%left  '+' '-'
%left  '*' '/'          /* later = tighter */
%right UMINUS

%%
expr : expr '+' expr    { $$ = mk(ADD, $1, $3); }
     | expr '-' expr    { $$ = mk(SUB, $1, $3); }
     | expr '*' expr    { $$ = mk(MUL, $1, $3); }
     | expr '/' expr    { $$ = mk(DIV, $1, $3); }
     | '-' expr %prec UMINUS { $$ = mk(NEG, $2); }

     ;

/* THE GRAMMAR IS AMBIGUOUS as written - and the %left
   declarations resolve every conflict. That is the appeal:
   the grammar reads like the language reference.

   THE CONFLICTS YOU WILL SEE:
     shift/reduce   usually benign; bison shifts by default,
                    which is correct for dangling-else
     reduce/reduce  ALWAYS a real ambiguity. Fix the grammar.

   Run `bison -Wcounterexamples` - it prints an actual input
   that triggers each conflict, which turns a cryptic warning
   into a concrete problem.                                 */

/* WHY PRODUCTION COMPILERS STILL USE RECURSIVE DESCENT:
     · error messages: a hand-written parser knows what it
       expected and can suggest a fix
     · error RECOVERY: continuing sensibly after a mistake
     · context sensitivity: C's typedef problem
```

```
     · incremental re-parsing, for IDEs
   GCC moved from bison to recursive descent for C++ in 2004
   for exactly these reasons.                                */
```

C declaration syntax

```
/* C's declarations follow the "declaration mirrors use"
   principle, which makes complex ones hard to read.       */

        int    *p;              /* *p is an int             */
        int    a[10];           /* a[i] is an int           */
        int    f(void);         /* f() is an int            */
        int   *f(void);         /* *f() is an int -> f
                                   returns int*             */
        int  (*f)(void);        /* (*f)() is an int -> f is a
                                   pointer to function      */
        int   *a[10];           /* array of 10 int*         */
        int  (*a)[10];          /* pointer to array of 10    */
        int (*f[10])(void);     /* array of 10 function
                                   pointers                 */

            *          -> pointers to
                (void) -> functions taking void
        int            -> returning int

/* THE TOOL: */
        cdecl> explain int (*(*f)(void))[10]
        declare f as pointer to function (void) returning
        pointer to array 10 of int

/* THE PRACTICAL ADVICE: use typedefs. */
        typedef int (*handler_fn)(void);
        handler_fn table[10];        /* obviously an array of
                                        10 handlers          */

/* WHY IT IS LIKE THIS: Dennis Ritchie chose it so that a
   declaration looks like the expression that uses the
   variable. It is internally consistent, and it composes
   badly - which is why every later language (Go, Rust, even
   C++'s trailing return types) spells declarations
   differently.                                             */
```

Error recovery

```
/* A compiler that stops at the first error is unusable. Good
   parsers RECOVER and keep going, without producing a
   cascade of bogus follow-on errors.                      */

/* PANIC MODE - the standard technique: */
static void synchronise(Parser *p)
{
        advance(p);

        while (!at_end(p)) {
                /* a semicolon ends a statement - resume there */
                if (previous(p).kind == TOK_SEMI)
                        return;

                /* or at a token that clearly STARTS something */
                switch (peek(p).kind) {
                case TOK_IF: case TOK_WHILE: case TOK_FOR:
                case TOK_RETURN: case TOK_STRUCT:
                case TOK_RBRACE:
                        return;
                default:
                        advance(p);
                }
        }
}

/* AND SUPPRESS CASCADES: after reporting an error, do not
   report another until the parser has successfully consumed
   something. Otherwise one missing brace produces two hundred
   messages and the real error scrolls off the screen.

/* GOOD ERROR MESSAGES, which Clang made the standard:
     · point at the exact column, with a caret
     · say what was EXPECTED, not just what was found
     · suggest a FIX when the situation is unambiguous
     · show the relevant note - "to match this '(' here"

     error: expected ';' after expression
        x = y + 1
                  ^
                  ;

   Compare "parse error before '}'" - which was normal in
   1998 and tells the reader almost nothing.             */
```

How it shows up

Symptom	Cause
Hundreds of errors from one typo	Poor error recovery, or a missing brace/parenthesis early on — fix the first one
"expected ';' before '*'"	A typedef name the parser does not know — a missing include
Expression evaluates in the wrong order	Precedence — particularly bitwise versus comparison
`else` attached to the wrong `if`	Dangling else — use braces
A declaration is read as a function	C++'s most vexing parse — use brace initialisation
Cannot read a declaration	Apply the right-left rule, or introduce a typedef

Symptom	Cause
bison reports shift/reduce conflicts	Usually benign; check with `-Wcounterexamples`
bison reports reduce/reduce conflicts	A real ambiguity — fix the grammar
Error points past the real problem	The parser only noticed when the construct failed to close

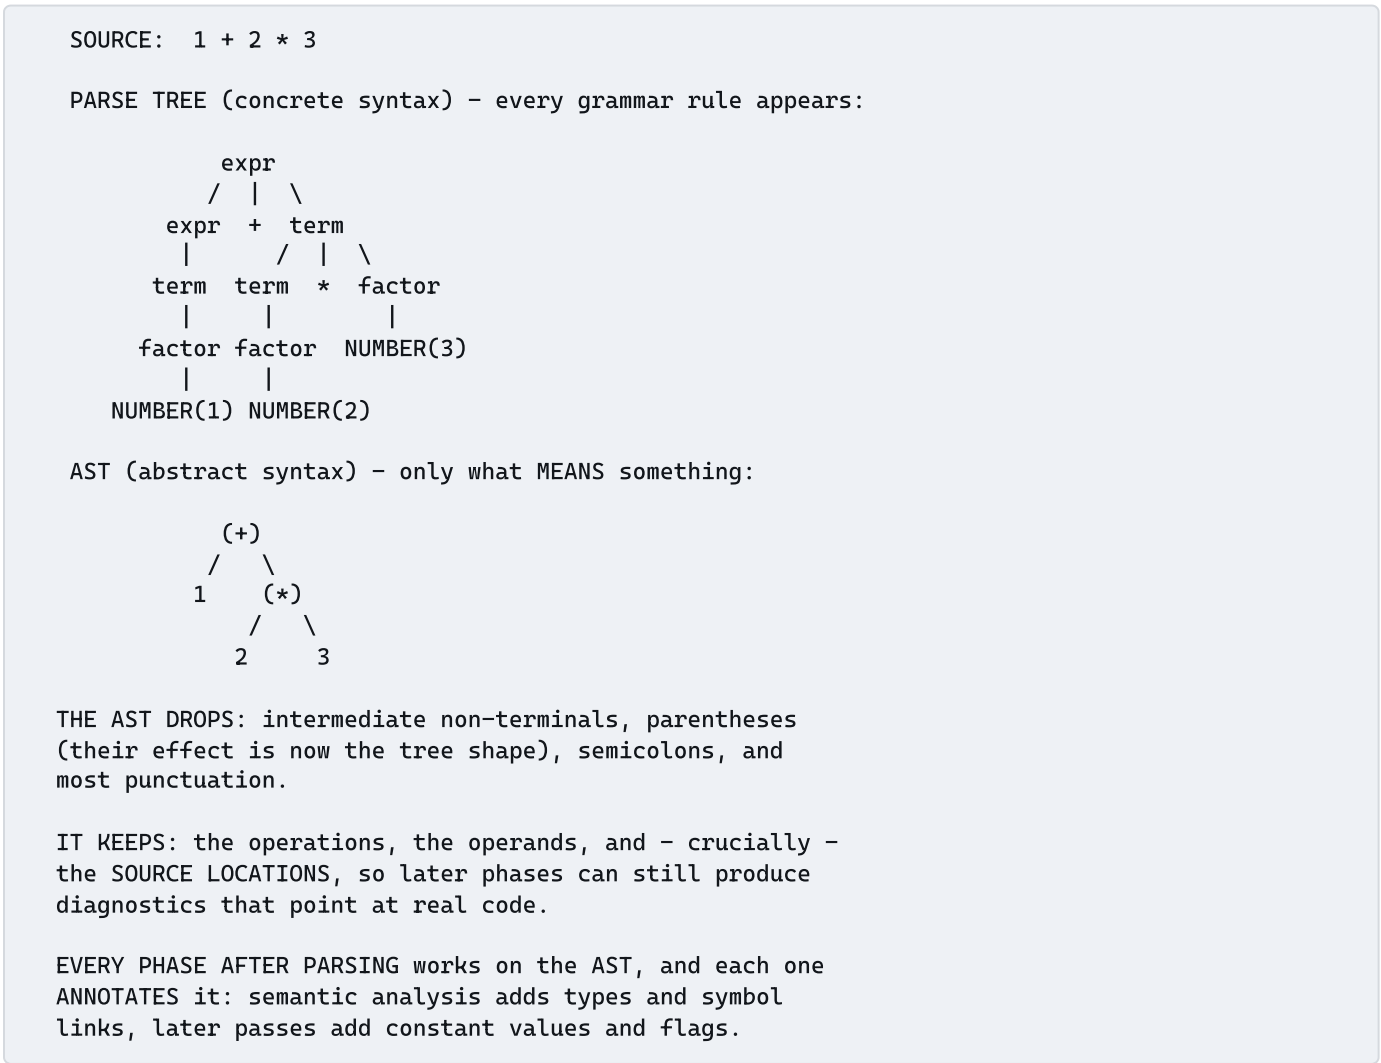
Check yourself

- ✓ Write a grammar whose shape encodes precedence and associativity.
- ✓ Explain how the recursion side determines associativity.
- ✓ Give three ambiguities in C or C++ and how each is resolved.
- ✓ Write a recursive descent parser for an expression language.
- ✓ Explain why left-recursive rules become loops.
- ✓ Implement precedence climbing and say where associativity lives in it.
- ✓ Trace an LR parse and identify a shift/reduce decision.
- ✓ Say why production compilers prefer recursive descent.
- ✓ Read four complex C declarations using the right-left rule.
- ✓ Explain panic-mode recovery and cascade suppression.

Abstract syntax trees and semantic analysis

The parse tree says what the program *looks like*. Semantic analysis works out what it *means*: which declaration each name refers to, what type every expression has, and whether the program is legal at all.

Parse tree versus AST



