# kmemleak - finds objects nothing points to any more:
    CONFIG_DEBUG_KMEMLEAK=y
    echo scan > /sys/kernel/debug/kmemleak
    cat /sys/kernel/debug/kmemleak
# Reports false positives; read them, do not just believe them.

# Slab poisoning and red zones, without full KASAN:
    slub_debug=FZPU              # on the command line
    slub_debug=FZPU,my_request   # or just your cache

# Where memory went:
    cat /proc/meminfo
    sudo slabtop -s c
    cat /proc/vmallocinfo
    cat /proc/buddyinfo
    cat /proc/pagetypeinfo
```

> **THE ALLOCATION-FAILURE MESSAGE IS A DIAGNOSIS, NOT JUST AN ERROR**
>
> When an allocation fails the kernel dumps the order requested, the GFP flags, the zone state and a full backtrace. The *order* tells you whether you hit real exhaustion (order 0 failing) or fragmentation (order 0 fine, order 4 failing) — and those have completely different fixes. Read the dump before concluding you are out of memory.

How it shows up

Symptom	Cause
DMA works sometimes, corrupts memory otherwise	`vmalloc` or stack memory used for DMA
Large allocation fails after long uptime	Fragmentation — check `/proc/buddyinfo`; use CMA
Memory shrinks steadily	A leak — `slabtop` to find the cache, then kmemleak
Crash long after a `kfree`	Use-after-free — enable KASAN
Corruption in an unrelated structure	Buffer overrun into the neighbouring object — KASAN or `slub_debug`
`kmem_cache_destroy` warns on unload	Objects still allocated — a leak your driver owns
Allocation returns NULL in an interrupt	`GFP_ATOMIC` pool exhausted — preallocate instead

Symptom	Cause
`BUG: sleeping function called from invalid context` at kmalloc	`GFP_KERNEL` in atomic context (ch. 06)
Memory use far above what you allocated	kmalloc rounding — check `ksize()`, consider a cache
CMA allocation fails	Pages pinned and unmigratable, or the pool is too small
`virt_to_phys` returns nonsense	Called on a vmalloc address

Check yourself

- ✓ Draw the allocator stack and say what each layer adds.
- ✓ Explain buddy fragmentation and read `/proc/buddyinfo`.
- ✓ Explain kmalloc size rounding and its cost in a hot path.
- ✓ Create a slab cache and say what it buys over `kmalloc`.
- ✓ List three things `vmalloc` must never be used for.
- ✓ Choose the right allocator for eight concrete situations.
- ✓ Explain what CMA does, and the difference `reusable` makes.
- ✓ Turn on KASAN and read one of its reports.
- ✓ Read an allocation-failure dump and say whether it is exhaustion or fragmentation.

GFP flags and allocation context

The second argument to every allocation answers one question: *what may the kernel do to satisfy this request?* Get it wrong and you either deadlock the machine or crash with a message you will learn to recognise instantly.

Why a flag at all

```
When memory is short, the allocator has options:

   · hand back a free page immediately          (always fine)
   · reclaim: drop clean page cache             (fast, safe)
   · write back dirty pages to disk             (SLOW, and it
                                                 needs the I/O
                                                 path - which
                                                 may be YOUR
                                                 driver)
   · swap out anonymous memory                  (slower still)
   · compact memory to make a contiguous run    (slow)
   · invoke the OOM killer                      (drastic)
   · give up and return NULL                    (honest)

  Which of those are ALLOWED depends entirely on who is
  asking. Consider:

     your block driver's interrupt handler calls
     kmalloc(GFP_KERNEL), memory is short, so the allocator
     starts writing dirty pages back to disk - through your
     driver - which is currently inside an interrupt handler
     waiting for that same allocation.

     DEADLOCK. The machine stops.

  The GFP flags exist to make that impossible to express by
  accident.
```

The three you will use

Flag	May sleep	Use in	Behaviour when memory is short
`GFP_KERNEL`	**Yes**	Process context: syscalls, ioctl, probe, workqueues	Reclaims, writes back, swaps, may OOM-kill. Rarely fails.
`GFP_ATOMIC`	No	Interrupt handlers, softirqs, holding a spinlock	Uses emergency reserves, then **fails immediately**.
`GFP_NOWAIT`	No	Anywhere you can handle failure	No reclaim, no reserves. Fails readily. Politer than `GFP_ATOMIC`.

```
/* THE RULE, and it is the whole chapter:

     GFP_KERNEL  if you may sleep
     GFP_ATOMIC  if you may not, and failure is a real problem
     GFP_NOWAIT  if you may not, and failure is fine

   "May I sleep?" is answered by your CONTEXT (chapter 02):

     process context, no locks held    -> GFP_KERNEL
     process context, spinlock held    -> GFP_ATOMIC/NOWAIT
     softirq / tasklet / timer         -> GFP_ATOMIC/NOWAIT
     hardirq handler                   -> GFP_ATOMIC/NOWAIT
     RCU read-side critical section    -> GFP_ATOMIC/NOWAIT
     with preemption or IRQs disabled  -> GFP_ATOMIC/NOWAIT  */

/* GFP_ATOMIC IS NOT FREE. It dips into a small emergency
   reserve that exists precisely so that the network stack can
   allocate an skb during an interrupt storm. Draining it
   affects the whole system.

   So: do not reach for GFP_ATOMIC because it "always works".
   It works less often than GFP_KERNEL, not more - it just
   fails instead of waiting. If you find yourself needing large
   or frequent GFP_ATOMIC allocations, the fix is to
   PREALLOCATE at probe time, or to move the work to a
   workqueue where you can sleep (chapter 13).             */
```

What they are made of

```
/* The named flags are compositions of modifiers: */

   GFP_ATOMIC   = __GFP_HIGH | __GFP_KSWAPD_RECLAIM
   GFP_KERNEL   = __GFP_RECLAIM | __GFP_IO | __GFP_FS
   GFP_NOWAIT   = __GFP_KSWAPD_RECLAIM
   GFP_NOIO     = __GFP_RECLAIM
   GFP_NOFS     = __GFP_RECLAIM | __GFP_IO
   GFP_USER     = GFP_KERNEL | __GFP_HARDWALL
   GFP_DMA32    = __GFP_DMA32

/* THE ACTION MODIFIERS:
     __GFP_RECLAIM         may reclaim (implies it can sleep)
     __GFP_IO              may start disk I/O
     __GFP_FS              may call into filesystems
     __GFP_HIGH            may use emergency reserves
     __GFP_NOFAIL          retry forever. Never returns NULL.
                           Discouraged, and for good reason.
     __GFP_NORETRY         try once, give up quickly
     __GFP_NOWARN          do not print the failure dump
     __GFP_ZERO            zero the memory (= kzalloc)
     __GFP_COMP            compound page, for higher orders
     __GFP_MOVABLE         may be migrated (CMA-friendly)

/* ZONE MODIFIERS - which physical memory: */
     __GFP_DMA             the low DMA zone (ISA-era, 16 MB)
     __GFP_DMA32           below 4 GB
     (none)                anywhere in the normal zone

/* On arm64 you rarely need the zone modifiers directly - the
   DMA API handles addressing limits properly via the device's
   dma_mask (chapter 24). Setting GFP_DMA32 by hand is usually
   a sign someone worked around a missing dma_set_mask().  */
```

GFP_NOIO and GFP_NOFS: the recursion flags

```
These exist for one reason: to stop the allocator calling back
into the subsystem that is currently allocating.

  GFP_NOFS   "reclaim, but do not call into filesystems"
       Used BY filesystem code. Without it:
         ext4 allocates -> reclaim -> writes back a dirty page
         -> calls ext4 -> which is already holding a lock
         -> deadlock.

  GFP_NOIO   "reclaim, but do not start any I/O at all"
       Used BY block and storage drivers, and in any code on
       the writeback path. Without it:
         your MMC driver allocates -> reclaim -> writes back
         -> submits a request to your MMC driver -> which is
         mid-allocation -> deadlock.

  WHEN YOU NEED THEM: if your driver is in the storage or
  filesystem path, or is called during suspend/resume while
  the block layer is frozen.

  THE MODERN WAY - scope, not per-call:

     unsigned int flags = memalloc_noio_save();
     ... everything in here, including code you call, behaves
         as if GFP_NOIO ...
     memalloc_noio_restore(flags);

  This is better than passing GFP_NOIO down through every
  function, because it also covers allocations made by library
  code you did not write. The block and MMC layers do this for
  you around resume, which is why you may see GFP_KERNEL
  working in a resume path that "should" need GFP_NOIO.
```

Patterns

```
/* --- 1. probe: the easy case ---------------------------- */
static int my_probe(struct platform_device *pdev)
{
        struct my_dev *d;

        /* process context, no locks -> GFP_KERNEL */
        d = devm_kzalloc(&pdev->dev, sizeof(*d), GFP_KERNEL);
        if (!d)
                return -ENOMEM;
        ...
}

/* --- 2. interrupt handler: preallocate ------------------ */
/* WRONG - allocating in an IRQ, where it can fail: */
static irqreturn_t my_isr(int irq, void *data)
{
        struct my_event *e = kmalloc(sizeof(*e), GFP_ATOMIC);
        if (!e)
                return IRQ_HANDLED;     /* EVENT LOST */
        ...
}

/* RIGHT - a preallocated pool, filled at probe: */
struct my_dev {
        struct my_event  events[MY_NR_EVENTS];  /* fixed pool */
        DECLARE_KFIFO(fifo, struct my_event, MY_NR_EVENTS);
};
static irqreturn_t my_isr(int irq, void *data)
{
        struct my_dev *d = data;
        struct my_event e = { .ts = ktime_get(), ... };

        if (!kfifo_put(&d->fifo, e))
                d->overruns++;          /* counted, not lost
                                           silently */
        return IRQ_HANDLED;
}
/* An overrun counter is a far better failure mode than an
   allocation that quietly returns NULL.                   */

/* --- 3. spinlock held: allocate outside it -------------- */
/* WRONG: */
        spin_lock(&d->lock);
        p = kmalloc(size, GFP_KERNEL);   /* BUG: may sleep */
        list_add(&p->node, &d->list);
        spin_unlock(&d->lock);

/* RIGHT - allocate first, then take the lock: */
        p = kmalloc(size, GFP_KERNEL);
        if (!p)
                return -ENOMEM;

        spin_lock(&d->lock);
        list_add(&p->node, &d->list);
        spin_unlock(&d->lock);

/* This restructuring - allocate outside, insert inside - is
   the standard fix, and it is almost always possible.     */

/* --- 4. a large, optional allocation -------------------- */
```

```
        buf = kmalloc(SZ_1M, GFP_KERNEL | __GFP_NOWARN |
                             __GFP_NORETRY);
        if (!buf)
                buf = vmalloc(SZ_1M);   /* fall back */
/* kvmalloc() does exactly this for you: */
        buf = kvmalloc(SZ_1M, GFP_KERNEL);
        ...
        kvfree(buf);
/* Use kvmalloc when the buffer is CPU-only and you do not
   care whether it is physically contiguous. Never for DMA. */
```

THE DESIGN LESSON UNDERNEATH

Almost every `GFP_ATOMIC` in a driver can be removed by allocating earlier. Fixed pools sized at probe time, kfifos, preallocated descriptor rings and mempools all trade a little memory for the guarantee that the hot path cannot fail. That trade is nearly always right in embedded work, where the memory budget is known and an allocation failure at 3 a.m. is not recoverable.

Mempools: when failure is not an option

```
/* A mempool keeps a guaranteed reserve. Allocation tries the
   normal allocator first; if that fails, it takes from the
   reserve; if the reserve is empty AND you may sleep, it waits
   for something to be returned.                              */

        mempool_t *pool;

        pool = mempool_create_kmalloc_pool(MIN_NR, sizeof(struct req));
        /* or with your own alloc/free callbacks:            */
        pool = mempool_create(MIN_NR, mempool_alloc_slab,
                              mempool_free_slab, my_cache);

        p = mempool_alloc(pool, GFP_NOIO);
        ...
        mempool_free(p, pool);

        mempool_destroy(pool);

/* USED BY: the block layer, dm, md, and anything on the
   writeback path - places where returning NULL would mean
   losing data rather than failing a request.

   THE GUARANTEE holds only if you RETURN objects promptly and
   the reserve is sized for your maximum in-flight count. A
   mempool with MIN_NR=4 and 8 concurrent requests will still
   block.                                                     */
```

Catching mistakes

```
# TURN THESE ON. They convert silent, rare, unreproducible
# corruption into a loud message with a backtrace.

    CONFIG_DEBUG_ATOMIC_SLEEP=y     # THE important one
    CONFIG_PROVE_LOCKING=y          # lockdep
    CONFIG_DEBUG_SPINLOCK=y
    CONFIG_KASAN=y

# What DEBUG_ATOMIC_SLEEP prints:

  BUG: sleeping function called from invalid context at mm/slab.h:494
  in_atomic(): 1, irqs_disabled(): 0, non_block: 0, pid: 431
  Call trace:
    dump_backtrace+0x0/0x1a0
    show_stack+0x18/0x24
    ___might_sleep+0x120/0x130
    __might_sleep+0x4c/0x88
    kmem_cache_alloc+0x40/0x2d0     <-- the allocation
    my_driver_handler+0x38/0xc0     <-- YOUR CODE
    ...

# Reads as: my_driver_handler called kmem_cache_alloc in a
# context where sleeping is illegal. Either the GFP flag is
# wrong, or the allocation is in the wrong place.

# FAULT INJECTION - test your error paths, which are otherwise
# never exercised:
    CONFIG_FAILSLAB=y
    CONFIG_FAIL_PAGE_ALLOC=y
    echo 10 > /sys/kernel/debug/failslab/probability
    echo 100 > /sys/kernel/debug/failslab/times
# Now 10% of allocations fail. Run your driver. Anything that
# crashes is an unchecked return value - and you will find
# some.
```

How it shows up

Symptom	Cause
`BUG: sleeping function called from invalid context`	`GFP_KERNEL` in atomic context
System deadlocks under memory pressure	Storage or filesystem driver allocating with `GFP_KERNEL` — needs `GFP_NOIO` / `NOFS`
Deadlock only during suspend/resume	Allocating on the frozen block path — use `memalloc_noio_save()`
Allocations fail in interrupts under load	`GFP_ATOMIC` reserves exhausted — preallocate
Events dropped during interrupt storms	Same; use a fixed pool and count overruns
Works with plenty of RAM, fails on a small board	Unchecked allocation return values — use fault injection to find them
Rare crash after an allocation failure	An error path that was never tested
Sluggish under memory pressure	`__GFP_NOFAIL` or heavy `GFP_KERNEL` use in a hot path
Allocation failure dump with order 0	Genuine exhaustion, not fragmentation

Check yourself

- ✓ Explain the deadlock GFP flags exist to prevent.
- ✓ Choose between `GFP_KERNEL`, `GFP_ATOMIC` and `GFP_NOWAIT` for six contexts.
- ✓ Explain why `GFP_ATOMIC` is less reliable than `GFP_KERNEL`, not more.
- ✓ Say when `GFP_NOIO` and `GFP_NOFS` are needed, and what `memalloc_noio_save()` adds.
- ✓ Rewrite an allocation under a spinlock so it is legal.
- ✓ Replace an interrupt-context allocation with a preallocated pool.
- ✓ Explain what a mempool guarantees and what breaks the guarantee.
- ✓ Read a `DEBUG_ATOMIC_SLEEP` backtrace and name the two possible fixes.
- ✓ Use fault injection to find an unchecked allocation in your own code.

The kernel address space

Where the kernel lives in virtual memory on arm64, which addresses can be translated to physical ones and which cannot, and why `virt_to_phys()` is right about half the pointers you will hand it.

The split

```
arm64 uses TTBR0 for user and TTBR1 for kernel (ARM ch. 12) -
so the split is architectural, not a software convention.

  With a 48-bit VA (CONFIG_ARM64_VA_BITS=48), the default:

  0x0000_0000_0000_0000  +--------------------------+
                         |  USER SPACE              |  TTBR0_EL1
                         |  256 TB                  |  per-process
  0x0000_ffff_ffff_ffff  +--------------------------+
                         |                          |
                         |   NON-CANONICAL          |  faults
                         |   (the "hole")           |
                         |                          |
  0xffff_0000_0000_0000  +--------------------------+  TTBR1_EL1
                         |  KERNEL SPACE            |  shared by
                         |  256 TB                  |  all tasks
  0xffff_ffff_ffff_ffff  +--------------------------+

  The top bits select the table, so the "hole" is addresses
  that are neither - and touching one is an immediate
  translation fault, which is a useful property: a corrupted
  pointer usually lands there rather than somewhere plausible.

  INSIDE THE KERNEL HALF (layout varies by version; this is
  the shape, check Documentation/arch/arm64/memory.rst for
  yours):

   +------------------------------+
   |  KASAN shadow                |  if enabled - a quarter
   |                              |  of the space
   +------------------------------+
   |  modules            128 MB   |  must be within branch
   |                              |  range of the kernel text
   +------------------------------+
   |  vmalloc / ioremap           |  large. vmalloc(), and
   |                              |  every ioremap() mapping
   +------------------------------+
   |  fixmap, PCI I/O             |
   +------------------------------+
   |  vmemmap                     |  the struct page array
   +------------------------------+
   |  LINEAR MAP                  |  <-- ALL of physical
   |  (the "direct map")          |      memory, mapped
   |                              |      contiguously
   +------------------------------+
```

The linear map is the key idea

```
/* Every byte of physical RAM appears at a fixed virtual
   address, in order, at a constant offset. So:            */

        virt = phys + PAGE_OFFSET_ADJUSTMENT

/* which makes translation ARITHMETIC, not a page-table walk: */

        phys_addr_t p = virt_to_phys(v);    /* subtract */
        void       *v = phys_to_virt(p);    /* add      */

        struct page *pg   = virt_to_page(v);
        void        *v2   = page_address(pg);
        unsigned long pfn = page_to_pfn(pg);

/* WHY IT EXISTS: the kernel constantly needs to convert
   between "a page I am tracking" and "a pointer I can
   dereference". Doing that with a page-table walk every time
   would be intolerable.

/* AND THE CRITICAL LIMITATION:

   These functions are ONLY valid for LINEAR MAP addresses -
   memory from kmalloc(), alloc_pages(), or the kernel image
   itself.

   THEY ARE WRONG, silently, for:
        vmalloc() addresses     - scattered physical pages
        ioremap() addresses     - device memory, not RAM
        user-space pointers     - a different address space
        stack addresses on a VMAP_STACK kernel - the kernel
                                 stack is vmalloc'd!

   "Silently wrong" is the problem. virt_to_phys() on a
   vmalloc address does not fault - it returns a number, which
   points at some unrelated physical memory. Hand that to a
   DMA engine and you have a device writing into whatever
   happens to live there.                                  */

/* THE CORRECT TOOLS for the non-linear cases: */
        vmalloc_to_page(addr)         /* vmalloc -> page     */
        virt_to_page(addr)            /* linear only         */
        dma_map_single(dev, ...)      /* the ONLY right way
                                         to get a device
                                         address (ch. 24)    */
```

FOUR KINDS OF POINTER, ONE C TYPE

A `void *` in the kernel may be a linear-map address, a vmalloc address, an `__iomem` cookie, or a `__user` address. They look identical to the compiler and behave completely differently. The annotations exist to make `sparse` tell them apart — which is the entire argument for running `make C=1` on your driver.

ioremap: reaching device registers

```
/* Device registers are NOT in the linear map. RAM is; MMIO is
   not. To touch a peripheral you must create a mapping.    */

        void __iomem *base;

        base = ioremap(0x1c000000, 0x1000);
        if (!base)
                return -ENOMEM;
        ...
        iounmap(base);

/* IN A DRIVER, do not do that. Use the managed, DT-driven
   form, which also RESERVES the region so two drivers cannot
   claim it:                                                */

        base = devm_platform_ioremap_resource(pdev, 0);
        if (IS_ERR(base))
                return PTR_ERR(base);

/* WHAT ioremap GIVES YOU:
     · a mapping with Device memory attributes (ARM ch. 11):
       nGnRE - no gathering, no reordering, no early write
       acknowledgement. So accesses reach the device in
       program order and are not merged.
     · a __iomem pointer, which sparse will police

   THE VARIANTS:
     ioremap()        Device nGnRE. The default. Use this.
     ioremap_wc()     write-combining - for framebuffers,
                      where merging writes is a huge win
     ioremap_np()     non-posted, strictly ordered
     ioremap_cache()  Normal cacheable - for RAM-like regions
                      such as a firmware image in a carve-out

   NEVER dereference an __iomem pointer directly:
        val = *base;                    /* WRONG            */
        val = readl(base);              /* right (ch. 23)   */

   On arm64 a direct dereference often appears to work, which
   makes it worse - it compiles to a load with the wrong
   assumptions about reordering and merging, and fails on a
   different core or compiler version.                      */
```

The page tables themselves

```
/* arm64, 4 KB granule, 48-bit VA -> four levels (ARM ch. 13): */

    PGD -> PUD -> PMD -> PTE -> page
    (level 0)(1)   (2)    (3)

/* Kernel types:
        pgd_t, p4d_t, pud_t, pmd_t, pte_t
   and the walk, which you will see in mm/ code:            */

static int walk_one(struct mm_struct *mm, unsigned long addr)
{
        pgd_t *pgd;  p4d_t *p4d;  pud_t *pud;
        pmd_t *pmd;  pte_t *pte;

        pgd = pgd_offset(mm, addr);
        if (pgd_none(*pgd) || pgd_bad(*pgd))  return -EFAULT;

        p4d = p4d_offset(pgd, addr);
        if (p4d_none(*p4d) || p4d_bad(*p4d))  return -EFAULT;

        pud = pud_offset(p4d, addr);
        if (pud_none(*pud) || pud_bad(*pud))  return -EFAULT;
        if (pud_huge(*pud))  { /* 1 GB block */ }

        pmd = pmd_offset(pud, addr);
        if (pmd_none(*pmd) || pmd_bad(*pmd))  return -EFAULT;
        if (pmd_huge(*pmd))  { /* 2 MB block */ }

        pte = pte_offset_map(pmd, addr);
        ...
        pte_unmap(pte);
        return 0;
}

/* You will rarely write this. You WILL read it, in mm/, in
   the DMA code, and in any driver doing something unusual
   with mappings.

   BLOCK MAPPINGS matter for performance: the kernel maps its
   own linear map with 2 MB or 1 GB blocks where it can, which
   collapses four TLB entries into one (ARM ch. 15). That is
   also why CONFIG_RODATA_FULL_DEFAULT_ENABLED, which splits
   blocks to apply finer permissions, costs a measurable
   amount of performance.                                   */
```

Looking at it

```
# The full kernel page tables, level by level:
    CONFIG_PTDUMP_DEBUGFS=y
    sudo cat /sys/kernel/debug/kernel_page_tables

  ---[ Linear Mapping start ]---
  0xffff000000000000-0xffff000040000000  1G PMD  RW NX SHD AF ...
  0xffff000040000000-0xffff000040200000  2M PTE  ro x  SHD AF ...
                                                 ^^^^ kernel text
  ---[ vmalloc() Area ]---
  0xffff800000000000-0xffff800000001000  4K PTE  RW NX ...

# Read the permissions: kernel TEXT should be `ro x`, RODATA
# `ro NX`, everything else `RW NX`. Anything both writable and
# executable is a finding.

# Physical memory layout:
    cat /proc/iomem

# vmalloc allocations, with the caller:
    sudo cat /proc/vmallocinfo
    0xffff800008000000-0xffff800008002000 8192 my_probe+0x40/0x200 ...

# The kernel's own summary at boot:
    dmesg | grep -A20 "Virtual kernel memory layout"

# Where a symbol lives:
    sudo grep my_symbol /proc/kallsyms
```

> **`/proc/vmallocinfo` ATTRIBUTES EVERY MAPPING TO A CALLER**
>
> It shows the size and the function that allocated it, including `ioremap` mappings. If vmalloc space is filling up, or you suspect a driver is leaking mappings across bind/unbind cycles, this file names the culprit directly.

KASLR and pointer hiding

```
/* Two things that surprise people reading addresses: */

/* 1. KASLR randomises the kernel's base address each boot.
      So an address from one boot means nothing in another,
      and a crash dump must be decoded against that boot's
      offset. Disable it while debugging:                  */
        nokaslr        # on the command line

/* 2. %p HASHES pointers for unprivileged readers, to avoid
      leaking kernel layout: */
        pr_info("ptr=%p\n", p);
                -> ptr=00000000e2f4a1b7      /* hashed */

        /* Real values, for debugging only: */
        pr_info("ptr=%px\n", p);          /* raw - NEVER ship */
        pr_info("ptr=%pK\n", p);          /* hashed unless
                                             privileged */
        no_hash_pointers                  /* cmdline: make all
                                             %p raw. Prints a
                                             warning banner. */

/* If two %p values print identically, they are the same
   pointer - hashing is stable within a boot. That is often
   enough to debug without unhashing at all.               */
```

A note on highmem

```
/* On 32-bit systems, the linear map could only cover ~896 MB,
   so memory above that ("highmem") needed temporary mappings:

        void *v = kmap(page);           /* map it        */
        ... use v ...
        kunmap(page);

   You will see kmap/kmap_atomic/kmap_local_page all over
   older mm code and in generic drivers.

   ON ARM64 THIS DOES NOT APPLY. The 48-bit address space maps
   all physical memory linearly; there is no highmem.
   kmap_local_page() is still the portable idiom and is
   essentially free on arm64 - so generic code uses it and
   arm64-only code need not.

   MENTION IT ONLY because you will read the calls and wonder
   why they exist.                                          */
```

How it shows up

Symptom	Cause
DMA writes land in unrelated memory	`virt_to_phys()` on a vmalloc or stack address
`Unable to handle kernel paging request at 0x0000...`	NULL or small-offset pointer dereference
Fault at an address in the non-canonical hole	Corrupted pointer, or uninitialised memory used as one

Symptom	Cause
Reading a register returns garbage	Direct dereference of an `__iomem` pointer instead of `readl()`
`ioremap` returns NULL	vmalloc space exhausted, or the region overlaps an existing mapping
Two drivers fight over a peripheral	Used bare `ioremap` instead of the resource-requesting form
Framebuffer writes are very slow	Mapped Device instead of write-combining — use `ioremap_wc()`
Addresses differ every boot	KASLR — use `nokaslr` while debugging
`%p` prints meaningless values	Pointer hashing; use `%px` in a debug build only
vmalloc space exhausted over time	Leaked `ioremap` / `vmalloc` — check `/proc/vmallocinfo`
Writable and executable kernel mapping	A real hardening bug — check the ptdump output

Check yourself

- ✓ Explain the TTBR0/TTBR1 split and what the non-canonical hole gives you.
- ✓ Name the major regions of the kernel half.
- ✓ Explain the linear map and why `virt_to_phys()` can be arithmetic.
- ✓ List four kinds of address for which `virt_to_phys()` is silently wrong.
- ✓ Explain what `ioremap` does and why direct dereference is wrong.
- ✓ Choose between `ioremap`, `ioremap_wc` and `ioremap_cache`.
- ✓ Walk a four-level page table in kernel types.
- ✓ Read `/sys/kernel/debug/kernel_page_tables` and spot a bad permission.
- ✓ Use `/proc/vmallocinfo` to attribute a mapping to a driver.
- ✓ Explain `%p` hashing and how to debug around it safely.

Copying to and from user space

The kernel/user boundary is the one place where a hostile caller meets privileged code every single second. Every pointer that crosses it is an attack, and the rules for handling one are short, strict, and universally applicable.

Why you cannot just dereference

```
A user pointer is a number in a DIFFERENT address space, chosen
by an untrusted program. Dereferencing it directly is wrong for
four separate reasons:

  1. IT MAY BE INVALID. Unmapped, freed, or never valid. In
     user space that is a segfault for one process; in the
     kernel it is an oops, and possibly a panic with a lock
     still held.

  2. IT MAY POINT AT KERNEL MEMORY. A caller passing
     0xffff800008000000 to your ioctl is asking your privileged
     code to read or write kernel memory on their behalf. This
     is the confused deputy again - the same shape as the TEE
     problem in isolation chapter 12, at a different boundary.

  3. IT MAY NOT BE RESIDENT. The page may be swapped out or
     not yet faulted in, so touching it requires SLEEPING to
     fault it in - illegal in atomic context.

  4. THE MAPPING MAY CHANGE. Another thread in the same process
     can munmap or remap it while you work. Anything you check
     and then re-read can differ.

  So arm64 also enforces it in hardware: PAN (Privileged Access
  Never, ARMv8.1) faults on ANY EL1 access to a user address
  unless it is explicitly permitted. The accessor functions
  toggle it; your stray dereference does not.

  Which means the "just dereference it" bug does not silently
  work on modern hardware - it faults immediately. That is a
  kindness.
```

The accessors

```
#include <linux/uaccess.h>

/* BULK - the workhorses. Return the number of bytes NOT
   copied. Zero means success.                              */

unsigned long copy_to_user(void __user *to, const void *from,
                           unsigned long n);
unsigned long copy_from_user(void *to, const void __user *from,
                             unsigned long n);

        if (copy_to_user(ubuf, kbuf, len))
                return -EFAULT;         /* the ONLY idiom */

/* NOT `if (copy_to_user(...) != 0)` and definitely not
   `if (copy_to_user(...) < 0)` - the return is UNSIGNED, so a
   `< 0` test is always false and your error handling never
   runs.                                                    */

/* SCALARS - faster, type-checked: */
        get_user(x, uptr);              /* one value in  */
        put_user(x, uptr);              /* one value out */
        /* these return 0 or -EFAULT, so: */
        if (get_user(val, (int __user *)arg))
                return -EFAULT;

/* STRINGS: */
        strncpy_from_user(dst, src, count);   /* returns the
                                                 length, or
                                                 -EFAULT      */
        strnlen_user(src, max);
        /* or, better, let the kernel allocate: */
        char *s = strndup_user(uptr, PATH_MAX);
        if (IS_ERR(s))
                return PTR_ERR(s);
        ...
        kfree(s);

/* CLEARING: */
        clear_user(uptr, n);

/* CHECKING WITHOUT COPYING - rarely what you want: */
        if (!access_ok(uptr, size))
                return -EFAULT;
/* access_ok only checks the address RANGE is plausibly user
   space. It does NOT check the memory is mapped. Between the
   check and the copy anything can change. The copy functions
   do this check themselves, so calling access_ok separately is
   almost always redundant - and relying on it INSTEAD of a
   real copy is a bug.                                      */
```

THE FOUR RULES

1. **Never dereference a `__user` pointer.** Only the accessors touch it.
2. **Always check the return.** A partial copy is a failure; return `-EFAULT`.
3. **Only in process context.** These functions can sleep — never in an interrupt, a softirq, or while holding a spinlock.
4. **Copy once, then use only the copy.** Re-reading user memory after validating it is the TOCTOU bug, and it is exploitable.

The double-fetch bug

```
/* WRONG - reads the same user memory twice: */
static long my_ioctl(struct file *f, unsigned cmd, unsigned long arg)
{
        struct my_req __user *ureq = (void __user *)arg;
        u32 len;

        if (get_user(len, &ureq->len))          /* fetch 1 */
                return -EFAULT;
        if (len > MAX_LEN)
                return -EINVAL;                 /* validated */

        buf = kmalloc(len, GFP_KERNEL);

        /* fetch 2 - another thread changed ureq->len in
           between, and copy_from_user now copies MORE than
           we allocated                                    */
        if (copy_from_user(buf, ureq->data, ureq->len))
                return -EFAULT;
        ...
}

/* RIGHT - one copy, then work entirely from kernel memory: */
static long my_ioctl(struct file *f, unsigned cmd, unsigned long arg)
{
        struct my_req req;
        void *buf;

        if (copy_from_user(&req, (void __user *)arg, sizeof(req)))
                return -EFAULT;         /* ONE fetch */

        if (req.len > MAX_LEN)
                return -EINVAL;         /* validate the COPY */

        buf = kmalloc(req.len, GFP_KERNEL);
        if (!buf)
                return -ENOMEM;

        if (copy_from_user(buf, u64_to_user_ptr(req.data),
                           req.len)) {  /* req.len is OURS now */
                kfree(buf);
                return -EFAULT;
        }
        ...
}

/* This is exactly the "copy in, then validate the copy" rule
   from the TEE chapters. Same boundary problem, same fix,
   different privilege levels.                             */
```

Leaking kernel memory outward

```
/* The other direction is just as dangerous. Copying a struct
   out copies its PADDING too - and padding contains whatever
   was previously on the kernel stack.                      */

struct my_info {
        u8  type;       /* offset 0 */
                        /* 3 BYTES OF PADDING */
        u32 value;      /* offset 4 */
        u16 flags;      /* offset 8 */
                        /* 6 BYTES OF PADDING */
        u64 timestamp;  /* offset 16 */
};                      /* sizeof = 24, 9 bytes uninitialised */

/* WRONG - leaks 9 bytes of stack: */
        struct my_info info;
        info.type = 1;
        info.value = x;
        info.flags = f;
        info.timestamp = t;
        if (copy_to_user(uptr, &info, sizeof(info)))
                return -EFAULT;

/* RIGHT - zero it first: */
        struct my_info info = { };        /* zeroes EVERYTHING,
                                             padding included */
        /* or: memset(&info, 0, sizeof(info)); */

/* THIS IS A REAL CVE CLASS. Kernel stack contents include
   return addresses (defeating KASLR), pointers, and fragments
   of other syscalls' data. Dozens of CVEs, year after year.

   MITIGATIONS to know:
     · `= { }` or memset on EVERY struct you copy out
     · design UAPI structs with NO PADDING: order fields
       largest-first, pad EXPLICITLY with reserved fields, and
       make the size a multiple of 8
     · CONFIG_INIT_STACK_ALL_ZERO=y - zero-initialises all
       stack variables. Cheap on modern compilers. Turn it on.
     · CONFIG_GCC_PLUGIN_STRUCTLEAK

   And the explicit-padding version of the struct above: */

struct my_info {
        __u64 timestamp;        /* 8-byte fields first */
        __u32 value;
        __u16 flags;
        __u8  type;
        __u8  reserved;         /* explicit, and DOCUMENTED as
                                   must-be-zero so it can be
                                   used later               */
};                              /* sizeof = 16, no holes */
```

32-bit callers on a 64-bit kernel

```
/* An arm64 kernel can run arm32 user space. Their struct
   layouts differ, so a struct that works natively silently
   mis-parses from a compat caller.                          */

/* THE PROBLEM: */
struct bad {
        int      n;
        void    *ptr;      /* 4 bytes on arm32, 8 on arm64 */
        long     val;      /* likewise */
};      /* different size AND different offsets */

/* THE FIX - use fixed-width types in ALL uapi structs, and
   __u64 for pointers: */
struct good {
        __u64 ptr;         /* always 8 bytes; convert with
                              u64_to_user_ptr()             */
        __u64 val;
        __u32 n;
        __u32 reserved;
};      /* identical on 32- and 64-bit */

        void __user *p = u64_to_user_ptr(req.ptr);

/* If you cannot change the layout, provide a compat handler: */
static const struct file_operations my_fops = {
        .unlocked_ioctl = my_ioctl,
        .compat_ioctl   = my_compat_ioctl,   /* or
                                compat_ptr_ioctl if the only
                                difference is pointer width */
};

/* compat_ptr_ioctl is the common case and handles it in one
   line - use it whenever your structs are already
   compat-clean.                                             */
```

> **DESIGN THE UAPI STRUCT AS IF IT WERE PERMANENT, BECAUSE IT IS**
>
> Fixed-width types, explicit reserved fields, no holes, no pointers-as-pointers, a size field or a version field. You get one chance: once a userspace program depends on the layout, "we do not break user space" means you are keeping it forever. Chapter 21 covers the interface design; this is the memory-layout half of the same decision.

Sharing instead of copying

```
/* For large or high-rate data, copying is the bottleneck.
   mmap() maps the buffer into user space so there is no copy
   at all.                                                    */

static int my_mmap(struct file *f, struct vm_area_struct *vma)
{
        struct my_dev *d = f->private_data;
        unsigned long size = vma->vm_end - vma->vm_start;

        /* 1. BOUNDS CHECK. The user chose the length. */
        if (size > d->buf_size)
                return -EINVAL;
        if (vma->vm_pgoff)              /* no offset support */
                return -EINVAL;

        /* 2. read-only if they should not write */
        if (vma->vm_flags & VM_WRITE)
                return -EPERM;

        /* 3. map it */
        return dma_mmap_coherent(d->dev, vma, d->cpu_addr,
                                 d->dma_addr, size);
        /* or for ordinary kernel memory:
             remap_pfn_range(vma, vma->vm_start,
                             virt_to_phys(d->buf) >> PAGE_SHIFT,
                             size, vma->vm_page_prot);        */
}

/* THE TRADE-OFF: no copy, but now user space can change the
   buffer AT ANY TIME, including while your driver or a DMA
   engine is reading it. Everything in the shared buffer is
   untrusted, permanently - the same discipline as TEE shared
   memory.

   So: use mmap for BULK DATA, and keep CONTROL - indices,
   lengths, commands - in ioctls where you can copy and
   validate. That split is what chapter 28's project is
   built around.                                              */
```

The boundary checklist

FOR EVERY IOCTL, READ, WRITE AND MMAP HANDLER

- Every user pointer is marked `__user`, and `sparse` is clean.
- Every copy's return value is checked, with `-EFAULT` on failure.
- Each field is fetched **once**; validation runs against the kernel copy.
- Sizes are validated *before* allocation, and the arithmetic cannot overflow.
- Structs copied out are zero-initialised.
- The UAPI layout is compat-clean: fixed-width types, no holes, no native pointers.
- Copies happen only in process context, never under a spinlock.
- Permissions are checked — `capable()`, file mode, or a device-node permission model.
- Error paths free everything they allocated.
- Shared (mmap'd) memory is treated as hostile on every read.

How it shows up

Symptom	Cause
Oops on a user address from kernel code	Direct dereference of a `__user` pointer — PAN caught it
Error handling never triggers	`if (copy_to_user(...) < 0)` — the return is unsigned
`BUG: sleeping function called from invalid context` in a copy	Copying under a spinlock or in an interrupt
Heap overflow reachable from an ioctl	Double fetch — the size changed between validation and use
Userspace sees stale kernel data in unused fields	Struct padding not zeroed — an information leak
Works for 64-bit programs, garbage for 32-bit	Missing `compat_ioctl`, or native types in the UAPI struct
`-EFAULT` from a valid-looking pointer	Address not mapped in that process, or the wrong process's address space
mmap succeeds, then the kernel crashes	Size not bounds-checked against the real buffer
Data corruption only under concurrent access	Trusting mmap'd memory that userspace is changing
Sparse warns "incorrect type in argument"	A `__user`/kernel pointer mix-up — a real bug, not noise

Check yourself

- ✓ Give four reasons a user pointer cannot be dereferenced, and say what PAN does.
- ✓ Write the correct idiom for `copy_to_user` and explain why `< 0` is wrong.
- ✓ Explain the double-fetch bug and rewrite a handler to avoid it.
- ✓ Explain how struct padding leaks kernel memory and give three mitigations.
- ✓ Design a UAPI struct that is compat-clean and hole-free.
- ✓ Say when `compat_ptr_ioctl` is sufficient.
- ✓ Write a bounds-checked `mmap` handler.
- ✓ Explain why mmap'd memory must be treated as hostile, and how to split control from data.

✓ Run the boundary checklist against a driver you have written.

Processes, threads and `task_struct`

Linux has no separate notion of a process and a thread. There is one structure, `task_struct`, and everything else is a question of what two tasks choose to share — which turns out to be a much cleaner model than the one most textbooks describe.

One structure for both

```
A "process" with three threads is really THREE task_structs
that share most of their pointers:

   task_struct (tid 100)      task_struct (tid 101)
   +------------------+       +------------------+
   | pid   = 100      |       | pid   = 100      |  <- SAME
   | tid   = 100      |       | tid   = 101      |  <- differs
   | mm    = ---------+---+---+ mm    =          |
   | files = ---------+-+ |   | files =          |
   | fs    = ...      | | |   | fs    =          |
   | signal= ...      | | |   | signal=          |
   | stack = 0xffff.. | | |   | stack = 0xffff.. |  <- OWN
   +------------------+ | |   +------------------+
                        | |
                        | +--> struct mm_struct   the address
                        |      (page tables, VMAs) space
                        |
                        +----> struct files_struct  the fd table

  WHAT IS ALWAYS PRIVATE:
     the kernel stack, the register state, the tid,
     the scheduler state, pending signals

  WHAT MAY BE SHARED, decided at clone() time:
     CLONE_VM       the address space   -> "threads"
     CLONE_FILES    the fd table
     CLONE_FS       cwd, root, umask
     CLONE_SIGHAND  signal handlers
     CLONE_THREAD   the thread group (same pid)
     CLONE_NEWNS/NEWPID/NEWNET/...  namespaces -> containers

  fork()   = clone(SIGCHLD)                    shares nothing
  pthread  = clone(CLONE_VM|CLONE_FILES|CLONE_FS|
                   CLONE_SIGHAND|CLONE_THREAD|...)
  container= clone(... | CLONE_NEWPID | CLONE_NEWNET | ...)

  So processes, threads and containers are three points on one
  continuum, not three mechanisms.
```

pid, tid, and the naming trap

```
/* The kernel's names are the OPPOSITE of what userspace calls
   them, and this confuses everyone once.                    */

   task->pid       the THREAD id.  Unique per task.
                   Userspace calls this the TID.
   task->tgid      the THREAD GROUP id. Shared by all threads
                   in a process. Userspace calls this the PID.

/* So: */
        getpid()  in userspace  returns  task->tgid
        gettid()  in userspace  returns  task->pid

/* In kernel code: */
        current->pid            /* this THREAD */
        current->tgid           /* the process */
        task_pid_nr(current)    /* pid in the INIT namespace */
        task_tgid_nr(current)
        task_pid_vnr(current)   /* pid as the task's own
                                   namespace sees it - what a
                                   containerised process
                                   believes its pid to be    */

/* WHICH TO USE when identifying a caller in a driver:
     for logging          -> current->pid and current->comm
     for ownership        -> the struct file, NOT the pid.
                             A pid can be reused after exit.
     across a namespace   -> think hard; a pid means nothing
                             outside the namespace that
                             created it                      */
```

current

```
#include <linux/sched.h>

        current             /* the task_struct running NOW */
        current->pid
        current->comm       /* the command name, 16 bytes */
        current->mm         /* NULL for a kernel thread! */
        current->flags

/* On arm64 `current` is SP_EL0, repurposed: the kernel keeps
   the current task_struct pointer there while running at EL1,
   so reading it is a single register read, not a lookup.
   (arch/arm64/include/asm/current.h)                        */

/* USEFUL IN A DRIVER: */
        dev_dbg(dev, "ioctl from %s[%d]\n",
                current->comm, current->pid);

/* AND THE TRAPS:

   1. `current` is only meaningful in PROCESS CONTEXT. In an
      interrupt handler it points at whatever task was
      unluckily interrupted - which has nothing to do with the
      device. Never attribute interrupt work to `current`.

   2. current->mm is NULL for KERNEL THREADS. Code that
      assumes an address space exists will crash when called
      from a kthread or a workqueue.

           if (!current->mm)
                   return -EINVAL;      /* kernel thread */

   3. Do not store `current` and use it later. The task can
      exit. If you need a reference, take one:
           get_task_struct(task);
           ...
           put_task_struct(task);                            */
```

Task states

State	`ps`	Meaning
`TASK_RUNNING`	R	Running, or on a runqueue ready to run
`TASK_INTERRUPTIBLE`	S	Sleeping; **signals wake it**
`TASK_UNINTERRUPTIBLE`	D	Sleeping; signals do **not** wake it
`TASK_KILLABLE`	D	Uninterruptible except by a fatal signal — usually the right choice
`__TASK_STOPPED`	T	Stopped by SIGSTOP
`EXIT_ZOMBIE`	Z	Exited, not yet reaped by its parent
`TASK_IDLE`	I	Uninterruptible but not counted in load average — for kthreads

THE D STATE IS A DRIVER'S FAULT MORE OFTEN THAN NOT

A process stuck in `D` cannot be killed, not even with `SIGKILL`, and it drives the load average up. It is almost always waiting on I/O in a driver that used `wait_event()` — the uninterruptible form — instead of `wait_event_interruptible()`. Use the interruptible or killable variants unless you can state exactly why a signal must not interrupt this wait; and if the hardware genuinely cannot be abandoned mid-operation, use a timeout so the wait is at least bounded.

Sleeping and waking, correctly

```
/* THE PATTERN every blocking driver uses. */

struct my_dev {
        wait_queue_head_t  wq;
        bool               data_ready;
        spinlock_t         lock;
};

        init_waitqueue_head(&d->wq);

/* --- the reader: wait for data --------------------------- */
static ssize_t my_read(struct file *f, char __user *buf,
                       size_t count, loff_t *ppos)
{
        struct my_dev *d = f->private_data;
        int ret;

        /* non-blocking mode must be honoured */
        if (f->f_flags & O_NONBLOCK) {
                if (!d->data_ready)
                        return -EAGAIN;
        } else {
                ret = wait_event_interruptible(d->wq,
                                               d->data_ready);
                if (ret)
                        return -ERESTARTSYS;   /* a signal:
                                                  let libc
                                                  restart it */
        }
        ...
}

/* --- the interrupt handler: wake it ---------------------- */
static irqreturn_t my_isr(int irq, void *dev_id)
{
        struct my_dev *d = dev_id;

        d->data_ready = true;
        wake_up_interruptible(&d->wq);
        return IRQ_HANDLED;
}

/* WHY wait_event_* IS A MACRO AND NOT A FUNCTION:
   it expands to the correct sleep sequence, which is subtle:

        for (;;) {
                prepare_to_wait(&wq, &entry, TASK_INTERRUPTIBLE);
                if (condition)         <-- re-check AFTER
                        break;             being queued
                if (signal_pending(current)) { ret = -ERESTARTSYS;
                                               break; }
                schedule();
        }
        finish_wait(&wq, &entry);

   The ORDER is what matters: queue yourself FIRST, then check
   the condition. Check first and a wakeup arriving in between
   is lost, and you sleep forever. This is the lost-wakeup
   race, and it is why you use the macro rather than writing
   it out.                                                  */
```

```
/* THE VARIANTS: */
        wait_event(wq, cond);                   /* D state  */
        wait_event_interruptible(wq, cond);     /* S state  */
        wait_event_killable(wq, cond);          /* SIGKILL  */
        wait_event_timeout(wq, cond, HZ);       /* bounded  */
        wait_event_interruptible_timeout(wq, cond, HZ);

/* AND THE RETURN VALUES DIFFER - a classic bug: */
        ret = wait_event_interruptible_timeout(wq, cond, HZ);
        if (ret == 0)   return -ETIMEDOUT;   /* timed out    */
        if (ret < 0)    return ret;          /* interrupted  */
        /* ret > 0: condition true, jiffies remaining        */
```

Kernel threads

```
#include <linux/kthread.h>

static int my_thread_fn(void *data)
{
        struct my_dev *d = data;

        while (!kthread_should_stop()) {
                wait_event_interruptible(d->wq,
                        d->work_pending || kthread_should_stop());
                if (kthread_should_stop())
                        break;
                do_the_work(d);
        }
        return 0;
}

        d->task = kthread_run(my_thread_fn, d, "my_worker/%d", id);
        if (IS_ERR(d->task))
                return PTR_ERR(d->task);
        ...
        kthread_stop(d->task);   /* sets the flag, wakes it,
                                    WAITS for it to return   */

/* PROPERTIES:
     · runs in process context - CAN SLEEP
     · current->mm is NULL - no user address space
     · appears in ps in [square brackets]
     · schedulable, so it can be niced and affined
     · kthread_should_stop() must be checked, AND the thread
       must be woken for it to notice - hence the condition
       above includes it

   WHEN TO USE ONE:
     you need a long-running, sleeping loop of your own.

   WHEN NOT TO - which is most of the time:
     for short deferred work, use a WORKQUEUE (chapter 13).
     A workqueue shares worker threads across the whole
     kernel; a dedicated kthread per device costs memory and
     scheduler entries. Reach for a kthread only when you
     genuinely need a private, long-lived, sleeping context -
     a polling loop, or a thread servicing a hardware queue.  */
```

Signals in the kernel

```
/* A driver rarely handles signals, but it must react to them
   correctly when interrupted.                                */

        if (signal_pending(current))
                return -ERESTARTSYS;

/* THE ERROR CODES, and the difference matters to userspace:

     -EINTR         "your syscall was interrupted". Userspace
                    sees EINTR and must retry itself.

     -ERESTARTSYS   "restart the syscall automatically, IF the
                    handler was installed with SA_RESTART".
                    Never reaches userspace as-is; the signal
                    machinery converts it to EINTR or restarts
                    the call. THIS IS USUALLY WHAT YOU WANT
                    from a wait that made no progress.

     -ERESTARTNOINTR  always restart, regardless of SA_RESTART

   THE RULE: if the operation made NO observable progress,
   return -ERESTARTSYS. If it partially completed - you copied
   some bytes - return the count you completed instead, and
   let the caller resume from there. Returning -ERESTARTSYS
   after partial progress causes the work to be done twice. */

        if (copied > 0)
                return copied;          /* partial success */
        if (signal_pending(current))
                return -ERESTARTSYS;    /* nothing done */
```

Looking at tasks

```
# From userspace:
    ps -eLf                 # -L shows THREADS, not just
                            # processes: LWP is the tid
    cat /proc/$PID/status   # Tgid, Pid, Threads, State, ...
    cat /proc/$PID/task/*/  # one directory per thread
    cat /proc/$PID/stack    # kernel backtrace - where is it
                            # blocked? THE tool for a D state
    cat /proc/$PID/wchan    # the function it is sleeping in
    cat /proc/$PID/maps     # the address space

# Finding what a D-state process is stuck on:
    ps -eo pid,stat,comm | awk '$2 ~ /D/'
    sudo cat /proc/1234/stack
      [<0>] my_driver_read+0x120/0x2a0     <-- there it is
      [<0>] vfs_read+0xb4/0x1e0
      ...

# Or the whole system's blocked tasks, from the kernel:
    echo w > /proc/sysrq-trigger
    dmesg                   # "Showing all locks held" and
                            # blocked task backtraces

# The hung task detector will do it for you automatically:
    CONFIG_DETECT_HUNG_TASK=y
    # prints a backtrace for any task in D state for 120s
```

How it shows up

Symptom	Cause
Process stuck in D, unkillable	Uninterruptible wait in a driver — check `/proc/PID/stack`
Load average high with idle CPUs	D-state tasks count toward it
Process sleeps forever despite the event happening	Lost wakeup — condition checked before queuing; use `wait_event_*`
Wakes up but the condition is false	Spurious wakeup — always re-check in a loop, which the macros do
`Ctrl-C` does not interrupt a read	Used `wait_event()` instead of the interruptible form
Data delivered twice after a signal	Returned `-ERESTARTSYS` after partial progress
Crash in an interrupt handler using `current->mm`	`current` is meaningless there
NULL deref on `current->mm`	Called from a kernel thread
`rmmod` hangs	`kthread_stop()` waiting on a thread that never checks `kthread_should_stop()`
PID-based ownership breaks	PIDs are reused; key off the `struct file`

Check yourself

- ✓ Explain how one structure represents processes, threads and containers.
- ✓ Say which of `pid` and `tgid` userspace calls "the PID".
- ✓ List three traps in using `current`.

- ✓ Name the task states and explain why D state is usually a driver bug.
- ✓ Write a correct blocking read with a wakeup from an interrupt.
- ✓ Explain the lost-wakeup race and why `wait_event` is a macro.
- ✓ Give the return-value convention for the timeout variants.
- ✓ Write a kernel thread with correct shutdown, and say when not to use one.
- ✓ Distinguish `-EINTR` from `-ERESTARTSYS`, and the partial-progress rule.
- ✓ Find where a D-state process is blocked, from userspace.

Scheduling in Linux

Five scheduling classes, one runqueue per CPU, and a set of latency properties that decide whether your embedded system meets its deadlines. This chapter is about what a driver author needs: which class to ask for, what preemption model you are running under, and where latency actually comes from.

The classes, in priority order

```
A task is picked from the HIGHEST non-empty class. Lower
classes only run when every higher one is idle.

  1. STOP          the stop-machine task. Not for you.
  2. DEADLINE      SCHED_DEADLINE - EDF with admission control
  3. REAL-TIME     SCHED_FIFO, SCHED_RR - fixed priority 1..99
  4. FAIR          SCHED_OTHER, SCHED_BATCH - CFS/EEVDF.
                   Where 99.9% of everything lives.
  5. IDLE          SCHED_IDLE - only when nothing else wants
                   the CPU

  CONSEQUENCE, and it is the one that bites: a runaway
  SCHED_FIFO task at priority 50 that never blocks will starve
  EVERY normal task on that CPU, forever. Including your shell.
  Including kernel threads that other things wait on.

  Linux ships a safety valve for exactly this:
     /proc/sys/kernel/sched_rt_runtime_us  = 950000
     /proc/sys/kernel/sched_rt_period_us   = 1000000
  RT tasks get at most 950 ms of every second, leaving 50 ms
  for everything else. Turn it off (-1) only on a system you
  have fully analysed.
```

The fair class

```
/* CFS (and EEVDF, which replaced it in 6.6) does not use
   priorities directly. It tracks how much VIRTUAL RUNTIME each
   task has consumed and runs the one that is furthest behind.

   NICE VALUES (-20 .. +19) scale the rate at which vruntime
   accumulates. Each step of 1 is about 1.25x, so:

        nice -20  ~ 88x the CPU share of nice +19
        nice   0  the default
        nice +19  minimal share

   NICE IS A RATIO, NOT A GUARANTEE. Two nice-0 tasks get 50%
   each; a nice-0 and a nice-5 get roughly 75/25. With one
   runnable task, nice is irrelevant - it gets everything.  */

/* THE KNOBS you will actually touch: */

  /sys/kernel/debug/sched/base_slice_ns
        the target time a task runs before being preempted.
        Smaller = lower latency, more context switches.

  /proc/sys/kernel/sched_child_runs_first
  /proc/sys/kernel/sched_autogroup_enabled
        desktop-oriented; usually off in embedded

/* AND THE ONE THAT MATTERS ON MOBILE SoCs: */

  SCHED_UTIL / schedutil governor + EAS (Energy Aware
  Scheduling). On a big.LITTLE system the scheduler uses a
  per-CPU energy model to decide WHERE to place a task, not
  just when. A task placed on a little core that then needs
  performance costs a migration plus a frequency ramp - which
  is why "the benchmark is slow for the first 200 ms" is a
  scheduling story, not a code story. (ARM ch. 33)         */
```

Real-time classes

```
#include <sched.h>      /* userspace */

        struct sched_param p = { .sched_priority = 50 };
        sched_setscheduler(0, SCHED_FIFO, &p);

/* SCHED_FIFO   runs until it blocks, yields, or is preempted
                by a HIGHER priority RT task. No time slice.
   SCHED_RR     same, but round-robins with equal-priority
                peers after a quantum
                (/proc/sys/kernel/sched_rr_timeslice_ms)

   Priorities 1 (lowest) to 99 (highest).

   IN THE KERNEL, for a thread you created: */
        sched_set_fifo(task);           /* a sane default RT */
        sched_set_fifo_low(task);       /* priority 1 */
        sched_set_normal(task, nice);

/* WHEN AN RT THREAD IS RIGHT:
     · a control loop with a hard period
     · servicing a hardware FIFO that overruns
     · audio, motor control, safety interlocks

   THE RULES for writing one:
     · it MUST block regularly. An RT task that spins is a
       system hang.
     · preallocate everything. No allocation in the loop.
     · mlockall() in userspace, so no page faults.
     · never take a lock also held by a non-RT task without
       priority inheritance (rt_mutex) - that is priority
       inversion, and it is how Mars Pathfinder famously
       failed.
     · pin it: sched_setaffinity, and isolate the CPU with
       isolcpus= or cpusets, so nothing else competes.     */

/* SCHED_DEADLINE - the honest one, when you can characterise
   the work: */
        struct sched_attr a = {
                .sched_policy   = SCHED_DEADLINE,
                .sched_runtime  =  1 * 1000 * 1000,  /* 1 ms  */
                .sched_deadline =  5 * 1000 * 1000,  /* 5 ms  */
                .sched_period   = 10 * 1000 * 1000,  /* 10 ms */
        };
        sched_setattr(0, &a, 0);
/* The kernel ADMITS it only if the system can still meet every
   existing deadline - it does the utilisation arithmetic for
   you and returns -EBUSY if not. That admission control is
   what makes it a real guarantee rather than a hope.       */
```

Preemption models

Model	Kernel code is	Typical worst-case latency	Use for
`PREEMPT_NONE`	Never preempted	Tens of ms	Throughput servers
`PREEMPT_VOLUNTARY`	Preempted at explicit points	Several ms	Desktops
`PREEMPT`	Preemptible except in critical sections	Hundreds of µs	**Most embedded**

Model	Kernel code is	Typical worst-case latency	Use for
`PREEMPT_RT`	Nearly fully preemptible	Tens of µs	Hard real-time

```
/* PREEMPT_RT, merged into mainline over 6.12, changes the
   rules your driver must obey:

     · spinlocks become SLEEPING locks (rt_mutex based). Code
       under a spin_lock() can be preempted.
     · interrupt handlers run in THREADS by default, so they
       can be prioritised and preempted.
     · raw_spinlock_t is the only truly non-preemptible lock,
       reserved for the scheduler and low-level arch code.
     · local_irq_disable() sections must be tiny.

   WHAT THIS MEANS FOR YOUR DRIVER:
     · a long spin_lock section that was merely rude on a
       normal kernel becomes a LATENCY BUG on RT
     · you must not assume spin_lock disables preemption
     · GFP_ATOMIC under a spinlock is now questionable, since
       the lock can sleep
     · code that must be atomic uses raw_spinlock_t - and
       every use of that needs justification

   TEST YOUR DRIVER ON PREEMPT_RT even if you do not ship it.
   It surfaces latency and locking assumptions that are
   invisible otherwise.                                    */
```

Where latency actually comes from

```
An interrupt fires. How long until your RT thread runs?

   1. INTERRUPTS DISABLED somewhere        <-- usually the
      the GIC cannot even deliver              biggest source
   2. hardware IRQ latency, GIC to CPU
   3. the top half runs
   4. it wakes your thread
   5. PREEMPTION DISABLED somewhere        <-- second biggest
      the scheduler cannot switch
   6. the scheduler picks your thread
   7. context switch, cache and TLB cold
   8. your code runs

  THE TWO DOMINANT TERMS are (1) and (5) - some other piece of
  code holding interrupts or preemption off. And they are
  caused by things you would not guess:

     · a long spinlock section in an unrelated driver
     · a printk to a slow serial console (milliseconds! and it
       happens with interrupts disabled)
     · TLB shootdowns and cache maintenance over a large range
     · a slow MMIO read in an interrupt handler
     · SMMU invalidation waiting for a sync completion
     · firmware: an SMC that takes a long time (isolation
       ch. 11), or SMI-equivalent secure work
     · CPU frequency changes and idle-state exit latency

  MEASURE, DO NOT GUESS:

     cyclictest -p 80 -t1 -n -i 200 -l 100000 -m
        the standard tool. Reports min/avg/MAX wakeup latency.
        The MAX is the only number that matters.

     ftrace's latency tracers name the culprit:
        echo preemptirqsoff > /sys/kernel/tracing/current_tracer
        echo 0 > /sys/kernel/tracing/tracing_max_latency
        ... run the load ...
        cat /sys/kernel/tracing/trace
     -> a full backtrace of the LONGEST section that had
        interrupts or preemption disabled. This tells you
        exactly which function to fix.
```

> **THE ONE THING TO REMEMBER ABOUT LATENCY**
>
> Your worst-case latency is not determined by your code. It is determined by the *worst* critical section anywhere in the kernel that runs on the same CPU — including drivers you did not write and did not enable deliberately. That is why real-time embedded systems isolate CPUs, strip the config down to what is needed, and measure with `cyclictest` under realistic load rather than reasoning about it.

Placing work on CPUs

```
# ISOLATE a CPU from the general scheduler:
    isolcpus=3 nohz_full=3 rcu_nocbs=3        # kernel cmdline

# isolcpus    no task is placed there unless explicitly affined
# nohz_full   no scheduler tick on that CPU when one task runs
# rcu_nocbs   RCU callbacks are offloaded elsewhere
# Together: CPU 3 becomes nearly quiet, and an RT thread pinned
# there sees dramatically better worst-case latency.

# Then pin your thread:
    taskset -c 3 ./my_control_loop
    # or in code: sched_setaffinity()

# IRQ affinity - route the device's interrupt to the same CPU
# (or deliberately away from it):
    cat /proc/interrupts
    echo 8 > /proc/irq/42/smp_affinity        # CPU 3 = bit 3
    # and stop irqbalance from undoing it:
    systemctl stop irqbalance

# In the kernel, for a threaded IRQ or kthread:
    irq_set_affinity_hint(irq, cpumask_of(3));
    kthread_bind(task, 3);

# WHY PIN AT ALL: migration costs a cold cache and a cold TLB
# (CA ch. 14), and on big.LITTLE it may cost a move to a
# slower core. For a periodic control loop the variance
# matters more than the average.
```

Observing the scheduler

```
# Per-task statistics:
    cat /proc/PID/sched
      se.sum_exec_runtime          : total CPU time
      se.statistics.wait_max       : LONGEST time waiting to
                                     run  <-- latency, per task
      nr_switches, nr_voluntary_switches
      nr_involuntary_switches      : preempted this often

# System-wide:
    cat /proc/schedstat
    cat /sys/kernel/debug/sched/debug     # runqueue contents

# Tracing - the real tool:
    trace-cmd record -e sched_switch -e sched_wakeup \
                     -e irq_handler_entry -e irq_handler_exit
    trace-cmd report
    # or kernelshark for the graphical view

# perf, for where time goes:
    perf sched record -- sleep 10
    perf sched latency --sort max
      # per-task: average and MAXIMUM scheduling delay
    perf sched timehist

# The single most useful one-liner for "why is my thread late":
    perf sched latency --sort max | head -20
```

What this means for a driver

```
/* You will rarely set a scheduling policy from a driver. What
   you WILL do is avoid making everyone else's latency worse: */

   · KEEP INTERRUPT HANDLERS SHORT. Acknowledge, grab the data,
     wake something, return. Everything else goes to a threaded
     handler or a workqueue (chapter 13).

   · KEEP SPINLOCK SECTIONS SHORT. Microseconds. Never do MMIO
     reads, memory allocation, or loops of unknown length under
     one.

   · NEVER busy-wait for hardware without a bound:
        /* WRONG */
        while (readl(base + STATUS) & BUSY)
                ;
        /* RIGHT */
        ret = readl_poll_timeout(base + STATUS, val,
                                 !(val & BUSY),
                                 10,        /* poll every 10us */
                                 1000);     /* give up at 1ms  */
        if (ret)
                return -ETIMEDOUT;
     /* and the _atomic variant if you cannot sleep:
        readl_poll_timeout_atomic()                          */

   · PREFER threaded IRQs, so the work is schedulable:
        devm_request_threaded_irq(dev, irq,
                                  my_hardirq,   /* quick */
                                  my_thread_fn, /* the work */
                                  IRQF_ONESHOT, name, d);

   · DO NOT printk in hot paths. A serial console printk can
     take MILLISECONDS with interrupts disabled. Use trace
     events or dev_dbg (compiled out unless enabled).      */
```

How it shows up

Symptom	Cause
System freezes, only the RT task runs	A `SCHED_FIFO` task that never blocks — RT throttling saves you, if enabled
Latency spikes under load	Some other critical section — find it with the `preemptirqsoff` tracer
Occasional multi-millisecond stall	A `printk` to a serial console, or a long TLB/cache maintenance
Latency fine on the bench, bad in the field	Real load exercises paths your test did not — `cyclictest` under load
An RT thread misses deadlines despite high priority	Priority inversion on a lock; or blocked on a non-RT kthread
Throughput drops when you raise priority	Preemption thrashing — more context switches, colder caches
First iterations slow, then fine	Frequency ramp and cache warming; big.LITTLE placement
`sched_setscheduler` returns `-EPERM`	Needs `CAP_SYS_NICE` or an `RLIMIT_RTPRIO` allowance
`SCHED_DEADLINE` returns `-EBUSY`	Admission control refused — the system cannot meet it
Driver works on `PREEMPT`, breaks on `PREEMPT_RT`	Assumed `spin_lock` disables preemption

Symptom	Cause
Interrupts land on the wrong CPU again	`irqbalance` is running

Check yourself

- ✓ Name the five scheduling classes in priority order.
- ✓ Explain what RT throttling protects against.
- ✓ Explain what a nice value actually controls, and when it does nothing.
- ✓ Distinguish `SCHED_FIFO`, `SCHED_RR` and `SCHED_DEADLINE`.
- ✓ List five rules for writing an RT thread.
- ✓ Name the four preemption models and what `PREEMPT_RT` changes for drivers.
- ✓ List the components of interrupt-to-thread latency and the two that dominate.
- ✓ Use `cyclictest` and the `preemptirqsoff` tracer to find a latency source.
- ✓ Isolate a CPU and pin both a thread and an IRQ to it.
- ✓ List five things a driver should do to avoid harming system latency.

Kernel concurrency: choosing a lock

The kernel gives you a dozen synchronisation primitives. Choosing correctly is nearly mechanical once you can answer two questions — *can this context sleep?* and *who else touches this data?* — and getting it wrong produces the hardest bugs you will ever chase.

The decision, as a flowchart

```
What am I protecting?
    |
    +-- a single integer or flag, no other invariant
    |      -> ATOMIC operations. No lock at all.
    |
    +-- data read constantly, written rarely, and readers
    |   can tolerate seeing the old version briefly
    |      -> RCU (chapter 12)
    |
    +-- anything else: I need a lock.
           |
           v
    Is the data ever touched from an INTERRUPT handler?
           |
    +------+------+
    |             |
   YES           NO
    |             |
    |             +-- Can every accessor SLEEP?
    |             |      (process context, no atomic ctx)
    |             |         |
    |             |    +----+----+
    |             |   YES       NO
    |             |    |         |
    |             |  MUTEX    SPINLOCK
    |             |    |
    |             |    +-- and if readers vastly outnumber
    |             |        writers: rw_semaphore
    |             |
    v
 spin_lock_irqsave() in process context
 spin_lock()        inside the handler itself

A MUTEX MAY NEVER BE TAKEN IN INTERRUPT CONTEXT. Not
"should not" - the machine will deadlock or oops.
```

Mutexes

```
#include <linux/mutex.h>

        DEFINE_MUTEX(my_mutex);            /* static */
        mutex_init(&d->lock);              /* dynamic */

        mutex_lock(&d->lock);
        ... critical section ...
        mutex_unlock(&d->lock);

        /* interruptible - the caller can be Ctrl-C'd while
           waiting. Use this in syscall paths.              */
        if (mutex_lock_interruptible(&d->lock))
                return -ERESTARTSYS;

        /* try, do not wait */
        if (!mutex_trylock(&d->lock))
                return -EBUSY;

/* PROPERTIES:
     · the waiter SLEEPS - so the CPU does other work
     · only in process context
     · you MAY sleep while holding one (kmalloc(GFP_KERNEL),
       copy_to_user, another mutex) - which is the main reason
       to prefer it
     · strictly one owner; must be released by the same task
       that took it
     · optimistically spins briefly if the owner is running on
       another CPU, so short holds are not as expensive as
       "it sleeps" suggests

   USE A MUTEX BY DEFAULT in process-context driver code. It is
   the right answer far more often than a spinlock, and code
   under it is far easier to write correctly.              */

/* THE SCOPED FORM, newer and worth adopting - it releases
   automatically on every exit path, including returns and
   gotos:                                                   */
        scoped_guard(mutex, &d->lock) {
                ...
        }
        /* or for a whole function: */
        guard(mutex)(&d->lock);
```

Spinlocks

```
#include <linux/spinlock.h>

        DEFINE_SPINLOCK(my_lock);
        spin_lock_init(&d->lock);

/* THE THREE FORMS, and choosing between them is the whole
   difficulty:                                              */

/* 1. Data touched ONLY in process context (but in an atomic
      section, so a mutex is not allowed):                  */
        spin_lock(&d->lock);
        ...
        spin_unlock(&d->lock);

/* 2. Data ALSO touched by a SOFTIRQ/tasklet: */
        spin_lock_bh(&d->lock);
        ...
        spin_unlock_bh(&d->lock);

/* 3. Data ALSO touched by a HARDWARE INTERRUPT handler: */
        unsigned long flags;

        spin_lock_irqsave(&d->lock, flags);
        ...
        spin_unlock_irqrestore(&d->lock, flags);

/* WHY THE _irqsave VARIANT EXISTS - the classic self-deadlock:

     process context:  spin_lock(&d->lock);
                       ... interrupt arrives on THIS CPU ...
     handler:          spin_lock(&d->lock);   /* spins    */
                       /* waiting for a lock held by the
                          code it interrupted, which cannot
                          continue until the handler returns */
                       DEADLOCK, this CPU, forever.

   Disabling local interrupts while holding the lock makes it
   impossible. Note it only needs to disable them LOCALLY -
   another CPU's handler spinning is fine, because the holder
   is still making progress.

/* INSIDE the interrupt handler itself, plain spin_lock() is
   correct - interrupts are already off for that line.      */

/* THE RULES while holding a spinlock:
     · MAY NOT SLEEP. Not kmalloc(GFP_KERNEL), not
       copy_to_user, not mutex_lock, not msleep.
     · keep it SHORT - microseconds. Every other CPU wanting
       it is burning cycles, and on PREEMPT_RT your section is
       a latency bound (chapter 10).
     · no unbounded loops, no MMIO polling.

   `flags` MUST be a local variable. Sharing one between
   CPUs is a subtle, devastating bug.                       */
```

> **THE RULE THAT PREVENTS MOST SPINLOCK BUGS**
>
> Ask: *what is the highest-priority context that touches this data?* Then use the form that protects against it, in **every** place the data is touched. Protecting a structure with `spin_lock_irqsave` in one function and plain `spin_lock` in another gives you no protection at all — and it will work perfectly until the interrupt happens to land at the wrong microsecond, in the field, months later.

Atomics: no lock at all

```
#include <linux/atomic.h>

        atomic_t counter = ATOMIC_INIT(0);

        atomic_inc(&counter);
        atomic_dec(&counter);
        atomic_add(5, &counter);
        val = atomic_read(&counter);
        atomic_set(&counter, 0);

        /* the ones that RETURN, and are the useful ones: */
        if (atomic_dec_and_test(&refcount))
                free_it();                  /* hit zero */
        old = atomic_cmpxchg(&v, expected, new);
        old = atomic_xchg(&v, new);
        if (atomic_add_unless(&v, 1, 0))    /* unless it is 0 */
                ...

        atomic64_t for 64-bit.

/* BIT OPERATIONS, also atomic: */
        set_bit(FLAG_BUSY, &d->flags);
        clear_bit(FLAG_BUSY, &d->flags);
        if (test_and_set_bit(FLAG_BUSY, &d->flags))
                return -EBUSY;              /* was already set */
        if (test_bit(FLAG_BUSY, &d->flags))
                ...
        /* __set_bit etc. are the NON-atomic versions - faster,
           and only safe under an existing lock                */

/* REFERENCE COUNTS - use the dedicated type, not atomic_t: */
        refcount_t ref;
        refcount_set(&ref, 1);
        refcount_inc(&ref);
        if (refcount_dec_and_test(&ref))
                free_it();
/* refcount_t detects overflow and use-after-free (increment
   from zero) and WARNs, where atomic_t silently wraps. That
   difference has closed real CVEs.                         */

/* THE LIMIT OF ATOMICS: they protect ONE variable. If your
   invariant spans two - "count matches the number of list
   entries" - atomics give you nothing. You need a lock.   */
```

Reader/writer locks

```
/* rw_semaphore - sleeping, many readers or one writer: */
        DECLARE_RWSEM(my_rwsem);

        down_read(&my_rwsem);   ... up_read(&my_rwsem);
        down_write(&my_rwsem);  ... up_write(&my_rwsem);

/* rwlock_t - the spinning version: */
        read_lock(&lock);   ... read_unlock(&lock);
        write_lock(&lock);  ... write_unlock(&lock);

/* USE THESE SPARINGLY. They are slower than a plain lock in
   the uncontended case, the cacheline still bounces between
   readers, and writers can starve.

   The kernel's general advice: if you think you want a
   reader/writer lock, you probably want RCU (chapter 12) or
   just a plain mutex. rwlock_t in particular is discouraged in
   new code and is being removed from many subsystems.

   THE EXCEPTION where rw_semaphore genuinely fits: readers
   that hold the lock for a LONG time (walking a large
   structure, doing I/O), where the parallelism is real.   */

/* seqlock - writers never block, readers retry: */
        unsigned seq;
        do {
                seq = read_seqbegin(&d->sl);
                a = d->value_a;
                b = d->value_b;
        } while (read_seqretry(&d->sl, seq));

        write_seqlock(&d->sl);
        d->value_a = x;  d->value_b = y;
        write_sequnlock(&d->sl);

/* Perfect for a few values updated by a writer that must not
   be delayed - timekeeping uses it. READERS MUST BE PURE:
   they may run several times and see torn intermediate state,
   so they must not have side effects or dereference pointers
   read inside the section without care.                    */
```

Deadlock, and how the kernel finds it for you

```
/* THE FOUR CLASSIC WAYS:

   1. AB-BA. Thread 1 takes A then B; thread 2 takes B then A.
   2. Self-deadlock. Taking a non-recursive lock twice.
   3. Interrupt inversion. The spin_lock case above.
   4. Sleeping while holding a spinlock, then something else
      needs that lock to make progress.

   THE FIX FOR (1) IS ALWAYS THE SAME: define a global LOCK
   ORDER and document it at the top of the file.            */

/*
 * Locking order:
 *      dev->config_mutex
 *        -> dev->queue_lock
 *          -> chan->lock
 * Never acquire in the reverse direction.
 */

/* AND THEN LET LOCKDEP CHECK IT: */
        CONFIG_PROVE_LOCKING=y
        CONFIG_DEBUG_ATOMIC_SLEEP=y
        CONFIG_DEBUG_SPINLOCK=y
        CONFIG_DEBUG_MUTEXES=y

/* Lockdep builds a graph of every lock ordering it has ever
   observed, and reports a POTENTIAL deadlock the first time it
   sees an inconsistent order - even if the deadlock did not
   actually happen. It also catches:
        · sleeping in atomic context
        · taking an IRQ-unsafe lock from IRQ context
        · a lock taken and never released
        · recursive acquisition

   The report looks like:

     ======================================================
     WARNING: possible circular locking dependency detected
     ------------------------------------------------------
     kworker/0:1/23 is trying to acquire lock:
      (&d->queue_lock){+.+.} at: my_queue_work+0x40
     but task is already holding lock:
      (&chan->lock){+.+.} at: my_chan_start+0x28
     which lock already depends on the new lock.

   It names both locks, both call sites, and the order it
   expected. It is the single most valuable debugging feature
   in the kernel for concurrency, and it finds bugs your
   testing never will. ENABLE IT IN DEVELOPMENT, ALWAYS.  */
```

Not needing a lock

```
/* The best lock is the one you removed. In order of
   preference: */

/* 1. DON'T SHARE. Per-CPU data needs no lock against other
      CPUs - only against interrupts on the same one:      */
        DEFINE_PER_CPU(struct my_stats, my_stats);

        struct my_stats *s = get_cpu_ptr(&my_stats);
        s->count++;
        put_cpu_ptr(&my_stats);         /* re-enables
                                           preemption      */
        /* or, if only ever from one context: */
        this_cpu_inc(my_stats.count);

/* 2. IMMUTABLE DATA needs no lock. Set it up in probe, never
      change it, and readers are free.

/* 3. OWNERSHIP TRANSFER. A single-producer, single-consumer
      ring needs no lock, only barriers - and kfifo does it
      for you:                                             */
        DECLARE_KFIFO(fifo, struct event, 128);
        kfifo_put(&fifo, ev);           /* producer */
        kfifo_get(&fifo, &ev);          /* consumer */

/* 4. A SMALLER CRITICAL SECTION. Compute outside, mutate
      inside:                                              */
        val = expensive_computation(input);     /* no lock */
        spin_lock(&d->lock);
        d->result = val;                        /* tiny    */
        spin_unlock(&d->lock);

/* 5. RCU, for read-mostly data (chapter 12).             */
```

The reference table

Primitive	Sleeps	IRQ context	Use for
`mutex`	Yes	No	**The default** in process context
`spinlock_t`	No	Yes	Short sections; data shared with interrupts
`atomic_t`	No	Yes	A single counter or flag
`refcount_t`	No	Yes	Object lifetimes
`rw_semaphore`	Yes	No	Long reads, rare writes
`seqlock_t`	No (readers)	Careful	A few values, writer must not block
`completion`	Yes	Signal from IRQ	"Wait until this finishes"
`semaphore`	Yes	No	Counting resources. Rare — usually a mutex is meant
RCU	No (readers)	Yes	Read-mostly pointers and lists
per-CPU	—	—	Statistics, caches

```
/* COMPLETION - the "wait for the hardware" primitive, and the
   one drivers use constantly: */

        struct completion done;
        init_completion(&done);

        /* start the operation, then: */
        if (!wait_for_completion_timeout(&done,
                                         msecs_to_jiffies(100)))
                return -ETIMEDOUT;

        /* in the interrupt handler: */
        complete(&done);

/* Always use the _timeout or _interruptible_timeout form.
   wait_for_completion() with no bound is how a driver hangs a
   process in D state forever when the hardware misbehaves
   (chapter 09).                                              */
```

How it shows up

Symptom	Cause
One CPU hangs, others fine	Spinlock self-deadlock — a handler took a lock the interrupted code holds
Whole system freezes	AB-BA deadlock, or a spinlock held while sleeping
`BUG: sleeping function called from invalid context`	Slept while holding a spinlock
Lockdep "possible circular locking dependency"	Inconsistent lock order — a real bug even if it never triggered
Rare corruption under load	Missing lock, or inconsistent variants of the same lock
Counter drifts from reality	Non-atomic read-modify-write
Works on one CPU, fails on SMP	It was always racy; single-CPU just hid it
Use-after-free on an object	Refcount race — use `refcount_t`, which would have warned
Soft lockup, "CPU stuck for 22s"	Spinning too long, or a spinlock never released
Latency spikes on PREEMPT_RT	Long spinlock sections that were merely rude before
Process in D state forever	Unbounded `wait_for_completion()`

Check yourself

- ✓ Walk the decision flowchart for four different data structures.
- ✓ Explain why a mutex may never be taken in interrupt context.
- ✓ Explain the spinlock self-deadlock and why `irqsave` only disables local interrupts.
- ✓ Say why using different spinlock variants on the same data gives no protection.
- ✓ Explain when atomics are enough and when they are not.
- ✓ Say why `refcount_t` is preferred over `atomic_t` for lifetimes.
- ✓ Explain what a seqlock requires of its readers.
- ✓ Name the four classic deadlocks and the universal fix for AB-BA.
- ✓ Enable lockdep and read one of its reports.

✓ Give five ways to avoid needing a lock at all.

Atomics, RCU and lockless techniques

RCU lets readers run with *zero* synchronisation overhead — no atomics, no cache-line bouncing, no waiting. The price is a discipline about how updates are published and when memory can be freed, and it rests entirely on the memory model from ARM chapters 20 and 21.

The idea

```
A pointer to a data structure, read constantly, updated rarely.

  WITH A LOCK: every reader takes and releases the lock. On an
  8-core system that is one cache line ping-ponging between
  all eight caches, thousands of times a second, purely to
  read data that almost never changes.

  WITH RCU: readers do NOTHING. No atomic, no write, no wait.
  The update instead works like this:

     1. the writer makes a NEW copy with the change
     2. it publishes the new one with a single pointer store
     3. new readers see the new version; readers already
        running keep using the old one - which is fine,
        because it is still a consistent, valid version
     4. the writer WAITS until every reader that could still
        hold the old pointer has finished
     5. only then does it free the old copy

  Read - Copy - Update. Step 4 is the whole trick, and it is
  cheap because of a clever definition of "finished".

     time ->
     reader A: [--- reads old ---]
     reader B:      [------ reads old ------]
     writer:     publish new
                       |
                       +-- grace period --+
                                          |
                                       free old
                                    (A and B are done;
                                     anyone starting after
                                     "publish" sees new)
```

Grace periods, and why they are cheap

```
/* THE KEY OBSERVATION: an RCU read-side critical section may
   not sleep or be preempted (in classic RCU). So if a CPU has
   passed through a CONTEXT SWITCH, it cannot possibly still be
   inside one.

   A "quiescent state" = context switch, idle, or userspace.
   A "grace period"    = every CPU has passed through at least
                         one quiescent state since the update.

   So RCU does not track individual readers at all. It waits
   for a system-wide condition that is already being reported
   for other reasons. That is why readers cost NOTHING - there
   is nothing to record.

   Typical grace period: a few milliseconds to tens of ms.
   RCU is therefore for data where UPDATES ARE RARE and the
   latency of reclaiming memory does not matter.           */
```

The API

```
#include <linux/rcupdate.h>

/* --- READER ------------------------------------------------ */
        rcu_read_lock();                /* NOT a lock. It just
                                           marks the section
                                           and disables
                                           preemption.       */
        p = rcu_dereference(gp);        /* the ONLY correct
                                           way to read the
                                           pointer           */
        if (p)
                use(p->field);          /* safe until
                                           rcu_read_unlock  */
        rcu_read_unlock();

/* RULES for the read side:
     · MAY NOT SLEEP inside (unless using SRCU)
     · the pointer is only valid INSIDE the section. Do not
       stash it in a global and use it later.
     · rcu_dereference() carries the dependency barrier that
       makes the ARM memory model safe here - a plain read is
       NOT equivalent (see below).

/* --- WRITER ------------------------------------------------ */
        struct foo *new, *old;

        new = kmalloc(sizeof(*new), GFP_KERNEL);
        *new = *old_contents;
        new->field = updated_value;      /* fully initialise
                                            BEFORE publishing */

        spin_lock(&update_lock);         /* writers still need
                                            mutual exclusion
                                            with EACH OTHER   */
        old = rcu_dereference_protected(gp,
                        lockdep_is_held(&update_lock));
        rcu_assign_pointer(gp, new);     /* PUBLISH */
        spin_unlock(&update_lock);

        synchronize_rcu();               /* wait for the grace
                                            period - SLEEPS  */
        kfree(old);

/* OR, without blocking: */
        call_rcu(&old->rcu_head, my_free_cb);
        /* the callback runs after the grace period */

static void my_free_cb(struct rcu_head *h)
{
        struct foo *p = container_of(h, struct foo, rcu_head);
        kfree(p);
}
/* For a plain kfree there is a shortcut: */
        kfree_rcu(old, rcu_head);
```

WHY `RCU_ASSIGN_POINTER` AND `RCU_DEREFERENCE` ARE NOT OPTIONAL

They are the memory barriers that make this correct on a weakly-ordered machine like ARM (ARM chapters 20 and 21). `rcu_assign_pointer` is a release store: it guarantees the initialisation of the new object is visible *before* the pointer to it. `rcu_dereference` preserves the address dependency so the reader cannot observe the new pointer with stale contents. Write `gp = new;` and `p = gp;` instead and it will work on x86 and fail on ARM, rarely, under load — the worst possible failure mode.

RCU-protected lists

```
/* The common real use: a list of devices, sessions, or rules,
   read on every operation, changed on hotplug.             */

        struct my_entry {
                struct list_head list;
                struct rcu_head  rcu;
                int              id;
                ...
        };

        LIST_HEAD(my_list);
        DEFINE_SPINLOCK(my_list_lock);   /* writers only */

/* --- READER: traverse without any lock ------------------- */
static struct my_entry *find_entry(int id)
{
        struct my_entry *e;

        list_for_each_entry_rcu(e, &my_list, list) {
                if (e->id == id)
                        return e;
        }
        return NULL;
}
        /* called as: */
        rcu_read_lock();
        e = find_entry(id);
        if (e)
                do_something(e->value);
        rcu_read_unlock();

/* --- WRITER: add ----------------------------------------- */
        spin_lock(&my_list_lock);
        list_add_rcu(&new->list, &my_list);
        spin_unlock(&my_list_lock);
        /* no grace period needed to ADD - a reader either
           sees it or does not, and both are correct       */

/* --- WRITER: remove -------------------------------------- */
        spin_lock(&my_list_lock);
        list_del_rcu(&e->list);
        spin_unlock(&my_list_lock);

        synchronize_rcu();       /* now no reader holds e */
        kfree(e);
        /* or: kfree_rcu(e, rcu); */

/* NOTE list_del_rcu leaves the FORWARD pointer intact, so a
   reader already traversing the deleted node can still walk
   onward to the rest of the list. That is deliberate, and it
   is why you must use the _rcu variants rather than the
   ordinary list functions.                                 */
```

The flavours

Flavour	Readers may sleep	Use
`rcu_read_lock()`	No	The default. Preemption disabled in the section.

Flavour	Readers may sleep	Use
`rcu_read_lock_bh()`	No	Data also touched from softirqs (networking).
`rcu_read_lock_sched()`	No	Preempt-disable regions.
`srcu_read_lock()`	**Yes**	Sleepable RCU — readers may block. Per-domain, so one slow reader does not stall everyone.
RCU Tasks	—	For trampolines and tracing; waits for voluntary context switches.

```
/* SRCU, when a reader must sleep - e.g. it does I/O or copies
   to userspace: */

        struct srcu_struct my_srcu;
        init_srcu_struct(&my_srcu);

        int idx = srcu_read_lock(&my_srcu);
        p = srcu_dereference(gp, &my_srcu);
        ... may sleep here ...
        srcu_read_unlock(&my_srcu, idx);

        synchronize_srcu(&my_srcu);     /* the writer side */

/* SRCU grace periods can be MUCH longer, because a sleeping
   reader may sleep for a long time. Do not use it where you
   need memory back promptly.                              */
```

Barriers, briefly

```
/* ARM is weakly ordered (ARM ch. 20-21). Without barriers,
   both the compiler and the CPU may reorder your accesses. */

        smp_mb()        full barrier
        smp_rmb()       reads before / reads after
        smp_wmb()       writes before / writes after
        smp_store_release(&p, v)    /* release store */
        v = smp_load_acquire(&p)    /* acquire load  */
        barrier()       compiler only, no CPU instruction

/* THE CANONICAL PAIR - publish a structure safely: */
        /* producer */
        obj->data = 42;
        smp_store_release(&shared_ptr, obj);

        /* consumer */
        p = smp_load_acquire(&shared_ptr);
        if (p)
                use(p->data);          /* guaranteed to be 42 */

/* WITHOUT the release/acquire pair, the consumer can observe
   shared_ptr as non-NULL while p->data is still stale. On
   arm64 this is not theoretical - it happens.

/* AND FOR DEVICE MEMORY, a DIFFERENT set (chapter 23):
        wmb()/rmb()/mb()       full barriers including devices
        dma_wmb()/dma_rmb()    ordering against a DMA engine
        writel()/readl()       already carry the ordering you
                               need for MMIO in most cases

   Do not use smp_* barriers for DMA ordering: the smp_
   variants compile to nothing on a UP kernel, and a DMA
   engine is a second agent regardless of how many CPUs you
   have. That substitution is a real and subtle bug.       */
```

> **THE HONEST ADVICE ABOUT LOCKLESS CODE**
>
> Use RCU where the pattern fits — a read-mostly pointer or list — because it is a well-tested framework with lockdep support and clear rules. **Do not invent your own lockless algorithms.** Hand-rolled lock-free code on a weakly-ordered architecture is beyond what code review reliably catches, and the bugs appear as one-in-a-billion corruption under load. If a mutex is fast enough, use the mutex.

Debugging RCU

```
# Enable these while developing anything using RCU:
    CONFIG_PROVE_RCU=y              # lockdep for RCU
    CONFIG_DEBUG_OBJECTS_RCU_HEAD=y # double call_rcu, etc.
    CONFIG_RCU_EQS_DEBUG=y

# PROVE_RCU catches the big one - dereferencing outside a
# read-side section:

  WARNING: suspicious RCU usage
  drivers/mydrv/mydrv.c:142 suspicious rcu_dereference_check()
  usage!
  other info that might help us debug this:
  rcu_scheduler_active = 2, debug_locks = 1
  no locks held by mytask/431.

# "no locks held" = you called rcu_dereference() without
# rcu_read_lock(). A real bug, caught statically at runtime.

# If you legitimately hold a lock instead, say so:
    p = rcu_dereference_protected(gp, lockdep_is_held(&my_lock));

# RCU STALLS - a reader that never finishes:
  INFO: rcu_sched self-detected stall on CPU
# Means a CPU spent tens of seconds without a quiescent state.
# Causes: an infinite loop with preemption disabled, a very
# long rcu_read_lock section, or a spinlock deadlock.