```
/* A representative AST node: */

typedef enum {
        NODE_INT_LITERAL, NODE_IDENT, NODE_BINARY,
        NODE_UNARY, NODE_CALL, NODE_MEMBER, NODE_CAST,
        NODE_IF, NODE_WHILE, NODE_RETURN, NODE_BLOCK,
        NODE_VAR_DECL, NODE_FUNC_DECL,
} NodeKind;

typedef struct Node {
        NodeKind    kind;
        SourceRange range;      /* for diagnostics */
        Type       *type;       /* filled in by semantic
                                   analysis - NULL until then */

        union {
                struct { long value; } int_lit;
                struct { Symbol *sym; } ident;   /* <- resolved
                                                    by name
                                                    lookup    */
                struct { TokenKind op;
                         struct Node *lhs, *rhs; } binary;
                struct { struct Node *fn;
                         struct Node **args;
                         int nargs; } call;
                struct { struct Node *cond, *then_br,
                                     *else_br; } if_stmt;
                ...
        };
} Node;

/* THE TWO FIELDS THAT MATTER MOST are `type` and, for
   identifiers, `sym`. Before semantic analysis both are
   empty; afterwards, every expression has a type and every
   name points at its declaration. That is what "semantic
   analysis" produces.                                    */
```

Symbol tables and scope

```
/* NAME RESOLUTION: given an identifier, find its
   declaration.                                          */

typedef struct Scope {
        struct Scope *parent;
        HashMap      *symbols;     /* name -> Symbol* */
} Scope;

static Symbol *lookup(Scope *s, const char *name)
{
        for (; s != NULL; s = s->parent) {
                Symbol *sym = map_get(s->symbols, name);
                if (sym)
                        return sym;       /* INNERMOST wins */
        }
        return NULL;      /* undeclared */
}

/* THE SCOPE CHAIN gives shadowing for free: an inner
   declaration hides an outer one, because lookup stops at the
   first match.                                          */

        int x = 1;              /* file scope */
        void f(void) {
                int x = 2;      /* shadows it */
                {
                        int x = 3;   /* shadows again */
                        printf("%d", x);   /* 3 */
                }
                printf("%d", x);           /* 2 */
        }

/* WHICH IS WHY -Wshadow IS WORTH ENABLING: shadowing is legal
   and occasionally intended, and far more often a bug where
   someone redeclared a variable they meant to assign.     */

/* C's SCOPE KINDS:
     file scope        outside any function
     block scope       inside { }
     function scope    LABELS ONLY - a goto label is visible
                       throughout its function regardless of
                       nesting
     function prototype scope   parameter names in a
                       declaration, which is why they can be
                       omitted

/* AND C's FOUR NAMESPACES - genuinely separate, so this is
   all legal and refers to four different things: */
        struct foo { int foo; };
        typedef struct foo foo;
        foo foo;
        goto foo;
        foo: ;
/*   1. ordinary identifiers: variables, functions, typedefs,
        enum constants
     2. TAGS: struct, union, enum names - which is why you
        write `struct foo` rather than `foo` without a typedef
     3. MEMBERS: one namespace per struct or union
     4. LABELS                                          */
```

Type checking

```
/* Every expression gets a type, computed bottom-up. */

static Type *check_binary(Node *n, Scope *scope)
{
        Type *lt = check_expr(n->binary.lhs, scope);
        Type *rt = check_expr(n->binary.rhs, scope);

        switch (n->binary.op) {
        case TOK_PLUS:
                /* POINTER ARITHMETIC is a special case: */
                if (is_pointer(lt) && is_integer(rt))
                        return lt;
                if (is_integer(lt) && is_pointer(rt))
                        return rt;
                if (is_arithmetic(lt) && is_arithmetic(rt))
                        return usual_arithmetic_conversions(lt, rt);
                error(n, "invalid operands to binary +");
                return type_error;

        case TOK_MINUS:
                if (is_pointer(lt) && is_pointer(rt)) {
                        if (!compatible(pointee(lt), pointee(rt)))
                                error(n, "incompatible pointers");
                        return type_ptrdiff_t;   /* NOT a
                                                    pointer! */
                }
                ...

        case TOK_EQEQ: case TOK_LT:
                ...
                return type_int;      /* comparisons yield int
                                         in C, bool in C++    */
        }
}

/* THE USUAL ARITHMETIC CONVERSIONS - the rules that decide
   what `int + unsigned` means (C track chapter 02): */

   1. if either is long double, convert both to long double
   2. else if either is double, ...
   3. else if either is float, ...
   4. else INTEGER PROMOTIONS on both (anything narrower than
      int becomes int)
   5. if both are now the same type, done
   6. if both signed or both unsigned: the lower rank
      converts to the higher
   7. if the UNSIGNED type has rank >= the signed type:
      the signed converts to UNSIGNED       <-- the trap
   8. if the signed type can represent every value of the
      unsigned type: unsigned converts to signed
   9. otherwise both convert to the unsigned version of the
      signed type

/* RULE 7 IS THE BUG SOURCE: */
        int i = -1;
        unsigned u = 1;
        if (i < u)              /* i converts to UNSIGNED */
                puts("less");   /* NOT PRINTED: -1 becomes
                                   4294967295             */
```

```
/* THE COMPILER IS FOLLOWING THE STANDARD EXACTLY. -Wextra
   warns (-Wsign-compare). Enable it.                    */
```

> **IMPLICIT CONVERSIONS ARE WHERE C BUGS LIVE**
> The conversion rules are consistent, documented, and almost nobody has them memorised. The practical defence is not memorisation: it is `-Wconversion -Wsign-compare -Wsign-conversion`, plus the habit of using explicitly sized types (`uint32_t`, not `unsigned`) so the rank question is at least visible in the source.

Lvalues and value categories

```
/* An LVALUE designates an object - something with an address
   you could take. An RVALUE is a value.                  */

        int x, a[10], *p;

        x           lvalue
        x + 1       rvalue
        a           lvalue (of array type - but it DECAYS to
                    a pointer rvalue in most contexts)
        a[0]        lvalue
        *p          lvalue
        &x          rvalue (a pointer VALUE)
        f()         rvalue in C; may be an lvalue in C++ if it
                    returns a reference
        (x = 5)     rvalue in C - which is why `(x = 5) = 6`
                    is illegal

/* WHERE IT MATTERS - the compiler must check: */
        x = 5;          /* left side must be a MODIFIABLE
                           lvalue                          */
        5 = x;          /* error: not an lvalue */
        &5;             /* error: cannot take the address */
        const int c = 1;
        c = 2;          /* error: not MODIFIABLE */
        x++;            /* needs a modifiable lvalue */

/* "MODIFIABLE LVALUE" excludes: arrays, const-qualified
   objects, incomplete types, and structs containing a const
   member.

/* AND THE ARRAY DECAY RULE, which surprises everyone once: */
        void f(int a[10]) { sizeof(a); }
/* `a` here is a POINTER - the [10] is ignored. sizeof(a) is
   8, not 40. Array parameters do not exist in C; they are
   silently rewritten to pointers.                        */

/* C++ REFINES this into five value categories - lvalue,
   xvalue, prvalue, glvalue, rvalue - to support move
   semantics (C++ track chapter 05). The C model is the
   simple ancestor.                                        */
```

What semantic analysis checks

Check	Example error
Name is declared	"undeclared identifier 'foo'"

Check	Example error
No duplicate declaration in a scope	"redefinition of 'x'"
Types are compatible	"incompatible pointer types"
Assignment target is a modifiable lvalue	"lvalue required as left operand"
Function call arity and argument types	"too few arguments to function"
Return type matches	"returning 'int *' from a function returning 'int'"
Struct member exists	"no member named 'x' in 'struct foo'"
Type is complete where required	"invalid use of incomplete type"
Constant expressions really are constant	"variably modified type at file scope"
Case labels are unique and constant	"duplicate case value"
`break` / `continue` are in a loop	"break statement not within loop or switch"
Qualifiers are respected	"assignment discards 'const' qualifier"

Flow-sensitive analysis

```
/* Some checks need to know the ORDER of execution, not just
   the tree shape. These are done on a control flow graph.  */

/* --- Uninitialised use --- */
        int x;
        if (cond)
                x = 1;
        printf("%d", x);        /* MAY be uninitialised */

/* gcc -Wmaybe-uninitialized. It is a MAY analysis, so it has
   false positives and false negatives - the exact question is
   undecidable. That is why the warning is separate from
   -Wuninitialized (which fires only when it is certain).  */

/* --- Missing return --- */
        int f(int x) {
                if (x > 0)
                        return 1;
                /* falls off the end -> UNDEFINED BEHAVIOUR if
                   the value is used                         */
        }
/* -Wreturn-type. In C++ this is worse than in C: the
   optimiser may assume the path is unreachable and delete
   the branch that reaches it (chapter 15).              */

/* --- Unreachable code --- */
        return 1;
        printf("never");        /* -Wunreachable-code */

/* --- Fallthrough in a switch --- */
        switch (x) {
        case 1:
                do_a();
                /* fallthrough - intentional? */
        case 2:
                do_b();
                break;
        }
/* -Wimplicit-fallthrough. Silence it deliberately: */
        __attribute__((fallthrough));
        /* or, C23: */
        [[fallthrough]];

/* --- Definite assignment, in other languages --- */
/* Java and C# REQUIRE definite assignment and reject the
   program otherwise. Rust goes further with ownership and
   borrow checking (Rust track chapter 04). C only warns,
   which is a language design choice with real consequences
   for how many bugs reach production.                    */
```

Looking at the AST

```
# Clang prints a genuinely readable AST:
    clang -Xclang -ast-dump -fsyntax-only test.c

    TranslationUnitDecl
    `-FunctionDecl 0x... <test.c:1:1, line:4:1> f 'int (int)'
      |-ParmVarDecl 0x... x 'int'
      `-CompoundStmt
        `-ReturnStmt
          `-BinaryOperator 'int' '+'
            |-ImplicitCastExpr 'int' <LValueToRValue>
            | `-DeclRefExpr 'int' lvalue ParmVar 0x... 'x'
            `-IntegerLiteral 'int' 1

# READ THE ANNOTATIONS - they are the output of semantic
# analysis:
#   'int (int)'          the function's computed type
#   ImplicitCastExpr     a conversion the compiler INSERTED
#   <LValueToRValue>     the specific conversion kind
#   lvalue               the value category
#   DeclRefExpr ... 0x...  the resolved declaration - the
#                          address links back to the ParmVarDecl

# THE IMPLICIT CASTS ARE THE INTERESTING PART. Every
# conversion C performs silently appears here as a node. If
# you have ever wondered where an unexpected promotion came
# from, this dump answers it exactly.

    clang -Xclang -ast-dump=json -fsyntax-only test.c
    ; machine-readable, for tooling

    gcc -fdump-tree-original-raw test.c
    ; GCC's equivalent, considerably less readable

# AND FOR C++, where the answer is much less obvious:
    clang++ -Xclang -ast-dump -fsyntax-only test.cpp
    ; shows which overload was selected, which template was
    ; instantiated, and every implicit conversion - the three
    ; things hardest to determine by reading.
```

How it shows up

Symptom	Cause
"undeclared identifier"	Missing include, typo, or a scope you did not expect
Comparison behaves backwards	Signed/unsigned conversion — enable `-Wsign-compare`
`sizeof` on a parameter is 8	Array decay — array parameters are pointers
"lvalue required"	Assigning to something with no address
"incompatible pointer types"	A real type error — never silence it with a cast without understanding it
Value changes unexpectedly in arithmetic	Integer promotion or the usual arithmetic conversions
Wrong variable modified	Shadowing — `-Wshadow`
Works, but a warning about maybe-uninitialised	Possibly a false positive; possibly a real path you have not considered
Missing return causes odd behaviour at `-O2`	UB — the optimiser assumed the path was unreachable

Symptom	Cause
Cannot tell which overload was chosen (C++)	Dump the AST

Check yourself

- ✓ Draw the parse tree and the AST for one expression, and say what was dropped.
- ✓ Explain how a scope chain gives shadowing, and why `-Wshadow` is worth enabling.
- ✓ Name C's four namespaces and give an example using all of them.
- ✓ State the usual arithmetic conversions and demonstrate the signed/unsigned trap.
- ✓ Classify six expressions as lvalues or rvalues.
- ✓ Explain array decay and its effect on `sizeof`.
- ✓ List ten checks semantic analysis performs.
- ✓ Explain why uninitialised-use analysis has false positives.
- ✓ Dump a Clang AST and identify every implicit conversion in it.
- ✓ Explain what the resolved `DeclRefExpr` address tells you.

Intermediate representations and SSA

The form a compiler thinks in. Static Single Assignment makes data flow explicit, which is what turns most optimisations from difficult analyses into simple graph walks — and it is why modern compilers optimise as well as they do.

Why an IR at all

```
Without an IR, supporting L languages on T targets needs
L * T compilers.