# Watch grace periods and callbacks:
    cat /sys/kernel/debug/rcu/rcu_preempt/rcugp
    cat /proc/sched_debug | grep -i rcu
```

When RCU is the answer

Situation	RCU?
A list of registered devices, read on every I/O	**Yes** — the textbook case
A configuration structure, changed via sysfs	**Yes**
A routing or filter table	**Yes**
A counter	No — use `atomic_t` or per-CPU
A queue with frequent adds and removes	No — grace periods will dominate
Data written as often as it is read	No — use a mutex
Memory that must be freed promptly	No — grace periods delay reclamation
Readers that need a consistent view across two structures	No — RCU gives per-pointer consistency only

How it shows up

Symptom	Cause
Use-after-free in a reader	Freed without a grace period, or the pointer used after `rcu_read_unlock`
Reader sees a partially initialised object	Plain store instead of `rcu_assign_pointer`

Symptom	Cause
Works on x86, corrupts on arm64	Missing barriers — the memory model is weaker
`suspicious rcu_dereference_check() usage`	Dereference outside a read-side section
`BUG: sleeping function called from invalid context` inside RCU	Slept in an RCU read section — use SRCU
`rcu_sched self-detected stall`	A CPU not reaching a quiescent state — a loop or a deadlock
Memory usage climbs under a rapid update rate	Callbacks queued faster than grace periods complete
Update latency of tens of milliseconds	`synchronize_rcu()` in a hot path — use `call_rcu` / `kfree_rcu`
Rare corruption with hand-rolled lockless code	Exactly why not to write it

Check yourself

- ✓ Explain the read-copy-update cycle and why readers pay nothing.
- ✓ Define a quiescent state and a grace period, and say why they are cheap to detect.
- ✓ Write a correct RCU reader and writer.
- ✓ Explain what `rcu_assign_pointer` and `rcu_dereference` guarantee on ARM.
- ✓ Convert a spinlock-protected list to RCU.
- ✓ Say when SRCU is needed and what it costs.
- ✓ Pair a release store with an acquire load and say what it guarantees.
- ✓ Explain why `smp_wmb()` is wrong for DMA ordering.
- ✓ Enable `PROVE_RCU` and interpret a warning.
- ✓ Decide, for eight situations, whether RCU is the right tool.

Deferred work: softirqs, tasklets and workqueues

An interrupt handler must be short. Everything it cannot do goes somewhere else — and Linux offers four somewhere-elses, differing in whether they can sleep, how soon they run, and how much they cost. Choosing is easy once you know the trade.

The top half / bottom half split

```
   device raises IRQ
        |
        v
   TOP HALF (hard IRQ handler)
        · interrupts may be disabled
        · MUST BE FAST - microseconds
        · CANNOT SLEEP
        · do only: acknowledge the device, stop it
          re-interrupting, grab the minimum state
        |
        +--> schedule the bottom half
        |
        v
   return IRQ_HANDLED
        ...
        |
        v
   BOTTOM HALF, later
        · the actual work: parse the data, wake readers,
          submit the next transfer, log the error
        · may or may not sleep, depending which kind

  WHY: while your handler runs, that interrupt is masked, and
  on many systems others are too. Every microsecond spent in a
  top half is added directly to the worst-case interrupt
  latency of the WHOLE SYSTEM (chapter 10).
```

The four mechanisms

	Can sleep	Runs on	Latency	Verdict
Softirq	No	The CPU that raised it	Very low	Core subsystems only — you cannot add one
Tasklet	No	The CPU that scheduled it	Low	**Deprecated.** Do not use in new code
Workqueue	**Yes**	Any CPU, a kworker thread	Scheduler-dependent	**The default choice**
Threaded IRQ	**Yes**	A dedicated thread per IRQ	Low, and prioritisable	**Best for device work**

THE SHORT ANSWER

For work arising from an interrupt on your device: use a **threaded IRQ**. For work arising from anywhere else — a timer, a syscall path that must not block, a retry — use a **workqueue**. You will almost never need anything else, and tasklets are actively being removed from the kernel.

Threaded interrupts

```
/* The modern pattern, and the one to reach for first. */

static irqreturn_t my_hardirq(int irq, void *dev_id)
{
        struct my_dev *d = dev_id;
        u32 status;

        status = readl(d->base + REG_STATUS);
        if (!(status & INT_PENDING))
                return IRQ_NONE;        /* not ours - important
                                           on a shared line   */

        /* acknowledge and mask, so it stops asserting */
        writel(status, d->base + REG_STATUS);

        d->pending_status = status;     /* hand it over */

        return IRQ_WAKE_THREAD;         /* run the thread fn */
}

static irqreturn_t my_thread_fn(int irq, void *dev_id)
{
        struct my_dev *d = dev_id;

        /* PROCESS CONTEXT. We may sleep here: */
        mutex_lock(&d->lock);
        process_data(d, d->pending_status);   /* can be slow  */
        mutex_unlock(&d->lock);

        wake_up_interruptible(&d->wq);

        return IRQ_HANDLED;
}

        ret = devm_request_threaded_irq(&pdev->dev, irq,
                                        my_hardirq,
                                        my_thread_fn,
                                        IRQF_ONESHOT,
                                        dev_name(&pdev->dev),
                                        d);

/* IRQF_ONESHOT keeps the interrupt MASKED until the thread
   function finishes. Essential for level-triggered interrupts
   and for slow buses - without it a device that keeps
   asserting will re-interrupt immediately and livelock the
   CPU.

/* THE DEGENERATE CASE, and it is very common - pass NULL for
   the hard handler and the core provides one that just wakes
   the thread: */
        devm_request_threaded_irq(dev, irq, NULL, my_thread_fn,
                                  IRQF_ONESHOT, name, d);
/* This is exactly right for I2C and SPI devices, where you
   cannot even READ the status register without sleeping.  */

/* WHY THREADED IRQs ARE BETTER THAN A WORKQUEUE HERE:
     · one thread per interrupt, so no sharing with unrelated
       work
     · it can be given a real-time priority and pinned
     · on PREEMPT_RT this is the default for ALL interrupts,
```

```
        so your driver already matches the model
      · the masking is handled for you                      */
```

Workqueues

```
#include <linux/workqueue.h>

/* --- simple: use the shared system queue ----------------- */
struct my_dev {
        struct work_struct  work;
        ...
};

static void my_work_fn(struct work_struct *w)
{
        struct my_dev *d = container_of(w, struct my_dev, work);

        /* process context - CAN SLEEP */
        mutex_lock(&d->lock);
        do_slow_thing(d);
        mutex_unlock(&d->lock);
}

        INIT_WORK(&d->work, my_work_fn);
        schedule_work(&d->work);        /* queue it */

/* --- delayed work ---------------------------------------- */
        struct delayed_work poll_work;

        INIT_DELAYED_WORK(&d->poll_work, poll_fn);
        schedule_delayed_work(&d->poll_work,
                              msecs_to_jiffies(100));
        /* and to re-arm from inside poll_fn, for a poller: */
        schedule_delayed_work(&d->poll_work, HZ);

/* --- your own workqueue, when you need control ----------- */
        d->wq = alloc_workqueue("my_dev_wq",
                                WQ_UNBOUND | WQ_MEM_RECLAIM,
                                1);           /* max_active */
        if (!d->wq)
                return -ENOMEM;

        queue_work(d->wq, &d->work);
        ...
        destroy_workqueue(d->wq);    /* drains first */

/* THE FLAGS THAT MATTER:
     WQ_MEM_RECLAIM   guarantees a rescuer thread, so the queue
                      can make progress under memory pressure.
                      REQUIRED if your work is on a memory
                      reclaim path (a storage or swap driver).
     WQ_UNBOUND       not tied to a CPU; the scheduler places
                      it. Better for long-running work.
     WQ_HIGHPRI       runs ahead of normal work
     WQ_FREEZABLE     stops during suspend
     max_active = 1   serialises - only one work item at a
                      time, which often replaces a lock

/* CANCELLING - and this is where drivers leak or crash: */
        cancel_work_sync(&d->work);           /* WAITS */
        cancel_delayed_work_sync(&d->poll_work);
        flush_workqueue(d->wq);

/* In remove(), you MUST use the _sync forms. cancel_work()
   without _sync returns immediately, the work may still be
```

```
   running, and it will touch your freed device structure
   moments later.                                          */
```

THE TEARDOWN ORDERING BUG

```
static void my_remove(struct platform_device *pdev)
{
        struct my_dev *d = platform_get_drvdata(pdev);

        /* 1. STOP THE SOURCE first - no new work can arrive */
        free_irq(d->irq, d);            /* or devm handles it */
        writel(0, d->base + REG_INT_ENABLE);

        /* 2. THEN cancel what is already queued, and WAIT   */
        cancel_delayed_work_sync(&d->poll_work);
        cancel_work_sync(&d->work);
        del_timer_sync(&d->timer);

        /* 3. ONLY NOW is it safe to free anything          */
}
```

Reverse steps 1 and 2 and the interrupt re-queues the work after you cancelled it. Skip the `_sync` and the work runs against freed memory. Both produce crashes minutes later, in unrelated code, and both are found instantly by KASAN.

Timers

```
/* --- timer_list: jiffy-resolution, runs in SOFTIRQ ------- */
#include <linux/timer.h>

static void my_timer_fn(struct timer_list *t)
{
        struct my_dev *d = from_timer(d, t, timer);
        /* SOFTIRQ CONTEXT - cannot sleep */
        schedule_work(&d->work);        /* punt if you must */
}

        timer_setup(&d->timer, my_timer_fn, 0);
        mod_timer(&d->timer, jiffies + msecs_to_jiffies(500));
        ...
        del_timer_sync(&d->timer);      /* _sync, always */

/* Resolution is one jiffy = 1/CONFIG_HZ, typically 1-10 ms,
   and timers fire LATE, never early. Fine for timeouts and
   watchdogs; useless for precise periods.                 */

/* --- hrtimer: nanosecond resolution ---------------------- */
#include <linux/hrtimer.h>

static enum hrtimer_restart my_hr_fn(struct hrtimer *t)
{
        struct my_dev *d = container_of(t, struct my_dev, hrt);

        /* HARD IRQ context by default - be quick */
        do_sample(d);

        hrtimer_forward_now(t, ns_to_ktime(1000000));  /* 1 ms */
        return HRTIMER_RESTART;
}

        hrtimer_init(&d->hrt, CLOCK_MONOTONIC, HRTIMER_MODE_REL);
        d->hrt.function = my_hr_fn;
        hrtimer_start(&d->hrt, ns_to_ktime(1000000),
                      HRTIMER_MODE_REL);
        ...
        hrtimer_cancel(&d->hrt);

/* Use hrtimer_forward_now() to re-arm a PERIODIC timer -
   it advances from the scheduled time, so the period does not
   drift with handler latency. Re-arming from "now" instead
   accumulates error, which is the classic sampling-rate
   bug.                                                    */

/* --- short delays, no timer at all ----------------------- */
        udelay(10);          /* BUSY-WAITS. atomic-safe.
                                Under ~10us only.           */
        ndelay(100);
        mdelay(5);           /* busy-waits MILLISECONDS -
                                almost always wrong          */

        usleep_range(100, 200);   /* SLEEPS. process context.
                                     Give a range so the
                                     kernel can coalesce it.  */
        msleep(20);              /* sleeps, coarse           */

/* NEVER mdelay() in a driver unless a datasheet demands a
```

```
   busy-wait. It burns a CPU for the whole duration with
   preemption implications for everything else.           */
```

Tasklets, and why not

```
/* You will see these in existing drivers: */
        DECLARE_TASKLET(my_tasklet, my_tasklet_fn);
        tasklet_schedule(&my_tasklet);

/* THEY ARE DEPRECATED. Reasons:
     · they run in softirq context, so they cannot sleep -
       yet they are used for work that wants to
     · a tasklet cannot be preempted, so a long one is a
       latency bug that nothing reports
     · the same tasklet never runs concurrently on two CPUs,
       which sounds helpful but hides races that appear the
       moment someone converts it
     · they are being actively removed from the tree

   IF YOU ARE MAINTAINING ONE, convert it:
        tasklet doing work that can sleep -> threaded IRQ
        tasklet doing quick work          -> the hard IRQ
                                             handler itself
        tasklet used for deferral         -> workqueue      */
```

Choosing

```
   Work arises from MY DEVICE'S INTERRUPT?
        |
        +-- and it can sleep, or takes more than ~10 us
        |      -> THREADED IRQ
        |
        +-- and it is a few register writes
               -> do it in the hard handler. Deferring it
                  costs more than doing it.

   Work arises from ELSEWHERE?
        |
        +-- must run periodically, precise timing
        |      -> hrtimer (+ workqueue if it must sleep)
        |
        +-- must run periodically, approximate
        |      -> delayed_work, re-armed
        |
        +-- must run once, soon, and may sleep
        |      -> workqueue
        |
        +-- must run once, after a delay
               -> delayed_work, or timer_list for a timeout

   And on a memory-reclaim path (storage, swap):
        -> a dedicated workqueue with WQ_MEM_RECLAIM
```

Observing

```
# Softirq activity:
    cat /proc/softirqs
    # HI, TIMER, NET_TX, NET_RX, BLOCK, TASKLET, SCHED,
    # HRTIMER, RCU - per CPU

# ksoftirqd busy = softirq load so high it was pushed to a
# thread. On an embedded system that usually means network or
# timer pressure:
    top -H | grep ksoftirq

# Workqueue state:
    ls /sys/bus/workqueue/devices/
    cat /sys/bus/workqueue/devices/my_dev_wq/max_active
    # and with CONFIG_WQ_WATCH:
    dmesg | grep "workqueue.*hogged CPU"

# Tracing - the useful one:
    trace-cmd record -e workqueue -e irq -e timer
    trace-cmd report
    # shows workqueue_queue_work / execute_start / execute_end,
    # so you can measure how long each item took and how long
    # it waited

# Stuck work is reported automatically:
    BUG: workqueue lockup - pool cpus=0 flags=0x0 nice=0
         stuck for 32s!
# Means a work item blocked forever, starving everything else
# on that queue. Common cause: work item A waiting on work
# item B, both on the same single-threaded queue.
```

How it shows up

Symptom	Cause
Crash after `rmmod` or unbind	Work, timer or IRQ not cancelled with a `_sync` variant
Crash in work function touching freed memory	Cancelled the work before stopping the interrupt that re-queues it
Interrupt storm, system livelocks	Level-triggered IRQ not masked — missing `IRQF_ONESHOT`
`BUG: scheduling while atomic` in a timer	`timer_list` callbacks run in softirq — cannot sleep
`workqueue lockup ... stuck for 32s`	A work item blocked, or two items on one queue waiting on each other
Work runs much later than expected	Shared system queue behind other work — use your own
Deadlock under memory pressure	Reclaim-path work without `WQ_MEM_RECLAIM`
Sampling period drifts	Re-armed from "now" instead of `hrtimer_forward_now()`
High CPU with nothing running	`mdelay()` busy-waiting
`ksoftirqd` at high CPU	Softirq load exceeding what can be handled inline
Two work items corrupt shared state	Concurrent execution on different CPUs — use `max_active = 1` or a lock

Check yourself

- ✓ Explain the top-half / bottom-half split and why top halves must be short.
- ✓ Compare the four mechanisms on sleeping, latency and cost.

- ✓ Write a threaded IRQ handler and explain `IRQF_ONESHOT`.
- ✓ Say when to pass NULL as the hard handler.
- ✓ Write a work item, a delayed work item and a private workqueue.
- ✓ Give the correct teardown order and explain both bugs the wrong order causes.
- ✓ Say when `WQ_MEM_RECLAIM` is required.
- ✓ Distinguish `timer_list` from `hrtimer`, and re-arm a periodic timer without drift.
- ✓ Choose between `udelay`, `usleep_range` and `msleep`.
- ✓ Explain why tasklets are deprecated and what replaces them.

Interrupt handling in Linux

From the GIC delivering an exception to your handler being called: the number spaces, the device-tree description, the registration API, and the handful of mistakes that produce interrupt storms and missed events.

The path from wire to handler

```
  device asserts its interrupt line
       |
       v
  GIC distributor -> redistributor -> CPU interface
       |  (ARM ch. 23-24: priority, targeting, grouping)
       v
  CPU takes an IRQ exception -> VBAR_EL1 + 0x280
       |  (ARM ch. 27-28)
       v
  arch/arm64/kernel/entry.S  el1_irq / el0_irq
       |
       v
  handle_arch_irq  ->  gic_handle_irq()
       |
       |  read GICC_IAR / ICC_IAR1_EL1 -> the hardware INTID
       v
  irq_find_mapping(domain, hwirq)  ->  the LINUX IRQ NUMBER
       |
       v
  generic_handle_irq(virq)
       |
       v
  handle_level_irq() / handle_edge_irq()   the FLOW HANDLER
       |    mask, ack, or eoi as the type requires
       v
  for each action on this irq:
       your_handler(irq, dev_id)
       |
       v
  IRQ_HANDLED / IRQ_WAKE_THREAD / IRQ_NONE
       |
       v
  EOI to the GIC, return from exception

TWO NUMBER SPACES, and confusing them wastes hours:

   HWIRQ    the hardware number. SPI 42, or "bit 3 of GPIO
            controller 2". Meaningful only to that
            controller. This is what the DEVICE TREE says.

   VIRQ     the Linux irq number. A global integer allocated
            by the kernel. What you pass to request_irq().
            What /proc/interrupts shows.

The IRQ DOMAIN maps between them, per controller. That is
what makes nested controllers work: a GPIO chip is an
interrupt controller whose own interrupt comes from the GIC,
and each of its pins gets a virq of its own.
```

Describing an interrupt in the device tree

```
/* GIC SPI, the common case: */

        my_device: device@1c000000 {
                compatible = "vendor,my-device";
                reg = <0x0 0x1c000000 0x0 0x1000>;
                interrupts = <GIC_SPI 42 IRQ_TYPE_LEVEL_HIGH>;
                interrupt-parent = <&gic>;   /* often inherited */
        };

/* THREE CELLS for a GICv2/v3:
     cell 1: GIC_SPI (0) or GIC_PPI (1)
     cell 2: the interrupt number WITHIN that type.
             SPI n in DT = INTID (n + 32) in the GIC.
             THIS OFF-BY-32 CATCHES EVERYONE. The TRM says
             "INTID 74"; the device tree says 42.
     cell 3: the trigger type:
                IRQ_TYPE_EDGE_RISING     1
                IRQ_TYPE_EDGE_FALLING    2
                IRQ_TYPE_LEVEL_HIGH      4
                IRQ_TYPE_LEVEL_LOW       8

/* NAMED interrupts, when a device has several - always prefer
   this over relying on index order: */
        interrupts = <GIC_SPI 42 IRQ_TYPE_LEVEL_HIGH>,
                     <GIC_SPI 43 IRQ_TYPE_LEVEL_HIGH>;
        interrupt-names = "tx", "rx";

/* A GPIO used as an interrupt - a NESTED controller: */
        interrupt-parent = <&gpio2>;
        interrupts = <7 IRQ_TYPE_EDGE_FALLING>;
        /* two cells here, because that is what gpio2's
           #interrupt-cells says. Every controller defines its
           own cell format - check its binding.            */

/* GETTING THE VIRQ IN YOUR DRIVER: */
        irq = platform_get_irq(pdev, 0);           /* by index */
        irq = platform_get_irq_byname(pdev, "rx"); /* by name  */
        if (irq < 0)
                return irq;      /* it already logged the error
                                    and may be -EPROBE_DEFER  */

/* platform_get_irq() does the whole domain translation for
   you. Never hard-code a number.                          */
```

THE SPI OFF-BY-32

GIC interrupt IDs 0–15 are SGIs, 16–31 are PPIs, and SPIs start at 32. The device tree's `GIC_SPI n` means INTID `n + 32`. A datasheet quoting "interrupt 74" almost always means INTID 74, which you write as `GIC_SPI 42`. Getting this wrong gives you a driver whose interrupt never fires, or — worse — one that steals another device's.

Registering a handler

```
/* The managed form. Use it. */

        ret = devm_request_irq(&pdev->dev, irq,
                               my_handler,
                               0,                 /* flags */
                               dev_name(&pdev->dev),
                               d);                /* dev_id */
        if (ret)
                return dev_err_probe(&pdev->dev, ret,
                                     "cannot request irq %d\n",
                                     irq);

/* Or threaded (chapter 13), which is usually what you want: */
        ret = devm_request_threaded_irq(&pdev->dev, irq,
                                        my_hardirq, my_thread,
                                        IRQF_ONESHOT,
                                        dev_name(&pdev->dev), d);

/* THE FLAGS:
     IRQF_SHARED       the line is shared with other devices
     IRQF_ONESHOT      keep masked until the thread finishes
     IRQF_TRIGGER_*    override the DT trigger type. Do not -
                       fix the device tree instead.
     IRQF_NO_SUSPEND   keep enabled across suspend
     IRQF_PERCPU       a per-CPU interrupt (a PPI)
     IRQF_NOBALANCING  exclude from irqbalance

/* dev_id MUST be unique and non-NULL for a shared interrupt -
   it is how free_irq() knows which action to remove, and it
   is what your handler receives. Pass your device struct.

/* THE HANDLER: */
static irqreturn_t my_handler(int irq, void *dev_id)
{
        struct my_dev *d = dev_id;
        u32 status;

        status = readl(d->base + REG_STATUS);

        /* ON A SHARED LINE THIS CHECK IS MANDATORY: */
        if (!(status & d->irq_mask))
                return IRQ_NONE;        /* not mine */

        writel(status, d->base + REG_STATUS);   /* ack */
        ... handle ...

        return IRQ_HANDLED;
}

/* RETURN VALUES:
     IRQ_HANDLED       it was mine and I dealt with it
     IRQ_NONE          not mine. On a shared line, essential.
     IRQ_WAKE_THREAD   run the threaded handler

   IF EVERY handler on a line returns IRQ_NONE repeatedly, the
   kernel disables the interrupt and prints:
        "irq 42: nobody cared (try booting with irqpoll)"
        "Disabling IRQ #42"
   which is the spurious-interrupt protection saving your
```

```
   system from a livelock. It means the interrupt is asserted
   and nobody is clearing it.                              */
```

Edge versus level: the failure modes differ

```
LEVEL-TRIGGERED: the line stays asserted until the device is
serviced.

  · If your handler does not CLEAR the condition in the
    device, the interrupt fires again immediately, forever.
    -> interrupt storm, system livelock, "nobody cared".
  · Cannot be missed: if it is still asserted, it will be
    taken.
  · Safe with sharing.
  · Needs IRQF_ONESHOT with a threaded handler.

EDGE-TRIGGERED: a transition latches a pending bit.

  · CAN BE MISSED. The classic race:

       handler reads STATUS       -> sees event A
       ... device raises event B, edge occurs ...
       handler clears STATUS      -> clears BOTH
       handler returns
       -> event B is lost, and no further edge will come
          because the device is now waiting for you

    THE FIX - loop until the device is genuinely idle:

       do {
               status = readl(d->base + REG_STATUS);
               if (!status)
                       break;
               writel(status, d->base + REG_STATUS); /* ack */
               handle(status);
       } while (1);

    Bound the loop if the hardware might never settle.

  · Also: clear the condition BEFORE re-enabling, or you
    latch your own acknowledgement.

  THE SYMPTOM of getting edge handling wrong is a device that
  works fine and then stops responding forever under load -
  one lost edge and it waits for an event that will never be
  re-signalled.
```

Controlling interrupts

```
        disable_irq(irq);          /* waits for handlers to
                                      finish. NOT from inside
                                      the handler - deadlock. */
        disable_irq_nosync(irq);   /* returns immediately */
        enable_irq(irq);           /* must MATCH the number of
                                      disables - they nest    */

        /* from within the handler, to mask your own line: */
        disable_irq_nosync(irq);

        /* wake-up capability, for suspend (chapter 25): */
        enable_irq_wake(irq);
        disable_irq_wake(irq);

/* LOCAL interrupt control - almost never right in a driver: */
        local_irq_disable();       /* this CPU only */
        local_irq_enable();
        local_irq_save(flags);
        local_irq_restore(flags);

/* Use spin_lock_irqsave() instead (chapter 11). Bare
   local_irq_disable() in a driver is a red flag: it does not
   protect against other CPUs, it hurts system latency, and it
   is almost always a lock in disguise.                    */

/* AFFINITY (chapter 10): */
        irq_set_affinity_hint(irq, cpumask_of(2));
```

Reading /proc/interrupts

```
$ cat /proc/interrupts
            CPU0       CPU1       CPU2       CPU3
   3:      12043      11982          0          0  GICv3  30 Level arch_timer
  42:       8471          0          0          0  GICv3  74 Level 1c000000.my-device
  43:          0          0          0          0  GICv3  75 Edge  1c000000.my-device
  56:     102394          0          0          0  GICv3  88 Level eth0
 IPI0:      4821       5102       4993       4877  Rescheduling interrupts

# COLUMN BY COLUMN:
#   42        the LINUX irq (virq)
#   counts    per CPU. This is the useful part.
#   GICv3     the controller
#   74        the HWIRQ - note 42 in DT became INTID 74
#   Level     the trigger type ACTUALLY configured
#   name      what you passed to request_irq

# WHAT TO LOOK FOR:
#   count is ZERO         -> the interrupt never fires. Wrong
#                            number, wrong trigger type, device
#                            not enabled, or pin not muxed.
#   count climbs wildly   -> a storm; the condition is not
#                            being cleared.
#   count on one CPU only -> normal unless you expected
#                            balancing.
#   your device missing   -> request_irq never succeeded.
#   trigger type differs from your DT -> something overrode it
#                            with IRQF_TRIGGER_*.

# Watch it live:
    watch -d -n1 'grep my-device /proc/interrupts'
```

When the interrupt does not fire

```
# Work down this list. It is almost always one of these.

# 1. Does the count in /proc/interrupts move at all?
#    No -> the interrupt is not reaching the CPU.

# 2. Is the device actually enabled?
    devmem 0x1c000004        # read the interrupt-enable reg
#    Many devices need BOTH a global enable and a per-source
#    unmask, and drivers commonly set only one.

# 3. Is the pin muxed as an interrupt?
    cat /sys/kernel/debug/pinctrl/*/pinmux-pins | grep ...
#    A GPIO-based interrupt with the pin in the wrong function
#    is silent.

# 4. Is the number right?
    cat /sys/kernel/debug/irq/domains/*        # the mappings
    cat /sys/kernel/debug/irq/irqs/42          # this one
#    Compare hwirq against the TRM, remembering the +32.

# 5. Is the trigger type right?
#    A level-high device described as edge-rising fires once
#    at most. Check the "Level"/"Edge" column.

# 6. Is it masked at the GIC?
    cat /sys/kernel/debug/irq/irqs/42
      handler:  handle_level_irq
      status:   0x00000000
      istate:   0x00000000
      ddepth:   1                <-- DISABLED. Someone called
                                     disable_irq and did not
                                     re-enable.
      wdepth:   0

# 7. Is the clock to the device running? An unclocked
#    peripheral cannot assert anything.

# TRACING, once it does fire:
    echo 1 > /sys/kernel/tracing/events/irq/enable
    cat /sys/kernel/tracing/trace_pipe
      irq_handler_entry: irq=42 name=1c000000.my-device
      irq_handler_exit:  irq=42 ret=handled
```

How it shows up

Symptom	Cause
Count stays at 0	Wrong number, wrong trigger, device not enabled, pin not muxed, or clock off
Device not in `/proc/interrupts`	`request_irq` failed — check the probe return
`nobody cared, disabling IRQ`	Condition never cleared, or the wrong device is being blamed on a shared line
System livelocks on the first interrupt	Level-triggered and not acknowledged; missing `IRQF_ONESHOT`
Fires once, then never again	Level source described as edge, or the ack sequence is wrong
Works, then stops under load	Lost edge — handler does not loop until the device is idle
`request_irq` returns `-EBUSY`	Line already claimed without `IRQF_SHARED`, or trigger types conflict

Symptom	Cause
Deadlock in `disable_irq`	Called from within the handler — use `_nosync`
Interrupt stays disabled	Unbalanced `disable_irq` / `enable_irq` — check `ddepth`
Handler crashes on `dev_id`	Passed NULL, or the device struct was already freed
Interrupt does not wake the system	`enable_irq_wake()` not called

Check yourself

- ✓ Trace an interrupt from the GIC to your handler.
- ✓ Explain hwirq versus virq and what an IRQ domain does.
- ✓ Write an `interrupts` property and explain the SPI off-by-32.
- ✓ Use named interrupts and `platform_get_irq_byname`.
- ✓ Write a handler that behaves correctly on a shared line.
- ✓ Explain what `IRQ_NONE` is for and what "nobody cared" means.
- ✓ Contrast the failure modes of edge and level triggering.
- ✓ Write an edge handler that cannot lose an event.
- ✓ Read every column of `/proc/interrupts`.
- ✓ Work the seven-step checklist for an interrupt that never fires.

Kernel modules

A module is kernel code you can load and unload while the system runs. That single property changes development from "reboot to test" into "reload in a second", which is worth more to your productivity than any other kernel skill.

The smallest complete module

```
/* hello.c */
#include <linux/module.h>
#include <linux/kernel.h>
#include <linux/init.h>

static int __init hello_init(void)
{
        pr_info("hello: loaded\n");
        return 0;              /* non-zero aborts the load */
}

static void __exit hello_exit(void)
{
        pr_info("hello: unloaded\n");
}

module_init(hello_init);
module_exit(hello_exit);

MODULE_LICENSE("GPL");         /* REQUIRED. See below.      */
MODULE_AUTHOR("Your Name");
MODULE_DESCRIPTION("A minimal example module");
MODULE_VERSION("1.0");
```

```
# Makefile
obj-m += hello.o

KDIR ?= /lib/modules/$(shell uname -r)/build

all:
        $(MAKE) -C $(KDIR) M=$(PWD) modules

clean:
        $(MAKE) -C $(KDIR) M=$(PWD) clean

# CROSS-COMPILING for an ARM64 target - what you will
# actually do:
#   make -C /path/to/kernel/source M=$(PWD) \
#        ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- modules
#
# KDIR must point at a CONFIGURED kernel tree that matches the
# target EXACTLY - same version, same .config. A module built
# against a different configuration will refuse to load, or
# load and corrupt memory.
```

```
# Using it:
    sudo insmod hello.ko              # load this exact file
    lsmod | grep hello                # is it there?
    dmesg | tail                      # what did it print?
    sudo rmmod hello                  # unload
    modinfo hello.ko                  # metadata, parameters,
                                      # dependencies, vermagic

# modprobe, the better tool - resolves DEPENDENCIES:
    sudo cp hello.ko /lib/modules/$(uname -r)/extra/
    sudo depmod -a                    # rebuild the dep map
    sudo modprobe hello               # loads what it needs
    sudo modprobe -r hello            # unload, with deps
```

MODULE_LICENSE is not paperwork

```
/* It has a mechanical effect: symbols exported with
   EXPORT_SYMBOL_GPL are only linkable from a module whose
   license string is GPL-compatible.                        */

   "GPL"                  GPL v2 or later
   "GPL v2"
   "GPL and additional rights"
   "Dual BSD/GPL"
   "Dual MIT/GPL"
   "Proprietary"          <-- TAINTS the kernel, and cannot
                              use GPL-only symbols

/* Omit it entirely and you get:

     hello: module license 'unspecified' taints kernel.
     Disabling lock debugging due to kernel taint

   A tainted kernel is reported in every oops, and many kernel
   developers will decline to debug one. More practically:
   most of the API you need for a real driver is
   EXPORT_SYMBOL_GPL, so a "Proprietary" module cannot call
   it. This is a deliberate design decision, not an
   oversight.                                               */

/* CHECK the taint state: */
        cat /proc/sys/kernel/tainted
        # or read the flags in an oops header:
        #   "CPU: 0 PID: 431 Tainted: G           O"
        #    O = an out-of-tree module is loaded
        #    P = a proprietary module
        #    E = an unsigned module
```

Module parameters

```
static int buffer_size = 4096;
module_param(buffer_size, int, 0644);
MODULE_PARM_DESC(buffer_size, "Ring buffer size in bytes");

static char *device_name = "mydev";
module_param(device_name, charp, 0444);

static bool verbose;
module_param(verbose, bool, 0644);

static int channels[4];
static int nr_channels;
module_param_array(channels, int, &nr_channels, 0444);

/* SET THEM: */
        insmod mydrv.ko buffer_size=8192 verbose=1 \
               channels=1,2,3
        modprobe mydrv buffer_size=8192
        # built into the kernel, on the command line:
        mydrv.buffer_size=8192
        # persistently:
        echo "options mydrv buffer_size=8192" \
            > /etc/modprobe.d/mydrv.conf

/* AND READ OR CHANGE AT RUNTIME, if the mode allows: */
        cat /sys/module/mydrv/parameters/buffer_size
        echo 1 > /sys/module/mydrv/parameters/verbose

/* THE PERMISSION ARGUMENT is the sysfs mode:
        0        not visible in sysfs at all
        0444     read-only
        0644     writable by root

   Only use 0644 if changing the value at runtime is actually
   SAFE. A buffer size that is read once at probe time should
   be 0444 - otherwise you invite someone to change it and
   wonder why nothing happened.

/* AND THE BIGGER POINT: module parameters are a poor
   configuration mechanism for a real driver. They are global,
   not per-device. For anything describing HARDWARE, use the
   device tree (chapter 18). Parameters are for debug knobs
   and for behaviour that genuinely applies to the whole
   driver.                                                  */
```

Exporting and using symbols

```
/* In one module: */
int my_shared_function(int arg)
{
        ...
}
EXPORT_SYMBOL_GPL(my_shared_function);

/* In another - just call it, but the FIRST module must be
   loaded first. modprobe works this out from the symbol
   table; insmod does not.                                  */

        depmod -a
        modprobe consumer          # loads provider first

/* SEEING what a module needs and provides: */
        modinfo mydrv.ko | grep depends
        cat /proc/kallsyms | grep my_shared_function
        nm -u mydrv.ko             # undefined = required
        nm -g --defined-only mydrv.ko

/* WHEN A SYMBOL IS MISSING: */
        insmod: ERROR: could not insert module: Unknown symbol
                in module
        dmesg:
          mydrv: Unknown symbol my_shared_function (err -2)
          mydrv: Unknown symbol dma_alloc_attrs (err 0)
                                                 ^^^^^^
        # err -2  = the symbol does not exist at all
        # err 0   = it exists but is GPL-only and your license
        #           string does not qualify

/* VERSION MAGIC - the other common load failure: */
        insmod: ERROR: could not insert module: Invalid module
                format
        dmesg:
          mydrv: version magic '6.6.0 SMP mod_unload aarch64'
          should be '6.6.0-vendor SMP preempt mod_unload aarch64'

   Every difference matters: version, SMP, PREEMPT, and the
   ABI-relevant config options. Rebuild against the target's
   exact tree. With CONFIG_MODVERSIONS the CRC of each
   exported function's signature is checked too, so a changed
   struct definition is caught rather than silently
   miscompiled.                                             */
```

Making a module safely unloadable

> **UNLOAD IS WHERE MODULES CRASH**
>
> Loading is easy. Unloading requires that *nothing* can still call into your code after `module_exit` returns, because the memory holding your functions is freed. Everything you registered must be unregistered, and everything asynchronous must be waited for.

```
static void __exit my_exit(void)
{
        /* IN REVERSE ORDER OF INITIALISATION, and stopping
           sources BEFORE cancelling consumers:            */

        /* 1. stop new work arriving */
        platform_driver_unregister(&my_driver);
        misc_deregister(&my_misc);
        unregister_chrdev_region(devno, 1);

        /* 2. stop the hardware */
        writel(0, base + REG_INT_ENABLE);
        free_irq(irq, d);

        /* 3. WAIT for anything already in flight */
        cancel_delayed_work_sync(&d->poll_work);
        cancel_work_sync(&d->work);
        del_timer_sync(&d->timer);
        hrtimer_cancel(&d->hrt);
        kthread_stop(d->task);
        synchronize_rcu();              /* if you used RCU */

        /* 4. only now, free */
        kfree(d->buffer);
        iounmap(base);
}

/* THE _sync SUFFIX IS NOT OPTIONAL. cancel_work() returns
   immediately; cancel_work_sync() waits for a running
   instance to finish. The first one gives you a crash a few
   microseconds after rmmod, in code that no longer exists.

/* REFERENCE COUNTING - preventing unload while in use:

   For file operations, .owner = THIS_MODULE in the
   file_operations struct does it automatically: the module
   count is incremented while any fd is open, and rmmod
   returns -EBUSY.

        static const struct file_operations my_fops = {
                .owner = THIS_MODULE,     <-- do not omit
                .open  = my_open,
                ...
        };

   For anything else:
        try_module_get(THIS_MODULE);
        module_put(THIS_MODULE);

   CHECK who is using you:
        lsmod
        Module      Size  Used by
        mydrv      16384  2 othermod,thirdmod
                          ^ refcount   ^ by whom

   "Used by 0" and rmmod still fails -> something took a
   reference without registering a name, or a device is still
   bound.                                                  */
```

Module versus built-in

	`=m` (module)	`=y` (built in)
Development speed	**Fast** — reload in a second	Slow — rebuild and reboot
Available at	Whenever loaded	Boot, at its initcall level
Needed for the root filesystem	Requires an initramfs	Works directly
Unloadable	Yes — exercises your teardown path	No
Memory	Only when loaded	Always
Ordering	By load order and dependencies	By initcall level, then link order

```
/* THE ADVICE: develop as a module, ship however you need.

   Building as a module during development is not just about
   iteration speed. It forces you to write a correct remove()
   path - and a driver whose teardown is correct is a driver
   that also survives unbind, suspend, and probe failure.

   TEST THE CYCLE, repeatedly:
        for i in $(seq 100); do
                insmod mydrv.ko && rmmod mydrv || break
        done
   with KASAN enabled. Anything that leaks or races shows up
   within a few iterations, and this is by far the cheapest
   bug-finding exercise available to you.

   ALSO TEST UNBIND/BIND, which exercises probe and remove
   without touching the module:
        echo 1c000000.my-device > \
             /sys/bus/platform/drivers/my-driver/unbind
        echo 1c000000.my-device > \
             /sys/bus/platform/drivers/my-driver/bind      */
```

Module signing

```
# A hardened kernel refuses unsigned modules (isolation
# ch. 14 - the chain of trust does not stop at the kernel):

    CONFIG_MODULE_SIG=y
    CONFIG_MODULE_SIG_FORCE=y       # REFUSE unsigned
    CONFIG_MODULE_SIG_ALL=y         # sign during the build
    CONFIG_MODULE_SIG_HASH="sha256"

# The build signs with certs/signing_key.pem. For a product,
# supply your own key and keep the private half in an HSM:
    CONFIG_MODULE_SIG_KEY="/path/to/key.pem"

# Sign an out-of-tree module by hand:
    scripts/sign-file sha256 signing_key.pem \
                      signing_key.x509 mydrv.ko

# SYMPTOM of an unsigned module on an enforcing kernel:
    insmod: ERROR: could not insert module: Key was rejected
            by service
    dmesg: Loading of unsigned module is rejected

# Without SIG_FORCE it loads but taints with 'E'.
```

How it shows up

Symptom	Cause
`Invalid module format`	Version magic mismatch — rebuild against the target's exact tree
`Unknown symbol ... (err -2)`	Provider module not loaded, or the function does not exist in this version
`Unknown symbol ... (err 0)`	GPL-only symbol, non-GPL `MODULE_LICENSE`
`module license 'unspecified' taints kernel`	Missing `MODULE_LICENSE`
`Key was rejected by service`	Unsigned module, `MODULE_SIG_FORCE` enabled
`rmmod: Device or resource busy`	Refcount non-zero — check `lsmod`'s "Used by"
Crash seconds after `rmmod`	Work, timer or IRQ not cancelled synchronously
Crash in freed module text	A callback still registered somewhere
Memory grows across load/unload cycles	A leak in the teardown path — the 100-cycle test finds it
Works as a module, fails built in	An ordering dependency — use deferred probe (ch. 04)
Parameter change has no effect	Read once at probe; the sysfs write only changed the variable
`modprobe` works, `insmod` fails	Unresolved dependencies — that is the difference between them

Check yourself

- ✓ Write a minimal module and its Makefile, and cross-compile it for arm64.
- ✓ Explain the mechanical effect of `MODULE_LICENSE`.
- ✓ Add parameters of three types and choose their sysfs modes correctly.
- ✓ Say why the device tree is preferable to parameters for hardware description.

- ✓ Diagnose `Unknown symbol` with `err -2` versus `err 0`.
- ✓ Explain version magic and what it protects against.
- ✓ Write a correct `__exit` function, in the right order, with `_sync` everywhere.
- ✓ Explain what `.owner = THIS_MODULE` does.
- ✓ Run a 100-iteration load/unload test under KASAN, and an unbind/bind cycle.
- ✓ Sign a module and explain where it fits in the chain of trust.

Building and booting a custom kernel

Configure, cross-compile, boot it under QEMU, and get to a shell — with a development loop fast enough that you will actually use it. This is the workbench everything else in the track runs on.

The toolchain

```
# Debian/Ubuntu:
sudo apt install gcc-aarch64-linux-gnu build-essential \
     bc bison flex libssl-dev libelf-dev libncurses-dev \
     qemu-system-arm qemu-user-static debootstrap \
     device-tree-compiler cpio

# Verify:
aarch64-linux-gnu-gcc --version
qemu-system-aarch64 --version

# EVERY kernel command needs these two, so export them once:
export ARCH=arm64
export CROSS_COMPILE=aarch64-linux-gnu-

# (Or pass them on each make line. Forgetting them and
# building a host x86 kernel by accident is the single most
# common wasted 20 minutes in embedded work.)
```

Configuring

```
# Start from a sensible base:
make defconfig              # arm64 generic - boots on QEMU
                            # virt and most server-class parts
make ARCH=arm64 vendor_defconfig      # a board's own config
                                      # in arch/arm64/configs/

# Then adjust:
make menuconfig             # ncurses. '/' SEARCHES - use it.
make nconfig                # nicer ncurses
make xconfig                # Qt
make savedefconfig          # writes a MINIMAL defconfig
                            # containing only non-default
                            # options - what you commit

# Scripted, which is what CI should do:
./scripts/config --enable  CONFIG_DEBUG_INFO_DWARF5
./scripts/config --enable  CONFIG_KASAN
./scripts/config --enable  CONFIG_PROVE_LOCKING
./scripts/config --module  CONFIG_MY_DRIVER
./scripts/config --disable CONFIG_MODULE_SIG_FORCE
./scripts/config --set-val CONFIG_LOG_BUF_SHIFT 18
make olddefconfig           # resolve the consequences
                            # WITHOUT prompting

# Other useful targets:
make oldconfig              # prompts for NEW options only -
                            # use after updating the tree
make listnewconfig          # what changed, without asking
make localmodconfig         # keep only modules currently
                            # loaded. Shrinks a distro config
                            # enormously; be careful, it
                            # drops anything not plugged in
                            # right now.
```

THE DEVELOPMENT CONFIG

Turn these on while writing drivers. They cost performance and find bugs your testing never will:

```
CONFIG_DEBUG_KERNEL=y
CONFIG_DEBUG_INFO_DWARF5=y     # for gdb and pahole
CONFIG_KASAN=y                 # memory errors
CONFIG_KASAN_INLINE=y
CONFIG_PROVE_LOCKING=y         # lockdep
CONFIG_DEBUG_ATOMIC_SLEEP=y    # sleeping in atomic context
CONFIG_DEBUG_SPINLOCK=y
CONFIG_DEBUG_MUTEXES=y
CONFIG_DEBUG_OBJECTS=y
CONFIG_DEBUG_LIST=y            # corrupted list_head
CONFIG_DEBUG_KMEMLEAK=y
CONFIG_DETECT_HUNG_TASK=y
CONFIG_PANIC_ON_OOPS=y         # fail loudly, do not limp on
CONFIG_FTRACE=y
CONFIG_FUNCTION_TRACER=y
CONFIG_DYNAMIC_DEBUG=y
CONFIG_MAGIC_SYSRQ=y
CONFIG_GDB_SCRIPTS=y
```

Building

```
# The whole thing:
make -j$(nproc) Image dtbs modules

# Targets that matter:
#   Image        the raw kernel (arm64 does not use zImage)
#   Image.gz     compressed - most bootloaders accept it
#   dtbs         all device trees for this arch
#   modules      the .ko files
#   vmlinux      the ELF with symbols - NOT bootable, but this
#                is what gdb and addr2line need. Keep it.

# Just one file, while iterating on a driver:
make drivers/mydrv/mydrv.ko

# Just one device tree:
make arch/arm64/boot/dts/vendor/myboard.dtb

# Install modules to a staging root:
make INSTALL_MOD_PATH=/path/to/rootfs modules_install

# SPEED, which matters more than anything else here:
    ccache      export CROSS_COMPILE="ccache aarch64-linux-gnu-"
                a rebuild after a config change goes from
                20 minutes to 2
    make -j$(nproc)
    -j with distcc or icecc if you have a build farm

# Verify what you produced:
    file arch/arm64/boot/Image
      Linux kernel ARM64 boot executable Image, little-endian
    ls -lh arch/arm64/boot/Image
```

Booting it under QEMU

```
# The fastest development loop available, and it needs no
# hardware. Start with an initramfs so there is no filesystem
# to manage.

# 1. Build a tiny userspace with busybox:
    wget https://busybox.net/downloads/busybox-1.36.1.tar.bz2
    tar xf busybox-1.36.1.tar.bz2 && cd busybox-1.36.1
    make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- \
         defconfig
    ./scripts/config --enable CONFIG_STATIC   # no libc needed
    make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- \
         -j$(nproc) install          # -> ./_install

# 2. Build the initramfs:
    cd _install
    mkdir -p proc sys dev
    cat > init <<'EOF'
#!/bin/sh
mount -t proc  none /proc
mount -t sysfs none /sys
mount -t devtmpfs none /dev
echo "=== userspace is up ==="
exec /bin/sh
EOF
    chmod +x init
    find . | cpio -o -H newc | gzip > ../initramfs.cpio.gz

# 3. Boot:
    qemu-system-aarch64 \
      -M virt -cpu cortex-a57 -smp 4 -m 1024 \
      -kernel arch/arm64/boot/Image \
      -initrd initramfs.cpio.gz \
      -append "console=ttyAMA0 earlycon rdinit=/init" \
      -nographic

# Ctrl-A then X quits. Ctrl-A then C is the QEMU monitor.

# THE ITERATION LOOP is now:
#   edit -> make -j -> qemu -> test        ~30 seconds
# versus flashing hardware, which is minutes. Do as much as
# possible here and move to real hardware only for what
# genuinely needs it.
```

Useful QEMU options

```
# Attach a virtual disk:
    -drive file=rootfs.ext4,format=raw,if=none,id=hd0 \
    -device virtio-blk-device,drive=hd0 \
    -append "root=/dev/vda rw console=ttyAMA0"

# Networking with a port forward to ssh:
    -netdev user,id=net0,hostfwd=tcp::5555-:22 \
    -device virtio-net-device,netdev=net0

# SHARE A HOST DIRECTORY - the best way to get a freshly
# built module into the guest without rebuilding anything:
    -virtfs local,path=/host/dir,mount_tag=host,\
security_model=none,id=host
    # in the guest:
    mount -t 9p -o trans=virtio host /mnt

# Dump the device tree QEMU generated, to read or modify:
    -machine dumpdtb=virt.dtb
    dtc -I dtb -O dts virt.dtb > virt.dts

# Emulate TrustZone with secure firmware (isolation ch. 11):
    -machine virt,secure=on -bios bl1.bin

# GDB - halt at the first instruction and wait:
    -s -S
    # then, in another terminal:
    aarch64-linux-gnu-gdb vmlinux
    (gdb) target remote :1234
    (gdb) hbreak start_kernel
    (gdb) continue
```

> **QEMU'S `VIRT` MACHINE IS A REAL, WELL-DOCUMENTED PLATFORM**
>
> It has a GIC, a PL011 UART, virtio devices, an SMMU (`-machine virt,iommu=smmuv3`), PSCI, and optional EL3 and EL2. Nearly everything in this track can be exercised on it, including SMMU faults, secure-world calls and CPU hotplug. Use hardware for timing, real peripherals, and power — and QEMU for everything else.

A real root filesystem

```
# Option 1: Debian, via debootstrap. Big, but complete -
# apt, gdb, perf, python all available.
    sudo debootstrap --arch=arm64 --foreign bookworm \
         ./rootfs http://deb.debian.org/debian
    sudo cp /usr/bin/qemu-aarch64-static ./rootfs/usr/bin/
    sudo chroot ./rootfs /debootstrap/debootstrap --second-stage
    sudo chroot ./rootfs passwd root

    dd if=/dev/zero of=rootfs.ext4 bs=1M count=2048
    mkfs.ext4 rootfs.ext4
    sudo mount -o loop rootfs.ext4 /mnt
    sudo cp -a rootfs/* /mnt/
    sudo umount /mnt

# Option 2: Buildroot. Small, fast, reproducible - what most
# embedded products actually use.
    git clone https://git.buildroot.net/buildroot
    cd buildroot
    make qemu_aarch64_virt_defconfig
    make menuconfig      # add packages, set the kernel
    make -j$(nproc)
    # produces output/images/{Image,rootfs.ext4,start-qemu.sh}

# Option 3: Yocto. Heaviest, most configurable, and the one
# you will meet at a vendor. Layers, recipes, bitbake.
# Worth learning if you ship products; overkill for study.

# INSTALL YOUR MODULES into whichever you chose:
    make INSTALL_MOD_PATH=./rootfs modules_install
    # then depmod against the TARGET's module tree:
    depmod -b ./rootfs $(make kernelrelease)
```

Onto real hardware

```
# The parts you now need that QEMU did not:

# 1. A SERIAL CONSOLE. Non-negotiable. A USB-TTL adapter and
#    three wires. Without it you are debugging blind.
    picocom -b 115200 /dev/ttyUSB0
    # or: screen /dev/ttyUSB0 115200

# 2. A device tree for YOUR board, not the generic one.
    make arch/arm64/boot/dts/vendor/myboard.dtb

# 3. A way to load a kernel without reflashing every time.
#    U-Boot over TFTP is the standard answer:
    # on the host:
    sudo apt install tftpd-hpa
    sudo cp Image myboard.dtb /srv/tftp/

    # in U-Boot:
    setenv serverip 192.168.1.10
    setenv ipaddr 192.168.1.20
    tftpboot ${kernel_addr_r} Image
    tftpboot ${fdt_addr_r} myboard.dtb
    setenv bootargs "console=ttyS0,115200 earlycon \
                     root=/dev/nfs nfsroot=192.168.1.10:/srv/nfs \
                     ip=dhcp rw"
    booti ${kernel_addr_r} - ${fdt_addr_r}

# 4. NFS ROOT, so userspace changes need no reflash either.
#    Kernel over TFTP + rootfs over NFS = a development loop
#    on real hardware that is nearly as fast as QEMU. Set this
#    up on day one of any board bring-up; it pays for itself
#    within a day.

# 5. A recovery path. Know how to get back to a working image
#    before you break the one that boots - a second boot slot,
#    an SD card, or a USB recovery mode.
```

Keeping the loop fast

Technique	Saves
`ccache`	Most of a rebuild after a config change
Build the driver as `=m`	The whole kernel rebuild, and the reboot
QEMU instead of hardware	Minutes per iteration
TFTP + NFS root	Reflashing, on real hardware
9p share into QEMU	Rebuilding the initramfs to test one module
`make M=drivers/mydrv`	Scanning the whole tree
Unbind/bind instead of reboot	Re-running probe without unloading
A scripted config	Re-deriving your options after every tree update

How it shows up

Symptom	Cause
Built an x86 kernel by accident	`ARCH` / `CROSS_COMPILE` not set
Config option keeps disappearing	Unmet dependency — `make menuconfig`, then `/` to search
`make olddefconfig` changes things you set	A `select` or dependency overrode you
Module will not load on the target	Version magic — built against the wrong tree or config
Kernel boots on QEMU, not on hardware	Wrong device tree, or a missing driver for the real console
No output on real hardware	Console mismatch — try `earlycon` (ch. 03)
Hangs mounting root	Storage driver is a module with no initramfs — build it in
Builds are slow	No ccache, no `-j`, or rebuilding everything for one file
QEMU exits immediately	Wrong `-M` / `-cpu`, or the Image is not arm64
Cannot type in QEMU	Missing `console=ttyAMA0` in `-append`
gdb symbols do not match	`vmlinux` is from a different build than the running Image

Check yourself

- ✓ Set up a cross toolchain and build an arm64 `Image` and `dtbs`.
- ✓ Configure with `scripts/config` and `olddefconfig`, and produce a minimal defconfig.
- ✓ List eight debug options worth enabling during development, and what each catches.
- ✓ Build a busybox initramfs and boot it under QEMU.
- ✓ Attach gdb to a QEMU-hosted kernel and break in `start_kernel`.
- ✓ Share a host directory into the guest to test a module without rebuilding the initramfs.
- ✓ Dump and read QEMU's generated device tree.
- ✓ Set up TFTP plus NFS root on real hardware.
- ✓ Explain why `vmlinux` must be kept even though it is not bootable.
- ✓ Get your edit-build-test loop under a minute, and say what dominates it.

The Linux device model

Buses, devices and drivers, and the matching process that brings them together. Once you can see this structure, every driver in the tree has the same shape — and the answer to "why does my probe never run" becomes a three-command investigation.

Three objects, one relationship

```
struct bus_type            "platform", "i2c", "spi", "pci"
     |     owns the MATCH function and the probe/remove
     |     protocol for everything on it
     |
     +-- struct device_driver     code that can drive
     |         · a name                something
     |         · a match table (of_match_table, id_table)
     |         · .probe / .remove
     |
     +-- struct device            a thing that exists
               · a parent (the topology)
               · a bus
               · resources: reg, irq, clocks, DMA config
               · a driver, once bound

THE CORE LOOP, in drivers/base/:

  a DEVICE is registered   -> try every driver on its bus
  a DRIVER is registered   -> try every unbound device on
                              its bus

  for each candidate:  bus->match(dev, drv)
                              |
                       matched? -> drv->probe(dev)
                                          |
                                    0     -> BOUND
                                    -EPROBE_DEFER -> retry later
                                    other -> not bound

That is the entire mechanism. Everything else is detail.

YOU SUBCLASS the generic structures:

  struct platform_device  { struct device dev; ... }
  struct i2c_client       { struct device dev; ... }
  struct spi_device       { struct device dev; ... }

and get back to yours with container_of(), or with the
helpers each bus provides (to_platform_device(dev)).
```

Where devices come from

Source	Bus	How
Device tree	platform, i2c, spi	`of_platform_populate()` walks the tree at boot. **The embedded default.**
ACPI	platform, pci	Firmware tables. Arm servers, some laptops.
Enumeration	PCI, USB	The bus itself reports what is plugged in, with vendor/product IDs.

Source	Bus	How
Parent driver	Any	An MFD or a controller registers its children.
Board file	platform	Static C tables. Legacy; replaced by DT on arm64.
Userspace	Any	Device tree overlays, or a bus-specific `new_device` sysfs file.

Matching

```
/* Each bus decides what "match" means. For platform devices
   (drivers/base/platform.c), it tries in order:              */

   1. OF: does dev->of_node's `compatible` appear in the
          driver's of_match_table?          <-- what you use
   2. ACPI match table
   3. the platform id_table
   4. plain strcmp of driver->name against device->name

/* THE OF WAY, which is what an embedded driver writes: */

static const struct of_device_id my_of_match[] = {
        { .compatible = "vendor,my-device-v2",
          .data = &v2_config },          /* per-variant data */
        { .compatible = "vendor,my-device",
          .data = &v1_config },
        { }                              /* SENTINEL - the
                                            empty entry is
                                            REQUIRED         */
};
MODULE_DEVICE_TABLE(of, my_of_match);   /* so modprobe can
                                           autoload this
                                           module for this
                                           compatible        */

static struct platform_driver my_driver = {
        .driver = {
                .name           = "my-driver",
                .of_match_table = my_of_match,
                .pm             = &my_pm_ops,
        },
        .probe  = my_probe,
        .remove = my_remove,
};
module_platform_driver(my_driver);       /* generates
                                            module_init and
                                            module_exit      */

/* USING THE MATCH DATA to support several variants with one
   driver - the standard pattern: */
static int my_probe(struct platform_device *pdev)
{
        const struct my_config *cfg;

        cfg = of_device_get_match_data(&pdev->dev);
        if (!cfg)
                return -EINVAL;

        d->nr_channels = cfg->nr_channels;
        d->has_dma     = cfg->has_dma;
        ...
}

/* THE SENTINEL MATTERS: the match loop runs until it finds an
   entry with an empty compatible string. Omit it and the
   kernel reads past the array - which manifests as a random
   crash during boot, or a driver that matches something
   absurd.                                                   */
```

A probe function, annotated

```
static int my_probe(struct platform_device *pdev)
{
        struct device *dev = &pdev->dev;
        struct my_dev *d;
        int ret;

        /* 1. allocate the driver's per-device state, managed
              so it is freed automatically (chapter 26)      */
        d = devm_kzalloc(dev, sizeof(*d), GFP_KERNEL);
        if (!d)
                return -ENOMEM;
        d->dev = dev;

        /* 2. MMIO - maps AND reserves the region */
        d->base = devm_platform_ioremap_resource(pdev, 0);
        if (IS_ERR(d->base))
                return PTR_ERR(d->base);

        /* 3. clocks. May defer if the clock driver is late. */
        d->clk = devm_clk_get_enabled(dev, "core");
        if (IS_ERR(d->clk))
                return dev_err_probe(dev, PTR_ERR(d->clk),
                                     "no core clock\n");

        /* 4. regulators, resets, GPIOs, phys - same shape */
        d->vdd = devm_regulator_get(dev, "vdd");
        if (IS_ERR(d->vdd))
                return dev_err_probe(dev, PTR_ERR(d->vdd),
                                     "no vdd supply\n");
        ret = regulator_enable(d->vdd);
        if (ret)
                return ret;

        /* 5. DT properties specific to this device */
        ret = device_property_read_u32(dev, "vendor,fifo-depth",
                                       &d->fifo_depth);
        if (ret)
                d->fifo_depth = 16;      /* a sane default */

        /* 6. per-device locks and structures */
        mutex_init(&d->lock);
        init_waitqueue_head(&d->wq);
        INIT_WORK(&d->work, my_work_fn);

        /* 7. the interrupt - LAST among resources, because
              from here on the hardware can call into us     */
        d->irq = platform_get_irq(pdev, 0);
        if (d->irq < 0)
                return d->irq;

        ret = devm_request_threaded_irq(dev, d->irq, NULL,
                                        my_thread_fn,
                                        IRQF_ONESHOT,
                                        dev_name(dev), d);
        if (ret)
                return dev_err_probe(dev, ret, "irq %d\n",
                                     d->irq);

        /* 8. stash it so remove() and the fops can find it */
        platform_set_drvdata(pdev, d);
```

```
        /* 9. initialise the hardware */
        ret = my_hw_init(d);
        if (ret)
                return ret;

        /* 10. LAST: expose it to userspace. Nothing before
               this point could be used by anyone, so there is
               no window in which a half-set-up device is
               reachable.                                      */
        ret = misc_register(&d->misc);
        if (ret)
                return ret;

        dev_info(dev, "ready, %u channels\n", d->nr_channels);
        return 0;
}

/* THE TWO ORDERING RULES that matter:
     · acquire resources before enabling anything that can
       generate events
     · register the userspace interface LAST, and unregister
       it FIRST in remove()                                  */
```

`DEV_ERR_PROBE()` IN ONE LINE

It logs the error *with the device name*, records the deferral reason where `/sys/kernel/debug/devices_deferred` can show it, downgrades `-EPROBE_DEFER` to a debug message so your logs are not flooded during normal boot, and returns the error code so you can `return` it directly. Use it for every resource acquisition in probe; there is no reason not to.

Deferred probe, properly understood

```
/* The problem: drivers probe in an order nobody controls, and
   your device needs a clock from a driver that has not loaded.

   The mechanism:

     probe returns -EPROBE_DEFER
        -> the device goes on the DEFERRED LIST
        -> every time ANY driver probes successfully, the
           whole deferred list is retried
        -> eventually the provider appears and you succeed

   So ordering becomes self-organising. No initcall levels, no
   Makefile ordering, no retry loops.                        */

/* WHICH APIs RETURN IT: essentially every resource getter -
   clk_get, regulator_get, gpiod_get, reset_control_get,
   dma_request_chan, phy_get, of_find_i2c_device_by_node...

   JUST PROPAGATE IT. Never swallow it:                     */
        if (IS_ERR(clk))
                return PTR_ERR(clk);     /* right */

        if (IS_ERR(clk)) {
                dev_err(dev, "no clock\n");
                return -ENODEV;          /* WRONG - destroys
                                            the deferral, and
                                            the device never
                                            probes           */
        }

/* WHEN IT NEVER RESOLVES: */
        cat /sys/kernel/debug/devices_deferred
        1c000000.my-device      platform: wait for supplier
                                /soc/clock-controller@1b000000

/* That names both the waiting device and what it waits for.
   If the supplier never appears:
     · its driver is not enabled in the config
     · its DT node is missing or has a typo in `compatible`
     · its own probe is failing - look further up the log

   AND THE END-OF-BOOT REPORT:
        deferred_probe_timeout=10        # cmdline
   After the timeout, remaining deferrals are converted to
   real failures and logged - which turns a silent
   never-probes into a visible error.                       */
```

The device model in sysfs

```
# Every device, by bus:
    ls /sys/bus/platform/devices/
    ls /sys/bus/i2c/devices/

# Every driver, and what it has bound:
    ls /sys/bus/platform/drivers/my-driver/
      bind  unbind  uevent  1c000000.my-device -> ...

# The physical topology:
    ls /sys/devices/platform/soc/1c000000.my-device/
      driver -> ../../../bus/platform/drivers/my-driver
      of_node -> ...
      power/
      uevent
      modalias

# MANUAL BIND AND UNBIND - the most useful debugging tool in
# this chapter:
    echo 1c000000.my-device > \
         /sys/bus/platform/drivers/my-driver/unbind
    echo 1c000000.my-device > \
         /sys/bus/platform/drivers/my-driver/bind

# This re-runs remove() and probe() without unloading the
# module or rebooting. It exercises exactly the paths that
# leak and race, and it is how you test error handling: make
# probe fail, unbind, fix, bind.

# What device tree node produced a device:
    cat /sys/devices/platform/.../of_node/compatible

# Which driver would autoload:
    cat /sys/devices/platform/.../modalias
      of:Nmy-deviceT(null)Cvendor,my-device
# udev matches this against MODULE_DEVICE_TABLE entries.
```

Classes and the userspace view

```
/* A device's place in /sys/devices is its PHYSICAL topology.
   A CLASS gives it a FUNCTIONAL identity:                  */

        /sys/class/net/eth0
        /sys/class/tty/ttyS0
        /sys/class/gpio/
        /sys/class/thermal/thermal_zone0
        /sys/class/misc/my-device

/* Registering with the right class is what makes generic
   userspace tools work with your device. A driver that
   registers as an IIO device gets libiio, a hwmon device gets
   `sensors`, an input device gets evdev - for free.

   THE ADVICE: before writing a character device with a custom
   ioctl interface (chapter 21), check whether a SUBSYSTEM
   already exists for your device class:

        IIO        sensors, ADCs, DACs
        hwmon      temperature, voltage, fan
        input      buttons, touch, keyboards
        rtc        real-time clocks
        watchdog   watchdogs
        pwm, led, gpio, regulator, clk, thermal
        v4l2       video capture
        ALSA       audio
        MTD        raw flash
        crypto     accelerators
        tee        trusted execution (isolation ch. 12)

   Using the right subsystem means: a stable, documented
   userspace ABI you did not have to design; existing tools;
   power management and buffering handled for you; and a much
   easier upstreaming path (chapter 30). Writing a bespoke
   char device for a temperature sensor is the most common
   avoidable mistake in embedded driver work.             */
```

Remove, the mirror image

```
static void my_remove(struct platform_device *pdev)
{
        struct my_dev *d = platform_get_drvdata(pdev);

        /* EXACT REVERSE of probe: */

        /* 1. userspace interface first - no new users */
        misc_deregister(&d->misc);

        /* 2. stop the hardware generating events */
        writel(0, d->base + REG_INT_ENABLE);

        /* 3. wait for anything in flight (chapter 13) */
        cancel_work_sync(&d->work);

        /* 4. quiesce the device */
        my_hw_shutdown(d);

        /* 5. devm_ handles the irq, ioremap, clk and the
              allocation itself - in reverse order,
              automatically                                */

        /* 6. what devm does NOT handle: anything you enabled
              or initialised by hand                       */
        regulator_disable(d->vdd);
}

/* NOTE remove() returns void in modern kernels (6.11+). It
   used to return int, and the return value was ignored
   anyway - because there is no meaningful way to refuse to
   remove a device that is going away.                    */
```

How it shows up

Symptom	Cause
Probe never runs	No matching `compatible`; check the DT node and `of_match_table`
Device in `/sys/bus/platform/devices` with no `driver` link	No driver matched — compare strings character by character
Device not in sysfs at all	DT node has `status = "disabled"`, or is not under a populated bus
Probe runs, returns `-517` forever	Supplier never appears — check `devices_deferred`
Device never probes and nothing is logged	Deferral swallowed and converted to another error
Random crash during boot enumeration	Missing sentinel in the match table
Module does not autoload	Missing `MODULE_DEVICE_TABLE`
Crash on unbind	Teardown order wrong, or missing `_sync` cancellations
Leak across bind/unbind cycles	Something acquired by hand and never released
Userspace sees a half-initialised device	Registered the interface before finishing setup
Wrong variant behaviour on a similar board	Match data not used; hard-coded per-SoC values

Check yourself

- ✓ Describe the bus/device/driver relationship and the core matching loop.
- ✓ Name six sources of devices and which dominates on embedded arm64.
- ✓ Write an `of_match_table` with variant data, and explain the sentinel.
- ✓ Explain what `MODULE_DEVICE_TABLE` enables.
- ✓ Write a probe function in the correct order and justify each step's position.
- ✓ Explain everything `dev_err_probe` does.
- ✓ Explain deferred probe and why swallowing `-EPROBE_DEFER` is fatal.
- ✓ Use `devices_deferred` to diagnose a device that never probes.
- ✓ Use unbind/bind to exercise probe and remove without rebooting.
- ✓ Name six kernel subsystems and say why using one beats a custom char device.

Device tree

A data structure describing hardware that cannot discover itself. It is how one kernel binary runs on a thousand different boards, and writing one correctly is half of embedded Linux bring-up.

Why it exists

```
PCI and USB devices announce themselves: vendor ID, device ID,
BARs, interrupts — all readable from the bus.

An SoC's peripherals do not. There is no way to ask a chip
"is there a UART at 0x1c000000, and which interrupt does it
use?" The answer exists only in the datasheet.

  BEFORE DEVICE TREE: "board files" — C code in
  arch/arm/mach-*/ with static tables per board. By 2011 this
  was tens of thousands of lines of near-duplicate data, one
  kernel per board, and it was famously unsustainable.

  WITH DEVICE TREE: the hardware description is DATA, passed
  to the kernel at boot. One arm64 kernel binary boots
  hundreds of boards — the difference is which .dtb the
  bootloader hands it.

  WHAT BELONGS IN IT:
     what hardware exists, and where
     addresses, interrupts, clocks, resets, regulators
     how blocks connect to one another
     board-specific wiring: which GPIO is the reset line

  WHAT DOES NOT:
     policy or configuration ("enable debug mode")
     anything discoverable at runtime
     driver implementation details
     Linux-specific concepts

  The last point is a real rule with real teeth: device tree
  bindings are an ABI shared with U-Boot, BSD, and other
  kernels. "It is what my driver happens to need" is not a
  justification for a property.
```

Syntax

```
/dts-v1/;

#include <dt-bindings/interrupt-controller/arm-gic.h>
#include <dt-bindings/gpio/gpio.h>

/ {                                   /* the ROOT node */
        model = "Vendor MyBoard v2";
        compatible = "vendor,myboard", "vendor,mysoc";
        #address-cells = <2>;         /* addresses use 2 cells */
        #size-cells = <2>;            /* sizes use 2 cells    */

        chosen {
                stdout-path = "serial0:115200n8";
                bootargs = "console=ttyAMA0 earlycon";
        };

        aliases {
                serial0 = &uart0;
        };

        memory@80000000 {
                device_type = "memory";
                reg = <0x0 0x80000000 0x0 0x40000000>;
        };

        soc {
                compatible = "simple-bus";
                #address-cells = <2>;
                #size-cells = <2>;
                ranges;               /* child addresses ==
                                         parent addresses    */

                uart0: serial@1c000000 {
                        compatible = "arm,pl011", "arm,primecell";
                        reg = <0x0 0x1c000000 0x0 0x1000>;
                        interrupts = <GIC_SPI 5 IRQ_TYPE_LEVEL_HIGH>;
                        clocks = <&uart_clk>, <&apb_clk>;
                        clock-names = "uartclk", "apb_pclk";
                        status = "okay";
                };
        };
};

/* THE PIECES:
     label:            uart0 - a handle for &references
     node@address      the @ part MUST match the first reg
                       entry, or dtc warns
     property = value;
     <>   cells: 32-bit big-endian integers
     ""   strings
     []   raw bytes
     &lbl a phandle - a reference to another node
     ;    every property ends with one                    */
```

#address-cells and #size-cells

```
The single most common source of silent breakage.

  A PARENT declares how many 32-bit cells its CHILDREN use in
  their `reg` properties:

     #address-cells = <1>;  -> a 32-bit address
     #address-cells = <2>;  -> a 64-bit address (two cells)
     #size-cells    = <1>;  -> a 32-bit size
     #size-cells    = <2>;  -> a 64-bit size

  So with #address-cells=2, #size-cells=2:

     reg = <0x0 0x1c000000 0x0 0x1000>;
            \_____________/ \________/
             address, 64-bit  size, 64-bit
             = 0x1c000000     = 0x1000

  and with #address-cells=1, #size-cells=1:

     reg = <0x1c000000 0x1000>;

  GET IT WRONG and the values are parsed as completely
  different numbers. Symptoms: the kernel reports absurd
  memory sizes, ioremap maps the wrong place, or a device gets
  a zero-length resource. NOTHING WARNS at runtime - the data
  is syntactically valid, just meaningless.

  THE RULE: the cells properties on the PARENT govern the
  child's reg. An i2c controller declares
  #address-cells = <1>; #size-cells = <0>; because its
  children have a bus address and no size:

     eeprom@50 { reg = <0x50>; };

  ALWAYS run `make dtbs_check` - it catches most of these.
```

The standard properties

Property	Meaning
`compatible`	What this is, most specific first. The match key.
`reg`	Address and size, per the parent's cells
`interrupts`	Per the interrupt parent's `#interrupt-cells`
`interrupt-parent`	Which controller; inherited if absent
`clocks` / `clock-names`	Clock inputs, by phandle and name
`resets` / `reset-names`	Reset lines
`*-supply`	A regulator, e.g. `vdd-supply = <&reg_1v8>`
`*-gpios`	GPIOs, e.g. `reset-gpios`, with flags
`dmas` / `dma-names`	DMA channels
`status`	`"okay"` or `"disabled"` — disabled nodes create no device
`ranges`	Address translation between a bus and its parent

Property	Meaning
`iommus`	The SMMU and StreamID (isolation ch. 03)
`dma-coherent`	This device's DMA is coherent with the CPU caches
`dma-ranges`	What physical range the device can address
`memory-region`	A reserved-memory carve-out

```
/* COMPATIBLE, most specific first - this is what lets one
   driver serve many parts: */

        compatible = "vendor,mysoc-uart", "arm,pl011",
                     "arm,primecell";

/* The kernel tries each in order. If nobody claims the
   SoC-specific string, the generic pl011 driver matches -
   which is exactly right when the block really is a pl011.

/* NAMING RULES for a new compatible:
        "manufacturer,model"
        lowercase, no underscores
        the manufacturer prefix must be in
        Documentation/devicetree/bindings/vendor-prefixes.yaml
        include a version or SoC name if variants differ:
             "vendor,mysoc-v2-uart"                          */
```

How real device trees are organised

```
# arch/arm64/boot/dts/vendor/

  mysoc.dtsi          the SoC: every peripheral, addresses,
                      interrupts, clocks. status = "disabled"
                      for anything optional.
  mysoc-pinctrl.dtsi  pin configurations
  myboard-common.dtsi shared across a board family
  myboard-v1.dts      one board: which peripherals are wired,
                      which regulators, which GPIOs
  myboard-v2.dts

# A board file INCLUDES the SoC and then OVERRIDES:

/dts-v1/;
#include "mysoc.dtsi"

/ {
        model = "Vendor MyBoard v2";
        compatible = "vendor,myboard-v2", "vendor,mysoc";
};

&uart0 {
        status = "okay";                /* enable it */
        pinctrl-0 = <&uart0_pins>;
        pinctrl-names = "default";
};

&i2c1 {
        status = "okay";
        clock-frequency = <400000>;

        /* a device that only exists on THIS board */
        sensor@48 {
                compatible = "vendor,my-sensor";
                reg = <0x48>;
                interrupt-parent = <&gpio2>;
                interrupts = <7 IRQ_TYPE_EDGE_FALLING>;
                vdd-supply = <&reg_3v3>;
                reset-gpios = <&gpio1 12 GPIO_ACTIVE_LOW>;
                vendor,sample-rate-hz = <100>;
        };
};

# THE PATTERN: the SoC .dtsi describes what the SILICON has,
# all disabled. Each board .dts enables what is actually wired
# and adds what is on the board. That separation is why one
# .dtsi supports dozens of products.
```

Reading properties in a driver

```
/* Prefer the FIRMWARE-AGNOSTIC device_property_* API - it
   works for DT and ACPI alike: */

        u32 val;
        ret = device_property_read_u32(dev, "vendor,fifo-depth",
                                       &val);
        if (ret)
                val = 16;               /* default */

        u32 array[4];
        device_property_read_u32_array(dev, "vendor,thresholds",
                                       array, 4);

        const char *mode;
        device_property_read_string(dev, "vendor,mode", &mode);

        if (device_property_read_bool(dev, "vendor,invert"))
                d->invert = true;
        /* a BOOLEAN in DT is PRESENCE, not a value. Writing
           `vendor,invert = <0>;` still reads as TRUE.      */

        int n = device_property_count_u32(dev, "vendor,list");

/* THE OF-SPECIFIC API, when you need node relationships: */
        struct device_node *np = dev->of_node;
        struct device_node *child;

        for_each_available_child_of_node(np, child) {
                /* iterate sub-nodes - channels, ports, ... */
                of_property_read_u32(child, "reg", &idx);
                ...
                /* of_node_put(child) is handled by the macro
                   on normal exit, but you MUST call it if you
                   break out early:                          */
                if (error) {
                        of_node_put(child);
                        break;
                }
        }

        struct device_node *other;
        other = of_parse_phandle(np, "vendor,partner", 0);
        ...
        of_node_put(other);             /* REFCOUNTED - leaking
                                           these is a real bug */

/* CUSTOM PROPERTY NAMING: always prefix with your vendor
   string. "fifo-depth" may collide with a future standard
   property; "vendor,fifo-depth" cannot.                    */
```

Bindings: the contract

```
# Documentation/devicetree/bindings/.../vendor,my-device.yaml
# A new binding MUST come with the driver, in YAML, and it is
# machine-checked.

%YAML 1.2
---
$id: http://devicetree.org/schemas/misc/vendor,my-device.yaml#
$schema: http://devicetree.org/meta-schemas/core.yaml#

title: Vendor My Device

maintainers:
  - Your Name <you@example.com>

properties:
  compatible:
    enum:
      - vendor,my-device
      - vendor,my-device-v2

  reg:
    maxItems: 1

  interrupts:
    maxItems: 1

  clocks:
    maxItems: 1

  vendor,fifo-depth:
    $ref: /schemas/types.yaml#/definitions/uint32
    enum: [8, 16, 32, 64]
    default: 16
    description: Depth of the hardware FIFO in entries.

required:
  - compatible
  - reg
  - interrupts
  - clocks

additionalProperties: false

examples:
  - |
    device@1c000000 {
        compatible = "vendor,my-device";
        reg = <0x1c000000 0x1000>;
        interrupts = <0 42 4>;
        clocks = <&clk 3>;
        vendor,fifo-depth = <32>;
    };

# CHECK IT:
    make dt_binding_check DT_SCHEMA_FILES=vendor,my-device.yaml
    make dtbs_check                # every dtb against every
                                   # schema - run this
    pip install dtschema           # needed for the above
```

> **A BINDING IS A PERMANENT ABI**
> Once a device tree using your property ships in a product or a bootloader, you cannot change its meaning. Old device trees must keep working with new kernels — that is why `dtbs_check` exists and why maintainers review bindings more carefully than driver code. Design the properties before you write the driver, not after.

Inspecting and debugging

```
# The live tree, as the running kernel sees it:
    ls /proc/device-tree/
    cat /proc/device-tree/model
    hexdump -C /proc/device-tree/soc/serial@1c000000/reg
    # or, much better:
    dtc -I fs -O dts /proc/device-tree > live.dts

# Compile and decompile:
    dtc -I dts -O dtb -o my.dtb my.dts
    dtc -I dtb -O dts my.dtb > readable.dts   # what ACTUALLY
                                              # got built,
                                              # after includes
# ALWAYS decompile after building. The result of #include and
# override chains is frequently not what you intended, and
# reading the flattened output takes ten seconds.

# Preprocess only, to debug an include problem:
    cpp -nostdinc -I include -undef -x assembler-with-cpp \
        my.dts | less

# Which devices exist and what bound:
    ls /sys/firmware/devicetree/base/
    ls /sys/bus/platform/devices/
    cat /sys/kernel/debug/devices_deferred

# OVERLAYS - patch the tree at runtime, for add-on boards:
    /dts-v1/;
    /plugin/;
    &{/soc/i2c@1c001000} {
            sensor@48 { compatible = "vendor,my-sensor";
                        reg = <0x48>; };
    };
    dtc -@ -I dts -O dtb -o overlay.dtbo overlay.dts
    # applied by the bootloader, or via configfs where
    # CONFIG_OF_OVERLAY and a suitable interface exist
```

How it shows up

Symptom	Cause
Device does not appear at all	`status = "disabled"`, or the node is not under a populated bus
Driver never probes	`compatible` string mismatch — compare exactly
Absurd memory size, or ioremap of the wrong address	`#address-cells` / `#size-cells` mismatch
Resource has size 0	Same cause, in the `reg` parse
Interrupt never fires	Wrong cell count, wrong trigger, or the SPI off-by-32 (ch. 14)
Boolean property has no effect	Presence is truth — `= <0>` is still true

Symptom	Cause
Your override did not apply	Label out of scope, or the include order puts the SoC file after it — decompile and look
Node refcount leak warnings	Missing `of_node_put()` on an early `break`
Works on one board revision, not another	Board-specific wiring in the shared `.dtsi`
`dtbs_check` failures	The binding and the DT disagree — one of them is wrong
New kernel breaks an old board	A binding was changed incompatibly

Check yourself

- ✓ Explain why device tree exists and what belongs in it versus what does not.
- ✓ Write a node with `compatible`, `reg`, `interrupts` and `clocks`.
- ✓ Explain `#address-cells`/`#size-cells` and decode a `reg` under each setting.
- ✓ Explain why `compatible` lists several strings and how the fallback works.
- ✓ Describe the SoC `.dtsi` / board `.dts` split and why it scales.
- ✓ Read four kinds of property in a driver and handle a missing one.
- ✓ Explain the boolean-property trap.
- ✓ Write a YAML binding and validate it with `dt_binding_check`.
- ✓ Decompile a built dtb and confirm your overrides applied.
- ✓ Say why a binding is an ABI and what that constrains.

Writing a platform driver

Everything from the last two chapters, assembled into one complete, correct driver. This is the skeleton you will start from every time — read it once carefully and you have the shape of most of `drivers/`.

What a platform device is

```
/* A device that is NOT on a discoverable bus. It exists
   because the device tree says so.

     · memory-mapped registers at a fixed address
     · one or more interrupts
     · clocks, resets, regulators, GPIOs, DMA channels
     · no vendor/product ID to enumerate

   That describes most of an SoC: UARTs, timers, watchdogs,
   crypto engines, DMA controllers, display pipelines, custom
   accelerators.

   IF YOUR DEVICE IS ON I2C, SPI OR PCI, use that bus's driver
   type instead - i2c_driver, spi_driver, pci_driver. The
   shape is identical; only the resource acquisition and the
   register access differ.                                  */
```

The complete driver

```
// SPDX-License-Identifier: GPL-2.0
/*
 * Vendor MyDevice driver
 *
 * Locking:
 *      d->lock protects d->state and the register block.
 *      Never held across a sleep other than the regmap I/O
 *      it wraps.
 */

READ THE ERROR PATH

The `goto` ladder unwinds in exactly the reverse order of setup, each label undoing one step. This is idiomatic kernel C, not a code smell — it is the only structure that stays correct when you add a step in the middle. Chapter 26 shows how `devm_` removes most of it, and why some of it always remains.

Acquiring the common resources

```
/* --- MMIO ----------------------------------------------- */
        d->base = devm_platform_ioremap_resource(pdev, 0);
        /* by name, better when there are several: */
        d->base = devm_platform_ioremap_resource_byname(pdev,
                                                        "ctrl");
        /* the long form, if you need the resource itself: */
        struct resource *res;
        res = platform_get_resource(pdev, IORESOURCE_MEM, 0);
        d->base = devm_ioremap_resource(dev, res);
        d->phys = res->start;

/* --- CLOCKS --------------------------------------------- */
        d->clk = devm_clk_get(dev, "core");     /* by name */
        d->clk = devm_clk_get(dev, NULL);       /* the only one */
        clk_prepare_enable(d->clk);
        clk_disable_unprepare(d->clk);

        /* the modern one-liner - gets AND enables, and
           disables automatically on unbind: */
        d->clk = devm_clk_get_enabled(dev, "core");

        /* several at once: */
        struct clk_bulk_data clks[] = {
                { .id = "core" }, { .id = "bus" },
        };
        devm_clk_bulk_get(dev, ARRAY_SIZE(clks), clks);
        clk_bulk_prepare_enable(ARRAY_SIZE(clks), clks);

        rate = clk_get_rate(d->clk);
        clk_set_rate(d->clk, 100000000);

/* --- OPTIONAL resources: use the _optional variants ------ */
        d->rst = devm_reset_control_get_optional_exclusive(dev,
                                                           NULL);
        /* returns NULL, not an error, if absent - and the
           reset_control_* calls accept NULL harmlessly. So
           optional resources need no `if` at every use.    */

        d->gpio = devm_gpiod_get_optional(dev, "reset",
                                          GPIOD_OUT_HIGH);
        gpiod_set_value_cansleep(d->gpio, 0);

/* --- REGULATORS ----------------------------------------- */
        d->vdd = devm_regulator_get(dev, "vdd");
        regulator_enable(d->vdd);
        /* several: */
        devm_regulator_bulk_get(dev, n, supplies);

/* --- DMA channels (chapter 24) -------------------------- */
        d->rxchan = dma_request_chan(dev, "rx");
        if (IS_ERR(d->rxchan))
                return dev_err_probe(dev, PTR_ERR(d->rxchan),
                                     "no rx dma\n");
```

Power-on ordering

```
Hardware has a sequence, and the datasheet's timing diagram is
the specification. The usual shape:

   1. REGULATORS on          (the device has power)
   2. wait the specified settling time
   3. CLOCKS enabled         (it has a clock to run on)
   4. RESET deasserted       (it starts)
   5. wait for it to be ready
   6. verify the ID register
   7. configure
   8. enable interrupts LAST

  AND EXACTLY THE REVERSE ON THE WAY DOWN.

  GETTING IT WRONG produces some of the most confusing
  symptoms in embedded work:

    reset released before the clock runs
        -> the block latches garbage; often works at room
           temperature and fails cold
    register written before power is stable
        -> the write is lost, silently
    clock enabled before the regulator
        -> in-rush current, a brownout, or a latch-up
    interrupts enabled before the handler is registered
        -> "nobody cared", or a crash in an unregistered
           handler
    no settling delay
        -> intermittent, temperature- and part-dependent

  READ THE POWER-UP SEQUENCE in the datasheet and implement it
  literally, including the delays. This is one of the few
  places in software where "it works on my board" is
  genuinely not evidence of correctness.
```

Testing it

```
# 1. Does it bind?
    dmesg | grep my-device
    ls -l /sys/bus/platform/drivers/my-device/

# 2. Are the registers reachable?
    dmesg      # the ID check tells you immediately

# 3. Does probe fail cleanly?
#    Force each failure and confirm no leak and no crash:
#      - remove the clock from the DT
#      - point reg at a wrong address
#      - make the ID check fail
#    Each should log one clear error and unwind fully.

# 4. Unbind and rebind, repeatedly, under KASAN:
    for i in $(seq 50); do
      echo 1c000000.my-device > .../my-device/unbind
      echo 1c000000.my-device > .../my-device/bind
    done
    dmesg | grep -i -e kasan -e warn -e bug

# 5. Load and unload as a module, 100 times (chapter 15).

# 6. Check for leaked resources after unbind:
    cat /proc/iomem | grep 1c000000     # should be gone
    cat /proc/interrupts | grep my-device
    cat /proc/vmallocinfo | grep my_probe

# ALL FIVE of these find real bugs in code that "works".
```

How it shows up

Symptom	Cause
Probe never called	Compatible mismatch, or `status = "disabled"`
ID register reads 0 or 0xFFFFFFFF	Clock off, in reset, wrong address, or an access-control denial
`devm_platform_ioremap_resource` fails with `-EBUSY`	Another driver already claimed the region — check `/proc/iomem`
Probe returns `-517` repeatedly	Deferred on a supplier — check `devices_deferred`
Works cold, fails warm (or the reverse)	Missing settling delay in the power-up sequence
Interrupt storm at probe	Interrupts enabled before the handler was registered
Crash on unbind	Hardware not quiesced before `devm` freed the IRQ
Resources leak across bind cycles	Something enabled by hand and not disabled in remove
Second probe fails after a successful unbind	State left in the hardware, or a regulator refcount imbalance
Works on v1 silicon, wrong on v2	Match data not used — values hard-coded
Optional resource treated as fatal	Used the non-`_optional` getter

Check yourself

- ✓ Say what makes a device a platform device, and when to use another bus type.
- ✓ Write a complete driver from memory: match table, probe, remove, module boilerplate.

- ✓ Explain why the error path is a `goto` ladder in reverse order.
- ✓ Acquire MMIO, clocks, resets, regulators and GPIOs, using the optional variants correctly.
- ✓ Explain what `devm_clk_get_enabled` saves you.
- ✓ Give the power-on ordering and four symptoms of getting it wrong.
- ✓ Explain why an ID-register check belongs in probe.
- ✓ Explain why interrupts are requested last and quiesced first.
- ✓ Use match data to support two silicon variants with one driver.
- ✓ Run all five tests and fix what they find.

Character devices

How a driver becomes a file in `/dev`. Major and minor numbers, the `file_operations` table, and the per-open state that makes concurrent users work — plus the much simpler misc-device shortcut that is right most of the time.

Major, minor, and the node

```
 $ ls -l /dev/mydev
 crw-rw----  1 root root  241, 0  Jan  1 00:00 /dev/mydev
 ^                         ^^^  ^
 |                         major minor
 character device

MAJOR   which driver
MINOR   which instance of it

A driver claims a range of (major, minor) pairs; the kernel
routes open() on a matching node to that driver.

dev_t packs both into one 32-bit value:
   MAJOR(dev), MINOR(dev), MKDEV(major, minor)

THREE WAYS TO GET THE NODE INTO /dev:

 1. udev/devtmpfs, automatically. The kernel creates the
    node when you call device_create(). THIS IS WHAT YOU
    WANT - no mknod, correct permissions, and it disappears
    on unbind.

 2. mknod by hand - for a minimal initramfs with no udev:
       mknod /dev/mydev c 241 0

 3. A misc device: major 10, a dynamically assigned minor,
    node created for you. Simplest of all.
```

The misc device: start here

```
/* If you need ONE device node and no special numbering, this
   is 15 lines instead of 60, and it is what most simple
   drivers should use.                                        */

#include <linux/miscdevice.h>

static const struct file_operations mydev_fops = {
        .owner          = THIS_MODULE,
        .open           = mydev_open,
        .release        = mydev_release,
        .read           = mydev_read,
        .write          = mydev_write,
        .unlocked_ioctl = mydev_ioctl,
        .compat_ioctl   = compat_ptr_ioctl,
        .poll           = mydev_poll,
        .llseek         = no_llseek,
};

/* RETURN CONVENTIONS - getting these wrong breaks userspace
   in ways that look like your hardware is faulty:

     > 0     bytes transferred. May be LESS than requested;
             a correct caller loops.
     0       end of file. For a device this usually means
             "no more data, ever" - do not return it for
             "nothing right now" (that is -EAGAIN).
     -EAGAIN nothing available, and O_NONBLOCK was set
     -EINTR / -ERESTARTSYS   interrupted before any progress
     -EFAULT bad user pointer
     -EINVAL bad arguments

   AND: never return more than `count`. Userspace sized the
   buffer.                                                  */
```

poll: making select() work

```
static __poll_t mydev_poll(struct file *file,
                           struct poll_table_struct *wait)
{
        struct mydev_session *s = file->private_data;
        struct mydev *d = s->dev;
        __poll_t mask = 0;

        /* register interest - does NOT sleep. It adds this
           task to the wait queue so a later wake_up() will
           notify poll().                                    */
        poll_wait(file, &d->wq, wait);

        if (d->done)
                mask |= EPOLLIN | EPOLLRDNORM;   /* readable */

        if (mydev_space_available(d))
                mask |= EPOLLOUT | EPOLLWRNORM;  /* writable */

        if (d->error)
                mask |= EPOLLERR;

        return mask;
}

/* THE CONTRACT:
     · poll_wait() first, ALWAYS, before checking anything.
       Checking first and registering after loses events - the
       same lost-wakeup race as chapter 09.
     · poll() must not block.
     · every wake_up() that changes readability must be on the
       queue you passed to poll_wait().

   WITHOUT .poll, select(), poll() and epoll() report your fd
   as always-ready, and a userspace event loop spins at 100%
   CPU. This is not optional for any device a program will
   wait on.                                                  */
```

PER-DEVICE STATE VERSUS PER-OPEN STATE

The `struct mydev` is the hardware — one per physical device, shared by every user. The session in `file->private_data` is per file descriptor: read position, subscribed events, requested mode. Putting a per-user value in the device struct means two programs silently corrupt each other's view, and it is the most common design bug in character drivers.