With one:   L front ends  +  1 optimiser  +  T back ends

AND THE IR MUST BE:
  · LANGUAGE-NEUTRAL: no C-specific or Rust-specific
    concepts
  · TARGET-NEUTRAL: no x86 or ARM assumptions, at least
    until the back end
  · SIMPLE: few operation kinds, so a pass handles all of
    them
  · ANALYSABLE: data flow and control flow explicit
  · TYPED: enough to reason about sizes and aliasing

THE LEVELS a compiler passes through:

  HIGH      close to the AST. Types, loops, structured
            control flow. GCC's GENERIC.
     |
  MID       three-address code, basic blocks, SSA.
            Most optimisation happens here.
            GCC's GIMPLE, LLVM IR.
     |
  LOW       close to machine code, but still virtual
            registers. GCC's RTL, LLVM's MachineIR.
     |
  MACHINE   real instructions, real registers.
```

Three-address code

```
/* SOURCE: */
        x = (a + b) * (c - d);

/* THREE-ADDRESS CODE - each instruction does ONE operation
   with at most three operands:                              */

        t1 = a + b
        t2 = c - d
        t3 = t1 * t2
        x  = t3

/* THE FORM: `result = operand1 op operand2`. Nested
   expressions become sequences of temporaries.

   WHY: every instruction is independently analysable and
   movable. A tree expression has to be walked; a flat list of
   simple operations can be reordered, deleted, or replaced
   one at a time.

/* THE OPERATION KINDS a mid-level IR needs, and it is a
   short list:
        arithmetic     add sub mul div rem

```

Basic blocks and the control flow graph

```
A BASIC BLOCK is a maximal straight-line sequence:
  - entered only at the first instruction
  - left only at the last

  SOURCE:
      if (a > 0)
              b = 1;
      else
              b = 2;
      c = b + 1;

  CFG:
                  +-------------+
                  | entry:      |
                  |  t = a > 0  |
                  |  br t, L1,L2|
                  +--+-------+--+
                     |       |
               true  |       |  false
                     v       v
            +-------+--+ +--+-------+
            | L1:      | | L2:      |
            |  b1 = 1  | |  b2 = 2  |
            |  br L3   | |  br L3   |
            +-------+--+ +--+-------+
                    |       |
                    +---+---+
                        v
                  +-----+--------+
                  | L3:          |
                  |  b3 = phi(...)|
                  |  c = b3 + 1  |
                  +--------------+

  THE CFG IS THE FOUNDATION of every flow analysis:
  reachability, liveness, dominance, loop detection.

  KEY RELATIONSHIPS:
    PREDECESSORS / SUCCESSORS   the edges
    DOMINATES     A dominates B if EVERY path from entry to B
                  passes through A. This is what makes
                  "definition reaches use" decidable, and it is
                  what SSA construction is built on.
    POST-DOMINATES  the mirror image, used for sinking code
    LOOP          a back edge to a dominator
    NATURAL LOOP  a loop with a single entry (a header) -
                  which is what loop optimisations require
                  (chapter 07)
```

Static Single Assignment

```
/* THE RULE: every variable is assigned EXACTLY ONCE. Reassign
   and you get a new name.                                    */

/* NOT SSA: */
        x = 1;
        x = x + 1;
        y = x * 2;

/* SSA: */
        x1 = 1
        x2 = x1 + 1
        y1 = x2 * 2

/* WHY THIS IS TRANSFORMATIVE:

   Before SSA, "what value does x have here?" requires a
   dataflow analysis over the whole function - which
   assignments reach this use, along which paths.

   In SSA, x2 has exactly ONE definition, and it is right
   there. THE NAME IS THE ANSWER. Use-def chains become
   pointers rather than analyses.

   CONSTANT PROPAGATION becomes: look at the definition; if
   it is a constant, substitute.
   DEAD CODE ELIMINATION becomes: does this definition have
   any uses? No -> delete.
   VALUE NUMBERING becomes: do two definitions compute the
   same expression from the same operands? -> they are equal.

   Each of these was a whole-function analysis; in SSA they
   are local.                                              */
```

Phi nodes

```
/* THE PROBLEM: at a merge point, which definition applies? */

        if (cond)
                x = 1;
        else
                x = 2;
        y = x;          /* which x? */

/* THE SOLUTION: a PHI FUNCTION at the top of the merge
   block, selecting by which predecessor you came from.    */

   entry:
        br cond, L1, L2

   L1:
        x1 = 1
        br L3

   L2:
        x2 = 2
        br L3

   L3:
        x3 = phi [x1, L1], [x2, L2]
        y1 = x3

/* A PHI IS NOT A REAL INSTRUCTION. It is a notation meaning
   "the value depends on the incoming edge". The back end
   removes them by inserting COPIES at the end of each
   predecessor block - "phi elimination" - and then register
   allocation usually makes those copies free by assigning
   x1, x2 and x3 the same register (chapter 09).

/* PHIS ARE ALWAYS AT THE TOP of a block, and they all execute
   "simultaneously" - a phi may reference a value defined by
   another phi in the same block, and the semantics are that
   all read the OLD values. That matters for loop-carried
   dependencies:                                            */

   loop:
        i2 = phi [0, entry], [i3, loop]
        s2 = phi [0, entry], [s3, loop]
        s3 = s2 + i2
        i3 = i2 + 1
        c  = i3 < n
        br c, loop, exit

/* Read that and the loop's structure is completely explicit:
   two loop-carried values, their initial values, and their
   updates. That legibility is why loop optimisations
   (chapter 07) are practical.                             */
```

WHERE PHI NODES GO: THE DOMINANCE FRONTIER

A phi for variable `x` is needed in block `B` exactly when two different definitions of `x` can reach `B` along different paths. The precise answer is the *iterated dominance frontier* of the blocks that define `x` — the first blocks where a definition's dominance "runs out". Cytron's 1991 algorithm computes this efficiently, and it is what made SSA practical rather than merely elegant.

LLVM IR

```
; C source:
;     int sum(int *a, int n) {
;             int s = 0;
;             for (int i = 0; i < n; i++)
;                     s += a[i];
;             return s;
;     }

; clang -S -emit-llvm -O1 sum.c -o -

define i32 @sum(ptr noundef %a, i32 noundef %n) {
entry:
  %cmp = icmp sgt i32 %n, 0
  br i1 %cmp, label %loop.preheader, label %exit

loop.preheader:
  %wide.n = zext i32 %n to i64
  br label %loop

loop:
  %i    = phi i64 [ 0, %loop.preheader ], [ %i.next, %loop ]
  %s    = phi i32 [ 0, %loop.preheader ], [ %s.next, %loop ]
  %ptr  = getelementptr inbounds i32, ptr %a, i64 %i
  %v    = load i32, ptr %ptr, align 4
  %s.next = add nsw i32 %s, %v
  %i.next = add nuw nsw i64 %i, 1
  %done = icmp eq i64 %i.next, %wide.n
  br i1 %done, label %exit, label %loop

exit:
  %result = phi i32 [ 0, %entry ], [ %s.next, %loop ]
  ret i32 %result
}

/* READ THE ANNOTATIONS - they carry the optimiser's
   knowledge:

     i32, i64, ptr    explicit types on everything
     %name            an SSA value; %0, %1 for unnamed
     phi              the loop-carried values, explicit
     getelementptr    address computation, type-aware. It
                      knows the element size, so no manual
                      multiply appears.
     inbounds         "this address stays within the object" -
                      a PROMISE from the front end, derived
                      from C's rules. It licenses
                      optimisations that would otherwise be
                      illegal.
     nsw / nuw        "no signed/unsigned wrap" - i.e. signed
                      overflow is UB in C, so the optimiser
                      may assume it does not happen
                      (chapter 15). THIS IS WHERE UB ENTERS
                      THE IR.
     noundef          the argument is not undef or poison
     align 4          the load's alignment

   THE `nsw` FLAG IS THE ONE TO UNDERSTAND. It is how
   "signed overflow is undefined" travels from the C standard
```

```
   into the optimiser, and it is why `i + 1 > i` can be folded
   to `true` for signed i but not for unsigned.          */
```

Memory and the SSA boundary

```
/* SSA works for SCALARS in registers. Memory is different:
   two pointers might alias, so a store through one may
   change what a load through the other sees. SSA cannot
   express that with names alone.                         */

/* SO CLANG STARTS by putting everything in memory: */

define i32 @f(i32 %x) {
  %x.addr = alloca i32            ; a stack slot
  store i32 %x, ptr %x.addr
  %1 = load i32, ptr %x.addr
  %2 = add i32 %1, 1
  store i32 %2, ptr %x.addr
  %3 = load i32, ptr %x.addr
  ret i32 %3
}

/* ...and then the `mem2reg` (or SROA) pass PROMOTES stack
   slots whose address is never taken into SSA values:    */

define i32 @f(i32 %x) {
  %1 = add i32 %x, 1
  ret i32 %1
}

/* THIS IS WHY `&x` MATTERS FOR PERFORMANCE. Take the address
   of a local and pass it somewhere the compiler cannot see,
   and the variable can no longer be promoted - it must live
   in memory, be reloaded after every call that might modify
   it, and cannot participate in most optimisations.

   THE PRACTICAL RULE: do not take the address of a local
   unless you need to. `int i` in a loop is free; `int i;
   f(&i);` is not.

/* AND FOR MEMORY THAT STAYS IN MEMORY, the optimiser needs
   ALIAS ANALYSIS: can this store affect that load? The
   answers come from
     · type-based rules (strict aliasing - chapter 15)
     · `restrict`, which promises no aliasing
     · escape analysis: an object whose address never leaves
       the function cannot be touched from outside
   and the quality of those answers is most of what separates
   a good optimiser from a mediocre one.                  */
```

GCC's IRs

```
# GCC uses several, in sequence:

# GENERIC - a language-independent tree, close to the AST
    gcc -fdump-tree-original test.c

# GIMPLE - three-address, then SSA form
    gcc -fdump-tree-gimple test.c
    gcc -fdump-tree-ssa test.c
    gcc -fdump-tree-optimized test.c    ; after all tree passes

    ;; sum (int * a, int n)
    ;; basic block 3:
    ;;   # i_15 = PHI <0(2), i_11(3)>
    ;;   # s_16 = PHI <0(2), s_10(3)>
    ;;   _1 = (long unsigned int) i_15;
    ;;   _2 = _1 * 4;
    ;;   _3 = a_8(D) + _2;
    ;;   _4 = *_3;
    ;;   s_10 = s_16 + _4;
    ;;   i_11 = i_15 + 1;
    ;;   if (i_11 < n_9(D)) goto bb 3; else goto bb 4;

# NOTE the naming: `i_15` is version 15 of `i` - GCC keeps the
# source name, which makes GIMPLE dumps easier to relate back
# to code than LLVM's numbered values. `(D)` marks a default
# definition, i.e. a parameter.

# RTL - low level, close to machine instructions
    gcc -fdump-rtl-all test.c

# EVERY PASS, in order, with statistics:
    gcc -fdump-tree-all-details test.c
    gcc -fopt-info-all test.c

# THE PRACTICAL USE: when a loop does not optimise as you
# expect, dump `-fdump-tree-optimized` and look at what the
# middle end actually produced. It is frequently obvious in
# the dump and invisible in the assembly.
```

How it shows up

Symptom	Cause
A local variable is never in a register	Its address was taken — `mem2reg` could not promote it
A value is reloaded after every call	The compiler cannot prove the call does not modify it
A loop is not optimised	Not a natural loop, or a memory dependency it cannot disprove
`i + 1 > i` folds to true for `int`	The `nsw` flag — signed overflow is UB (ch. 15)
The same code is faster with `restrict`	Alias analysis could not prove independence without it
Assembly does not match the source at all	Read the IR dump — the transformation is visible there
Optimisation differs between GCC and Clang	Different alias analysis and pass ordering, not a bug in either
Struct fields not kept in registers	SROA could not split it — usually because its address escaped

Check yourself

- ✓ Explain why an IR exists and what properties it needs.
- ✓ Convert an expression to three-address code.
- ✓ Draw a control flow graph and identify dominance and a natural loop.
- ✓ Convert straight-line code to SSA and explain what SSA makes cheap.
- ✓ Explain what a phi node means and how the back end removes it.
- ✓ Read an LLVM IR loop and identify the loop-carried values.
- ✓ Explain `nsw`, `inbounds` and where they come from.
- ✓ Explain `mem2reg` and why taking an address costs performance.
- ✓ Say what alias analysis is for and three sources of its answers.
- ✓ Dump GIMPLE for a loop and relate each statement to the source.

Machine-independent optimisation

What the middle end actually does to your code, why each transformation is legal, and the one assumption underneath all of it: that your program has no undefined behaviour.

The rule every optimisation obeys

THE AS-IF RULE

A compiler may perform any transformation, however drastic, provided the *observable behaviour* of the program is unchanged. In C, observable behaviour is: I/O, accesses to `volatile` objects, and the final state at program termination.

Everything else — the order of computations, whether a variable exists at all, how many times a loop body runs, whether a function call happens — is fair game. And because **undefined behaviour has no defined observable behaviour**, a program containing UB places no constraint on the compiler at all along that path (chapter 15).

The local transformations

```
/* --- CONSTANT FOLDING: evaluate at compile time --------- */
       int x = 2 * 3 + 4;              ->  int x = 10;
       if (sizeof(int) == 4)           ->  if (1)

/* --- CONSTANT PROPAGATION ------------------------------- */
       x = 5;
       y = x + 1;      ->  y = 6;
       z = y * 2;      ->  z = 12;

/* --- ALGEBRAIC SIMPLIFICATION --------------------------- */
       x * 1     -> x            x + 0     -> x
       x * 0     -> 0            x - x     -> 0
       x / 1     -> x            x & x     -> x
       x | 0     -> x            x ^ x     -> 0
       !!x       -> x != 0       -(-x)     -> x
       (x+1)-1   -> x            <-- ONLY if overflow is UB!

/* --- STRENGTH REDUCTION: cheaper operations ------------- */
       x * 8       ->  x << 3
       x / 8       ->  x >> 3      (unsigned; signed needs a
                                    correction for negatives)
       x % 8       ->  x & 7       (unsigned)
       x * 10      ->  (x << 3) + (x << 1)
       pow(x, 2)   ->  x * x

/* THE SIGNED DIVISION ONE is worth seeing, because it
   explains a common "why is this so many instructions?": */
       int f(int x) { return x / 8; }
   ->  add   w8, w0, #7        ; if negative, bias by 7
       cmp   w0, #0
       csel  w8, w8, w0, lt    ; select the biased value
       asr   w0, w8, #3        ; arithmetic shift
   Four instructions, because C rounds toward zero and a
   plain shift rounds toward negative infinity. Unsigned
   division by 8 is ONE instruction. That is a real reason to
   use unsigned types for indices and sizes.