Permissions and access control

```
/* By default your node is root-only. Real products need
   something better than "run everything as root".          */

/* 1. A udev rule - the normal answer:
     /etc/udev/rules.d/99-mydev.rules                       */
        KERNEL=="mydev", MODE="0660", GROUP="mydev"
        SUBSYSTEM=="mydev", TAG+="uaccess"   /* the logged-in
                                                user          */

/* 2. Set the mode from the driver, via the class: */
static char *mydev_devnode(const struct device *dev,
                           umode_t *mode)
{
        if (mode)
                *mode = 0660;
        return NULL;
}
        mydev_class->devnode = mydev_devnode;

/* 3. Capability checks inside a specific operation: */
        if (!capable(CAP_SYS_RAWIO))
                return -EPERM;
/* Use the most specific capability that fits, not
   CAP_SYS_ADMIN, which is effectively root.                */

/* 4. Check the open mode for write operations: */
        if (!(file->f_mode & FMODE_WRITE))
                return -EBADF;
/* Important for ioctls: a file opened O_RDONLY can still
   issue any ioctl unless you check. A "set configuration"
   ioctl reachable from a read-only fd is a real privilege
   bug.                                                     */
```

Testing from userspace

```
#include <fcntl.h>
#include <poll.h>
#include <stdint.h>
#include <stdio.h>
#include <unistd.h>

int main(void)
{
        struct pollfd pfd;
        uint32_t sample;
        int fd;

        fd = open("/dev/mydev", O_RDWR);
        if (fd < 0) { perror("open"); return 1; }

        pfd.fd = fd;
        pfd.events = POLLIN;

        for (;;) {
                int ret = poll(&pfd, 1, 1000);
                if (ret < 0)  { perror("poll"); break; }
                if (ret == 0) { printf("timeout\n"); continue; }

                if (read(fd, &sample, sizeof(sample)) < 0) {
                        perror("read");
                        break;
                }
                printf("sample: %u\n", sample);
        }

        close(fd);
        return 0;
}
```

```
# Quick checks without writing a program:
    cat /dev/mydev | hexdump -C
    echo -ne '\x01\x00\x00\x00' > /dev/mydev
    dd if=/dev/mydev bs=4 count=10 | xxd

# Does poll work, or does it spin?
    strace -e poll,read ./mytest
    # A correct driver blocks in poll. A broken one returns
    # immediately, forever.

# Confirm the node and its numbers:
    ls -l /dev/mydev
    cat /proc/devices | grep mydev
    ls /sys/class/mydev/
```

How it shows up

Symptom	Cause
`/dev/mydev` does not appear	`device_create` not called, or no devtmpfs/udev
`open` returns `-ENODEV`	Node exists with numbers no driver claims — stale `mknod`

Symptom	Cause
`open` returns `-EPERM`	Node permissions — add a udev rule
Crash on the first `open`	`cdev_add` called before the state it uses was initialised
Two programs corrupt each other	Per-open state kept in the device struct
`select` / `poll` spins at 100% CPU	No `.poll` handler, or it does not call `poll_wait`
Events missed under load	`poll_wait` called after checking the condition
`read` returns 0 and the program exits	Returned EOF instead of `-EAGAIN`
Program hangs, unkillable	Uninterruptible wait (ch. 09)
`rmmod` says busy while an fd is open	Correct — `.owner = THIS_MODULE` working
Crash after `rmmod` with an fd open	`.owner` not set
Read-only fd can change configuration	`f_mode` not checked in the ioctl

Check yourself

- ✓ Explain major and minor numbers and the three ways a node appears in `/dev`.
- ✓ Register a misc device and recover your device struct from a file operation.
- ✓ Use the full cdev interface for four minors, with correct init and teardown order.
- ✓ Explain why `cdev_add` is the point of no return.
- ✓ Write `open`, `release`, `read` and `write` with correct return values.
- ✓ Distinguish per-device from per-open state and say what breaks if you confuse them.
- ✓ Write a `poll` handler and explain the ordering requirement.
- ✓ Handle `O_NONBLOCK` correctly.
- ✓ Set node permissions three different ways.
- ✓ Explain why an ioctl must check `f_mode`.

Designing an ioctl interface

read() and write() move bytes. An ioctl is everything else — configure, query, control — and because it becomes part of the user-facing ABI the moment it ships, it deserves more care than any other part of a driver.

Encoding a request number

```
#include <linux/ioctl.h>

/* NEVER a bare integer. The encoding macros pack DIRECTION,
   SIZE and TYPE into the number, which is what lets the
   kernel validate calls generically and what lets tools like
   strace decode them without your driver's headers.        */

#define MYDEV_MAGIC  'k'                /* pick something
                                           unused - see
                                           Documentation/
                                           userspace-api/
                                           ioctl/ioctl-number.rst */

struct mydev_config {
        __u32  sample_rate_hz;
        __u32  channel_mask;
        __u8   gain;
        __u8   _pad[3];                 /* EXPLICIT padding -
                                           see below           */
};

#define MYDEV_GET_CONFIG   _IOR(MYDEV_MAGIC, 1, struct mydev_config)
#define MYDEV_SET_CONFIG   _IOW(MYDEV_MAGIC, 2, struct mydev_config)
#define MYDEV_RESET        _IO (MYDEV_MAGIC, 3)
#define MYDEV_XFER         _IOWR(MYDEV_MAGIC, 4, struct mydev_xfer)

/* _IO    no data transferred
   _IOR   kernel -> user  (a "get")
   _IOW   user -> kernel  (a "set")
   _IOWR  both

   These are NAMES for humans; nothing enforces that _IOR
   actually only reads. But get it right anyway - strace and
   generic ioctl tracers use it to know which direction to
   dump.                                                    */
```

THE STRUCT IS A PERMANENT ABI

Once a binary in the field calls `MYDEV_SET_CONFIG` with this struct layout, that layout is frozen forever. Pad explicitly — never rely on the compiler's implicit padding, which can differ between 32-bit and 64-bit builds of the *same* struct. Use fixed-width types (`__u32`, not `int` or `unsigned long`) so the size does not change with the architecture. And leave room: reserved fields cost nothing today and save you from ever needing `MYDEV_SET_CONFIG_V2`.

The handler

```
static long mydev_ioctl(struct file *file, unsigned int cmd,
                        unsigned long arg)
{
        struct mydev_session *s = file->private_data;
        struct mydev *d = s->dev;
        void __user *uarg = (void __user *)arg;
        struct mydev_config cfg;
        int ret;

        switch (cmd) {
        case MYDEV_GET_CONFIG:
                mutex_lock(&d->lock);
                cfg = d->config;
                mutex_unlock(&d->lock);

                if (copy_to_user(uarg, &cfg, sizeof(cfg)))
                        return -EFAULT;
                return 0;

        case MYDEV_SET_CONFIG:
                if (!(file->f_mode & FMODE_WRITE))
                        return -EBADF;    /* a read-only fd may
                                             not configure it   */

                if (copy_from_user(&cfg, uarg, sizeof(cfg)))
                        return -EFAULT;

                /* VALIDATE EVERYTHING. This struct came from
                   userspace and userspace is the attacker.   */
                if (cfg.sample_rate_hz == 0 ||
                    cfg.sample_rate_hz > MYDEV_MAX_RATE)
                        return -EINVAL;
                if (cfg.channel_mask & ~MYDEV_VALID_CHANNELS)
                        return -EINVAL;
                if (cfg.gain > MYDEV_MAX_GAIN)
                        return -EINVAL;

                mutex_lock(&d->lock);
                ret = mydev_apply_config(d, &cfg);
                if (!ret)
                        d->config = cfg;
                mutex_unlock(&d->lock);
                return ret;

        case MYDEV_RESET:
                if (!(file->f_mode & FMODE_WRITE))
                        return -EBADF;
                return mydev_hw_reset(d);

        default:
                return -ENOTTY;          /* THE conventional
                                            "no such ioctl",
                                            not -EINVAL       */
        }
}
```

FIVE RULES, IN ORDER OF HOW OFTEN THEY ARE VIOLATED

1. **Validate every field.** Range, mask, size — the struct crossed a trust boundary.
2. **Check** `f_mode` for anything that changes state.
3. **Use** `copy_to_user` **/** `copy_from_user`**, never a direct dereference** of a user pointer (chapter 08).
4. **Return** `-ENOTTY` **for an unknown command**, so a program can probe for support.
5. **Never trust a size or count field to bound a copy** without an upper limit check first — that is a remotely-triggered `kmalloc(attacker_controlled)`.

Variable-length transfers

```
/* A common and commonly wrong pattern: a struct that carries a
   pointer and a count, for a buffer of user-chosen size.    */

struct mydev_xfer {
        __u64  buf;              /* NOT a pointer type - see
                                    below */
        __u32  len;
        __u32  flags;
};

static long mydev_xfer_ioctl(struct mydev *d, unsigned long arg)
{
        struct mydev_xfer x;
        void __user *ubuf;
        void *kbuf;
        int ret;

        if (copy_from_user(&x, (void __user *)arg, sizeof(x)))
                return -EFAULT;

        /* BOUND IT before allocating. Without this, a
           malicious len of 0xFFFFFFFF either fails an
           allocation harmlessly, or - on a kernel without
           kmalloc's internal limits - is a resource
           exhaustion vector. Always cap explicitly.        */
        if (x.len == 0 || x.len > MYDEV_MAX_XFER)
                return -EINVAL;

        kbuf = kmalloc(x.len, GFP_KERNEL);
        if (!kbuf)
                return -ENOMEM;

        ubuf = u64_to_user_ptr(x.buf);   /* the CORRECT cast -
                                            see below          */

        if (x.flags & MYDEV_XFER_WRITE) {
                if (copy_from_user(kbuf, ubuf, x.len)) {
                        ret = -EFAULT;
                        goto out;
                }
                ret = mydev_hw_write(d, kbuf, x.len);
        } else {
                ret = mydev_hw_read(d, kbuf, x.len);
                if (!ret && copy_to_user(ubuf, kbuf, x.len))
                        ret = -EFAULT;
        }

out:
        kfree(kbuf);
        return ret;
}

/* WHY __u64 buf, not a pointer field:

   A struct with a real pointer member has a DIFFERENT SIZE
   and LAYOUT on a 32-bit process running on a 64-bit kernel
   (compat mode) versus a native 64-bit process. __u64 is the
   same size everywhere, and u64_to_user_ptr() does the
   sign-correct, warning-free cast:
```

```
        #define u64_to_user_ptr(x) ( \
                (void __user *)(uintptr_t)(x) )

   This single choice is what saves you from writing a
   .compat_ioctl handler at all (see below).               */
```

32-bit compatibility

```
/* If a 32-bit binary can ever run on this kernel - and on
   arm64 that is common - a struct containing a real pointer
   or a `long` has a DIFFERENT layout when called from that
   32-bit process. Without a compat handler, SET_CONFIG from a
   32-bit program corrupts the kernel's read of the struct.  */

static const struct file_operations mydev_fops = {
        .unlocked_ioctl = mydev_ioctl,
        .compat_ioctl   = compat_ptr_ioctl,   /* the escape
                                                 hatch, below */
};

/* compat_ptr_ioctl() is a generic helper that works AS LONG
   AS your structs contain no raw pointers or `long` fields -
   exactly the discipline the __u64/__u32-only design above
   already gives you. It converts the compat pointer and calls
   your normal handler. No second implementation needed.

/* If you cannot avoid a pointer-shaped field (rare, and
   usually a sign to redesign), you need a REAL compat
   handler with a parallel struct and explicit translation.
   Avoid that path; it doubles your maintenance burden and is
   a frequent source of security bugs in real drivers.       */
```

Consider not using ioctl at all

Need	Better than a custom ioctl
A simple scalar setting	A sysfs attribute (chapter 22) — discoverable, self-documenting, one `cat` / `echo`
Streaming samples	`read()`, or a subsystem with its own buffering (IIO, V4L2)
Asynchronous events	`poll()` plus `read()`, or `uevent`
A sensor, ADC, DAC	The IIO subsystem — a whole ABI already exists
Temperature, voltage, fan	hwmon
A structured, extensible protocol	Netlink — versioned, introspectable, used by real subsystems
Something genuinely device-specific and complex	ioctl — the right tool, sometimes

An ioctl interface is invisible to generic tools, undiscoverable without your header, and — once shipped — permanent. Every one of the alternatives above is inspectable with tools that already exist. Reach for ioctl last, after checking whether a subsystem already solves your problem (chapter 17).

Shipping the header

```
/* include/uapi/linux/mydev.h - the UAPI header, shared
   VERBATIM between the kernel and any userspace program.   */

#ifndef _UAPI_LINUX_MYDEV_H
#define _UAPI_LINUX_MYDEV_H

#include <linux/types.h>
#include <linux/ioctl.h>

struct mydev_config {
        __u32 sample_rate_hz;
        __u32 channel_mask;
        __u8  gain;
        __u8  reserved[3];       /* MUST be zeroed by callers;
                                    reserved for future use   */
};

#define MYDEV_MAGIC        'k'
#define MYDEV_GET_CONFIG   _IOR(MYDEV_MAGIC, 1, struct mydev_config)
#define MYDEV_SET_CONFIG   _IOW(MYDEV_MAGIC, 2, struct mydev_config)
#define MYDEV_RESET        _IO (MYDEV_MAGIC, 3)

#endif

/* RULES for this file specifically:
     · __u8/__u16/__u32/__u64 only - never int, long, size_t
     · no kernel-only types (struct list_head, spinlock_t...)
     · no #ifdef __KERNEL__ tricks to hide fields - one struct,
       one meaning, for both sides
     · never remove or renumber an ioctl or a struct field
     · a NEW, incompatible need gets a NEW number - never
       redefine an existing one

   This header is literally installed into
   /usr/include/linux/mydev.h on end systems and copied into
   the musl/glibc UAPI headers. Programs compile against it
   for years after you have forgotten it exists.             */
```

Testing an ioctl

```
#include <fcntl.h>
#include <stdio.h>
#include <string.h>
#include <sys/ioctl.h>
#include <unistd.h>
#include <linux/mydev.h>

int main(void)
{
        int fd = open("/dev/mydev", O_RDWR);
        struct mydev_config cfg;

        if (ioctl(fd, MYDEV_GET_CONFIG, &cfg) < 0) {
                perror("GET_CONFIG");
                return 1;
        }
        printf("rate=%u mask=0x%x gain=%u\n",
               cfg.sample_rate_hz, cfg.channel_mask, cfg.gain);

        cfg.sample_rate_hz = 48000;
        if (ioctl(fd, MYDEV_SET_CONFIG, &cfg) < 0)
                perror("SET_CONFIG");        /* expect -EINVAL
                                                cases to work
                                                too - test them*/

        close(fd);
        return 0;
}
```

```
# strace decodes the direction/size/type automatically once it
# has your header or a matching ioctl.rst entry:
    strace -e ioctl ./mytest
      ioctl(3, MYDEV_GET_CONFIG or _IOC(_IOC_READ, 0x6b, 1, 8), ...) = 0

# NEGATIVE TESTS - the ones that actually find bugs:
    · call with a NULL pointer                -> -EFAULT
    · call with an unmapped pointer           -> -EFAULT
    · call an unknown command number          -> -ENOTTY
    · SET_CONFIG on an O_RDONLY fd             -> -EBADF
    · out-of-range fields                     -> -EINVAL
    · a huge `len` in a variable transfer     -> -EINVAL,
                                                  not a hang
    · call from a 32-bit binary, if supported  -> matches
                                                  64-bit result

# Fuzz it - genuinely effective on ioctl handlers:
    syzkaller, or a simple harness with
    CONFIG_KCOV + CONFIG_KASAN, feeding random cmd/arg pairs
    at your fd. This finds the missing validation checks that
    manual testing never will.                          */
```

How it shows up

Symptom	Cause
Works on x86 host, corrupts on the arm64 target	Implicit struct padding differs — pad explicitly

Symptom	Cause
Works as a 64-bit binary, garbage from a 32-bit one	Missing `.compat_ioctl`, or a pointer/`long` field in the struct
Kernel crash from a userspace ioctl call	Unvalidated length used to size an allocation or copy — a real vulnerability
`-EFAULT` on every call	Direct pointer dereference instead of `copy_to/from_user`
Read-only fd can reconfigure the device	`f_mode` not checked
Unknown ioctl returns `-EINVAL`	Should be `-ENOTTY` — breaks capability probing
A future kernel breaks an old binary	A struct field was reused or renumbered instead of extended
`strace` shows garbage for the ioctl name	Number not registered in `ioctl-number.rst`, or magic collides with another driver
Huge allocation from a small request	Length field trusted without an upper bound

Check yourself

- ✓ Encode a request number with `_IOR` / `_IOW` / `_IOWR` and explain each field.
- ✓ Explain why the struct is a permanent ABI and what explicit padding buys you.
- ✓ Write an ioctl handler that validates every field of an incoming struct.
- ✓ Explain why an unknown command returns `-ENOTTY`, not `-EINVAL`.
- ✓ Design a variable-length transfer struct that needs no `.compat_ioctl` of its own.
- ✓ Explain why a pointer field breaks 32-bit compatibility and how `__u64` avoids it.
- ✓ List five subsystems to check before writing a custom ioctl interface.
- ✓ Write a correct UAPI header and state its permanence rules.
- ✓ List six negative tests every ioctl handler should pass.

sysfs, debugfs and procfs

Three filesystems that expose kernel state as files. They look interchangeable and are not: one is a permanent ABI, one is a debugging free-for-all, and one you should not add to at all.

Which is which

	sysfs	debugfs	procfs
Mounted at	`/sys`	`/sys/kernel/debug`	`/proc`
Stability	**Permanent ABI**	**None** — change freely	Permanent for what exists
Rule	**One value per file**	Anything you like	Historical mess
Available in production	Yes	Usually not mounted	Yes
Documented in	`Documentation/ABI/`	Nowhere required	—
Use for	Configuration and status userspace depends on	Development, diagnostics, dumps	**Do not add new files**

THE DECISION

If a program will depend on it, it goes in **sysfs**, one value per file, with an entry in `Documentation/ABI/`. If it is for you and your colleagues while debugging, it goes in **debugfs**, where you can restructure it tomorrow. Nothing new goes in **procfs** — it predates both and is reserved for process information.

sysfs attributes

```
#include <linux/sysfs.h>
#include <linux/device.h>

/* --- a read-only attribute ------------------------------- */
static ssize_t temperature_show(struct device *dev,
                                struct device_attribute *attr,
                                char *buf)
{
        struct mydev *d = dev_get_drvdata(dev);
        int milli_c;

        milli_c = mydev_read_temp(d);

        /* sysfs_emit() is the correct helper: it knows the
           buffer is one PAGE and bounds the write for you.
           Use it, not sprintf.                              */
        return sysfs_emit(buf, "%d\n", milli_c);
}
static DEVICE_ATTR_RO(temperature);
        /* creates: struct device_attribute dev_attr_temperature
           with .show = temperature_show, mode 0444          */

/* --- a read/write attribute ------------------------------ */
static ssize_t gain_show(struct device *dev,
                         struct device_attribute *attr, char *buf)
{
        struct mydev *d = dev_get_drvdata(dev);

        return sysfs_emit(buf, "%u\n", d->gain);
}

static ssize_t gain_store(struct device *dev,
                          struct device_attribute *attr,
                          const char *buf, size_t count)
{
        struct mydev *d = dev_get_drvdata(dev);
        unsigned int val;
        int ret;

        ret = kstrtouint(buf, 0, &val);   /* base 0: accepts
                                             decimal AND 0x   */
        if (ret)
                return ret;

        if (val > MYDEV_MAX_GAIN)
                return -EINVAL;

        mutex_lock(&d->lock);
        ret = mydev_set_gain(d, val);
        mutex_unlock(&d->lock);
        if (ret)
                return ret;

        return count;         /* RETURN count ON SUCCESS.
                                 Returning 0 makes the writing
                                 program loop forever, because
                                 it thinks nothing was
                                 consumed.                  */
}
static DEVICE_ATTR_RW(gain);
```

```
/* --- grouping and registering ---------------------------- */
static struct attribute *mydev_attrs[] = {
        &dev_attr_temperature.attr,
        &dev_attr_gain.attr,
        NULL,                           /* sentinel */
};
ATTRIBUTE_GROUPS(mydev);        /* -> mydev_groups */

static struct platform_driver mydev_driver = {
        .driver = {
                .name = "my-device",
                .dev_groups = mydev_groups,   /* <-- the core
                                                 creates and
                                                 removes them
                                                 around probe */
                ...
        },
        ...
};

/* USING dev_groups is much better than device_create_file()
   in probe: the attributes exist BEFORE probe returns and are
   removed AFTER remove, so there is no window where userspace
   can see a file backed by a half-initialised device - and no
   cleanup for you to forget.                                  */
```

The sysfs rules

```
/* These are enforced in review, and for good reasons: */

   1. ONE VALUE PER FILE.
        good:  /sys/.../temperature       "42000\n"
        bad:   /sys/.../status            "temp=42 gain=3 ok"
      A multi-value file cannot be parsed reliably, cannot be
      extended without breaking parsers, and cannot be watched
      with poll() per-value.

   2. TEXT, human readable, with a trailing newline.

   3. USE THE STANDARD UNITS. The sysfs convention is
      milli-units: millivolts, millidegrees, milliamps. Not
      degrees, not raw ADC counts. Userspace tools assume it.

   4. NO ACTIONS WITH SIDE EFFECTS beyond the obvious. A file
      called `gain` sets the gain. A file that reprograms the
      firmware when you write "1" to it is a surprise and
      belongs elsewhere.

   5. DOCUMENT IT in Documentation/ABI/testing/sysfs-...
      before it becomes stable:

        What:           /sys/bus/platform/devices/*/gain
        Date:           March 2026
        KernelVersion:  6.14
        Contact:        you@example.com
        Description:
                        Amplifier gain, 0-15. Writing a value
                        outside that range returns -EINVAL.

   6. RETURN count FROM store(), or a negative error. Never 0.

   7. THE BUFFER IN show() IS ONE PAGE. sysfs_emit() enforces
      it; sprintf does not.                                  */
```

Making a sysfs file pollable

```
/* An attribute can notify userspace of a change, so a program
   can wait on it rather than polling in a loop.            */

        /* when the value changes, in your driver: */
        sysfs_notify(&dev->kobj, NULL, "alarm");

/* userspace: */
        fd = open("/sys/.../alarm", O_RDONLY);
        read(fd, buf, sizeof(buf));      /* read it once FIRST */

        pfd.fd = fd;
        pfd.events = POLLPRI | POLLERR;  /* NOT POLLIN - sysfs
                                            uses POLLPRI      */
        poll(&pfd, 1, -1);

        lseek(fd, 0, SEEK_SET);          /* rewind */
        read(fd, buf, sizeof(buf));      /* the new value */

/* THE THREE THINGS PEOPLE GET WRONG:
     · waiting on POLLIN instead of POLLPRI
     · not reading once before the first poll (the initial
       read arms the notification)
     · not lseek()ing back to 0 before re-reading           */
```

debugfs

```
#include <linux/debugfs.h>

/* --- the one-liners, for simple values ---------------------- */
static int __init mydev_debugfs_init(struct mydev *d)
{
        d->dbg = debugfs_create_dir("mydev", NULL);
        /* NOTE: debugfs_create_dir NEVER returns NULL on
           failure - it returns an ERR_PTR, and every other
           debugfs function accepts an ERR_PTR harmlessly. So
           you do NOT need to check it. This is deliberate:
           debugfs failures must never break a driver.      */

        debugfs_create_u32("irq_count",  0444, d->dbg,
                           &d->irq_count);
        debugfs_create_u32("error_count", 0444, d->dbg,
                           &d->error_count);
        debugfs_create_bool("verbose", 0644, d->dbg,
                            &d->verbose);
        debugfs_create_x32("last_status", 0444, d->dbg,
                           &d->last_status);   /* hex */

        /* a raw memory blob */
        d->blob.data = d->fw_image;
        d->blob.size = d->fw_size;
        debugfs_create_blob("firmware", 0444, d->dbg, &d->blob);

        return 0;
}
        debugfs_remove_recursive(d->dbg);      /* in remove */

/* --- a custom file, for anything structured ----------------- */
static int mydev_regs_show(struct seq_file *s, void *unused)
{
        struct mydev *d = s->private;
        int i;

        seq_printf(s, "%-16s %s\n", "REGISTER", "VALUE");
        for (i = 0; i < ARRAY_SIZE(mydev_reg_names); i++)
                seq_printf(s, "%-16s 0x%08x\n",
                           mydev_reg_names[i],
                           mydev_rd(d, i * 4));
        return 0;
}
DEFINE_SHOW_ATTRIBUTE(mydev_regs);
        /* generates the whole file_operations for you */

        debugfs_create_file("registers", 0444, d->dbg, d,
                            &mydev_regs_fops);

/* seq_file handles pagination for you - output larger than a
   page just works, unlike sysfs. That is why register dumps,
   tables and statistics belong here.                       */

/* MOUNT IT: */
        mount -t debugfs none /sys/kernel/debug
        cat /sys/kernel/debug/mydev/registers
```

> **DEBUGFS IS ROOT-ONLY AND OFTEN ABSENT**
> Production kernels frequently do not enable `CONFIG_DEBUG_FS`, and hardened ones do not mount it. So a driver must **work correctly when debugfs does not exist** — never put required functionality there, and never make a debugfs failure fatal. The API is designed so that ignoring every return value is the correct thing to do.

Dynamic debug

```
/* The best debug-printing mechanism the kernel has: messages
   compiled in but disabled, switchable at runtime with zero
   cost when off (they are patched out with jump labels).   */

        CONFIG_DYNAMIC_DEBUG=y

/* In your driver, just use these: */
        pr_debug("value is %d\n", val);
        dev_dbg(dev, "channel %u ready\n", ch);

/* Then at runtime: */
    # everything in one file
    echo 'file mydev.c +p' > /sys/kernel/debug/dynamic_debug/control

    # one function
    echo 'func mydev_probe +p' > .../control

    # one module
    echo 'module mydev +p' > .../control

    # a line range
    echo 'file mydev.c line 100-200 +p' > .../control

    # turn it off again
    echo 'module mydev -p' > .../control

    # add the module, function, line and thread id to each
    # message:
    echo 'module mydev +pmfl' > .../control

    # see what is available and what is enabled:
    cat /sys/kernel/debug/dynamic_debug/control | grep mydev

/* AND AT BOOT, before debugfs is even mounted: */
        dyndbg="module mydev +p"          # kernel command line
        mydev.dyndbg="+p"                 # per-module form

/* THIS REPLACES the #ifdef DEBUG / custom-verbosity-flag
   pattern entirely. Use dev_dbg() liberally in your driver -
   it costs nothing when off, and it means a field problem can
   be diagnosed without a rebuild.                          */
```

Trace events

```
/* For anything in a hot path, a trace event beats a printk:
   it is nearly free when disabled, has a binary format, and
   integrates with ftrace, perf and trace-cmd.             */

/* include/trace/events/mydev.h */
#undef TRACE_SYSTEM
#define TRACE_SYSTEM mydev

#if !defined(_TRACE_MYDEV_H) || defined(TRACE_HEADER_MULTI_READ)
#define _TRACE_MYDEV_H

#include <linux/tracepoint.h>

TRACE_EVENT(mydev_xfer,
        TP_PROTO(unsigned int chan, unsigned int len, int ret),
        TP_ARGS(chan, len, ret),
        TP_STRUCT__entry(
                __field(unsigned int, chan)
                __field(unsigned int, len)
                __field(int,          ret)
        ),
        TP_fast_assign(
                __entry->chan = chan;
                __entry->len  = len;
                __entry->ret  = ret;
        ),
        TP_printk("chan=%u len=%u ret=%d",
                  __entry->chan, __entry->len, __entry->ret)
);

#endif
#include <trace/define_trace.h>

/* in the driver: */
        trace_mydev_xfer(chan, len, ret);

/* use it: */
    echo 1 > /sys/kernel/tracing/events/mydev/mydev_xfer/enable
    cat /sys/kernel/tracing/trace_pipe
    # or:
    trace-cmd record -e mydev
    trace-cmd report
```

How it shows up

Symptom	Cause
Writing to a sysfs file hangs the program	`store()` returned 0 instead of `count`
sysfs output truncated	Used `sprintf` past one page — use `sysfs_emit`
Attribute exists before the device works	Created in probe instead of via `dev_groups`
Attribute left behind after unbind	Manual `device_create_file` without a matching remove
`poll()` on a sysfs file never fires	Waiting on POLLIN instead of POLLPRI, or no initial read
Userspace tool cannot parse your value	Multiple values in one file, or non-standard units
debugfs files missing in production	`CONFIG_DEBUG_FS` off or not mounted — as expected

Symptom	Cause
Driver fails to probe when debugfs is absent	Checked a debugfs return value and treated it as fatal
Large debugfs output truncated	Not using `seq_file`
`dev_dbg` prints nothing	Dynamic debug not enabled for that file/module
Kernel upgrade breaks a userspace tool	A sysfs attribute was renamed or its format changed — it was an ABI

Check yourself

- ✓ Say which of the three filesystems a given piece of information belongs in, and why.
- ✓ Write a read-only and a read/write sysfs attribute correctly.
- ✓ Explain why `store()` must return `count`.
- ✓ Explain the advantage of `dev_groups` over creating files in probe.
- ✓ List the seven sysfs rules.
- ✓ Make an attribute pollable and write the userspace side correctly.
- ✓ Add debugfs counters and a `seq_file` register dump.
- ✓ Explain why debugfs return values need not be checked.
- ✓ Use dynamic debug to enable one function's messages at runtime and at boot.
- ✓ Add a trace event and say when to prefer it over `dev_dbg`.

MMIO access and regmap

Touching hardware registers correctly: the accessor functions, the ordering guarantees they carry, why a plain pointer dereference is wrong, and the framework that removes most of the boilerplate along with a class of bugs.

The accessors

```
#include <linux/io.h>

        u8  readb(const volatile void __iomem *addr);
        u16 readw(...);         /* 16-bit */
        u32 readl(...);         /* 32-bit - the common one */
        u64 readq(...);         /* 64-bit */

        void writeb(u8  value, volatile void __iomem *addr);
        void writew(u16 value, ...);
        void writel(u32 value, ...);
        void writeq(u64 value, ...);

/* NOTE THE ARGUMENT ORDER: writel(VALUE, ADDRESS). It is the
   opposite of what most people expect and of memcpy. Getting
   it backwards compiles fine and writes an address into a
   register.                                                  */

/* WHAT readl/writel GUARANTEE:
     · exactly one access of exactly that width. The compiler
       cannot split, merge, reorder, or elide it.
     · ordering with respect to OTHER readl/writel calls -
       they carry the barriers needed so accesses reach the
       device in program order.
     · correct byte order: they assume LITTLE-ENDIAN device
       registers and convert if the CPU is big-endian.

/* WHY A PLAIN DEREFERENCE IS WRONG: */
        val = *(volatile u32 *)base;      /* NO */
   volatile stops the compiler reordering, but does NOTHING
   about the CPU's memory ordering, nothing about access
   width (the compiler may use a different instruction), and
   nothing about endianness. On arm64 it often appears to
   work, which is what makes it dangerous - it fails on
   another core, another compiler, or under load.

/* THE RELAXED VARIANTS - no ordering barriers: */
        readl_relaxed(), writel_relaxed()

   Faster, because they omit the barrier. Use them ONLY when
   you know ordering does not matter - typically a burst of
   writes to a FIFO where only the last one must be ordered:

        for (i = 0; i < n; i++)
                writel_relaxed(data[i], base + FIFO);
        writel(GO, base + CTRL);    /* ordered: this one
                                       carries the barrier   */

   THE RULE: use readl/writel by default. Reach for _relaxed
   only in a measured hot path, and then make sure the last
   access in the sequence is ordered.                       */
```

Ordering, DMA and the barriers that matter

```
Three different ordering questions, three different tools:

  1. CPU-to-DEVICE ordering
        Does the device see my writes in the order I made
        them?
     -> readl()/writel() handle this. Device memory
        (nGnRE, ARM ch. 11) is not reordered by the CPU,
        and the accessors add the compiler barriers.

  2. MEMORY-to-DEVICE ordering
        I filled a DMA buffer in RAM, then wrote the "GO"
        register. Will the device see the DATA before it
        acts on GO?
     -> NOT AUTOMATIC. Normal memory writes and Device
        writes are ordered differently. You need:

           fill_dma_buffer(buf);
           dma_wmb();                /* buffer visible to
                                        the device FIRST   */
           writel(GO, base + CTRL);

        And on the receive side:

           if (readl(base + STATUS) & DONE) {
                   dma_rmb();        /* do not read the
                                        buffer before the
                                        status read        */
                   consume(buf);
           }

  3. CPU-to-CPU ordering
        -> smp_wmb(), smp_rmb(), smp_mb() (chapter 12).
        NEVER substitute these for the DMA ones: smp_* compile
        to nothing on a uniprocessor kernel, and a DMA engine
        is a second agent regardless of CPU count.

  THE MISTAKE that costs the most time: using smp_wmb() where
  dma_wmb() is needed. It works on your 4-core test board and
  silently corrupts on a single-core variant, or under a
  different compiler.
```

Waiting for hardware

```
#include <linux/iopoll.h>

/* NEVER an unbounded spin: */
        while (readl(base + STATUS) & BUSY)     /* NO */
                ;
/* If the device wedges - and it will - this hangs a CPU
   forever with no diagnostic.                              */

/* SLEEPING VERSION - process context: */
        u32 val;
        int ret;

        ret = readl_poll_timeout(base + REG_STATUS,  /* addr   */
                                 val,                /* var    */
                                 !(val & BUSY),      /* cond   */
                                 10,          /* poll every 10us*/
                                 1000);       /* give up at 1ms */
        if (ret)
                return dev_err_probe(dev, ret, "timed out\n");

/* ATOMIC VERSION - interrupt context, holding a spinlock: */
        ret = readl_poll_timeout_atomic(base + REG_STATUS, val,
                                        !(val & BUSY), 1, 100);

/* PICKING THE NUMBERS:
     sleep_us   how long between polls. Too small and you burn
                CPU; too large and you add latency. Roughly
                one tenth of the expected completion time.
     timeout_us the datasheet's worst case, times a safety
                factor of two or three. NEVER "a number that
                works on my board".

   AND ALWAYS handle the timeout. A driver that logs
   "timed out" and returns an error is debuggable; one that
   ignores it produces corrupt data with no clue why.       */
```

regmap: the framework

```
/* regmap abstracts "a set of registers" over MMIO, I2C, SPI or
   anything else, and adds caching, locking and debugfs for
   free. Use it unless you have a reason not to.            */

#include <linux/regmap.h>

static const struct regmap_config mydev_regmap_config = {
        .reg_bits      = 32,       /* register address width */
        .val_bits      = 32,       /* register value width   */
        .reg_stride    = 4,        /* registers are 4 apart  */
        .max_register  = 0xff,

        .cache_type    = REGCACHE_MAPLE,   /* or RBTREE, FLAT,
                                              or NONE         */
        .volatile_reg  = mydev_volatile_reg,
        .writeable_reg = mydev_writeable_reg,
        .readable_reg  = mydev_readable_reg,
        .precious_reg  = mydev_precious_reg,
};

/* WHICH REGISTERS ARE WHICH - this is the important part: */

static bool mydev_volatile_reg(struct device *dev, unsigned int reg)
{
        /* VOLATILE = the hardware can change it by itself.
           Never cache these; always read the hardware.     */
        switch (reg) {
        case MYDEV_REG_STATUS:
        case MYDEV_REG_FIFO_DATA:
        case MYDEV_REG_IRQ_STATUS:
                return true;
        default:
                return false;
        }
}

}

/* in probe: */
        d->regmap = devm_regmap_init_mmio(dev, d->base,
                                          &mydev_regmap_config);
        if (IS_ERR(d->regmap))
                return PTR_ERR(d->regmap);

/* USING IT: */
        unsigned int val;

        ret = regmap_read(d->regmap, MYDEV_REG_STATUS, &val);
        ret = regmap_write(d->regmap, MYDEV_REG_CTRL, 0x1);

        /* read-modify-write, ATOMICALLY with respect to other
           regmap users - this is the big win over hand-rolled
```

```
   MMIO, where the RMW race is easy to write        */
ret = regmap_update_bits(d->regmap, MYDEV_REG_CTRL,
                         MYDEV_CTRL_ENABLE,   /* mask */
                         MYDEV_CTRL_ENABLE);  /* val  */

/* bulk, for FIFOs and contiguous blocks */
ret = regmap_bulk_read(d->regmap, MYDEV_REG_DATA,
                       buf, count);

/* poll, the regmap equivalent of readl_poll_timeout */
ret = regmap_read_poll_timeout(d->regmap,
                               MYDEV_REG_STATUS, val,
                               !(val & BUSY), 10, 1000);

/* fields, when you work with one bitfield repeatedly */
static const struct reg_field gain_field =
        REG_FIELD(MYDEV_REG_CTRL, 4, 7);
d->gain_rf = devm_regmap_field_alloc(dev, d->regmap,
                                     gain_field);
regmap_field_write(d->gain_rf, 3);   /* shifts and
                                        masks for you */
```

WHAT REGMAP BUYS YOU

- **Atomic read-modify-write** — the single most common MMIO race, eliminated.
- **Locking** against concurrent access, without you writing it.
- **A register cache**, so a chatty I2C or SPI device is not re-read constantly, and so suspend/resume can restore state with `regcache_sync()`.
- **Bus independence** — the same driver logic over MMIO, I2C and SPI variants of one chip.
- **A free debugfs register dump** at `/sys/kernel/debug/regmap/<dev>/registers`.
- **Endianness and width handling** declared once instead of at every call site.

Cached registers and suspend

```
/* The cache is what makes regmap worth using on a slow bus,
   and it is also what makes resume simple.                */

static int mydev_suspend(struct device *dev)
{
        struct mydev *d = dev_get_drvdata(dev);

        /* stop touching the hardware, and remember everything
           by marking the cache dirty                       */
        regcache_cache_only(d->regmap, true);
        regcache_mark_dirty(d->regmap);

        clk_disable_unprepare(d->clk);
        return 0;
}

static int mydev_resume(struct device *dev)
{
        struct mydev *d = dev_get_drvdata(dev);
        int ret;

        ret = clk_prepare_enable(d->clk);
        if (ret)
                return ret;

        regcache_cache_only(d->regmap, false);

        /* write every cached value back to hardware that just
           came up from reset - the whole register state,
           restored in one call                             */
        ret = regcache_sync(d->regmap);
        if (ret)
                dev_err(dev, "cache sync failed: %d\n", ret);

        return ret;
}

/* Without regmap you would write, and maintain, a shadow copy
   of every register plus a restore function - and get it
   subtly wrong when someone adds a register.

/* THE CACHE TYPES:
     REGCACHE_NONE    no caching. Correct for MMIO where reads
                      are cheap and you want the truth.
     REGCACHE_FLAT    an array. Fast, uses max_register words
                      of memory. Good for small maps.
     REGCACHE_MAPLE   the modern sparse cache. Good default.
     REGCACHE_RBTREE  the older sparse cache.

   For a plain MMIO device, NONE is often right - the cache
   exists to avoid slow bus traffic, and MMIO is not slow.
   But even with NONE you keep the locking, the atomic RMW and
   the debugfs dump.                                        */
```

Register definition style

```
/* Define registers and their fields together, with the bit
   positions expressed structurally rather than as magic
   numbers.                                                  */

#include <linux/bitfield.h>
#include <linux/bits.h>

#define MYDEV_REG_CTRL          0x04
#define  MYDEV_CTRL_ENABLE      BIT(0)
#define  MYDEV_CTRL_RESET       BIT(1)
#define  MYDEV_CTRL_MODE        GENMASK(5, 4)   /* bits 5:4 */
#define  MYDEV_CTRL_GAIN        GENMASK(11, 8)  /* bits 11:8 */

/* FIELD_PREP shifts a value INTO position;
   FIELD_GET extracts one OUT. Both check at compile time
   that the value fits the mask.                             */

        u32 ctrl = MYDEV_CTRL_ENABLE
                 | FIELD_PREP(MYDEV_CTRL_MODE, MODE_BURST)
                 | FIELD_PREP(MYDEV_CTRL_GAIN, 7);
        writel(ctrl, base + MYDEV_REG_CTRL);

        u32 gain = FIELD_GET(MYDEV_CTRL_GAIN,
                             readl(base + MYDEV_REG_CTRL));

/* versus the hand-rolled version, which has two bugs waiting
   to happen (a wrong shift, and an unmasked value that
   overflows into the neighbouring field):                   */
        ctrl = 1 | (MODE_BURST << 4) | (7 << 8);   /* avoid */

/* A NAMING CONVENTION that pays for itself:
     MYDEV_REG_xxx     a register offset
     MYDEV_xxx_yyy     a field within register xxx
   and indent the field defines under their register, as
   above, so the structure is visible at a glance.         */
```

Debugging register access

```
# regmap's free debugfs interface:
    ls /sys/kernel/debug/regmap/1c000000.my-device/
      access  name  range  registers  rbtree
    cat /sys/kernel/debug/regmap/*/registers
      00: 4d594445
      04: 00000701
      08: 00000000

# From userspace, without any driver support:
    devmem 0x1c000004                # read
    devmem 0x1c000004 32 0x1         # write
    busybox devmem 0x1c000004

# Trace every regmap access - extremely useful:
    echo 1 > /sys/kernel/tracing/events/regmap/enable
    cat /sys/kernel/tracing/trace_pipe
      regmap_reg_write: 1c000000.my-device reg=4 val=1
      regmap_reg_read:  1c000000.my-device reg=8 val=0

# This is the regmap feature that most often justifies using
# it: a complete, timestamped log of every register access,
# with no code changes. Reproducing a bug once with this
# enabled usually shows you the wrong write immediately.
```

How it shows up

Symptom	Cause
Register writes have no effect	Arguments reversed — `writel(value, addr)`
Reads return 0 or 0xFFFFFFFF	Clock off, in reset, wrong address, or access denied (isolation ch. 20)
Works on one compiler, breaks on another	Direct dereference instead of `readl` / `writel`
DMA reads stale data	Missing `dma_wmb()` before the doorbell write
Corruption on a single-core build only	`smp_wmb()` used where `dma_wmb()` was needed
CPU hangs waiting for the device	Unbounded polling loop — use `readl_poll_timeout`
Two threads clobber a shared register	Non-atomic read-modify-write — use `regmap_update_bits`
A FIFO empties by itself	Regmap read it speculatively — mark it `precious`
Status register never changes	Cached — mark it `volatile`
Device is misconfigured after resume	No `regcache_sync()`, or the cache was not marked dirty
A field write corrupts the neighbouring field	Hand-rolled shift without masking — use `FIELD_PREP`

Check yourself

- ✓ Write the accessors with the correct argument order and say what they guarantee.
- ✓ Explain why `volatile` plus a cast is not equivalent.
- ✓ Say when `_relaxed` is appropriate and what must still be ordered.
- ✓ Distinguish the three ordering questions and pick the right barrier for each.
- ✓ Explain why `smp_wmb()` is wrong for DMA ordering.

- ✓ Replace a spin loop with `readl_poll_timeout` and justify the timings.
- ✓ Write a `regmap_config` with correct volatile and precious predicates.
- ✓ Explain what `precious` prevents and give an example register.
- ✓ Use the register cache to implement suspend and resume.
- ✓ Define a register with `BIT` / `GENMASK` and use `FIELD_PREP` / `FIELD_GET`.

The DMA API

Giving a device direct access to memory, correctly. Three address spaces, two allocation styles, cache coherency, and the SMMU underneath it all — this is where the isolation track's theory becomes code you write.