/* --- COMMON SUBEXPRESSION ELIMINATION ------------------- */
       a = b * c + g;
       d = b * c * e;
   ->  t = b * c;
       a = t + g;
       d = t * e;

/* --- COPY PROPAGATION ----------------------------------- */
       y = x;
       z = y + 1;      ->  z = x + 1;

/* --- DEAD CODE ELIMINATION ------------------------------ */
       x = compute();          /* if x is never used AND
                                  compute() has no side
                                  effects -> delete both  */

/* --- DEAD STORE ELIMINATION ----------------------------- */
       x = 1;
       x = 2;          ->  x = 2;
/* AND THE SECURITY PROBLEM this causes: */
       memset(key, 0, sizeof(key));    /* DELETED - the
                                          buffer is never
                                          read afterwards */
```

```
        free(key);
/* Use explicit_bzero(), memset_s(), SecureZeroMemory(), or a
   volatile pointer. This is a real, exploited bug class
   (isolation chapter 16).                                  */
```

Inlining

```
/* THE MOST IMPORTANT OPTIMISATION, because it enables all the
   others. */

        static int square(int x) { return x * x; }
        int f(int a) { return square(a) + square(3); }

/* after inlining: */
        int f(int a) { return a * a + 3 * 3; }
/* after constant folding: */
        int f(int a) { return a * a + 9; }

/* THE COMPOUNDING EFFECT is the point: inlining exposes the
   arguments as constants, which enables folding, which
   enables branch elimination, which enables dead code
   removal, which may enable more inlining.

/* WHAT THE HEURISTIC WEIGHS:
     · the callee's size (LLVM's cost model, GCC's
       -finline-limit)
     · how many call sites there are
     · whether the callee is `static` and called once - then
       inlining is FREE, because the out-of-line copy can be
       deleted
     · whether arguments are constants at the call site
     · whether it is in a loop
     · profile data, if available (PGO)

/* THE ATTRIBUTES: */
        static inline int f(void) { ... }
        /* `inline` is a HINT, and in C it primarily affects
           linkage rules, not the decision. */

        __attribute__((always_inline))     /* force it */
        __attribute__((noinline))          /* forbid it */
        __attribute__((flatten))           /* inline
                                              everything this
                                              function calls */

/* WHEN NOT TO INLINE - and these are real:
     · large functions called from many places: I-cache
       pressure costs more than the call (CA chapter 14)
     · cold error paths: inlining them pushes the hot path out
       of the cache. Mark them noinline.
     · anything you need to see in a profile or a backtrace

/* THE EMBEDDED CONSIDERATION: -O2 inlines aggressively and
   can grow code substantially. On a flash-constrained part
   measure with `size` and consider -Os, which uses a much
   more conservative inlining threshold.                    */
```

Global transformations

```
/* --- GLOBAL VALUE NUMBERING ------------------------------ */
/* CSE across basic blocks, using SSA to identify expressions
   that provably compute the same value.                    */

/* --- PARTIAL REDUNDANCY ELIMINATION ---------------------- */
        if (cond)
                x = a + b;      /* computed here */
        y = a + b;              /* redundant on that path,
                                   not on the other        */
   ->   if (cond)  { t = a + b; x = t; }
        else       { t = a + b; }
        y = t;
/* Hoist the computation onto the path that lacked it, so it
   is computed exactly once on every path.                  */

/* --- TAIL CALL ELIMINATION ------------------------------- */
        int f(int n, int acc) {
                if (n == 0) return acc;
                return f(n - 1, acc * n);    /* TAIL call */
        }
   ->   a LOOP. No stack growth.
/* Which is why the recursive version is as fast as the
   iterative one at -O2, and why it stack-overflows at -O0.
   C does not GUARANTEE this - it is an optimisation, not a
   language rule, unlike in Scheme.                         */

/* --- JUMP THREADING -------------------------------------- */
        if (a) x = 1; else x = 2;
        if (a) y = 3; else y = 4;
   ->   if (a) { x = 1; y = 3; } else { x = 2; y = 4; }
/* The second test is known on each path.                   */

/* --- IF-CONVERSION: branches to conditional moves ------- */
        if (a > b) m = a; else m = b;
   ->   cmp  w0, w1
        csel w0, w0, w1, gt          ; ONE instruction, no
                                     ; branch, no misprediction
/* On ARM this is very effective because of the rich
   conditional-select instructions (ARM chapter 07). It is
   also why a "branchless" hand-optimisation is usually
   unnecessary: the compiler already did it.
   BUT: it evaluates BOTH sides, so it is only legal when
   both are side-effect free and safe to execute. This is
   also why if-conversion is NOT constant-time-safe in the
   way people assume for crypto (cryptography ch. 19).   */

/* --- FUNCTION SPECIALISATION (IPA-CP) -------------------- */
        static void f(int mode) { if (mode) ... else ... }
        f(1); f(1); f(0);
   ->   two specialised copies, each with the branch folded
        away.

/* --- DEVIRTUALISATION (C++) ------------------------------ */
/* If the dynamic type is provable, replace an indirect call
   through a vtable with a direct call - which then allows
   inlining. Enormously important for C++ performance
   (C++ track chapter 07).                                  */
```

Pass ordering

```
Optimisations ENABLE one another, so order matters and no
single order is optimal for all programs. A representative
LLVM -O2 pipeline:

   SROA                     split aggregates, promote to SSA
   EarlyCSE
   InstCombine              peephole on the IR
   SimplifyCFG              merge and delete blocks
      |
   INLINING  <--------------+  (the "CGSCC" pass manager runs
      |                     |   this bottom-up over the call
   more InstCombine,        |   graph, so a callee is
   SimplifyCFG, SROA -------+   optimised before its caller
      |                         is considered for inlining)
   GVN                      global value numbering
   MemCpyOpt
   DSE                      dead store elimination
      |
   LOOP PASSES:
     LoopRotate             turn while into do-while
     LICM                   hoist invariants (chapter 07)
     LoopUnswitch
     IndVarSimplify         canonicalise induction variables
     LoopIdiom              recognise memset/memcpy patterns
     LoopDeletion
     LoopUnroll
     LoopVectorize          (chapter 07)
     SLPVectorize
      |
   InstCombine, SimplifyFG  again - the loop passes exposed
      |                     new opportunities
   ADCE                     aggressive dead code elimination
      |
   -> the back end (chapters 08-09)

  NOTE HOW OFTEN InstCombine AND SimplifyCFG REPEAT. Cleanup
  passes run after every major transformation because each one
  leaves debris the next pass would otherwise trip over.

  SEE THE REAL ONE:
     llvm: opt -O2 -debug-pass-manager < in.ll > /dev/null
     gcc:  -fdump-tree-all -fdump-ipa-all
```

Link-time optimisation

```
# The problem: separate compilation (chapter 01) means the
# compiler cannot inline across translation units, or prove
# anything about a function defined elsewhere.

# LTO defers optimisation until link time, when everything is
# visible.

    gcc -flto -O2 -c a.c b.c
    gcc -flto -O2 a.o b.o -o prog
    ; the .o files contain IR, not machine code

    clang -flto=thin -O2 ...     ; ThinLTO: parallel, scalable,
                                 ; nearly as effective, much
                                 ; faster to link

# WHAT IT ENABLES:
#   cross-module inlining
#   whole-program dead code elimination - unused functions
#     across the whole program disappear
#   better devirtualisation
#   global constant propagation
#   identical code folding

# TYPICAL RESULTS: 5-15% faster, and often SMALLER because of
# the dead code elimination - which on an embedded target may
# matter more than the speed.