Three kinds of address

```
 VIRTUAL ADDRESS      what the CPU uses. void *.
      |               Only meaningful to the kernel.
      |
 PHYSICAL ADDRESS     what is on the memory bus.
      |               phys_addr_t.
      |
 DMA ADDRESS          what the DEVICE must be programmed
                      with. dma_addr_t.

THEY ARE NOT THE SAME NUMBER, and assuming they are is the
defining DMA bug.

The DMA address differs from the physical address when:
   · an SMMU/IOMMU is translating (isolation ch. 03-05) -
     then the DMA address is an IOVA, an entirely made-up
     number that exists only in the SMMU's page tables
   · a bus applies an offset (dma-ranges in the DT)
   · bounce buffering (SWIOTLB) is in play because the
     device cannot address the memory you allocated
   · the device sits behind a bridge that remaps

SO: NEVER program a device with virt_to_phys(). Always with
the dma_addr_t the DMA API gave you. The API is what knows
about the SMMU, the offsets and the bounce buffers - and it
is what SETS UP the SMMU mapping, so a hand-computed
physical address is not merely wrong, it is unmapped and
will fault (isolation ch. 06).
```

Step one: declare what the device can address

```
/* Before any allocation or mapping, in probe: */

        ret = dma_set_mask_and_coherent(dev, DMA_BIT_MASK(40));
        if (ret) {
                dev_err(dev, "no suitable DMA mask\n");
                return ret;
        }

/* WHAT THIS DECLARES: "this device's address register is 40
   bits wide". The kernel then:
     · allocates only from memory the device can reach
     · sets up bounce buffers if you later map something above
       that limit
     · configures the SMMU's IOVA range accordingly

   GET IT WRONG — claim 64 bits on a device with a 32-bit
   address register — and the top bits are silently dropped by
   the hardware. The DMA lands somewhere else in memory. This
   is one of the nastiest bugs in the field: it works on a
   board with 2 GB of RAM and corrupts memory on the 8 GB
   variant, because only then do allocations land above 4 GB.

   THE DEFAULT is 32 bits. If your device really is 32-bit,
   you can omit the call — but state it explicitly anyway, so
   the next reader knows it was considered.                */
```

Coherent (consistent) mappings

```
/* For memory the CPU and device both touch REPEATEDLY, for
   the lifetime of the driver: descriptor rings, command
   queues, status blocks.                                    */

        void *cpu_addr;
        dma_addr_t dma_handle;

        cpu_addr = dma_alloc_coherent(dev, size, &dma_handle,
                                      GFP_KERNEL);
        if (!cpu_addr)
                return -ENOMEM;

        /* program the device with dma_handle */
        writel(lower_32_bits(dma_handle), base + REG_DESC_LO);
        writel(upper_32_bits(dma_handle), base + REG_DESC_HI);

        /* the CPU uses cpu_addr normally - NO cache
           maintenance needed, ever                          */
        ring[0].addr = ...;
        ring[0].len  = ...;

        ...
        dma_free_coherent(dev, size, cpu_addr, dma_handle);

/* WHAT "COHERENT" MEANS: the CPU and device see the same
   data without explicit cache maintenance. How that is
   achieved depends on the hardware:

     · on a system with hardware coherency (dma-coherent in
       the DT, ARM ch. 19), it is ordinary cached memory and
       the interconnect keeps it consistent
     · without it, the kernel maps the memory NON-CACHED

   THAT SECOND CASE IS THE COST. Non-cached CPU access is
   slow - every read goes to DRAM. So use coherent mappings
   for SMALL, control-plane structures, and streaming mappings
   for BULK data.

/* AND EVEN COHERENT MEMORY NEEDS ORDERING BARRIERS
   (chapter 23) - coherency is about caches, not about the
   order in which writes become visible: */

        ring[idx].flags = DESC_OWN;
        dma_wmb();                      /* descriptor visible
                                           BEFORE the doorbell */
        writel(idx, base + REG_DOORBELL);

/* A POOL, for many small identical buffers - avoids wasting a
   page each: */
        pool = dma_pool_create("mydev", dev, 64, /* size  */
                                             64, /* align */
                                             0); /* boundary */
        p = dma_pool_alloc(pool, GFP_KERNEL, &dma);
        dma_pool_free(pool, p, dma);
        dma_pool_destroy(pool);
```

Streaming mappings

```
/* For buffers used for ONE transfer, that the CPU already
   owns: a network packet, a block of user data, a frame.   */

        dma_addr_t dma;

        dma = dma_map_single(dev, buf, len, DMA_TO_DEVICE);
        if (dma_mapping_error(dev, dma))     /* CHECK IT */
                return -ENOMEM;

        /* the buffer now belongs to the DEVICE. The CPU MUST
           NOT touch it until it is unmapped.               */
        writel(lower_32_bits(dma), base + REG_ADDR);
        writel(len, base + REG_LEN);
        writel(GO, base + REG_CTRL);

        wait_for_completion(&d->done);

        dma_unmap_single(dev, dma, len, DMA_TO_DEVICE);
        /* now the CPU owns it again */

/* THE DIRECTIONS, and they are not decorative: */
        DMA_TO_DEVICE       CPU wrote it, device reads it
        DMA_FROM_DEVICE     device writes it, CPU reads it
        DMA_BIDIRECTIONAL   both. More cache maintenance.
        DMA_NONE            debugging only

/* WHAT map/unmap ACTUALLY DO on a non-coherent system:
     map,   TO_DEVICE:    CLEAN the cache - push the CPU's
                           writes out to memory so the device
                           sees them
     unmap, FROM_DEVICE:  INVALIDATE the cache - discard stale
                           lines so the CPU reads what the
                           device wrote
   plus, always: set up (or tear down) the SMMU mapping for
   this buffer, allocating an IOVA.

   THE OWNERSHIP RULE follows directly: touching the buffer
   while the device owns it either loses your write (it gets
   invalidated) or reads stale data. It is not a convention;
   it is what the cache maintenance implies.              */

/* TOUCHING IT MID-TRANSFER, when you genuinely must: */
        dma_sync_single_for_cpu(dev, dma, len, DMA_FROM_DEVICE);
        inspect(buf);                   /* CPU owns it now */
        dma_sync_single_for_device(dev, dma, len, DMA_FROM_DEVICE);
        /* device owns it again */
```

WHAT YOU MUST NEVER DMA TO

- **Stack memory.** On a `VMAP_STACK` kernel the stack is vmalloc'd, so it is not physically contiguous and `virt_to_phys` is meaningless. Even without that, it may share a cache line with other stack data, which cache maintenance would corrupt.
- `vmalloc` **memory.** Physically scattered (chapter 05).
- **Module static data.** May be in the module's vmalloc area.
- **Anything you did not map.** With an SMMU present, an unmapped address is not "the wrong data" — it is a fault.

Allocate with `kmalloc` and map it, or use `dma_alloc_coherent`. Every other route is a bug that hides until the machine configuration changes.

Scatter-gather

```
/* Large buffers are rarely physically contiguous. Rather than
   forcing a contiguous allocation, describe the pieces.    */

        struct sg_table sgt;
        struct scatterlist *sg;
        int i, nents;

        /* build the list - or get one from a caller */
        sg_alloc_table(&sgt, nr_pages, GFP_KERNEL);
        for_each_sgtable_sg(&sgt, sg, i)
                sg_set_page(sg, pages[i], PAGE_SIZE, 0);

        /* map it ALL at once */
        nents = dma_map_sgtable(dev, &sgt, DMA_FROM_DEVICE, 0);
        if (nents)
                return nents;

        /* CRITICAL: iterate the MAPPED list, not the original.
           The IOMMU may have COALESCED several physical
           segments into one contiguous IOVA range, so the
           mapped list can be SHORTER.                       */
        for_each_sgtable_dma_sg(&sgt, sg, i) {
                program_descriptor(d, i,
                                   sg_dma_address(sg),
                                   sg_dma_len(sg));
        }

        ... transfer ...

        dma_unmap_sgtable(dev, &sgt, DMA_FROM_DEVICE, 0);
        sg_free_table(&sgt);

/* THE COALESCING POINT IS THE COMMON BUG: code that iterates
   with for_each_sg() using the ORIGINAL nents, and reads
   sg->length instead of sg_dma_len(sg), programs the wrong
   descriptors. It works without an SMMU (where no coalescing
   happens) and breaks the moment one is enabled - which is
   exactly when someone turns on isolation.              */
```

Using a DMA engine

```
/* Many SoC peripherals do not master the bus themselves; a
   shared DMA controller moves data for them. The dmaengine
   API drives it.                                          */

#include <linux/dmaengine.h>

/* device tree: */
        dmas = <&dmac 12>, <&dmac 13>;
        dma-names = "tx", "rx";

/* probe: */
        d->rxchan = dma_request_chan(dev, "rx");
        if (IS_ERR(d->rxchan))
                return dev_err_probe(dev, PTR_ERR(d->rxchan),
                                     "no rx channel\n");

        struct dma_slave_config cfg = {
                .direction    = DMA_DEV_TO_MEM,
                .src_addr     = d->phys_base + REG_FIFO,
                .src_addr_width = DMA_SLAVE_BUSWIDTH_4_BYTES,
                .src_maxburst = 8,
        };
        dmaengine_slave_config(d->rxchan, &cfg);

/* one transfer: */
        struct dma_async_tx_descriptor *desc;
        dma_cookie_t cookie;

        desc = dmaengine_prep_slave_sg(d->rxchan, sgt.sgl,
                                       sgt.nents,
                                       DMA_DEV_TO_MEM,
                                       DMA_PREP_INTERRUPT |
                                       DMA_CTRL_ACK);
        if (!desc)
                return -EINVAL;

        desc->callback       = mydev_dma_done;
        desc->callback_param = d;

        cookie = dmaengine_submit(desc);
        if (dma_submit_error(cookie))
                return -EIO;

        dma_async_issue_pending(d->rxchan);   /* GO */

        ... the callback fires ...

        dmaengine_terminate_sync(d->rxchan);  /* in remove -
                                                 _sync waits  */
        dma_release_channel(d->rxchan);

/* CYCLIC transfers, for continuous capture - audio, ADCs:  */
        desc = dmaengine_prep_dma_cyclic(chan, dma_addr,
                                         buf_len, period_len,
                                         DMA_DEV_TO_MEM,
                                         DMA_PREP_INTERRUPT);
/* the callback fires once per PERIOD and the transfer never
   ends, which is how you build a ring without gaps.       */
```

The SMMU, from the driver's side

```
/* Everything the isolation track described (chapters 03-07)
   happens inside the DMA API. From the driver you see it in
   three places:                                            */

/* 1. THE DEVICE TREE declares the relationship: */
        my_device: dma-thing@1c000000 {
                compatible = "vendor,dma-thing";
                reg = <0x0 0x1c000000 0x0 0x1000>;
                iommus = <&smmu 0x42>;    /* StreamID 0x42 */
                dma-coherent;             /* hardware coherency */
        };

/* 2. dma_map_* SETS UP THE TRANSLATION and returns an IOVA,
      not a physical address. dma_unmap_* tears it down and
      invalidates the SMMU TLB.

      This is why a "clever" driver that caches a dma_addr_t
      and reuses it after unmapping gets an SMMU fault: the
      mapping is gone.

/* 3. FAULTS APPEAR IN dmesg with the StreamID: */
      arm-smmu-v3 : event 0x10 received:
      arm-smmu-v3 : 0x0000004200000010
      arm-smmu-v3 : 0x0000000000000000
        -> C_BAD_STREAMID, or F_TRANSLATION at an IOVA

      Read them with isolation chapter 06. The usual causes,
      from a driver author's point of view:
        · programmed the device with a physical address
        · used a dma_addr_t after unmapping
        · the device is issuing a longer transfer than you
          mapped
        · wrong StreamID in the DT, so the SMMU has no
          context for this device at all

/* AND THE DEBUGGING SWITCH worth knowing: */
        iommu.passthrough=1        # kernel cmdline: bypass
                                   # translation entirely
   If the problem disappears with passthrough, it is a mapping
   problem, not a hardware one. Never ship with it.        */
```

Debugging DMA

```
# THE DMA DEBUG INFRASTRUCTURE - turn it on while developing:
    CONFIG_DMA_API_DEBUG=y

# It tracks every mapping and reports:
#   · unmapping with the wrong size or direction
#   · freeing memory that is still mapped
#   · CPU access to a buffer the device owns
#   · mapping the same buffer twice
#   · a dma_addr_t used after unmap
#   · DMA to a stack or vmalloc address
#
# The report names both the map and the misuse site. This
# option finds more real DMA bugs than any amount of testing.

    DMA-API: device driver tries to free DMA memory it has
             not allocated [device address=0x00000000abcd0000]
    DMA-API: device driver maps memory from stack

# See the mappings:
    cat /sys/kernel/debug/dma-api/dump
    cat /sys/kernel/debug/dma-api/error_count

# Force bounce buffering, to test that path:
    swiotlb=force                # kernel cmdline

# Is the SMMU actually translating for this device?
    ls /sys/kernel/iommu_groups/*/devices/
    dmesg | grep -i smmu
```

How it shows up

Symptom	Cause
DMA writes land in unrelated memory	Programmed with a physical or virtual address instead of the `dma_addr_t`
SMMU translation fault at a plausible address	Same cause — the physical address is not a valid IOVA
Works on 2 GB board, corrupts on 8 GB	DMA mask too wide for the hardware; top address bits dropped
Device reads stale data	Missing `dma_wmb()`, or the CPU wrote after mapping
CPU reads stale data	Read before `dma_unmap` or `dma_sync_for_cpu`
Random corruption near a buffer	DMA to a stack buffer sharing a cache line
Works without an SMMU, faults with one	Iterating the unmapped scatterlist, or using `sg->length` instead of `sg_dma_len`
Fault after a successful transfer	`dma_addr_t` reused after unmapping
Only the first N bytes transfer	Device programmed with a length longer than the mapping, truncated at the fault
Everything works with `iommu.passthrough=1`	Confirms a mapping bug, not a hardware one
`dma_alloc_coherent` fails for a large size	Fragmentation — use CMA (ch. 05)
CPU access to a coherent buffer is very slow	Non-coherent system: it is mapped uncached. Use streaming for bulk data

Check yourself

- ✓ Name the three address spaces and four reasons a DMA address differs from a physical one.
- ✓ Set a DMA mask and explain the failure a too-wide mask causes.
- ✓ Choose between coherent and streaming mappings, with the reason.
- ✓ Explain what `dma_map_single` does on a non-coherent system, per direction.
- ✓ State the ownership rule and why it follows from cache maintenance.
- ✓ List four kinds of memory you must never DMA to.
- ✓ Map a scatterlist and explain why you must iterate the mapped list.
- ✓ Drive a transfer through the dmaengine API, including teardown.
- ✓ Explain what the DMA API does with the SMMU, and read a fault.
- ✓ Enable `DMA_API_DEBUG` and name five things it catches.

Power management and runtime PM

On a battery-powered device, a driver that never lets its hardware sleep is a bug — even if it works perfectly. Two independent mechanisms handle it: system suspend, for the whole machine, and runtime PM, for one idle device.

Two mechanisms, one set of callbacks

```
SYSTEM SUSPEND                RUNTIME PM
--------------                ----------
the whole machine sleeps      ONE device sleeps while the
user or policy initiated      system runs
everything goes down in       reference counted: sleeps when
  dependency order            nobody is using it
.suspend / .resume            .runtime_suspend /
                                .runtime_resume

THEY COMPOSE. A device may be runtime-suspended when system
suspend arrives, and must handle that. The core helps:

   pm_runtime_force_suspend()
   pm_runtime_force_resume()

used as the system callbacks, do the right thing in both
cases.

THE STATES a device moves through:

   RPM_ACTIVE      powered, usable
      |  usage_count drops to 0, autosuspend delay expires
      v
   RPM_SUSPENDING  .runtime_suspend running
      |
      v
   RPM_SUSPENDED   powered down
      |  someone calls pm_runtime_get()
      v
   RPM_RESUMING    .runtime_resume running
      |
      v
   RPM_ACTIVE
```

Runtime PM

```
#include <linux/pm_runtime.h>

/* --- probe: opt in ---------------------------------------- */
static int mydev_probe(struct platform_device *pdev)
{
        struct device *dev = &pdev->dev;
        ...

        /* the hardware IS on at this point, so tell the core */
        pm_runtime_set_active(dev);

        /* wait this long after the last use before suspending -
           avoids thrashing on a bursty workload             */
        pm_runtime_set_autosuspend_delay(dev, 1000);   /* ms  */
        pm_runtime_use_autosuspend(dev);

        /* from here, the core may call our callbacks */
        pm_runtime_enable(dev);

        /* devm form, which handles disable on unbind: */
        ret = devm_pm_runtime_enable(dev);
        if (ret)
                return ret;

        ...
        /* let it go idle once probe is done */
        pm_runtime_put_autosuspend(dev);
        return 0;
}

/* --- the callbacks ---------------------------------------- */
static int mydev_runtime_suspend(struct device *dev)
{
        struct mydev *d = dev_get_drvdata(dev);

        /* save anything the hardware will forget */
        regcache_cache_only(d->regmap, true);
        regcache_mark_dirty(d->regmap);

        clk_disable_unprepare(d->clk);
        regulator_disable(d->vdd);
        return 0;
}

static int mydev_runtime_resume(struct device *dev)
{
        struct mydev *d = dev_get_drvdata(dev);
        int ret;

        ret = regulator_enable(d->vdd);
        if (ret)
                return ret;

        ret = clk_prepare_enable(d->clk);
        if (ret)
                goto err_reg;

        /* the hardware came up from reset - restore it
           (chapter 23)                                      */
        regcache_cache_only(d->regmap, false);
```

```
        ret = regcache_sync(d->regmap);
        if (ret)
                goto err_clk;

        return 0;

err_clk:
        clk_disable_unprepare(d->clk);
err_reg:
        regulator_disable(d->vdd);
        return ret;
}

/* --- wrapping every hardware access ---------------------- */
static ssize_t mydev_read(struct file *f, char __user *buf,
                          size_t count, loff_t *ppos)
{
        struct mydev *d = ...;
        int ret;

        /* resume if needed, and BLOCK until it is up */
        ret = pm_runtime_resume_and_get(d->dev);
        if (ret < 0)
                return ret;

        ... touch the hardware ...

        pm_runtime_mark_last_busy(d->dev);
        pm_runtime_put_autosuspend(d->dev);
        return ret;
}

/* USE pm_runtime_resume_and_get(), not the older
   pm_runtime_get_sync(). The older one leaves the usage
   count INCREMENTED on failure, so an error path that
   returns without a put() pins the device awake forever.
   resume_and_get() drops it for you on error. This is a real
   and very common leak in older drivers.                   */
```

THE REFERENCE-COUNTING DISCIPLINE

Every path that touches hardware must be bracketed by a get and a put — *including every error path*. An unbalanced get pins the device permanently awake, which looks like "power management does not work" and is invisible in testing. An unbalanced put lets the device suspend under an active user, which looks like random hardware failure. Both are found immediately by watching `/sys/.../power/runtime_status` while exercising the driver.

System suspend

```
static int mydev_suspend(struct device *dev)
{
        struct mydev *d = dev_get_drvdata(dev);

        /* refuse if we are mid-operation and cannot stop */
        if (mydev_busy(d))
                return -EBUSY;      /* aborts the suspend */

        /* stop new work, quiesce the hardware */
        disable_irq(d->irq);
        mydev_stop(d);

        /* if this device can wake the system, arm it */
        if (device_may_wakeup(dev))
                enable_irq_wake(d->irq);

        return 0;
}

static int mydev_resume(struct device *dev)
{
        struct mydev *d = dev_get_drvdata(dev);

        if (device_may_wakeup(dev))
                disable_irq_wake(d->irq);

        mydev_hw_init(d);          /* it came up from reset */
        enable_irq(d->irq);
        return 0;
}

/* --- declaring them ------------------------------------- */
static const struct dev_pm_ops mydev_pm_ops = {
        SYSTEM_SLEEP_PM_OPS(mydev_suspend, mydev_resume)
        RUNTIME_PM_OPS(mydev_runtime_suspend,
                       mydev_runtime_resume, NULL)
};

/* or, when the runtime callbacks do the whole job: */
static const struct dev_pm_ops mydev_pm_ops = {
        SET_SYSTEM_SLEEP_PM_OPS(pm_runtime_force_suspend,
                                pm_runtime_force_resume)
        SET_RUNTIME_PM_OPS(mydev_runtime_suspend,
                           mydev_runtime_resume, NULL)
};

static struct platform_driver mydev_driver = {
        .driver = {
                .name = "my-device",
                .pm   = pm_ptr(&mydev_pm_ops),
                ...
        },
        ...
};
/* pm_ptr() compiles the reference away when CONFIG_PM is off,
   so the ops struct is discarded rather than kept as dead
   weight. Pair it with __maybe_unused or the
   DEFINE_*_DEV_PM_OPS macros on the callbacks.            */
```

Suspend phases

```
System suspend runs in stages, and which one you need depends
on what your callback must do:

   prepare()          may sleep, may allocate. Last chance to
                      refuse.
   suspend()          the normal one. Interrupts enabled,
                      may sleep. USE THIS.
   suspend_late()     after other devices; still can sleep
   suspend_noirq()    interrupts DISABLED. Only for interrupt
                      controllers and things that must be last.
                      Cannot sleep on anything that needs an
                      interrupt - which includes most I2C and
                      SPI transfers.

   ... the system sleeps ...

   resume_noirq()
   resume_early()
   resume()           the normal one
   complete()

  THE ORDERING GUARANTEE: children suspend before parents, and
  resume after them. So an I2C client suspends before its bus
  controller - which is what makes it safe to talk to the chip
  in .suspend but not in .suspend_noirq.

  IF YOU NEED I2C/SPI IN A CALLBACK, it must be in
  .suspend/.resume, not the _noirq variants. Putting it later
  produces a hang at suspend that is very hard to diagnose,
  because the console is usually gone by then.
```

Wakeup sources

```
/* A device that can wake the system - a button, an RTC alarm,
   a network packet, a modem interrupt.                     */

/* in probe: */
        device_init_wakeup(dev, true);      /* capable */
        /* or, respecting the DT: */
        if (device_property_read_bool(dev, "wakeup-source"))
                device_init_wakeup(dev, true);

/* in suspend: */
        if (device_may_wakeup(dev))
                enable_irq_wake(d->irq);

/* USERSPACE CONTROLS whether it is ENABLED: */
        cat /sys/devices/.../power/wakeup       # enabled/disabled
        echo enabled > /sys/devices/.../power/wakeup

/* device_init_wakeup() says "this CAN wake"; the sysfs file
   says "this SHOULD". Respect device_may_wakeup(), which
   combines them - a driver that always arms its wakeup
   ignores a user decision and drains the battery.        */

/* SEE WHAT WOKE THE SYSTEM: */
        cat /sys/kernel/debug/wakeup_sources
        dmesg | grep -i wakeup
        cat /sys/power/pm_wakeup_irq
```

Watching it work

```
# Per-device runtime PM state - the file to watch:
    cat /sys/devices/platform/.../power/runtime_status
      active | suspended | suspending | resuming
    cat .../power/runtime_active_time      # ms awake
    cat .../power/runtime_suspended_time   # ms asleep
    cat .../power/autosuspend_delay_ms
    cat .../power/control                  # auto | on

# FORCE a device to stay awake, to test whether PM is the
# cause of a bug:
    echo on > /sys/devices/.../power/control
    # and back:
    echo auto > /sys/devices/.../power/control

# Test system suspend:
    echo mem > /sys/power/state          # suspend-to-RAM
    echo freeze > /sys/power/state       # s2idle - lighter
    cat /sys/power/state                 # what is supported

# Suspend for a fixed time using the RTC, so you get back:
    rtcwake -m mem -s 10

# WHEN SUSPEND FAILS, this names the device:
    echo 1 > /sys/power/pm_debug_messages
    dmesg | grep -i "PM:"
      PM: suspend of devices aborted after ...
      my-device: PM: failed to suspend: error -16

# Where the time goes during suspend/resume:
    echo 1 > /sys/power/pm_print_times
    dmesg | grep "PM: "
      call my-device+ returned 0 after 12043 usecs
# A device taking hundreds of milliseconds is your resume
# latency, and users notice it.

# Power usage attribution, on hardware that supports it:
    cat /sys/kernel/debug/pm_genpd/pm_genpd_summary
    powertop
```

Power domains

```
/* Several devices often share one power rail or one clock
   domain in silicon. The genpd framework models that: the
   domain powers down only when EVERY device in it is idle. */

        /* device tree: */
        my_device: device@1c000000 {
                compatible = "vendor,my-device";
                power-domains = <&pd_periph>;
        };

/* You usually need no driver code at all - the core attaches
   the device to the domain and the domain's own driver
   handles the rail. Your runtime_suspend runs first, then the
   domain powers off if nobody else is holding it.

   THE CONSEQUENCE worth understanding: your device may not
   actually lose power when it suspends, because a sibling is
   still active. So resume must be correct whether or not the
   hardware was reset - which is another argument for
   regcache_sync() rather than assuming a known state.     */

/* SEE THE DOMAINS: */
        cat /sys/kernel/debug/pm_genpd/pm_genpd_summary
        domain          status    children   performance
        pd_periph       on                   0
            /device:1c000000.my-device  active
            /device:1c001000.other      suspended
```

A PM review checklist

Check	Why
Every hardware access bracketed by get/put	Otherwise you touch a powered-down device
Every error path drops its reference	Otherwise the device never sleeps
`pm_runtime_resume_and_get`, not `get_sync`	Avoids the failure-path count leak
Resume restores *all* register state	The hardware may have been reset
Resume works even if it was *not* reset	A shared power domain may have stayed on
Suspend refuses (`-EBUSY`) if mid-operation	Better than corrupting a transfer
No I2C/SPI in `_noirq` phases	The bus is already suspended
Wakeup respects `device_may_wakeup()`	The user's choice, not yours
Interrupts disabled before suspending the hardware	Avoids a handler on a dead device
Tested with `rtcwake` in a loop	Suspend bugs are often intermittent

How it shows up

Symptom	Cause
Device never runtime-suspends	Unbalanced `get`, often on an error path
`runtime_status` stuck at `active`	Same, or `power/control` is `on`
Crash or timeout on the first access after idle	Hardware access without a `get`

Symptom	Cause
Device misbehaves after resume	Register state not restored — use `regcache_sync()`
Works after system resume, not after runtime resume	Resume assumes a full reset that did not happen
Suspend hangs the machine	I2C/SPI access in a `_noirq` callback
Suspend aborts with `-EBUSY`	Your `.suspend` refused — usually correct
System wakes immediately	A wakeup source armed that should not be — check `pm_wakeup_irq`
Device cannot wake the system	`enable_irq_wake()` not called, or wakeup disabled in sysfs
Resume takes hundreds of milliseconds	`pm_print_times` names the device
Battery drains with the screen off	Some device never suspending — check every `runtime_status`

Check yourself

- ✓ Distinguish system suspend from runtime PM and say how they compose.
- ✓ Enable runtime PM in probe with autosuspend, and explain each call.
- ✓ Write runtime suspend and resume callbacks with correct error unwinding.
- ✓ Bracket a hardware access correctly, including the error path.
- ✓ Explain why `pm_runtime_resume_and_get` replaced `get_sync`.
- ✓ Name the suspend phases and say which may talk to an I2C device.
- ✓ Explain the parent/child ordering guarantee.
- ✓ Implement a wakeup source that respects the user's setting.
- ✓ Use `rtcwake`, `pm_print_times` and `runtime_status` to verify behaviour.
- ✓ Explain why resume must work whether or not the hardware was reset.

Error handling patterns and `devm`

The kernel has no exceptions and no destructors, so unwinding is manual — and error paths are the least-tested code in any driver. Two disciplines make them reliable: the `goto` ladder, and letting the device model free things for you.

The goto ladder

```
/* This is idiomatic kernel C, not a code smell. Every label
   undoes exactly one step, in reverse order.               */

static int mydev_probe(struct platform_device *pdev)
{
        struct mydev *d;
        int ret;

        d = kzalloc(sizeof(*d), GFP_KERNEL);
        if (!d)
                return -ENOMEM;

        ret = regulator_enable(d->vdd);
        if (ret)
                goto err_free;

        ret = clk_prepare_enable(d->clk);
        if (ret)
                goto err_reg;

        ret = mydev_hw_init(d);
        if (ret)
                goto err_clk;

        ret = request_irq(d->irq, mydev_isr, 0, "mydev", d);
        if (ret)
                goto err_hw;

        return 0;

err_hw:
        mydev_hw_shutdown(d);
err_clk:
        clk_disable_unprepare(d->clk);
err_reg:
        regulator_disable(d->vdd);
err_free:
        kfree(d);
        return ret;
}

/* WHY IT BEATS THE ALTERNATIVES:

   · nested ifs get unreadable past three levels, and the
     cleanup is duplicated at each depth
   · a single "cleanup everything" function must guess how far
     you got, which means tracking state - more code, more
     bugs
   · early returns duplicate the unwind at every exit

   THE RULE THAT MAKES IT WORK: label names say WHAT THEY
   UNDO, not where they came from. `err_clk` disables the
   clock. Add a step in the middle and you insert one label
   and one goto - nothing else changes.

   NAME THEM AFTER THE THING BEING UNDONE, never err1, err2,
   err3 - those force a renumber every time the order
   changes, and renumbering is where the mistakes creep in. */
```

devm: managed resources

```
/* The device model can free things automatically when the
   device unbinds - which deletes most of the ladder.       */

static int mydev_probe(struct platform_device *pdev)
{
        struct device *dev = &pdev->dev;
        struct mydev *d;

        d = devm_kzalloc(dev, sizeof(*d), GFP_KERNEL);
        if (!d)
                return -ENOMEM;

        d->base = devm_platform_ioremap_resource(pdev, 0);
        if (IS_ERR(d->base))
                return PTR_ERR(d->base);

        d->clk = devm_clk_get_enabled(dev, NULL);
        if (IS_ERR(d->clk))
                return PTR_ERR(d->clk);

        d->irq = platform_get_irq(pdev, 0);
        if (d->irq < 0)
                return d->irq;

        ret = devm_request_irq(dev, d->irq, mydev_isr, 0,
                               "mydev", d);
        if (ret)
                return ret;

        return 0;      /* no labels, no unwind, no leaks */
}

/* HOW IT WORKS: each devm_ call appends an entry to a list on
   the struct device. When the device unbinds - whether
   because probe failed, remove ran, or the module unloaded -
   the core walks that list IN REVERSE and calls each release
   function.

   So the unwinding order is automatically correct, and it is
   correct on the failure path too, without you writing it.

/* THE COMMON ONES: */
        devm_kzalloc, devm_kcalloc, devm_kstrdup
        devm_ioremap, devm_platform_ioremap_resource
        devm_clk_get, devm_clk_get_enabled, devm_clk_bulk_get
        devm_regulator_get, devm_regulator_bulk_get
        devm_reset_control_get
        devm_gpiod_get, devm_gpiod_get_optional
        devm_request_irq, devm_request_threaded_irq
        devm_regmap_init_mmio
        devm_pm_runtime_enable
        devm_add_action_or_reset   /* <-- the general one */
```

WHAT `DEVM` DOES NOT DO

`devm_clk_get()` releases the clock reference — it does **not** disable the clock. `devm_regulator_get()` does not disable the regulator. `devm_gpiod_get()` does not restore the pin state. Anything you *enabled* by hand, you must disable by hand in remove. Use `devm_clk_get_enabled()` and the bulk enable helpers where they exist; for the rest, the pattern below closes the gap.

devm_add_action_or_reset

```
/* Register YOUR OWN cleanup with the device, so anything can
   participate in managed unwinding.                          */

static void mydev_disable_vdd(void *data)
{
        regulator_disable(data);
}

        ret = regulator_enable(d->vdd);
        if (ret)
                return ret;

        ret = devm_add_action_or_reset(dev, mydev_disable_vdd,
                                       d->vdd);
        if (ret)
                return ret;
        /* from here on, the regulator is disabled
           automatically on unbind - and if the registration
           itself failed, _or_reset already called the action,
           so there is nothing to unwind.                     */

/* THE "_or_reset" SUFFIX IS THE POINT: plain
   devm_add_action() leaves you holding the resource if the
   registration fails, so you would need an error path for the
   error path. _or_reset calls the action immediately on
   failure, so `return ret;` is always correct.

   ALWAYS USE _or_reset. There is no good reason for the
   plain form in new code.                                    */

/* THIS PATTERN GENERALISES to anything: */
static void mydev_hw_off(void *data)
{
        mydev_hw_shutdown(data);
}
        ret = mydev_hw_init(d);
        if (ret)
                return ret;
        ret = devm_add_action_or_reset(dev, mydev_hw_off, d);
        if (ret)
                return ret;

/* Now even hardware shutdown is managed, and remove() can be
   empty - which is the goal: a driver whose teardown cannot
   be wrong because there is no teardown code to get wrong. */
```

ERR_PTR and error returns

```
/* Kernel convention: functions returning a pointer encode
   errors IN the pointer, using the top page of the address
   space, which no valid pointer occupies.                  */

        void *p = some_function();

        if (IS_ERR(p))
                return PTR_ERR(p);      /* extract the errno */

/* NOT: */
        if (!p)                          /* WRONG - an error
                                            pointer is NOT
                                            NULL              */

/* WRITING one: */
struct mydev *mydev_find(int id)
{
        if (id < 0)
                return ERR_PTR(-EINVAL);
        if (!exists(id))
                return ERR_PTR(-ENODEV);
        return &devices[id];
}

/* THE THREE-WAY CASE - can return NULL, an error, or a valid
   pointer (optional resources do this): */
        if (IS_ERR_OR_NULL(p))
                ...
        /* or, more precisely: */
        if (IS_ERR(p))
                return PTR_ERR(p);      /* a real error */
        if (!p)
                /* legitimately absent - the optional case */

/* PRINTING one: */
        dev_err(dev, "failed: %pe\n", p);
                -> "failed: -ENOMEM"

/* AND THE ERRNO CODES that matter in drivers: */
        -ENOMEM         out of memory
        -EINVAL         bad argument from a caller
        -ENODEV         no such device / not present
        -EIO            hardware failed
        -EBUSY          in use, try later
        -ETIMEDOUT      hardware did not respond
        -EPROBE_DEFER   a supplier is not ready yet
        -ENOTSUPP       this hardware cannot do that
        -ENOTTY         no such ioctl
        -EAGAIN         nothing available right now
        -ERESTARTSYS    interrupted, please restart

/* PICK THE SPECIFIC ONE. -EINVAL for everything makes a
   userspace program's diagnostics useless, and yours too. */
```

dev_err_probe

```
/* Every resource acquisition in probe should use it: */

        d->clk = devm_clk_get(dev, "core");
        if (IS_ERR(d->clk))
                return dev_err_probe(dev, PTR_ERR(d->clk),
                                     "failed to get core clock\n");

/* IT DOES FOUR THINGS:
     1. logs with the device name prefixed
     2. for -EPROBE_DEFER, logs at DEBUG level instead of
        ERROR - so normal boot is not flooded with messages
        about deferrals that resolve
     3. records the deferral reason, visible in
        /sys/kernel/debug/devices_deferred
     4. returns the error code, so `return` composes

   THE ALTERNATIVE people write: */
        if (IS_ERR(d->clk)) {
                dev_err(dev, "no clock\n");      /* spams on
                                                    every retry */
                return PTR_ERR(d->clk);
        }
/* which works but floods the log during normal deferred
   probe, and loses the deferral reason.                    */
```

Scope-based cleanup

```
/* Newer kernels have __cleanup__-based helpers, borrowed from
   C++ RAII. They release on EVERY exit from the scope,
   including returns and gotos.                              */

#include <linux/cleanup.h>

/* LOCKS: */
static int mydev_do_thing(struct mydev *d)
{
        guard(mutex)(&d->lock);       /* held until return */

        if (!d->ready)
                return -EAGAIN;        /* unlocked correctly */

        return mydev_thing(d);         /* and here too */
}

/* a narrower scope: */
        scoped_guard(spinlock_irqsave, &d->lock) {
                d->count++;
        }

/* MEMORY: */
        char *buf __free(kfree) = kmalloc(len, GFP_KERNEL);
        if (!buf)
                return -ENOMEM;
        ...
        return 0;              /* buf freed automatically */

/* REFERENCE COUNTS: */
        struct device_node *np __free(device_node) =
                of_parse_phandle(dev->of_node, "partner", 0);

/* WHERE THIS HELPS MOST: functions with many early returns
   under a lock, which is exactly where forgotten unlocks
   live. It does not replace the goto ladder for probe -
   ordered hardware teardown still needs explicit sequencing -
   but it removes a whole class of lock leaks.

   Check whether your target kernel has it before relying on
   it; it landed in 6.4 and later.                           */
```

Testing error paths

```
# Error paths are the least-executed and least-tested code in
# any driver. Force them.

# 1. FAULT INJECTION on allocations:
    CONFIG_FAILSLAB=y
    CONFIG_FAULT_INJECTION_DEBUG_FS=y
    echo 10   > /sys/kernel/debug/failslab/probability
    echo 100  > /sys/kernel/debug/failslab/times
    echo 1    > /sys/kernel/debug/failslab/verbose
    # then load your driver repeatedly. 10% of allocations
    # fail; anything that crashes is an unchecked return.

# 2. REMOVE RESOURCES from the device tree, one at a time:
#      delete the clocks property   -> probe must fail cleanly
#      delete the interrupt         -> same
#      point reg at a bad address   -> the ID check must catch it

# 3. BIND/UNBIND in a loop, under KASAN:
    for i in $(seq 100); do
      echo 1c000000.my-device > .../unbind
      echo 1c000000.my-device > .../bind
    done
    dmesg | grep -i -e kasan -e "warn" -e "bug"

# 4. CHECK FOR LEAKS after a failed probe:
    cat /proc/iomem      | grep 1c000000    # should be gone
    cat /proc/interrupts | grep my-device   # should be gone
    cat /sys/kernel/debug/kmemleak

# EVERY ONE of these finds real bugs in drivers that pass
# their functional tests. The fault-injection run in
# particular usually finds two or three unchecked returns the
# first time it is used on a driver.
```

> **THE RULE THAT PREVENTS MOST OF IT**
>
> Whenever you write a line that acquires something, write the line that releases it *in the same edit* — the `goto` label, the `devm_add_action_or_reset`, or the `__free` annotation. Deferring "I will add the cleanup later" is how leaks are born, because later never has the full context of what order things were acquired in.

How it shows up

Symptom	Cause
Crash when a NULL check "passed"	Checked for NULL where `IS_ERR` was needed
Resource leak after a failed probe	Missing unwind step, or an early return past the ladder
Region still in `/proc/iomem` after unbind	Bare `ioremap` instead of the devm/resource form
Clock stays on after unbind	`devm_clk_get` does not disable — use `devm_clk_get_enabled`
Regulator refcount imbalance warnings	`regulator_enable` without a matching disable path
Second bind fails after a successful unbind	State left behind — something not released
Log flooded with "failed to get clock" at boot	`dev_err` instead of `dev_err_probe` on a deferral
Deadlock on an error path	Early return under a lock — `guard()` prevents this class

Symptom	Cause
Crash only under memory pressure	Unchecked allocation — fault injection finds it in minutes
Unwind order wrong, hardware left in a bad state	Manual cleanup function that guessed how far setup got

Check yourself

- ✓ Write a `goto` ladder and explain the label-naming rule.
- ✓ Explain how `devm` unwinding works and in what order.
- ✓ List three things `devm` does *not* release for you.
- ✓ Use `devm_add_action_or_reset` and explain what the suffix guarantees.
- ✓ Distinguish `IS_ERR`, NULL and `IS_ERR_OR_NULL`, and print an error pointer.
- ✓ Choose the right errno for six different failures.
- ✓ Explain all four things `dev_err_probe` does.
- ✓ Use `guard()` and `__free()` and say which problem each removes.
- ✓ Run fault injection against your driver and fix what it finds.
- ✓ Verify no resources leak after a deliberately failed probe.

Debugging the kernel

Reading an oops, tracing with ftrace, attaching a debugger, and the config options that turn silent corruption into a loud message with a backtrace. The single highest-leverage skill in kernel work is extracting the maximum from one crash.

Reading an oops

```
Unable to handle kernel NULL pointer dereference at virtual
        address 0000000000000018
Mem abort info:
  ESR = 0x0000000096000004
  EC = 0x25: DABT (current EL), IL = 32 bits
  SET = 0, FnV = 0
  EA = 0, S1PTW = 0
  FSC = 0x04: level 0 translation fault
Data abort info:
  ISV = 0, ISS = 0x00000004
  CM = 0, WnR = 0
CPU: 2 PID: 431 Comm: mytest Tainted: G           O
                                     6.12.0 #1
Hardware name: ARM Juno development board (DT)
pstate: 60000005 (nZCv daif -PAN -UAO)

Code: aa0003f3 f9400400 91006000 f9400c00 (f9400c01)
---[ end trace 0000000000000000 ]---
```

```
READ IT IN THIS ORDER:

  1. THE FIRST LINE says what happened.
       "NULL pointer dereference at 0000000000000018"
       -> a pointer was NULL and something read offset 0x18
          from it. Look for a struct whose member is at 0x18.

  2. ESR/FSC decode the fault (ARM ch. 29):
       EC 0x25 = data abort, same EL
       FSC 0x04 = level 0 translation fault (nothing mapped)
       WnR = 0  = it was a READ

  3. pc : mydev_read+0x48/0x1c0 [mydev]
              ^^^^^^^^^^ ^^^^ ^^^^^  ^^^^^
              function   offset size  module
     -> THIS IS THE INSTRUCTION THAT FAULTED. Everything
        else is context.

  4. THE CALL TRACE, read bottom-up, is how you got there:
     userspace read() -> syscall -> vfs_read -> your function.

  5. "Tainted: G O" - O means an out-of-tree module is
     loaded. Other letters matter too (chapter 15).

  6. Code: shows the instructions around the fault, with the
     faulting one in (parentheses).

  THE ONE NUMBER THAT MATTERS: +0x48 in mydev_read. Turn it
  into a source line:
```

```
# Function + offset to file and line:
    aarch64-linux-gnu-addr2line -e mydev.ko -f -i 0x48
      mydev_read
      /home/you/mydev/mydev.c:142

# For a built-in function, use vmlinux and the absolute
# address (with nokaslr, or after adjusting for the offset):
    aarch64-linux-gnu-addr2line -e vmlinux -f -i ffff800008123456

# THE BEST TOOL - decodes a whole oops at once:
    ./scripts/decode_stacktrace.sh vmlinux . < oops.txt
# It annotates every frame with file:line. Paste an oops in,
# get a readable trace out. Learn this one command.

# Or disassemble around the offset:
    aarch64-linux-gnu-objdump -dS --start-address=0x30 \
        --stop-address=0x60 mydev.ko

# KEEP vmlinux AND THE UNSTRIPPED .ko from the exact build
# that is running. Without them an oops is just numbers.
```

NULL-PLUS-OFFSET TELLS YOU WHICH MEMBER

A fault at `0x18` means the code did `ptr->something` where `something` is 24 bytes into the struct and `ptr` was NULL. Use `pahole -C mydev mydev.ko` to print the struct layout with offsets, and the member is named directly. That usually identifies the bug faster than reading the source.

The other crash messages

Message	Means	First thing to check
`NULL pointer dereference`	Unchecked return, or use-after-free that poisoned the pointer	The offset, via `pahole`
`Unable to handle paging request`	A wild pointer	Whether the address looks like a poison pattern
`BUG: sleeping function called from invalid context`	Slept while atomic	The backtrace's caller (ch. 06)
`BUG: scheduling while atomic`	Same class	Locks held at the time
`WARNING: at ...`	A `WARN_ON` fired — a bug the kernel survived	The condition at that line
`soft lockup - CPU stuck for 22s`	A loop with preemption off	The looping function in the trace
`hard LOCKUP`	Interrupts disabled too long	Same
`INFO: task blocked for more than 120 seconds`	D state (ch. 09)	`/proc/PID/stack`
`rcu_sched self-detected stall`	No quiescent state	A loop or deadlock (ch. 12)
`possible circular locking dependency`	Lockdep found an AB-BA	Both lock sites it prints
`Kernel panic - not syncing`	Unrecoverable	The line above the panic

```
/* POISON PATTERNS - a faulting address that is one of these
   tells you immediately what kind of bug it is: */

   0x6b6b6b6b6b6b6b6b   SLAB_POISON: freed memory, reused
   0xa5a5a5a5a5a5a5a5   uninitialised slab memory
   0x5a5a5a5a5a5a5a5a   uninitialised
   0xdead000000000100   LIST_POISON1 - a list_head that was
                        deleted, then used
   0xdead000000000122   LIST_POISON2
   0xffffffffffffffff   often an ERR_PTR treated as a pointer

/* "Unable to handle kernel paging request at dead000000000100"
   means: you used a list entry after list_del(). That is a
   complete diagnosis from the address alone.              */
```

The config options that do the work

```
# A bug that KASAN catches at the moment it happens is a
# ten-minute fix. The same bug found by its downstream crash
# is a week. Enable these in every development build.

   ^^^ there is your bug, in three lines
```

ftrace

```
# Mounted at /sys/kernel/tracing (or debug/tracing).

# --- WHICH FUNCTIONS RUN, and how long ---
    cd /sys/kernel/tracing
    echo function_graph > current_tracer
    echo 'mydev_*'      > set_ftrace_filter
    echo 1 > tracing_on
    ... run the thing ...
    echo 0 > tracing_on
    cat trace

  2)               |  mydev_read() {
  2)   0.520 us    |    mydev_rd();
  2) + 15.240 us   |    wait_event_interruptible();
  2)   1.100 us    |    copy_to_user();
  2) + 18.140 us   |  }

# The durations are real. This is a profiler you did not have
# to instrument.

# --- WHO CALLS THIS FUNCTION ---
    echo 1 > options/func_stack_trace
    echo mydev_reset > set_ftrace_filter
    echo function > current_tracer
    cat trace         # every call, with a full backtrace

# --- EVENTS, cheaper and structured ---
    echo 1 > events/irq/enable
    echo 1 > events/sched/sched_switch/enable
    echo 1 > events/regmap/enable
    cat trace_pipe                    # live stream

# --- LATENCY: find the longest critical section ---
    echo preemptirqsoff > current_tracer
    echo 0 > tracing_max_latency
    ... run the load ...
    cat trace     # a backtrace of the WORST offender

# --- KPROBES: trace a function without recompiling ---
    echo 'p:myprobe mydev_read dev=%x0 count=%x2' \
         > kprobe_events
    echo 1 > events/kprobes/myprobe/enable
    cat trace_pipe

# --- trace-cmd, which is much nicer than the raw files ---
    trace-cmd record -p function_graph -l 'mydev_*' -- sleep 5
    trace-cmd report
    kernelshark                       # graphical

# --- A ONE-SHOT SNAPSHOT from inside your driver ---
    trace_printk("state=%d count=%d\n", state, count);
# Writes into the ftrace ring buffer, orders of magnitude
# faster than printk, and never blocks. Ideal in a hot path or
# an interrupt handler. Remove them before submitting - the
# kernel prints a banner warning if any remain.
```

A real debugger

```
# --- QEMU: the easy case (chapter 16) ---
    qemu-system-aarch64 ... -s -S
    # in another terminal:
    aarch64-linux-gnu-gdb vmlinux
    (gdb) target remote :1234
    (gdb) hbreak start_kernel
    (gdb) continue

# --- Debugging a MODULE: gdb needs to know where it landed ---
    # on the target:
    cat /sys/module/mydev/sections/.text
      0xffff800008a00000
    # in gdb:
    (gdb) add-symbol-file mydev.ko 0xffff800008a00000
    (gdb) break mydev_read
    (gdb) continue

# --- The kernel's own gdb helpers (CONFIG_GDB_SCRIPTS) ---
    (gdb) lx-dmesg              # the kernel log
    (gdb) lx-lsmod              # loaded modules
    (gdb) lx-ps                 # every task
    (gdb) lx-symbols            # AUTO-loads module symbols
    (gdb) lx-device-tree        # the DT
    (gdb) lx-iomem
# lx-symbols alone justifies enabling the option.

# --- KGDB on real hardware, over serial ---
    # kernel cmdline:
    kgdboc=ttyS0,115200 kgdbwait
    # the kernel waits for a debugger at boot
    (gdb) target remote /dev/ttyUSB0
    # or break in at any time:
    echo g > /proc/sysrq-trigger

# --- crash, for post-mortem on a dump ---
    crash vmlinux vmcore
    crash> bt                   # backtrace
    crash> ps
    crash> log
    crash> struct mydev ffff0000c1234000

# CAPTURING a dump needs kdump/kexec configured in advance -
# set it up before you need it, not after.
```

SysRq: when the system is nearly dead

```
# Over serial: send a BREAK, then the letter.
# From a shell: echo <letter> > /proc/sysrq-trigger

    l   backtrace of ALL CPUs         <-- for a hang
    w   backtrace of all BLOCKED tasks <-- for D states
    t   backtrace of every task
    m   memory statistics
    d   show all locks held            <-- for a deadlock
    p   registers
    c   crash deliberately (to trigger kdump)
    g   enter kgdb
    9   set loglevel to maximum
    s   sync disks
    u   remount read-only
    b   reboot immediately

# THE SEQUENCE FOR A HANG YOU CANNOT LOG INTO:
    <break>l      # what is every CPU doing?
    <break>w      # what is blocked?
    <break>d      # who holds what?
# Those three usually identify the culprit without any other
# tooling, and they work when nothing else does.

# Enable it: CONFIG_MAGIC_SYSRQ=y and
    echo 1 > /proc/sys/kernel/sysrq
```

A method

```
   1. MAKE IT REPRODUCE. A bug you can trigger on demand is
      most of the way solved. Script it.

   2. TURN ON THE DEBUG OPTIONS and reproduce again. KASAN,
      lockdep and DMA_API_DEBUG frequently name the bug
      outright, and you have just skipped steps 3-6.

   3. READ THE WHOLE MESSAGE. The first line, the ESR, the
      offset, the taint flags, the poison pattern. Most oopses
      contain more diagnosis than people extract.

   4. LOCALISE IN TIME. Was it always broken, or did it start?
      git bisect on the kernel, or on your driver.

   5. LOCALISE IN CODE. ftrace function_graph on your module
      shows exactly which function last ran.

   6. INSTRUMENT. trace_printk or a trace event around the
      suspect region. Cheap, fast, and safe in atomic context.

   7. CHANGE ONE THING. Then check. Never two.

   8. UNDERSTAND WHY IT WORKED. A fix you cannot explain is a
      timing change that moved the bug somewhere else - which
      is the most expensive kind of "fix" there is.
```

How it shows up

Symptom	Approach
Reproducible oops	`decode_stacktrace.sh`, then read the offset
Crash far from the cause	KASAN — it reports at the moment of the bad access
Memory grows over time	kmemleak, `slabtop`
Intermittent corruption	KASAN plus `slub_debug=FZPU`
Hang with no output	SysRq `l`, `w`, `d`
Process stuck in D	`/proc/PID/stack`
Deadlock	lockdep — it usually reports before the deadlock happens
Latency spike	`preemptirqsoff` tracer
Works, but slowly	`function_graph` with durations, or `perf`
Boot hang	`initcall_debug`, `earlycon` (ch. 03)
Regression after an upgrade	`git bisect` on the kernel
Only on production hardware	kdump, or serial logging with `keep_bootcon`

Check yourself

- ✓ Read an oops and name the faulting function, offset and call path.
- ✓ Turn a function+offset into a source line, three different ways.
- ✓ Use a NULL-plus-offset fault and `pahole` to name the struct member.
- ✓ Recognise five poison patterns and say what each implies.
- ✓ List ten debug config options and what each catches.
- ✓ Read a KASAN report and identify the allocation and free sites.
- ✓ Use `function_graph` to profile your driver's entry points.
- ✓ Add a kprobe to a function you did not compile in.
- ✓ Attach gdb to a module and set a breakpoint in it.
- ✓ Diagnose a hang using only SysRq.

Project: the ring-buffer character driver

A complete, working Linux driver you build, load and break yourself. No hardware needed — it runs on QEMU or any Linux machine. It exercises character devices, blocking I/O, poll, ioctl, locking, sysfs and correct teardown: nearly everything in the last twenty chapters.

What you are building

```
   /dev/ringbuf         a character device

   write(fd, data, n)   -> push bytes into a circular buffer
   read(fd, buf, n)     -> pop bytes out; BLOCKS if empty
   poll(fd, POLLIN)     -> wakes when data arrives
   ioctl(RB_GET_STATS)  -> how many bytes, drops, wakeups
   ioctl(RB_RESET)      -> empty it
   /sys/class/ringbuf/ringbuf/size     -> capacity, read-only
   /sys/class/ringbuf/ringbuf/used     -> bytes in it now

  THE POINT is not the ring buffer - it is everything around
  it: the concurrency between a reader that sleeps and a writer
  that wakes it, the teardown that must not race, the ioctl
  ABI, the error paths. That is what a real driver is made of;
  the hardware part is usually the easy half.
```

The files

```
ringbuf/
  ringbuf.c          the driver
  ringbuf.h          the UAPI header, shared with userspace
  Makefile
  test/
    rbtest.c         a userspace exerciser
    Makefile
```

ringbuf.h — the ABI

```
/* SPDX-License-Identifier: GPL-2.0 */
#ifndef _UAPI_RINGBUF_H
#define _UAPI_RINGBUF_H

#include <linux/types.h>
#include <linux/ioctl.h>

{
        printf("--- roundtrip ---\n");   test_roundtrip();
        printf("--- nonblock ---\n");    test_nonblock();
        printf("--- poll ---\n");        test_poll();
        printf("--- bad ioctl ---\n");   test_bad_ioctl();
        return 0;
}
```

Building and running it

```
# On the machine you will run it on (or cross-compile):
    cd ringbuf
    make
    sudo insmod ringbuf.ko
    dmesg | tail -2
      ringbuf: ready, 4096 bytes, major 241

    ls -l /dev/ringbuf
    cat /sys/class/ringbuf/ringbuf/size
      4096

# The shell can drive it directly:
    sudo sh -c 'echo hello > /dev/ringbuf'
    cat /sys/class/ringbuf/ringbuf/used
      6
    sudo cat /dev/ringbuf        # blocks after "hello" - Ctrl-C

# Run the exerciser:
    cd test && make && sudo ./rbtest

# Try the parameters:
    sudo rmmod ringbuf
    sudo insmod ringbuf.ko bufsize=65536
    echo 1 | sudo tee /sys/module/ringbuf/parameters/overwrite
```

Exercises — where the learning is

DO THESE IN ORDER. EACH ONE BREAKS SOMETHING YOU MUST THEN DIAGNOSE.

1. **Prove the lock matters.** Delete the `spin_lock_irqsave` pairs. Run two writers and a reader concurrently. Watch the counters drift from reality. Then put it back.
2. **Break the copy-outside-the-lock rule.** Move `copy_to_user` inside the spinlock. Build with `CONFIG_DEBUG_ATOMIC_SLEEP=y` and read the BUG message.
3. **Create a lost wakeup.** Replace `wait_event_interruptible` with a manual `set_current_state` / `schedule` that checks the condition *before* queueing. Reproduce the hang.
4. **Remove `.poll`.** Run `rbtest` and watch it spin at 100% CPU.
5. **Remove `poll_wait` on `writeq`.** Fill the buffer, then poll for `POLLOUT`. Observe that it never fires.
6. **Leak the buffer.** Delete `kfree(rb->buf)` from `rb_exit`. Load and unload 50 times with `CONFIG_DEBUG_KMEMLEAK=y`, then `echo scan > /sys/kernel/debug/kmemleak`.
7. **Use after free.** Move `kfree(rb)` before `cdev_del`. Hold an fd open, unload, and read. With KASAN you get a report naming both sites.
8. **Drop the `f_mode` check** in `RB_RESET` and confirm a read-only fd can now clear the buffer — a real privilege bug, in four lines.
9. **Add a feature:** a `RB_SET_SIZE` ioctl that reallocates the buffer. Think carefully about what must be locked, what happens to data in flight, and what a concurrent blocked reader sees. This is harder than it looks, which is the point.
10. **Add a second minor** so `/dev/ringbuf0` and `/dev/ringbuf1` are independent buffers. This converts the module-global design into a per-device one — the shape every real driver needs.

Reviewing your own work

```
# Run all of these before you consider it finished:

# 1. Style
    make check                      # checkpatch.pl

# 2. Sparse - __user annotations, endianness
    make C=1 M=$PWD

# 3. Load/unload 100 times under KASAN
    for i in $(seq 100); do
      sudo insmod ringbuf.ko && sudo rmmod ringbuf || break
    done
    dmesg | grep -i -e kasan -e bug -e warn

# 4. Concurrency: several writers and readers at once
    for i in 1 2 3 4; do
      (sudo dd if=/dev/urandom of=/dev/ringbuf bs=512 \
            count=1000 2>/dev/null) &
    done
    sudo dd if=/dev/ringbuf of=/dev/null bs=512 count=4000

# 5. Fault injection on the allocations
    echo 10  | sudo tee /sys/kernel/debug/failslab/probability
    echo 100 | sudo tee /sys/kernel/debug/failslab/times
    # load repeatedly; nothing should crash

# 6. rmmod while an fd is open - must return EBUSY
    exec 3</dev/ringbuf
    sudo rmmod ringbuf            # expect: Device or resource busy
    exec 3<&-

# THE ONES THAT USUALLY FIND SOMETHING are 3, 4 and 5.
```

Check yourself

- ✓ Explain why free-running head and tail counters avoid the full/empty ambiguity.
- ✓ Say why the user copy happens outside the spinlock, and what happens if it does not.
- ✓ Explain why `poll` registers on both wait queues before checking anything.
- ✓ Explain the partial-read rule: why `done > 0` returns rather than blocking again.
- ✓ Justify the order of every step in `rb_init` and `rb_exit`.
- ✓ Say what `.owner = THIS_MODULE` prevents, and demonstrate it.
- ✓ Complete exercises 1 through 8 and describe the symptom each produced.
- ✓ Implement exercise 9 or 10 and defend your locking.
- ✓ Run the full six-step review with no findings.

> **NEXT**
> Chapter 29 takes the same driver and attaches it to real hardware description — a device tree node, MMIO registers, an interrupt and DMA — turning it from a software toy into the shape of a shipping driver.

Project: the device-tree platform driver

The second project: a driver bound to a real device-tree node, driving MMIO registers, handling an interrupt, and exposing samples through a character device. Built and tested on QEMU against a device that actually exists — so everything you learn transfers directly to silicon.

The target device

```
We drive the PL031 real-time clock on QEMU's `virt` machine.
It is a real ARM PrimeCell, documented in a public TRM, present
on countless boards - and simple enough to fit in one chapter
while still having every element that matters:

     memory-mapped registers
     an interrupt
     a device-tree binding
     clocks
     a userspace interface

  REGISTER MAP (base 0x09010000 on qemu virt):

     0x00  RTCDR    data      - the current count (RO)
     0x04  RTCMR    match     - fire an interrupt at this value
     0x08  RTCLR    load      - set the counter
     0x0C  RTCCR    control   - bit 0: enable
     0x10  RTCIMSC  interrupt mask set/clear
     0x14  RTCRIS   raw interrupt status
     0x18  RTCMIS   masked interrupt status
     0x1C  RTCICR   interrupt clear (write 1)
     0xFE0 PeriphID0..3  - 0x31, 0x10, 0x14, 0x00
     0xFF0 PCellID0..3   - 0x0D, 0xF0, 0x05, 0xB1

  WHAT WE BUILD:  /dev/rtcalarm

     read()   blocks until the alarm fires, then returns the
              timestamp
     poll()   wakes on the alarm
     ioctl    set an alarm N seconds ahead; query state
     sysfs    current time, alarm time, count of alarms fired

  Linux already has a PL031 driver, so we bind to a DIFFERENT
  compatible string on a node we add ourselves. That keeps the
  real driver out of the way and teaches the binding mechanics
  properly.
```

Step 1: the device tree

```
# Get QEMU's own device tree, add our node, and feed it back.

# 1. dump what QEMU generates:
    qemu-system-aarch64 -M virt,dumpdtb=virt.dtb \
        -cpu cortex-a57 -nographic
    dtc -I dtb -O dts virt.dtb > virt.dts

# 2. find the existing pl031 node in virt.dts:
    pl031@9010000 {
        clock-names = "apb_pclk";
        clocks = <0x8000>;
        interrupts = <0x00 0x02 0x04>;
        reg = <0x00 0x9010000 0x00 0x1000>;
        compatible = "arm,pl031", "arm,primecell";
    };

# 3. CHANGE the compatible so OUR driver claims it, and add a
#    custom property to read:
    pl031@9010000 {
        clock-names = "apb_pclk";
        clocks = <0x8000>;
        interrupts = <0x00 0x02 0x04>;
        reg = <0x00 0x9010000 0x00 0x1000>;
        compatible = "hub,rtcalarm";           /* <-- ours */
        hub,default-alarm-seconds = <5>;       /* <-- custom */
    };

# 4. rebuild and boot with it:
    dtc -I dts -O dtb -o virt-mod.dtb virt.dts
    qemu-system-aarch64 -M virt -cpu cortex-a57 -m 512 \
      -dtb virt-mod.dtb \
      -kernel Image -initrd initramfs.cpio.gz \
      -append "console=ttyAMA0 earlycon rdinit=/init" \
      -nographic

# 5. confirm the device exists but nothing has claimed it:
    ls /sys/bus/platform/devices/ | grep 9010000
    ls -l /sys/bus/platform/devices/9010000.pl031/driver
      # No such file - no driver bound. Good.

# NOTE the interrupt: <0x00 0x02 0x04> = GIC_SPI 2, level high
# -> INTID 34 (chapter 14's off-by-32). You will see it in
# /proc/interrupts as hwirq 34.
```

Step 2: the driver

```
// SPDX-License-Identifier: GPL-2.0
/*
 * rtcalarm - a teaching platform driver for the PL031.
 *
 * Locking: d->lock (spinlock, irqsave) protects alarm_set,
 * alarm_time, fired and the counters. Taken from both process
 * context and the interrupt handler, hence irqsave.
 */

Step 3: run it

```
# Build for the target, install into the initramfs, and boot
# with the modified DTB from step 1.

    make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- \
         -C $KDIR M=$PWD modules

# In the guest:
    insmod rtcalarm.ko
    dmesg | tail -1
      rtcalarm 9010000.pl031: ready: count=1718000000 \
                default alarm 5s

# It bound - confirm through the device model (chapter 17):
    ls -l /sys/bus/platform/devices/9010000.pl031/driver
      -> ../../../bus/platform/drivers/rtcalarm

    ls /sys/bus/platform/devices/9010000.pl031/
      alarm_count  alarm_in  now  driver  of_node  ...

# Drive it entirely from the shell:
    cat /sys/bus/platform/devices/9010000.pl031/now
      1718000042
    echo 3 > /sys/bus/platform/devices/9010000.pl031/alarm_in
    sleep 4
    cat /sys/bus/platform/devices/9010000.pl031/alarm_count
      1

# Watch the interrupt actually arrive (chapter 14):
    grep rtcalarm /proc/interrupts
     34:   1   0   0   0  GICv3  34 Level  9010000.pl031
           ^ it fired once, on CPU0, hwirq 34

# Blocking read:
    cat /dev/rtcalarm | hexdump -C &
    echo 2 > /sys/bus/platform/devices/9010000.pl031/alarm_in
    # two seconds later, 16 bytes appear

# Unbind and rebind - exercises probe and remove (ch. 17):
    echo 9010000.pl031 > /sys/bus/platform/drivers/rtcalarm/unbind
    echo 9010000.pl031 > /sys/bus/platform/drivers/rtcalarm/bind
```

The userspace client

```
/* ratest.c */
#include <fcntl.h>
#include <poll.h>
#include <stdio.h>
#include <sys/ioctl.h>
#include <unistd.h>
#include "rtcalarm.h"

int main(int argc, char **argv)
{
        unsigned int seconds = (argc > 1) ? atoi(argv[1]) : 3;
        struct ra_state st;
        struct ra_event ev;
        struct pollfd pfd;
        int fd;

        fd = open("/dev/rtcalarm", O_RDWR);
        if (fd < 0) { perror("open"); return 1; }

        if (ioctl(fd, RA_GET_STATE, &st) < 0) {
                perror("RA_GET_STATE");
                return 1;
        }
        printf("now=%u fired=%u count=%llu\n", st.now, st.fired,
               (unsigned long long)st.alarm_count);

        if (ioctl(fd, RA_SET_ALARM, &seconds) < 0) {
                perror("RA_SET_ALARM");
                return 1;
        }
        printf("armed for %u seconds; waiting...\n", seconds);

        pfd.fd = fd;
        pfd.events = POLLIN;
        if (poll(&pfd, 1, (seconds + 5) * 1000) <= 0) {
                fprintf(stderr, "timed out - did the interrupt fire?\n");
                return 1;
        }

        if (read(fd, &ev, sizeof(ev)) != sizeof(ev)) {
                perror("read");
                return 1;
        }
        printf("ALARM at %u (alarm #%llu)\n", ev.timestamp,
               (unsigned long long)ev.count);

        close(fd);
        return 0;
}
```

Exercises

BREAK IT DELIBERATELY, THEN DIAGNOSE FROM THE SYMPTOM ALONE

1. **Wrong compatible.** Change it to `"hub,rtcalarm2"` in the driver only. Load it. Confirm probe never runs and the device has no `driver` link (ch. 17).
2. **Wrong address.** Change the `reg` in the DTS to `0x09011000`. The ID check fires — read the error and understand why an ID check is worth the five lines.
3. **Remove the clock.** Delete the `clocks` property. Observe `-EPROBE_DEFER` or a clean failure, and check `/sys/kernel/debug/devices_deferred`.
4. **Forget the acknowledge.** Delete `ra_wr(d, RTC_ICR, 1)` from the ISR. Arm an alarm. Watch the interrupt storm and the kernel's `nobody cared` protection (ch. 14).
5. **Return `IRQ_HANDLED` unconditionally**, dropping the `MIS` check. Nothing breaks here — then explain why it would on a genuinely shared line.
6. **Break the teardown order.** Move `misc_deregister` to the end of `remove`. Hold an fd open, unbind, and use it.
7. **Leave interrupts enabled in remove.** Unbind with an alarm armed. Watch what happens when it fires against a freed handler — with KASAN on, you get a report (ch. 27).
8. **Drop the lock** in the ISR and in `read`. Arm alarms in a tight loop from several processes and watch `alarm_count` lose increments.
9. **Add a feature:** a periodic mode that re-arms automatically in the ISR. Decide whether the re-arm belongs in the hard handler or a threaded one, and defend the choice (ch. 13).
10. **Add a proper binding.** Write `hub,rtcalarm.yaml` and validate it with `make dt_binding_check` (ch. 18).
11. **Convert to regmap** (ch. 23), marking `RTC_DR`, `RTC_RIS` and `RTC_MIS` volatile and `RTC_ICR` appropriately. Then enable the regmap trace events and watch every access.
12. **Add runtime PM** (ch. 25): suspend the block when no alarm is armed, resume on arm. Verify with `runtime_status`.

The review pass

```
# Before you call it done:

    make check                          # checkpatch
    make C=1 M=$PWD                     # sparse

# probe/remove cycles under KASAN:
    for i in $(seq 100); do
      echo 9010000.pl031 > /sys/bus/platform/drivers/rtcalarm/unbind
      echo 9010000.pl031 > /sys/bus/platform/drivers/rtcalarm/bind
    done
    dmesg | grep -i -e kasan -e warn -e bug

# no leaked resources after unbind:
    grep 9010000 /proc/iomem              # should be gone
    grep rtcalarm /proc/interrupts        # should be gone

# module load/unload cycles:
    for i in $(seq 100); do
      insmod rtcalarm.ko && rmmod rtcalarm || break
    done

# fault injection on probe:
    echo 20 > /sys/kernel/debug/failslab/probability
    # then bind repeatedly - no crashes, clean failures only

# the interrupt really fires, every time:
    for i in $(seq 20); do ./ratest 1; done
```

What transfers to real hardware

Everything structural. Swap the PL031 for your SoC's block and the changes are: a different register map, a different compatible string, more clocks and regulators, and probably DMA (chapter 24) instead of a single interrupt. The probe order, the teardown order, the locking discipline, the ioctl ABI rules, the sysfs conventions and the review checklist are identical.

That is the argument for building this on QEMU first: the parts you get wrong on real silicon are almost never the hardware parts. They are the ordering, the concurrency and the error paths — and you can practise all three without owning a board.

Check yourself

- ✓ Modify a device tree, rebuild it, and boot QEMU with your node.
- ✓ Explain how the `compatible` string binds your driver to that node.
- ✓ Justify the order of every step in probe and remove.
- ✓ Explain why the ID check belongs in probe and what three problems it catches.
- ✓ Explain why the ISR acknowledges before doing anything else.
- ✓ Say why `IRQF_SHARED` requires the `MIS` check.
- ✓ Read a custom DT property with a sensible fallback.
- ✓ Drive the device entirely from the shell via sysfs.
- ✓ Confirm the interrupt fires by reading `/proc/interrupts`.

- ✓ Complete exercises 1 through 8 and describe each symptom.
- ✓ Complete at least one of exercises 9 through 12.
- ✓ Pass the whole review with no findings.

Upstreaming and kernel culture

Getting your driver into mainline: why it is worth the effort, the mechanics of submitting a patch series, and what reviewers are actually looking for. The last chapter of the Linux track, and the one that decides whether your work outlives the product.

Why bother

```
THE OUT-OF-TREE COST, which compounds:

   the internal kernel API has no stability guarantee
   (chapter 02), so every kernel upgrade breaks your driver
      -> someone must fix it, forever
      -> that someone eventually leaves
      -> the product is stuck on a 2019 kernel with known CVEs

   THE VENDOR BSP PATTERN: a 4.19 kernel with 4,000 patches,
   which cannot take security fixes without a merge that
   nobody has budget for. This is the normal state of shipped
   embedded Linux, and it is a direct consequence of staying
   out of tree.

THE UPSTREAM BENEFIT:

   · other people fix your driver during API refactors, for
     free, forever
   · you get code review from people who have seen a thousand
     drivers
   · your users can run any kernel
   · security fixes flow automatically
   · new SoC variants are cheaper - the framework is already
     there
   · it is a portable, public record of your work

  THE HONEST COST: the first patch series takes weeks and
  several review rounds. The second takes days. It is a fixed
  learning cost, not a recurring one.
```

Before you send anything

```
# 1. IS IT ALREADY THERE? Search first.
    git log --oneline --all -- drivers/whatever/
    # and search lore.kernel.org for the device name, the
    # compatible string, and the vendor.
    # Finding an existing driver, or someone else's series
    # in flight, saves weeks.

# 2. USE THE RIGHT SUBSYSTEM (chapter 17). A temperature
#    sensor submitted as a custom char device will be asked
#    to become a hwmon driver. Find that out now, not after
#    three review rounds.

# 3. BASE ON THE RIGHT TREE.
    git remote add next \
      https://git.kernel.org/pub/scm/linux/kernel/git/next/linux-next.git
    # develop against linux-next or the relevant maintainer
    # tree, not against your vendor BSP.

# 4. CHECKPATCH, CLEAN.
    ./scripts/checkpatch.pl --strict -g HEAD~5..HEAD
    # --strict is what maintainers run. Fix everything it
    # reports, or be ready to explain why not.

# 5. SPARSE, COCCINELLE, THE BUILD BOTS' CHECKS.
    make C=1 M=drivers/mydrv/
    make W=1 M=drivers/mydrv/
    make coccicheck M=drivers/mydrv/

# 6. BUILD FOR OTHER ARCHITECTURES. The 0-day bot will do
#    this and email you if it breaks. Beat it to it:
    make ARCH=x86_64 allmodconfig && make M=drivers/mydrv/
    make ARCH=arm allmodconfig    && make M=drivers/mydrv/
    # a 32-bit build catches the u64-division and pointer-size
    # bugs that arm64-only testing never will.

# 7. THE DT BINDING VALIDATES (chapter 18).
    make dt_binding_check DT_SCHEMA_FILES=vendor,my-device.yaml
    make dtbs_check
```

Splitting the series

```
# ONE LOGICAL CHANGE PER PATCH. A typical new-driver series:

  [PATCH 0/4] Add support for the Vendor MyDevice
  [PATCH 1/4] dt-bindings: misc: add vendor,my-device
  [PATCH 2/4] misc: mydev: add Vendor MyDevice driver
  [PATCH 3/4] arm64: dts: vendor: add mydev node to mysoc
  [PATCH 4/4] MAINTAINERS: add entry for Vendor MyDevice

# WHY THIS ORDER: the binding comes first because it defines
# the interface the driver implements, and because it goes to
# a different maintainer who reviews it independently.
# The DTS patch comes after the driver, and often goes through
# the SoC tree rather than the subsystem tree - which is why
# it must be a SEPARATE patch.

# EACH PATCH MUST:
#   · compile on its own
#   · not break anything on its own (bisectability)
#   · do one thing, described in its subject line

# THE SUBJECT LINE FORMAT matters and is checked:
    subsystem: driver: short imperative description
# Get the prefix right by looking at history:
    git log --oneline -10 -- drivers/misc/
```

Writing the commit message

```
misc: mydev: add Vendor MyDevice driver

The MyDevice block is a data acquisition controller found on
Vendor MySoC parts. It provides four sampling channels with a
configurable hardware FIFO, and raises an interrupt when the
FIFO reaches a programmable threshold.

Add a driver exposing the device through a character node,
with blocking reads, poll() support and per-channel
configuration via ioctl. The v2 variant has eight channels and
a deeper FIFO; both are supported through match data.

The device is documented in the MySoC TRM revision 1.4,
section 12.

Signed-off-by: Your Name <you@example.com>

/* WHAT MAKES THIS ONE ACCEPTABLE:

   · says WHAT the hardware is, for a reviewer who has never
     heard of it
   · says WHAT the patch adds, in the imperative mood
     ("Add a driver", not "Added" or "This adds")
   · mentions the variants and how they are handled
   · cites the documentation
   · wrapped at 72 columns
   · has a Signed-off-by

   WHAT TO AVOID:
     · "misc: mydev: fixes" - says nothing
     · a message that only restates the diff
     · internal ticket numbers with no public meaning
     · "as discussed offline"                          */
```

The trailer tags

Tag	Meaning	Who adds it
`Signed-off-by`	The Developer's Certificate of Origin — a legal statement that you may contribute this	You, and everyone in the chain

    git config sendemail.smtpuser you@example.com
    git config sendemail.smtpencryption tls
    git config sendemail.smtpserverport 587

# 4. TEST IT ON YOURSELF FIRST. Always.
    git send-email --to=you@example.com outgoing/*.patch
# Then check the received mail: no HTML, no wrapped lines, no
# base64, no signature separator eating the diff. Apply it:
    git am received.mbox
# If it does not apply cleanly to your own tree, it will not
# apply to anyone's.

# 5. SEND:
    git send-email \
      --to="Maintainer <maint@example.com>" \
      --cc="linux-kernel@vger.kernel.org" \
      --cc="linux-arm-kernel@lists.infradead.org" \
      outgoing/*.patch

# 6. OR use b4, which handles most of this:
    b4 prep --new my-driver
    b4 send --dry-run
    b4 send
```

> **YOUR MAIL CLIENT WILL MANGLE THE PATCH**
> Gmail's web interface, Outlook, and any client that sends HTML or re-wraps lines will corrupt a patch beyond recovery, and the reply you get will be "your patch is whitespace-damaged, please resend". Use `git send-email` or `b4`. There is no third option that reliably works, and `Documentation/process/email-clients.rst` exists because so many people have learned this the hard way.

The cover letter

```
Subject: [PATCH v3 0/4] Add support for the Vendor MyDevice

This series adds support for the MyDevice data acquisition
block found on Vendor MySoC parts.

The device provides four (v1) or eight (v2) sampling channels
feeding a hardware FIFO, with a threshold interrupt. Userspace
reads samples through a character device and configures
channels with ioctl.

Tested on the Vendor EVK board with both v1 and v2 silicon,
and under QEMU with a stub model.

Changes in v3:
 - use dev_err_probe() throughout, per Krzysztof's review
 - drop the custom "vendor,irq-threshold" property and derive
   it from the FIFO depth instead
 - fix the 32-bit build (u64 division), reported by the 0-day
   bot
 - add the MAINTAINERS entry that was missing in v2

Changes in v2:
 - convert the binding to YAML schema
 - use devm_clk_get_enabled() instead of manual enable/disable
 - drop the module parameter; the DT property covers it

Your Name (4):
  dt-bindings: misc: add vendor,my-device
  misc: mydev: add Vendor MyDevice driver
  arm64: dts: vendor: add mydev node to mysoc
  MAINTAINERS: add entry for Vendor MyDevice

/* THE CHANGELOG IS THE MOST IMPORTANT PART for a v2 or
   later. Reviewers who commented on v1 read it first to see
   whether you addressed them. Omitting it means they must
   re-derive your changes by diffing, and they will not.  */
```

Handling review

WHAT REVIEWERS ARE ACTUALLY CHECKING

- **The userspace ABI** — the one thing that cannot be fixed later (ch. 21). Expect the most scrutiny here.
- **The DT binding** — also permanent. Are the properties describing *hardware*, or your driver's preferences?
- **Is there already a subsystem for this?** The most common substantive review outcome for a new driver.
- **Error paths** — every one, including the unwinding order (ch. 26).
- **Locking** — is it documented, is it consistent, is it necessary.
- **Modern APIs** — `devm_`, `dev_err_probe`, `of_device_get_match_data` rather than the patterns of ten years ago.
- **Does it build everywhere** — 32-bit, other architectures, `allmodconfig`.
- **Style** — cheaply checked, so failing it signals you did not run checkpatch.

```
# HOW TO RESPOND:

# · Reply to every comment. Even "will fix" - silence reads as
#   disagreement or absence.
# · Reply inline, below the quoted text, trimming the rest.
#   Top-posting makes threads unreadable and will be noted.
# · Plain text only.
# · If you disagree, say why, technically. Reviewers change
#   their minds when given a reason.
# · Do not argue about style. Just change it.
# · WAIT a week before resending. Maintainers batch review;
#   a v2 sent four hours after v1 wastes everyone's time.
# · Send v2 as a NEW thread, with In-Reply-To pointing at the
#   v1 cover letter, and a changelog.

# THE TONE: reviews are blunt and about the code. "This is
# wrong because X" is a technical statement, not an insult.
# The kernel has a Code of Conduct
# (Documentation/process/code-of-conduct.rst) and it is
# enforced - but expect directness, and give directness back.

# HOW LONG IT TAKES:
#   first response:   days to two weeks
#   a merge:          two to six versions, over one to three
#                     months, is entirely normal for a new
#                     driver
#   NOTHING AT ALL:   ping politely after two weeks, in-thread.
#                     Patches do get lost.
```

Tracking your patch

```
# Is it applied?
    git log --oneline --all --grep="MyDevice"

# The public archive of your thread:
    https://lore.kernel.org/all/?q=MyDevice
    b4 mbox <message-id>        # fetch the whole thread

# Automated feedback arrives within a day or two:
#   the 0-day bot: build failures on architectures you did not
#                  try, sparse warnings, coccinelle findings
#   the DT bot:    binding schema errors
#   syzbot:        if it finds a crash later
# These emails are automated but the findings are real. Fix
# them before a human has to point them out.

# WHEN IT IS ACCEPTED, a maintainer replies "Applied, thanks"
# and it lands in their tree -> linux-next -> the next merge
# window -> a release. That is typically 2-10 weeks after
# acceptance.

# THEN: you are the maintainer. Add yourself to MAINTAINERS,
# and expect bug reports.
```

The recurring mistakes

Mistake	Consequence
A new custom char device where a subsystem exists	Asked to rewrite against IIO/hwmon/input
DT properties describing driver policy, not hardware	Binding rejected
No YAML binding, or an unvalidated one	Bounced by the DT maintainers immediately
Sent from an HTML mail client	"Whitespace damaged, please resend"
One giant patch	Asked to split; nobody reviews a 3,000-line diff
No changelog on v2	Reviewers cannot tell what you changed
Resending within hours	Reviewers stop reading the series
Ignoring the 0-day bot	A human eventually says the same thing, less patiently
Arguing about coding style	Goodwill spent on nothing
Silence on review comments	The patch is dropped
Module parameters for hardware description	Asked to use DT
Missing `Signed-off-by`	Cannot be applied at all

What to read

Document	Why
`Documentation/process/submitting-patches.rst`	The definitive guide. Read it once, fully.
`Documentation/process/coding-style.rst`	Short, opinionated, and worth reading for the reasoning
`Documentation/process/email-clients.rst`	Saves you one embarrassing round
`Documentation/process/submit-checklist.rst`	Run through it before every send

Document	Why
`Documentation/process/stable-kernel-rules.rst`	What qualifies for a backport
`Documentation/driver-api/`	Subsystem-specific expectations
lore.kernel.org	Read a few accepted series in your subsystem before writing yours
LWN.net	Context for why things are the way they are

> **THE BEST PREPARATION COSTS AN AFTERNOON**
>
> Find three recently-merged driver series in your target subsystem on lore, and read every message in each thread — the patches, the review comments, and the revisions. You will learn what that specific maintainer cares about, what the house patterns are, and what gets pushed back on, far faster than from any documentation. Then write yours to match.

How it shows up

Symptom	Cause
No response at all after two weeks	Wrong recipients, mangled patch, or genuinely lost — ping in-thread
"Please resend, whitespace damaged"	Mail client — use `git send-email`
"Please split this up"	One patch doing several things
"Use the IIO subsystem"	Reinvented an existing ABI
"This property is not hardware description"	Driver policy in the DT
0-day bot reports a build failure	An architecture or config you did not build
Applied, then reverted	Broke something in linux-next — fix and resend quickly
Maintainer asks for a v2 you already sent	Sent as a new thread with no `In-Reply-To`
Merged, then bug reports arrive	Working as intended — you are the maintainer now

Check yourself

- ✓ Explain the compounding cost of staying out of tree.
- ✓ Run the seven pre-submission checks on your own driver.
- ✓ Split a new driver into a properly ordered patch series.
- ✓ Write a commit message that a stranger could act on.
- ✓ Explain what `Signed-off-by` asserts and why it is required.
- ✓ Use `get_maintainer.pl` and send a patch to yourself successfully.
- ✓ Write a cover letter with a real changelog.
- ✓ Name eight things reviewers check, in order of how permanent they are.
- ✓ Describe how to respond to review, including disagreement.
- ✓ Read three merged series in your subsystem and list what that maintainer asks for.

END OF THE LINUX TRACK

Thirty chapters, from the source tree to upstream, with two working drivers in between. Next: Windows kernel and drivers, which solves the same problems with a completely different architecture — and the comparison is what makes both clearer.

Project: a C2PA capture-attestation driver

Content Credentials are only as trustworthy as the moment the shutter closed. This project puts that moment inside the kernel and the signing key inside the secure world, so that a provenance claim is a statement about pixels the hardware actually produced — not about a file someone handed the signer. This chapter builds the capture side; chapter 32 builds the trusted application and the manifest.

What C2PA actually is

C2PA — the Coalition for Content Provenance and Authenticity — standardises a signed metadata block travelling with a media file. Strip away the vocabulary and it is four things.

```
A C2PA MANIFEST, from the inside out

1. ASSERTIONS - statements about the asset
     c2pa.hash.data   a hash over the asset's bytes, with
                      exclusions for the manifest itself.
                      THE HARD BINDING. Everything rests here.
     c2pa.actions     "created", "edited", "colour adjusted"
     stds.exif        camera, lens, exposure
     c2pa.thumbnail   a small preview
     (and ingredients, referencing parent assets)

2. CLAIM - a CBOR map that lists the assertions by URI and
     hash, names the generator, and picks the signature
     algorithm. The claim is what gets signed.

3. CLAIM SIGNATURE - a COSE_Sign1 structure over the claim,
     with an X.509 certificate chain in the protected header.

4. MANIFEST STORE - all of the above packed into JUMBF boxes
     and embedded in the file (an APP11 segment in JPEG, an
     iTXt/eXIf-adjacent box in PNG, a uuid box in BMFF).

THE CHAIN OF REASONING A VERIFIER FOLLOWS:

  the certificate chains to a trusted root
    -> so I know who signed
  the COSE_Sign1 signature is valid over the claim
    -> so the claim is what the signer said
  each assertion's hash matches the assertion bytes
    -> so the assertion list is intact
  c2pa.hash.data matches the asset's actual bytes
    -> so THIS FILE is the file that was signed

Break any link and the credential is invalid. Notice what
the chain does NOT establish: that the pixels depict
reality. C2PA proves PROVENANCE, not TRUTH.
```

The problem hardware solves

```
THE NAIVE CAMERA

sensor -> kernel -> user space -> signing library -> file
                        ^
                        |
                  an attacker with code execution here
                  substitutes any image they like, and the
                  signature over it is PERFECTLY VALID.

The credential now says "this device produced this image",
with a real device key, and it is a lie. The signature is
not forged; it is genuine, over forged content.

THIS IS THE ENTIRE THREAT. A device signing key protects
against someone ELSE claiming to be your camera. It does
nothing about your camera being told to sign a picture it
never took.

WHAT ACTUALLY HELPS

sensor -> kernel ----------------+
            |  hash the frame    |
            |  HERE, before any  |
            |  user process can  |
            |  see it            |
            v                    |
     +--------------+            |
     | attest(hash) |            |
     +------+-------+            |
            | SMC                | frame bytes
            v                    v
     +-------------------+   user space assembles the
     | TA remembers the  |   manifest, and asks the TA
     | hashes it has     |   to sign the claim
     | witnessed         |
     |                   |<-- sign(claim)
     | REFUSES to sign a |
     | claim whose hard  |    the TA parses out the
     | binding is not on |    c2pa.hash.data value and
     | that list         |    checks it against its list
     +-------------------+

Now user space can still lie about EXIF, about the title,
about anything soft. It cannot get a signature over an image
the kernel did not hash.
```

THE DESIGN IDEA WORTH TAKING AWAY

A signing service that signs whatever it is given proves only that the key was available. Binding the signature to something the *lower* layer witnessed is what turns a key into an attestation. The same pattern is a TPM quote (OP-TEE chapter 23), a measured-boot PCR, and a secure-element camera credential.

WHAT THIS DOES *NOT* DEFEND AGAINST

A compromised **kernel** can attest whatever it likes — the kernel is inside the trust boundary by construction, which is why real camera implementations put the hash even lower, in the ISP or the sensor package. A compromised **TA** is game over. And nothing here stops someone photographing a screen: C2PA never claimed to. State the boundary honestly whenever you describe such a system, because the marketing around Content Credentials frequently does not.

The ABI

```
/* include/uapi/linux/c2pa_capture.h
 *
 * Shared by the driver, the user-space tool and (via the command
 * ids at the bottom) the trusted application.
 */

#ifndef _UAPI_LINUX_C2PA_CAPTURE_H
#define _UAPI_LINUX_C2PA_CAPTURE_H

#include <linux/types.h>
#include <linux/ioctl.h>

#define C2PA_ABI_VERSION   1
#define C2PA_HASH_LEN      32      /* SHA-256                    */
#define C2PA_SIG_LEN       64      /* ES256: raw r || s          */
#define C2PA_PUBKEY_LEN    64      /* P-256: X || Y              */
#define C2PA_MAX_SIGSTRUCT 4096    /* a COSE Sig_structure       */

/* One capture. The driver fills this in; user space never gets
 * to choose any of it except by asking for another capture.
 */
struct c2pa_capture {

#define C2PA_IOC_PUBKEY  _IOWR(C2PA_IOC_MAGIC, 3, struct c2pa_pubkey)

/* Commands on the far side of the SMC. Separate numbering from
 * the ioctls on purpose: the driver translates, and the two
 * interfaces version independently.
 */
```

```
#define TA_CMD_GET_PUBKEY     0
#define TA_CMD_ATTEST_CAPTURE 1
#define TA_CMD_SIGN_CLAIM     2

#endif /* _UAPI_LINUX_C2PA_CAPTURE_H */
```

> **WHY `BINDING` IS A SEPARATE FIELD**
>
> The TA could parse the CBOR claim out of the Sig_structure and find `c2pa.hash.data` itself. It deliberately does not: a CBOR parser inside a TA is a large, attacker-reachable piece of code (OP-TEE chapter 20). Instead user space *declares* the binding, the TA checks that declaration against its witnessed list, and — the part that makes it sound — chapter 32 shows the TA also verifying that the declared binding actually appears in the bytes it is about to sign, with a fixed-offset memcmp rather than a parser.

The driver

```
// SPDX-License-Identifier: GPL-2.0
/*
 * c2pa_capture.c - a C2PA capture-attestation test driver.
 *
 * Produces synthetic frames, hashes them in the kernel, and has
 * an OP-TEE trusted application witness each hash before user
 * space ever sees the pixels.
 *
 * On real hardware the frame source is a V4L2 subdev or an ISP
 * DMA completion; everything else is unchanged.
 */

MODULE_LICENSE("GPL");
```

THE ORDERING THAT CARRIES THE WHOLE ARGUMENT

In `c2pa_do_capture`: generate, hash, attest, *then* `copy_to_user`. Move the copy earlier — which looks harmless, and which a later refactor will be tempted to do — and a second thread sharing the buffer could in principle observe or race the pixels before the TA has committed to their hash. Comment the ordering in the code, not just in the design document, because that is where the next person edits.

Building and loading

```
# Kbuild
obj-m += c2pa_capture.o
ccflags-y += -I$(src)/include

# Build against the OP-TEE QEMU kernel (OP-TEE chapter 4).
$ cd ~/optee/linux
$ ./scripts/config --enable TEE --enable OPTEE \
                   --enable CRYPTO_SHA256 --enable CRYPTO_USER_API_HASH
$ make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- olddefconfig
$ make ARCH=arm64 CROSS_COMPILE=aarch64-linux-gnu- -j$(nproc) Image modules

$ cd ~/c2pa/driver
$ make -C ~/optee/linux M=$PWD ARCH=arm64 \
       CROSS_COMPILE=aarch64-linux-gnu- modules

$ cp c2pa_capture.ko ~/optee/out-br/target/root/
$ cd ~/optee/build && make buildroot run-only
```

```
# In the guest:
# insmod c2pa_capture.ko
[   14.221408] c2pa-capture: /dev/c2pa0 ready

# The secure console, at the same moment:
I/TA: c2pa TA loaded

# If instead you see this, the TA is not installed:
[   14.220110] c2pa-capture: open_session rc=0 ret=0xffff0008
insmod: ERROR: could not insert module: No such file or directory

# And this means OP-TEE itself is not up:
[   14.219980] c2pa-capture: probing deferred
$ dmesg | grep optee
```

A smoke test before the manifest work

refused an unwitnessed binding, as it should

# That last line is the project. Everything in chapter 32 is
# packaging around it.
```

How it shows up

Symptom	Cause
`insmod` fails, `ret=0xffff0008`	`ITEM_NOT_FOUND`: the `.ta` is not in `/lib/optee_armtz`, or its filename does not match the UUID
Module load deferred for ever	OP-TEE driver absent — check `CONFIG_OPTEE` and `dmesg | grep optee`
`open_session` hangs	`tee-supplicant` not running; loading a TA needs it (OP-TEE chapter 9)
`crypto_alloc_shash` returns `-ENOENT`	`CONFIG_CRYPTO_SHA256` not enabled
Signing returns `-EACCES` for a real capture	The TA's witnessed list was cleared — it is bounded, and an old capture ages out (chapter 32)
Signing succeeds for a tampered binding	**The security property is broken.** The TA is not checking, or the driver is passing the wrong buffer
Every capture has the same hash	The test pattern is not advancing — `frame_no` not incrementing
Sporadic `-EFAULT`	User buffer smaller than `frame_len` claims, or freed while the ioctl runs
Deadlock under concurrent use	An error path returning without `mutex_unlock`
`rmmod` oopses	Teardown order — shared memory freed after the context, or a file still open

Check yourself

- ✓ Name the four layers of a C2PA manifest and say which one is the hard binding.
- ✓ State what a C2PA credential proves and what it explicitly does not.
- ✓ Explain the attack a device signing key alone does not prevent.
- ✓ Explain why the frame is hashed in the kernel rather than in user space.
- ✓ Say what the TA checks before signing, and why that turns a key into an attestation.
- ✓ Name two things this design still does not defend against.
- ✓ Explain why the driver logs in as `REE_KERNEL` rather than `PUBLIC`.
- ✓ Explain why the binding is declared by user space rather than parsed by the TA.
- ✓ Point to the ordering in `c2pa_do_capture` that the security argument depends on.

- ✓ Describe the shared-memory layout used by the sign command and count the memrefs.
- ✓ Run the smoke test and explain what its final line demonstrates.

Project: the C2PA trusted application and manifest

The secure half of the capture project: a trusted application that will only sign claims about images it witnessed, the COSE structure that carries the signature, and a real Content Credential that `c2patool` validates. Plus a clear list of what still stands between this and something you could ship.

COSE_Sign1, and a pleasant surprise

```
A C2PA claim signature is a COSE_Sign1 (RFC 9052):

  COSE_Sign1 = [
     protected   : bstr,   ; a serialised CBOR map
     unprotected : map,
     payload     : bstr,   ; the claim CBOR
     signature   : bstr
  ]

The protected header, for C2PA with ES256:

  {
     1  : -7,              ; alg = ES256 (ECDSA P-256 + SHA-256)
     33 : [ bstr, ... ]    ; x5chain - the certificate chain,
  }                        ;   RFC 9360, leaf first

WHAT IS ACTUALLY SIGNED is not the COSE_Sign1 and not the
payload. It is the Sig_structure:

  Sig_structure = [
     "Signature1",         ; context
     protected,            ; bstr, exactly as it appears above
     external_aad,         ; bstr, empty for C2PA
     payload               ; bstr, the claim
  ]

Serialise that array to CBOR, SHA-256 it, sign the digest.