# THE COSTS:
#   link time grows substantially (ThinLTO mitigates this)
#   memory use at link time
#   debugging is harder - inlining across files confuses
#     backtraces
#   it EXPOSES UB that separate compilation hid. Code that
#     "worked" may now break, because the optimiser can finally
#     see the contradiction (chapter 15).

# THE LAST POINT IS THE ONE TO EXPECT: enabling LTO on an old
# codebase frequently surfaces latent bugs. They were always
# bugs.
```

Profile-guided optimisation

```
# The compiler's heuristics guess which branches are taken and
# which functions are hot. PGO replaces the guess with
# measurement.

# 1. build instrumented
    gcc -fprofile-generate -O2 prog.c -o prog
    clang -fprofile-instr-generate -O2 prog.c -o prog

# 2. RUN IT on a REPRESENTATIVE workload
    ./prog typical-input

# 3. rebuild using the data
    gcc -fprofile-use -O2 prog.c -o prog
    clang -fprofile-instr-use=prog.profdata -O2 prog.c -o prog

# WHAT IT IMPROVES:
#   branch layout - the hot path becomes the fall-through, so
#     the I-cache holds contiguous hot code (CA chapter 12)
#   inlining decisions - inline what is actually hot
#   hot/cold splitting - cold code moved to a separate section
#   loop unrolling based on real trip counts
#   register allocation priorities

# TYPICAL: 10-20% on branch-heavy code. Sometimes much more on
# interpreters and parsers.

# SAMPLE-BASED PGO, which avoids the instrumented build:
    perf record -b ./prog
    create_llvm_prof --binary=./prog --out=prog.prof
    clang -fprofile-sample-use=prog.prof ...
# Lower overhead, usable on production workloads, slightly
# less accurate.

# THE CAVEAT: a profile from an unrepresentative workload can
# make things WORSE, because the compiler will optimise
# confidently for the wrong case. Profile what you actually
# run.
```

Watching it happen

```
# Which optimisations fired, and which did not and why:
    gcc -fopt-info-all
    gcc -fopt-info-inline-optimized
    gcc -fopt-info-vec-missed

    clang -Rpass=inline
    clang -Rpass-missed=loop-vectorize
    clang -Rpass-analysis=loop-vectorize
    ; the -missed and -analysis forms print the REASON, which
    ; is the useful part

# Step through the IR one pass at a time:
    opt -O2 -print-after-all input.ll 2> passes.txt
    opt -passes='sroa,instcombine' -S input.ll
    ; run exactly the passes you want, and see the effect of
    ; each. This is the best way to understand what a pass
    ; actually does.

# GCC's equivalent:
    gcc -fdump-tree-all-details
    ls *.c.*t.*        ; one file per pass, in order

# AND ALWAYS: godbolt.org, with the "Optimization Pipeline"
# view enabled - it shows the IR after every pass, diffed.
```

How it shows up

Symptom	Cause
A `memset` that clears a key is gone	Dead store elimination — use `explicit_bzero`
A loop that should run is deleted	Its result is unused, or it contains UB
Signed division is four instructions	C's round-toward-zero rule — use unsigned where correct
A "branchless" hand-optimisation is slower	The compiler already did if-conversion, better
Recursive code overflows only at `-O0`	Tail call elimination at higher levels
Code grows a lot at `-O2`	Inlining — try `-Os` on constrained targets
Hot path slower after inlining	I-cache pressure — mark cold paths `noinline`
LTO breaks a working program	Latent UB the optimiser can now see
PGO makes it slower	Unrepresentative profile
A function does not appear in a profile	Inlined — `-fno-inline` to check
Assembly bears no resemblance to the source	Working as intended; read the IR to follow it

Check yourself

- ✓ State the as-if rule and what counts as observable behaviour in C.
- ✓ Name eight local optimisations and give an example of each.
- ✓ Explain why signed division by a power of two costs more than unsigned.
- ✓ Explain why dead store elimination is a security problem, and the fix.
- ✓ Explain why inlining is the most important optimisation.

- ✓ Give three cases where inlining should be prevented.
- ✓ Explain tail call elimination and why it is not guaranteed in C.
- ✓ Explain if-conversion and one situation where it is not what you want.
- ✓ Say why cleanup passes repeat throughout the pipeline.
- ✓ Explain what LTO enables and why it exposes latent bugs.
- ✓ Run a PGO build and say what it improves.

Loop optimisation and vectorisation

Programs spend most of their time in loops, so compilers spend most of their effort there. This chapter covers the transformations, why a loop fails to vectorise, and how to find out which reason applies to yours.

The loop transformations

```
/* --- LICM: loop-invariant code motion -------------------- */
        for (i = 0; i < n; i++)
                a[i] = b[i] * (x * y);      /* x*y each time */
   ->   t = x * y;
        for (i = 0; i < n; i++)
                a[i] = b[i] * t;

/* LICM is why manually hoisting is usually unnecessary - AND
   why it sometimes IS necessary: the compiler can only hoist
   what it can prove is invariant. A call it cannot see into,
   or a load it cannot prove is unaliased, stays inside.  */

/* --- STRENGTH REDUCTION on induction variables ---------- */
        for (i = 0; i < n; i++)
                a[i * 4] = 0;           /* a multiply per
                                           iteration        */
   ->   for (p = a; p < a + n*4; p += 4)
                *p = 0;                 /* an add           */

/* --- LOOP ROTATION: while -> do-while ------------------- */
        while (cond) { body }
   ->   if (cond) { do { body } while (cond); }
/* One test per iteration instead of a test plus a jump, and
   the loop body becomes a single block ending in a
   conditional branch - which is what most later loop passes
   require. Nearly every loop is rotated first.          */

/* --- LOOP UNROLLING ------------------------------------- */
        for (i = 0; i < n; i++)
                a[i] = b[i] + 1;
   ->   for (i = 0; i < n - 3; i += 4) {
                a[i]   = b[i]   + 1;
                a[i+1] = b[i+1] + 1;
                a[i+2] = b[i+2] + 1;
                a[i+3] = b[i+3] + 1;
        }
        for (; i < n; i++)              /* the EPILOGUE, for
                a[i] = b[i] + 1;           the remainder    */

/* WHY: fewer branches, more instruction-level parallelism,
   and it exposes vectorisation. COST: code size, and on a
   small I-cache that can lose more than it gains.
        #pragma GCC unroll 4
        #pragma clang loop unroll_count(4)
        #pragma clang loop unroll(disable)              */

/* --- LOOP FUSION ---------------------------------------- */
        for (i = 0; i < n; i++) a[i] = b[i];
        for (i = 0; i < n; i++) c[i] = a[i] * 2;
   ->   for (i = 0; i < n; i++) { a[i] = b[i];
                                  c[i] = a[i] * 2; }
/* One pass over memory instead of two - a cache win
   (CA chapter 14), often larger than the arithmetic saving. */

/* --- LOOP INTERCHANGE ----------------------------------- */
        for (j = 0; j < n; j++)
                for (i = 0; i < n; i++)
                        a[i][j] = 0;    /* STRIDE n - a cache
                                           miss per element */
   ->   for (i = 0; i < n; i++)
```

```
                for (j = 0; j < n; j++)
                        a[i][j] = 0;    /* stride 1          */
/* THE SINGLE BIGGEST WIN available on array code, and one the
   compiler often cannot do because it cannot prove the
   interchange is legal. Writing the loops in the right order
   is worth more than any flag.                              */

/* --- LOOP UNSWITCHING ----------------------------------- */
        for (i = 0; i < n; i++) {
                if (flag) do_a(i); else do_b(i);
        }
   ->   if (flag) for (i = 0; i < n; i++) do_a(i);
        else      for (i = 0; i < n; i++) do_b(i);
/* Hoist a loop-invariant condition out, at the cost of
   duplicating the loop.                                      */

/* --- IDIOM RECOGNITION ---------------------------------- */
        for (i = 0; i < n; i++) a[i] = 0;
   ->   memset(a, 0, n * sizeof(*a));
        for (i = 0; i < n; i++) a[i] = b[i];
   ->   memcpy(a, b, n * sizeof(*a));
/* Which is why hand-written copy loops are not faster than
   memcpy - they usually BECOME memcpy. And why
   -ffreestanding code still needs memcpy to exist
   (C track chapter 20).                                      */
```

Vectorisation

```
SIMD: one instruction, several data elements.

   SCALAR, 4 iterations:
      ldr  w1, [x0]        a[0]
      add  w1, w1, #1
      str  w1, [x2]
      ... x4

   VECTOR, 1 iteration:
      ldr  q0, [x0]        a[0..3], 128 bits at once
      add  v0.4s, v0.4s, v1.4s      four adds
      str  q0, [x2]

  ARM's SIMD:
     NEON (Advanced SIMD)   fixed 128-bit registers v0-v31.
                            Universally available on ARMv8-A.
     SVE / SVE2             VECTOR-LENGTH AGNOSTIC: the same
                            binary runs on 128-bit and
                            2048-bit implementations, using
                            predicates and a loop that adapts.
                            Server and newer mobile parts.

  ELEMENT ARRANGEMENTS on a 128-bit NEON register:
     v0.16b   16 x  8-bit
     v0.8h     8 x 16-bit
     v0.4s     4 x 32-bit
     v0.2d     2 x 64-bit

  THE THEORETICAL SPEEDUP is the element count - 4x for
  32-bit. THE REAL SPEEDUP is usually 2-3x, because loads,
  stores and loop overhead do not vectorise, and memory
  bandwidth often becomes the limit (CA chapter 18).
```

Why a loop does not vectorise

```
/* --- 1. LOOP-CARRIED DEPENDENCE ------------------------- */
        for (i = 1; i < n; i++)
                a[i] = a[i-1] + 1;      /* each iteration
                                           needs the previous */
/* Genuinely not vectorisable. Restructure the algorithm, or
   accept it.                                               */

/* BUT THIS ONE IS FINE: */
        for (i = 1; i < n; i++)
                a[i-1] = a[i] + 1;      /* reads ahead of
                                           writes - safe    */

/* --- 2. POSSIBLE ALIASING ------------------------------- */
        void add(int *a, int *b, int *c, int n) {
                for (int i = 0; i < n; i++)
                        a[i] = b[i] + c[i];
        }
/* The compiler cannot prove a, b and c do not overlap. It
   will either refuse, or - more commonly at -O3 - emit a
   RUNTIME ALIAS CHECK and two versions of the loop.

   THE FIX: */
        void add(int * restrict a, const int * restrict b,
                 const int * restrict c, int n)
/* `restrict` PROMISES no aliasing through these pointers for
   the object's lifetime. Break the promise and you get
   undefined behaviour and wrong results - so only use it
   when it is true.                                          */

/* --- 3. NON-CONTIGUOUS ACCESS --------------------------- */
        for (i = 0; i < n; i++)
                sum += a[i].field;      /* stride = sizeof
                                           the struct        */
/* Gather/scatter is possible on SVE but slow, and NEON has no
   general gather. THE FIX is a data layout change:
   structure-of-arrays instead of array-of-structures.    */

        /* AoS - poor for SIMD */
        struct P { float x, y, z; } points[N];
        /* SoA - vectorises perfectly */
        struct { float x[N], y[N], z[N]; } points;

/* --- 4. CONTROL FLOW INSIDE THE LOOP -------------------- */
        for (i = 0; i < n; i++)
                if (a[i] > 0)
                        b[i] = a[i];
/* Vectorisable via MASKING - compute all lanes, then blend by
   a predicate. NEON can do this; SVE does it natively. But an
   early `break` cannot be vectorised at all, because the trip
   count is not known in advance.                          */

/* --- 5. FUNCTION CALLS ---------------------------------- */
        for (i = 0; i < n; i++)
                a[i] = sinf(b[i]);
/* Needs a VECTORISED VERSION of the function. libmvec
   provides these for the maths functions; -ffast-math or
   -fveclib=libmvec may enable their use. A call to a
   function the compiler cannot see blocks vectorisation
   entirely.                                               */
```

```
/* --- 6. UNKNOWN TRIP COUNT OR COMPLEX EXIT ------------- */
        while (*p) { ... p++; }     /* length unknown */
/* Some of these can be vectorised speculatively; most are
   not.                                                    */

/* --- 7. REDUCTIONS ON FLOATING POINT ------------------- */
        for (i = 0; i < n; i++) sum += a[i];
/* FP addition is NOT ASSOCIATIVE (CA chapter 03), so
   reordering changes the result. The compiler will not do it
   by default. Options:
        -ffast-math          (dangerous - relaxes everything)
        -fassociative-math   (narrower)
        #pragma omp simd reduction(+:sum)   (explicit consent)
   INTEGER reductions vectorise freely, because integer
   addition IS associative - modulo wrapping, which is why
   unsigned is easier here too.                            */
```

ASK THE COMPILER WHY

```
gcc  -O3 -fopt-info-vec-missed
clang -O3 -Rpass-missed=loop-vectorize \
          -Rpass-analysis=loop-vectorize
```

These print the specific reason each loop failed: "loop not vectorized: cannot identify array bounds", "unsafe dependent memory operations", "value that could not be identified as reduction". That output turns vectorisation from guesswork into a checklist, and it is the single most useful flag in this chapter.

Helping the compiler

```
/* --- restrict, when it is true ------------------------- */
        void saxpy(int n, float a,
                   const float * restrict x,
                   float * restrict y)
        {
                for (int i = 0; i < n; i++)
                        y[i] = a * x[i] + y[i];
        }

/* --- tell it about alignment --------------------------- */
        float *p = __builtin_assume_aligned(ptr, 16);
        alignas(16) float buf[N];
/* An aligned vector load is faster than an unaligned one on
   many cores, and knowing the alignment lets the compiler
   skip the prologue that handles the misaligned head.   */

/* --- pragmas ------------------------------------------- */
        #pragma GCC ivdep               /* ignore assumed
                                           dependences      */
        #pragma clang loop vectorize(enable)
        #pragma clang loop vectorize_width(4) interleave_count(2)
        #pragma omp simd                /* OpenMP - portable */
        #pragma omp simd reduction(+:sum)

/* --- write loops the compiler can analyse -------------- */
        /* HARD: */
        for (p = start; p != end; p = p->next)   /* pointer
                                                    chasing */
        /* EASY: */
        for (i = 0; i < n; i++)                  /* counted,
                                                    contiguous */

        /* HARD: a loop with several exits */
        /* EASY: one entry, one exit, known trip count */

/* --- and when nothing works, intrinsics ---------------- */
#include <arm_neon.h>

void add_neon(int32_t *a, const int32_t *b,
              const int32_t *c, int n)
{
        int i;

        for (i = 0; i <= n - 4; i += 4) {
                int32x4_t vb = vld1q_s32(b + i);