THE PLEASANT PART:

  RFC 9053 s2.1 - "The signature value is the concatenation
  of the R and S values", fixed width, big-endian.

  So COSE wants RAW r || s. Exactly what
  TEE_AsymmetricSignDigest produces. No DER anywhere.

  Compare:
    COSE / JOSE / CNG   -> raw r || s      (64 bytes for P-256)
    OpenSSL / X.509 /   -> DER SEQUENCE of two INTEGERs
      TLS / CMS

  The Rust project needed a converter; this one does not.
  The TA's output drops straight into the signature slot.
```

BE PRECISE ABOUT WHAT CHECK 2 BUYS

The substring search proves the witnessed hash is *somewhere* in the bytes being signed. It does not prove it is the `c2pa.hash.data` value rather than, say, a thumbnail hash the caller planted. That residual gap is stated in the code comment on purpose. The honest ways to close it are a CBOR parser inside the TA — more attack surface — or having the TA construct the claim itself, which is what a production camera does and what the exercises at the end suggest you try.

Building the claim in user space

```
/* tools/c2pa-sign.c - a minimal CBOR/COSE encoder, and the
 * assembly of one real Content Credential.
 *
 * Nothing here is secret, so it all lives in the normal world.
 */

#include <stdint.h>

        return 0;
}
```

The manifest container

```
The three CBOR blobs above must be packed into JUMBF boxes
and embedded in the file:

JPEG file
 +-- SOI
 +-- APP11  "JP"  <- JUMBF superbox, split across segments
 |    +-- c2pa   (manifest store)
 |         +-- <manifest label>
 |              +-- c2pa.assertions
 |              |    +-- c2pa.hash.data   <- assertion.cbor
 |              +-- c2pa.claim            <- claim.cbor
 |              +-- c2pa.signature        <- signature.cose
 +-- ... the actual image data ...
 +-- EOI

Hand-rolling this is possible and tedious: box headers, UUIDs
per box type, label strings, and the APP11 segmentation rules
for payloads over 64 KB.

DO NOT hand-roll it for anything real. Use c2pa-rs, which is
the reference implementation, and plug the TEE in as a SIGNER
rather than reimplementing the container:

  c2pa-rs exposes a `Signer` trait whose whole job is

      fn sign(&self, data: &[u8]) -> Result<Vec<u8>>

  where `data` is precisely the Sig_structure our TA already
  signs. Implement it over /dev/c2pa0 and the SDK does the
  claim, the assertions, the JUMBF and the embedding.

That is the integration this project is really for: the SDK
handles the format, and the TEE handles the only part that
must not be forgeable.
```

Verifying

```
# Build and install everything (OP-TEE chapter 4 for the tree).
$ cd ~/c2pa/ta && make CROSS_COMPILE=aarch64-linux-gnu- \
      TA_DEV_KIT_DIR=~/optee/optee_os/out/arm-plat-vexpress/export-ta_arm64
$ cp *.ta ~/optee/out-br/target/lib/optee_armtz/
$ cp ~/c2pa/driver/c2pa_capture.ko ~/c2pa/tools/c2pa-sign \
     ~/optee/out-br/target/root/
$ cd ~/optee/build && make buildroot run-only

# In the guest:
# insmod c2pa_capture.ko
[   14.221408] c2pa-capture: /dev/c2pa0 ready
# ./c2pa-sign
capture id 1, 412 bytes of COSE_Sign1

# Secure console:
I/TA: c2pa TA loaded
I/TA: generating device key

# --- Verify the COSE signature by hand, on the host ---------------
# Reconstruct the Sig_structure, hash it, check the signature
# against the device public key. This is the whole cryptographic
# claim, checked without any C2PA tooling at all.

$ python3 <<'EOF'
import hashlib, binascii
from cryptography.hazmat.primitives.asymmetric import ec, utils
from cryptography.hazmat.primitives import hashes

pub = bytes.fromhex(open("pubkey.hex").read().strip())
key = ec.EllipticCurvePublicNumbers(
        int.from_bytes(pub[:32], "big"),
        int.from_bytes(pub[32:], "big"),
        ec.SECP256R1()).public_key()

ss  = open("sigstruct.cbor", "rb").read()
raw = open("signature.raw", "rb").read()      # 64 bytes, r||s
der = utils.encode_dss_signature(
        int.from_bytes(raw[:32], "big"),
        int.from_bytes(raw[32:], "big"))

key.verify(der, ss, ec.ECDSA(hashes.SHA256()))
print("COSE signature verifies")
EOF
COSE signature verifies

# Note the conversion on the Python side: `cryptography`, like
# OpenSSL, wants DER. COSE and the TA speak raw r||s. Same
# mathematics, two conventions.

# --- And with the reference tooling -------------------------------
$ cargo install c2patool
$ c2patool capture.jpg

    }
  ]
}

# signingCredential.untrusted is EXPECTED and CORRECT here. The
# signature is valid; the certificate is self-signed and chains
# to nothing anyone trusts. See below.
```

WHAT STILL STANDS BETWEEN THIS AND A SHIPPABLE CAMERA

1. A real certificate. C2PA validators check the leaf against a trust list of accepted CAs, and require specific extended key usages. A self-signed cert produces `signingCredential.untrusted` for ever. Getting on the list is a commercial and audit process, not a code change. **2. A trusted timestamp.** Without an RFC 3161 `sigTst`, a credential stops validating when the signing certificate expires. The TA's monotonic counter is *not* a timestamp — it proves ordering, not time. **3. Binding to the encoded file, not the raw frame** — see the comment in `c2pa-sign.c`. **4. A hardened key.** On QEMU the HUK is a fixed test value, so secure storage is not device-bound (OP-TEE chapter 15).

Testing the property, not the happy path

```
# A working demo proves nothing. These four tests are the ones
# that matter, and all four must behave as shown.

# 1. Sign a claim about an image the kernel never produced.
#    Craft a Sig_structure containing a hash of your own choosing.
# ./c2pa-attack --forge-binding
SIGN: Permission denied
#    TA log: E/TA: refusing to sign: binding not witnessed

# 2. Declare a witnessed binding, but sign a DIFFERENT claim.
# ./c2pa-attack --swap-claim
SIGN: Permission denied
#    TA log: E/TA: refusing to sign: binding absent from the claim

# 3. Replay: sign the same capture twice.
# ./c2pa-attack --replay
first  signature ok
second SIGN: Permission denied
#    Single-use witness slots.

# 4. Attest from user space, bypassing the kernel.
#    Open a session directly with libteec and call ATTEST.
# ./c2pa-attack --user-attest
TEEC_InvokeCommand: 0xffff000f
#    ACCESS_DENIED - the TA saw LOGIN_USER, not LOGIN_REE_KERNEL.

# If any of these SUCCEEDS, the project is decoration. Write
# them before you write the manifest code, not after.
```

Extensions worth doing

Exercise	What it teaches
Implement the `c2pa-rs` `Signer` trait over `/dev/c2pa0`	The real integration path, and how little of the SDK you have to touch
Move JPEG encoding into the kernel and bind to the encoded bytes	Closes the biggest gap in the design
Have the TA build the claim CBOR itself	Removes the residual gap in check 2, at the cost of CBOR in the TA
Add an RFC 3161 timestamp to the COSE unprotected header	Why signatures outlive certificates
Add `c2pa.actions` and an ingredient referencing a parent asset	How edit chains work, which is most of what C2PA is for
Replace the test pattern with a V4L2 `vivid` device	A realistic capture path (chapter 29)
Store the witness ring in secure storage instead of TA globals	Survives TA unload; costs a write per capture
Run the hostile client from OP-TEE chapter 20 against the TA	Whether the parameter validation is real
Measure the per-frame cost of the synchronous counter write	Why real cameras batch, and what they give up

How it shows up

Symptom	Cause
Signing always returns `-EACCES`	The declared binding does not match any witnessed hash — check that `CAPTURE` ran first and the hash was not modified
`-EACCES` with the right binding, after many frames	The witness slot aged out of the ring; sign sooner or enlarge `C2PA_WITNESS_SLOTS`
Second signature over one capture fails	Correct — witness slots are single-use
All witnessed captures vanish between runs	`TA_FLAG_INSTANCE_KEEP_ALIVE` missing
User-space attest succeeds	**The property is broken.** The login check is absent or the driver is not using `LOGIN_REE_KERNEL`
`c2patool`: `signingCredential.untrusted`	Expected on a self-signed certificate
`c2patool`: `claimSignature.mismatch`	The Sig_structure you signed is not the one you embedded — most often the protected header was re-encoded between signing and assembly
`c2patool`: `assertion.hashedURI.mismatch`	The assertion bytes changed after its hash went into the claim
`c2patool`: `assertion.dataHash.mismatch`	The hard binding does not match the file — the exclusion range is wrong, or you bound to the raw frame and embedded a JPEG
Signature verifies in Python, rejected by `c2patool`	DER versus raw r‖s confusion in the COSE signature slot
Verification fails about 1 time in 128	ECC coordinates not left-padded to 32 bytes
Counter resets on reboot	Secure storage on a volatile rootfs, or no RPMB (OP-TEE chapter 17)

Check yourself

✓ Write out a `Sig_structure` and say which of its four elements is hashed and signed.

- ✓ State which signature encoding COSE uses and contrast it with OpenSSL's.
- ✓ Explain why `ATTEST` is restricted to `LOGIN_REE_KERNEL`.
- ✓ Give the two checks the TA performs before signing, and what each one alone would fail to prevent.
- ✓ State precisely what check 2 does *not* prove, and two ways to close that gap.
- ✓ Explain why the witness ring is bounded and what the bound costs.
- ✓ Explain why witness slots are single-use.
- ✓ Describe the difference between binding to the raw frame and binding to the encoded file, and why it matters.
- ✓ Explain what `signingCredential.untrusted` means and why it is expected here.
- ✓ Say why a monotonic counter is not a substitute for an RFC 3161 timestamp.
- ✓ Run all four attack tests and confirm each is refused for the stated reason.
- ✓ Describe how you would plug this TA into `c2pa-rs` instead of hand-rolling JUMBF.

TRACK

Windows kernel & drivers

NT internals and KMDF driver development, ending in a complete signed driver and its user-mode client.

27 chapters

NT architecture

Windows solves the same problems as Linux with a different structure, different names, and a different philosophy about stability. This chapter is the map — and because you have just finished the Linux track, the comparisons will do most of the teaching.

The layers

```
 USER MODE
 +-----------------------------------------------------+
 | applications                                        |
 +-----------------------------------------------------+
 | subsystem DLLs:  kernel32.dll  user32.dll  advapi32 |
 +-----------------------------------------------------+
 | ntdll.dll        the syscall stubs. NtCreateFile etc.  |
 +--------------------------+--------------------------+
                            |  syscall (SVC on arm64)
 ===========================================================
 KERNEL MODE                |
 +--------------------------v--------------------------+
 |  ntoskrnl.exe  -  THE EXECUTIVE                      |
 |                                                      |
 |   Ob  object manager     Io  I/O manager             |
 |   Mm  memory manager     Ps  process/thread manager  |
 |   Cc  cache manager      Se  security reference monitor|
 |   Cm  configuration      Ex  executive support       |
 |       (registry)         Po  power manager           |
 |   Pnp plug and play      Rtl runtime library         |
 +------------------------------------------------------+
 |  KERNEL (Ke)  -  scheduling, interrupts, spinlocks,  |
 |                  DPCs, IRQL. The lowest software layer.|
 +------------------------------------------------------+
 |  HAL  -  hardware abstraction layer                  |
 |          interrupt controller, timers, bus access    |
 +------------------------------------------------------+
 |  DRIVERS  -  loaded into the same address space,     |
 |              at the same privilege, as everything above|
 +------------------------------------------------------+

THE PREFIXES ARE THE MAP. Every kernel function begins with
the two- or three-letter tag of the component that owns it:

   ObReferenceObjectByHandle    object manager
   IoCreateDevice               I/O manager
   MmGetSystemAddressForMdlSafe memory manager
   KeAcquireSpinLock            kernel
   ExAllocatePool2              executive
   PsGetCurrentProcessId        process manager
   RtlCopyMemory                runtime library
   ZwCreateFile                 the kernel-mode syscall entry

Learn the prefixes and you can guess where to look for
almost anything - which is the Windows equivalent of knowing
the Linux source tree layout (Linux ch. 01).
```

Against Linux

	Linux	Windows
Driver ABI	**Unstable** — rebuild every version	**Stable** — a 2015 driver often still loads
Source	Open; upstream or perish	Closed; drivers ship as binaries
Driver model	One: `struct device_driver`	Several: WDM, KMDF, UMDF
Hardware description	Device tree	ACPI and the registry
Installation	Copy a `.ko`, `modprobe`	An INF file, driver store, PnP
Signing	Optional (ch. 15)	**Mandatory** on x64 and arm64
Priority discipline	Context (process/softirq/hardirq)	**IRQL**, a numeric level
Sleeping rule	"Am I in atomic context?"	"Is IRQL <= PASSIVE_LEVEL?"
Request object	`struct bio`, `struct urb`, ad hoc	**The IRP**, universally
Layering	Subsystem-specific	**The device stack**, universal
Allocation	`kmalloc(size, GFP_*)`	`ExAllocatePool2(flags, size, tag)`
Debugging	printk, ftrace, KASAN	WinDbg, Driver Verifier, WPP

THE ONE DIFFERENCE THAT SHAPES EVERYTHING ELSE

Windows guarantees a **stable kernel driver ABI**. That single decision explains the closed driver ecosystem, the INF/driver-store installation model, mandatory signing, the WDF frameworks, and why Microsoft invests so heavily in verification tools: they cannot fix your driver during a refactor, because they never see it. Linux made the opposite trade — churn the API freely, and fix every in-tree driver when you do.

Neither is wrong. They are consistent answers to "who is responsible for keeping drivers working".

A syscall, end to end

```
application:  ReadFile(hFile, buf, len, &read, NULL);
      |
      v
kernel32.dll: parameter marshalling, then
      |
      v
ntdll.dll:    NtReadFile
                mov  x8, #0x06        ; the syscall number
                svc  #0               ; (arm64)
      |
      v  =============== kernel mode ===============
      |
KiSystemService -> the SSDT -> NtReadFile in ntoskrnl
      |
      v
I/O MANAGER (Io):
      · validate the handle    -> ObReferenceObjectByHandle
      · find the FILE_OBJECT and its DEVICE_OBJECT
      · BUILD AN IRP: IRP_MJ_READ, with the buffer, length
        and offset
      · IoCallDriver(deviceObject, irp)
      |
      v
THE TOP DRIVER in the stack
      · may complete it, or pass it down
      |
      v
... each lower driver in turn ...
      |
      v
THE FUNCTION DRIVER (yours)
      · does the work, or queues the IRP and returns
        STATUS_PENDING
      |
      v
IoCompleteRequest(irp, IO_NO_INCREMENT)
      · completion routines run, bottom-up
      · the I/O manager copies results back
      · the waiting thread is woken
      |
      v
ReadFile returns TRUE

COMPARE Linux: read() -> vfs_read -> f_op->read on your
file_operations. One indirection, one driver.

Windows routes EVERYTHING through a self-contained REQUEST
OBJECT (the IRP) that travels down a STACK of drivers, and
may complete asynchronously at any level. That is more
machinery, and it is what makes filter drivers, layered
storage, and asynchronous I/O uniform rather than
per-subsystem.
```

Everything is an object

```
/* The object manager (Ob) is the closest Windows analogue to
   Linux's VFS-plus-everything, and it is more general.     */

   \                        the root
   \Device\                 device objects
   \Device\HarddiskVolume1
   \Driver\                 loaded drivers
   \DosDevices\  (\??\)     symbolic links: C: -> \Device\...
   \BaseNamedObjects\       named events, mutexes, sections
   \Windows\                windowing
   \REGISTRY\               the registry, as objects
   \KernelObjects\

/* EVERY object has:
     a header with a type, a NAME (optionally), a reference
     count, a handle count, and a security descriptor
     a body specific to its type

   TYPES: Process, Thread, File, Device, Driver, Event,
   Mutant, Semaphore, Timer, Section, Key, Token, Job, ...

   HANDLES are per-process indices into a handle table, with
   an access mask. A handle is NOT a pointer, and converting
   one is an explicit, checked operation:                   */

        status = ObReferenceObjectByHandle(handle,
                                           FILE_READ_DATA,
                                           *IoFileObjectType,
                                           UserMode,   /* CHECK
                                                          ACCESS */
                                           &fileObject,
                                           NULL);
        ...
        ObDereferenceObject(fileObject);

/* THE `UserMode` ARGUMENT IS A SECURITY CONTROL: it tells the
   object manager to enforce the access mask as if a user-mode
   caller asked. Passing KernelMode skips those checks - and
   passing it while handling a user request is a classic
   privilege-escalation bug (chapter 03).                   */

/* SEE IT: the WinObj tool from Sysinternals browses the whole
   namespace. Run it once; it makes the model concrete.   */
```

The registry, not the device tree

```
; Where a driver's configuration lives:

HKLM\SYSTEM\CurrentControlSet\Services\MyDriver
    ImagePath     = \SystemRoot\System32\drivers\mydriver.sys
    Type          = 1          ; SERVICE_KERNEL_DRIVER
    Start         = 3          ; 0=boot 1=system 2=auto
                               ; 3=demand 4=disabled
    ErrorControl  = 1
    Group         = Extended Base

HKLM\SYSTEM\CurrentControlSet\Enum\PCI\VEN_1234&DEV_5678\...
    Service       = MyDriver   ; which driver claims it
    ClassGUID     = {...}
    HardwareID    = PCI\VEN_1234&DEV_5678
    Driver        = {class}\0001

; Per-device settings, the closest thing to DT properties:
HKLM\SYSTEM\CurrentControlSet\Enum\...\Device Parameters
    FifoDepth     = 32
    SampleRate    = 48000

/* READING them from a driver, via WDF: */
        WDFKEY key;
        ULONG  value;
        DECLARE_CONST_UNICODE_STRING(name, L"FifoDepth");

        status = WdfDeviceOpenRegistryKey(device,
                        PLUGPLAY_REGKEY_DEVICE,
                        KEY_READ, WDF_NO_OBJECT_ATTRIBUTES,
                        &key);
        if (NT_SUCCESS(status)) {
                status = WdfRegistryQueryULong(key, &name,
                                               &value);
                WdfRegistryClose(key);
        }
        if (!NT_SUCCESS(status))
                value = DEFAULT_FIFO_DEPTH;   /* always have a
                                                 default      */

/* WHERE THE VALUES COME FROM: the INF file writes them at
   install time (chapter 19). So the INF plays the role the
   device tree plays on Linux - describing this particular
   device - but it is applied once, into the registry, rather
   than parsed at every boot.

   ON ARM64 WINDOWS, hardware enumeration comes from ACPI
   rather than a device tree: the ACPI namespace describes the
   devices, and the PnP manager creates a device object for
   each.                                                    */
```

NTSTATUS

```
/* Windows kernel functions return NTSTATUS, not a negative
   errno.                                                    */

        NTSTATUS status;

        status = SomeFunction();
        if (!NT_SUCCESS(status))
                return status;

/* THE ENCODING - bits 31:30 are the severity: */
        0x0.......   SUCCESS
        0x4.......   INFORMATIONAL
        0x8.......   WARNING

        STATUS_ACCESS_DENIED
        STATUS_NOT_SUPPORTED
        STATUS_CANCELLED
        STATUS_TIMEOUT
        STATUS_UNSUCCESSFUL           /* the last resort */

/* Win32 error codes are DIFFERENT again; user mode sees those
   via GetLastError(). The I/O manager translates. So one
   failure has two names, and the WinDbg command
   `!error <value>` decodes either.                       */
```

UNICODE_STRING

```
/* Kernel strings are counted UTF-16, not NUL-terminated
   char*. This catches every newcomer once.                */

typedef struct _UNICODE_STRING {
        USHORT Length;           /* in BYTES, not characters */
        USHORT MaximumLength;    /* in BYTES */
        PWSTR  Buffer;           /* NOT necessarily
                                    NUL-terminated!          */
} UNICODE_STRING, *PUNICODE_STRING;

/* CREATING one: */
        UNICODE_STRING name;
        RtlInitUnicodeString(&name, L"\\Device\\MyDevice");

        /* or, for a constant, with no runtime cost: */
        DECLARE_CONST_UNICODE_STRING(name,
                                     L"\\Device\\MyDevice");

/* WORKING with them: */
        RtlCopyUnicodeString(&dst, &src);        /* truncates */
        RtlAppendUnicodeStringToString(&dst, &src);
        RtlCompareUnicodeString(&a, &b, TRUE);   /* case-insens */
        RtlEqualUnicodeString(&a, &b, TRUE);
        RtlUnicodeStringToAnsiString(&ansi, &uni, TRUE);

/* PRINTING one - the %wZ specifier takes a POINTER: */
        DbgPrint("name: %wZ\n", &name);

/* THE TRAPS:
     · Length is in BYTES. A 5-character string has
       Length == 10. Off-by-two-times is common.
     · the buffer may not be NUL-terminated, so wcslen() and
       friends can run off the end. Use Length.
     · a UNICODE_STRING from user mode has an attacker-chosen
       Length AND Buffer. Validate both, and probe the buffer
       (chapter 07).                                          */
```

Getting set up

```
# WHAT YOU NEED:
#   Visual Studio 2022 (Community is fine)
#     + "Desktop development with C++"
#     + the Windows SDK
#   The Windows Driver Kit (WDK), matching the SDK version
#   The WDK's Visual Studio extension
#
# https://learn.microsoft.com/windows-hardware/drivers/download-the-wdk

# NEW PROJECT -> "Kernel Mode Driver, Empty (KMDF)"
# That template gives you a .sys, a .inf, and the signing and
# packaging steps already wired up.

# A TEST MACHINE IS NOT OPTIONAL. A driver bug bugchecks the
# machine, and you do not want that to be your development
# box. Use a VM:
#   Hyper-V, VMware or VirtualBox
#   with a serial or network kernel-debugging connection to
#   the host (chapter 22)

# ENABLE TEST SIGNING on the target, so unsigned-by-Microsoft
# builds will load (chapter 20):
    bcdedit /set testsigning on
    bcdedit /set nointegritychecks off
    shutdown /r /t 0
# A "Test Mode" watermark appears on the desktop. That is
# expected.

# AND SET UP KERNEL DEBUGGING on the target now, before you
# need it:
    bcdedit /debug on
    bcdedit /dbgsettings net hostip:192.168.1.10 port:50000 \
            key:1.2.3.4
```

How it shows up

Symptom	Cause
Driver will not load, "digitally signed" error	Test signing not enabled (ch. 20)
Bugcheck immediately on load	Almost always IRQL or a bad pointer (ch. 02)
String prints as garbage	Used `%s` instead of `%wZ`, or a non-terminated buffer
Buffer overrun in string handling	`Length` is bytes, not characters
Code treats a warning as success	`NT_SUCCESS` is true for `0x8...` — check the specific status
Access check bypassed	Passed `KernelMode` where `UserMode` was required
Device never appears	INF did not match the hardware ID (ch. 19)
Registry value not found	The INF did not write it; always have a default
Debugging the dev box, box is dead	Use a VM — this is the first lesson everyone learns twice

Check yourself

✓ Name the executive components and their function prefixes.

- ✓ List eight differences between Linux and Windows driver architecture.
- ✓ Explain why a stable driver ABI leads to signing, INFs and WDF.
- ✓ Trace `ReadFile` from the application to a driver and back.
- ✓ Explain what an IRP is and how it differs from Linux's per-subsystem request types.
- ✓ Describe the object manager namespace and what a handle is.
- ✓ Explain why `UserMode` versus `KernelMode` matters in an object reference.
- ✓ Say where a driver's per-device configuration lives and how it got there.
- ✓ Explain the NTSTATUS severity encoding and the `NT_SUCCESS` trap.
- ✓ Use `UNICODE_STRING` correctly and name its three traps.
- ✓ Set up a VM with test signing and kernel debugging enabled.

IRQL

Interrupt Request Level is the single most important concept in Windows kernel programming. It is a per-CPU number that determines what your code is allowed to do, and violating its rules is the cause of most driver bugchecks.

The levels

```
 HIGH_LEVEL        (15)  bugcheck, everything masked
 ...
 CLOCK_LEVEL       (13)  the clock interrupt
 IPI_LEVEL         (14)  inter-processor interrupts
 ...
 DIRQL             (3-12) DEVICE interrupt levels - your ISR
                          runs here
 DISPATCH_LEVEL     (2)  the scheduler and DPCs
 APC_LEVEL          (1)  asynchronous procedure calls
 PASSIVE_LEVEL      (0)  normal thread execution
                                ^ lowest

THE RULE THAT DEFINES EVERYTHING:

   Code running at IRQL N can only be interrupted by code at
   IRQL > N, on the same CPU. Code at IRQL N cannot be
   preempted by anything at or below N.

So raising IRQL MASKS everything at or below it. At
DISPATCH_LEVEL the scheduler itself cannot run - which is
why you cannot block, wait, or page fault there.

THE CRITICAL BOUNDARY IS BETWEEN 1 AND 2:

   <= APC_LEVEL       the scheduler still works.
                      You may block, wait, and touch
                      paged memory.

   >= DISPATCH_LEVEL  the scheduler is masked.
                      NO blocking. NO waiting. NO paged
                      memory. NO page faults.

Everything else in this chapter follows from that line.
```

THE LINUX COMPARISON

IRQL does the job that "context" does in Linux (chapter 02), but as an explicit, readable, *settable* number rather than an implicit property of how you were called. Roughly: `PASSIVE_LEVEL` is process context; `DISPATCH_LEVEL` is softirq context or holding a spinlock; `DIRQL` is hardirq context. The difference is that Windows lets you *query* it (`KeGetCurrentIrql()`) and *raise* it deliberately, and every API's documentation states the IRQL it requires.

What you may do at each level

	PASSIVE (0)	APC (1)	DISPATCH (2)	DIRQL (3+)
Block / wait with a timeout	Yes	Yes	**No**	**No**

	PASSIVE (0)	APC (1)	DISPATCH (2)	DIRQL (3+)
Touch paged memory	Yes	Yes	**No**	**No**
Allocate paged pool	Yes	Yes	**No**	**No**
Allocate non-paged pool	Yes	Yes	Yes	Yes
Acquire a fast mutex	Yes	Yes	**No**	**No**
Acquire a spinlock	Yes (raises to DISPATCH)	Yes	Yes	Only at that DIRQL
Access user memory	Yes, in the right process	Careful	**No**	**No**
Call most Zw* / Io* APIs	Yes	Some	Few	Almost none
Queue a DPC	Yes	Yes	Yes	Yes
`DbgPrint`	Yes	Yes	Yes	Careful

```
/* THE PAGED MEMORY RULE IS THE SUBTLE ONE.

   Touching paged-out memory takes a page fault. Servicing a
   page fault requires disk I/O, which requires the scheduler
   to block the thread. At DISPATCH_LEVEL the scheduler cannot
   run.

   RESULT: bugcheck 0xA, IRQL_NOT_LESS_OR_EQUAL.

   And it is a LATENT bug: the memory is usually resident, so
   the code works for weeks. Then the machine is under memory
   pressure, the page is evicted, and the driver crashes -
   apparently at random.

   THIS IS WHY Driver Verifier has a "force IRQL checking"
   option that makes every pageable page non-resident, turning
   the latent bug into a reliable one (chapter 21). Use it.  */
```

Querying and changing IRQL

```
        KIRQL irql = KeGetCurrentIrql();

        if (irql > DISPATCH_LEVEL)
                return STATUS_INVALID_DEVICE_STATE;

/* RAISING and LOWERING - always paired, always LIFO: */
        KIRQL oldIrql;

        KeRaiseIrql(DISPATCH_LEVEL, &oldIrql);
        /* ... the scheduler cannot run here ... */
        KeLowerIrql(oldIrql);

/* You rarely do this explicitly. Acquiring a spinlock does it
   for you: */
        KIRQL oldIrql;

        KeAcquireSpinLock(&lock, &oldIrql);   /* raises to
                                                 DISPATCH     */
        /* ... critical section ... */
        KeReleaseSpinLock(&lock, oldIrql);    /* restores */

/* Or, when you KNOW you are already at DISPATCH_LEVEL: */
        KeAcquireSpinLockAtDpcLevel(&lock);
        ...
        KeReleaseSpinLockFromDpcLevel(&lock);
/* Cheaper - no IRQL change. Calling it below DISPATCH_LEVEL
   is a bug that Driver Verifier catches.                   */

/* ASSERT IT, in every function whose IRQL matters: */
        NT_ASSERT(KeGetCurrentIrql() == PASSIVE_LEVEL);
        NT_ASSERT(KeGetCurrentIrql() <= DISPATCH_LEVEL);

/* And DOCUMENT it in the function header, the way Microsoft's
   own headers do:

     IRQL_requires_max_(DISPATCH_LEVEL)
     NTSTATUS MyFunction(...);

   Those SAL annotations are checked by static analysis
   (chapter 21) - so an annotated codebase catches IRQL
   violations at BUILD time rather than at run time. That is
   the highest-value habit in this chapter.               */
```

SAL annotations

```
/* Windows drivers are annotated with SAL - Microsoft's source
   annotation language. Code Analysis reads them and finds
   real bugs statically.                                      */

_IRQL_requires_max_(DISPATCH_LEVEL)
_IRQL_requires_min_(PASSIVE_LEVEL)
_IRQL_requires_(PASSIVE_LEVEL)
_IRQL_raises_(DISPATCH_LEVEL)
_IRQL_saves_                    /* on an out KIRQL parameter */
_IRQL_restores_

_Must_inspect_result_
_Check_return_

_In_            /* input, must be valid */
_Out_           /* output, written by the callee */
_Inout_
_In_opt_        /* may be NULL */
_In_reads_bytes_(n)
_Out_writes_bytes_(n)

_Requires_lock_held_(lock)
_Acquires_lock_(lock)
_Releases_lock_(lock)

/* A realistic annotated declaration: */
_IRQL_requires_max_(DISPATCH_LEVEL)
_Must_inspect_result_
NTSTATUS
MyQueueRequest(
        _In_ PMY_DEVICE Device,
        _In_reads_bytes_(Length) PVOID Buffer,
        _In_ SIZE_T Length
        );

/* WHY BOTHER: Code Analysis will then tell you, at compile
   time, that you called this from a DIRQL ISR, or ignored its
   return value, or passed a buffer shorter than Length. Those
   are exactly the bugs that otherwise become bugchecks on a
   customer machine.

   ANNOTATE AS YOU WRITE. Retrofitting SAL to an existing
   driver is tedious; adding it to a new function costs
   seconds.                                                   */
```

The bugchecks IRQL causes

```
/* --- 0x0A  IRQL_NOT_LESS_OR_EQUAL --------------------------
   The most common driver bugcheck by a wide margin.

   MEANS: memory was touched at too high an IRQL. Either the
   memory is paged out, or the address is garbage.

   Parameters:
     1  the address referenced
     2  the IRQL at the time
     3  0 = read, 1 = write, 8 = execute
     4  the instruction address

   PARAMETER 2 IS THE DIAGNOSIS. If it is 2 or higher and the
   address looks plausible, you touched paged memory at
   DISPATCH_LEVEL. If the address is near zero, it is a NULL
   dereference that happens to have occurred at high IRQL. */

/* --- 0xD1  DRIVER_IRQL_NOT_LESS_OR_EQUAL ------------------
   The same thing, but the faulting code was identified as a
   driver. Same parameters. Parameter 4 names YOUR function.

/* --- 0xC4  DRIVER_VERIFIER_DETECTED_VIOLATION -------------
   Verifier caught an IRQL rule violation before it became a
   crash. The subcode says which rule (chapter 21).

/* --- 0x1E  KMODE_EXCEPTION_NOT_HANDLED --------------------
   An unhandled exception - often an access violation at high
   IRQL.

/* --- 0x7E  SYSTEM_THREAD_EXCEPTION_NOT_HANDLED ------------
   Same, in a system thread.

/* --- 0x133 DPC_WATCHDOG_VIOLATION -------------------------
   A DPC ran for more than ~20 microseconds too long, or the
   system stayed at DISPATCH_LEVEL for more than ~10 seconds.
   MEANS: your DPC is doing far too much work
   (chapter 10).                                          */

/* READING ONE in WinDbg (chapter 22): */
        !analyze -v
        .bugcheck
        kb                    /* the stack */
        !irql                 /* the IRQL at crash time */
```

Patterns that keep you correct

```
/* 1. KNOW WHICH IRQL YOUR CALLBACK RUNS AT. Every framework
      callback documents it. Memorise the common ones:      */

        DriverEntry                     PASSIVE_LEVEL
        EvtDriverDeviceAdd              PASSIVE_LEVEL
        EvtDevicePrepareHardware        PASSIVE_LEVEL
        EvtDeviceD0Entry                PASSIVE_LEVEL
        EvtIoRead / EvtIoWrite          <= DISPATCH_LEVEL
        EvtIoDeviceControl              <= DISPATCH_LEVEL
        EvtInterruptIsr                 DIRQL
        EvtInterruptDpc                 DISPATCH_LEVEL
        EvtWorkItem                     PASSIVE_LEVEL
        EvtTimerFunc                    DISPATCH_LEVEL
        EvtCleanupCallback              <= DISPATCH_LEVEL

/* 2. IF YOU NEED PASSIVE_LEVEL FROM A HIGHER ONE, queue a
      WORK ITEM (chapter 10). You cannot simply lower IRQL to
      escape - lowering below where you were called is a
      serious bug.

/* 3. MARK CODE PAGEABLE ONLY IF IT RUNS AT PASSIVE_LEVEL: */

        #pragma alloc_text(INIT,  DriverEntry)
        #pragma alloc_text(PAGE,  MyDeviceAdd)
        #pragma alloc_text(PAGE,  MyPrepareHardware)

        NTSTATUS MyDeviceAdd(...)
        {
                PAGED_CODE();     /* ASSERTS PASSIVE_LEVEL -
                                     put this at the top of
                                     every PAGE function     */
                ...
        }

   INIT   discarded after boot (like Linux's __init)
   PAGE   pageable
   .text  always resident - the default

/* PAGED_CODE() costs nothing in a release build and catches
   the mistake immediately in a checked one. Use it in every
   pageable function without exception.

/* 4. NON-PAGED DATA for anything touched above PASSIVE: */
        ExAllocatePool2(POOL_FLAG_NON_PAGED, size, 'GATd');
   and never a global marked with #pragma data_seg("PAGE").

/* 5. THE ONE-LINE HABIT that prevents most of this: before
      writing any line that touches memory or calls an API,
      ask "what IRQL am I at?" If you cannot answer instantly,
      look at the callback that got you here.             */
```

IRQL and spinlocks

```
/* A spinlock protects data; raising IRQL protects against
   PREEMPTION. Windows combines them because you almost always
   need both.                                                  */

/* Data shared between PASSIVE code and a DPC: */
        KeAcquireSpinLock(&d->Lock, &oldIrql);
        /* now at DISPATCH_LEVEL: the DPC cannot run on this
           CPU, and the spinlock excludes other CPUs        */
        ...
        KeReleaseSpinLock(&d->Lock, oldIrql);

/* Data shared with an ISR - the spinlock must be acquired at
   the DEVICE's IRQL, or the ISR can interrupt you while you
   hold it and deadlock (exactly the Linux spinlock
   self-deadlock, chapter 11):                              */
        KeAcquireInterruptSpinLock(interrupt, &oldIrql);
        ...
        KeReleaseInterruptSpinLock(interrupt, oldIrql);

/* In WDF this is: */
        WdfInterruptAcquireLock(interrupt);
        ...
        WdfInterruptReleaseLock(interrupt);

/* THE RULES:
     · a spinlock section runs at DISPATCH_LEVEL or higher, so
       everything forbidden at DISPATCH_LEVEL is forbidden
       inside it - no paged memory, no blocking, no
       paged-pool allocation
     · keep it SHORT. Other CPUs spin.
     · never acquire a lower-IRQL lock while holding a
       higher-IRQL one
     · the `oldIrql` variable must be LOCAL. Sharing one
       between CPUs corrupts the IRQL restore.            */
```

How it shows up

Symptom	Cause
Bugcheck 0xA or 0xD1, parameter 2 >= 2	Paged memory touched at DISPATCH_LEVEL or above
Works for days, then crashes under memory pressure	The same bug, latent — Verifier's IRQL checking exposes it
Bugcheck 0x133 DPC_WATCHDOG	A DPC doing far too much work
Hang with one CPU spinning	Spinlock acquired at the wrong IRQL, then interrupted by the ISR
Random corruption after a spinlock release	`oldIrql` shared instead of local
Verifier reports an IRQL violation on a working driver	A latent bug it made deterministic
Crash only on a multi-processor machine	Missing spinlock; IRQL alone does not exclude other CPUs
`ExAllocatePool2` fails or crashes in a DPC	Requested paged pool above PASSIVE_LEVEL
Code Analysis warns about IRQL	A real bug found at build time — fix it, do not suppress
Crash in a pageable function	Called above PASSIVE_LEVEL — `PAGED_CODE()` would have asserted

Check yourself

- ✓ List the IRQL levels in order and say what runs at each.
- ✓ State the masking rule and why DISPATCH_LEVEL is the critical boundary.
- ✓ Map IRQL onto Linux's execution contexts.
- ✓ Explain the paged-memory rule and why the resulting bug is latent.
- ✓ Raise and lower IRQL correctly, and say why you rarely should.
- ✓ Annotate a function with SAL and say what Code Analysis will then check.
- ✓ Decode bugcheck 0xD1 from its four parameters.
- ✓ State the IRQL of eight common framework callbacks.
- ✓ Use `#pragma alloc_text` and `PAGED_CODE()` correctly.
- ✓ Explain why data shared with an ISR needs an interrupt spinlock.

The object manager and handles

Windows unifies processes, files, devices, events and the registry into one object system with uniform naming, reference counting and security. Understanding it explains handle leaks, access checks, and a whole class of privilege-escalation bugs.

Anatomy of an object

```
 +-----------------------------------+
 |  OBJECT HEADER                    |
 |    PointerCount   kernel refs     |  <-- ObReference/
 |    HandleCount    open handles    |      ObDereference
 |    Type           -> OBJECT_TYPE  |
 |    SecurityDescriptor             |
 |    Name / Directory  (optional)   |
 |    Flags: permanent, exclusive... |
 +-----------------------------------+
 |  OBJECT BODY                      |
 |    type-specific data:            |
 |      FILE_OBJECT, DEVICE_OBJECT,  |
 |      EPROCESS, ETHREAD, KEVENT... |
 +-----------------------------------+

A POINTER to an object points at the BODY. The header is at
a negative offset, which is why you never touch it directly.

TWO INDEPENDENT COUNTS:
   HandleCount    how many open handles exist
   PointerCount   how many kernel references exist
                  (includes one per handle)

The object is destroyed when BOTH reach zero. That is what
makes it safe for a driver to keep using an object after
userspace has closed its handle - as long as it took a
reference.

THE TYPE OBJECT holds the procedures for that type:
   OpenProcedure, CloseProcedure, DeleteProcedure,
   ParseProcedure, SecurityProcedure, QueryNameProcedure

The ParseProcedure is how \Device\HarddiskVolume1\foo\bar
works: the object manager resolves as far as the device
object, then hands the REST OF THE PATH to the file system,
which parses it. That single mechanism is why the object
namespace and file system namespaces compose.
```

The namespace

```
\                          root
\Device\                   device objects created by drivers
    \Device\HarddiskVolume1
    \Device\MyDevice           <-- yours
\GLOBAL??\  (was \DosDevices\)  symbolic links
    \GLOBAL??\C:      -> \Device\HarddiskVolume3
    \GLOBAL??\MyDev   -> \Device\MyDevice
\Driver\                   loaded driver objects
\FileSystem\
\BaseNamedObjects\         named events, mutexes, sections
                           created by user mode
\Sessions\<n>\             per-session namespace
\KernelObjects\
\REGISTRY\MACHINE\...      the registry, as objects
\ObjectTypes\              the type objects themselves

/* WHY \GLOBAL?? MATTERS TO YOU: user mode cannot open
   \Device\MyDevice directly with CreateFile - it resolves
   names relative to \GLOBAL?? (and the per-session \??).
   So a driver that wants to be reachable creates a symbolic
   link:                                                  */

        DECLARE_CONST_UNICODE_STRING(devName,
                                     L"\\Device\\MyDevice");
        DECLARE_CONST_UNICODE_STRING(symLink,
                                     L"\\DosDevices\\MyDevice");

        status = IoCreateSymbolicLink(&symLink, &devName);
        ...
        IoDeleteSymbolicLink(&symLink);    /* in unload! */

/* then user mode opens: */
        h = CreateFileW(L"\\\\.\\MyDevice", ...);
              /* \\.\ maps to \GLOBAL?? */

/* BROWSE IT with Sysinternals WinObj. Do this once - seeing
   the real namespace makes the model concrete in a way no
   description does.                                      */
```

Handles

```
/* A handle is a per-process index into a handle table, not a
   pointer. Each entry holds:
        a pointer to the object
        a GRANTED ACCESS MASK
        flags: inheritable, protect-from-close, audit        */

/* THE ACCESS MASK is fixed at OPEN time. The object manager
   checks the requested access against the object's security
   descriptor once, then records what was granted. Every later
   operation is checked against the RECORDED mask - which is
   why a handle opened for read cannot later be used to
   write, even if the security descriptor changes.        */

        GENERIC_READ / GENERIC_WRITE / GENERIC_ALL
        FILE_READ_DATA / FILE_WRITE_DATA
        SYNCHRONIZE
        DELETE / READ_CONTROL / WRITE_DAC / WRITE_OWNER

/* CONVERTING A HANDLE TO AN OBJECT, in a driver: */
        PFILE_OBJECT fileObject;
        NTSTATUS status;

        status = ObReferenceObjectByHandle(
                        handle,
                        FILE_READ_DATA,     /* required access */
                        *IoFileObjectType,  /* expected TYPE   */
                        UserMode,           /* <-- CRITICAL    */
                        (PVOID *)&fileObject,
                        NULL);
        if (!NT_SUCCESS(status))
                return status;

        /* ... use fileObject ... */

        ObDereferenceObject(fileObject);    /* ALWAYS */
```

THE `ACCESSMODE` PARAMETER IS A SECURITY CONTROL, NOT A FORMALITY

`UserMode` tells the object manager to validate the handle as if a user-mode caller presented it: check that it is a user handle, that the type matches, and that the granted access covers what you asked for. `KernelMode` skips all of that.

Passing `KernelMode` while handling a request that *came from user mode* lets an unprivileged caller hand you a kernel handle value, or a handle without the access you require, and have your driver operate on it with full privilege. This is a textbook elevation-of-privilege bug and it has shipped in real drivers repeatedly. When servicing a user request, pass `Irp->RequestorMode` or `UserMode` — never a hard-coded `KernelMode`.

Reference counting

```
/* THE RULE: every ObReferenceObject* must be matched by
   exactly one ObDereferenceObject, on EVERY path including
   errors.                                                  */

        ObReferenceObject(object);              /* +1 */
        ObDereferenceObject(object);            /* -1 */

        ObReferenceObjectByPointer(object,
                                   DesiredAccess,
                                   ObjectType,
                                   AccessMode);

/* WHY A DRIVER TAKES A REFERENCE: you want to keep using an
   object after the operation that gave it to you returns -
   for example, storing a FILE_OBJECT to complete a request
   later. Without a reference, the object can be freed the
   moment the handle is closed, and you have a use-after-free
   in a place you cannot reproduce.                         */

/* THE FAILURE MODES:
     · leaked reference -> the object never dies. A device that
       cannot be removed, a process stuck in "Terminated"
       state, a driver that cannot be unloaded. Diagnosed with
       !object and !handle in WinDbg (chapter 22).
     · extra dereference -> premature free, then a
       use-after-free crash somewhere unrelated. Verifier's
       special pool catches it.

/* HANDLES YOU OPEN must be closed: */
        ZwClose(handle);

/* AND ALWAYS ASK: does this function return a referenced
   object? The documentation says so explicitly, and the
   answer determines whether you owe a dereference. Examples:

     IoGetCurrentProcess()            NO reference
     PsGetCurrentProcess()            NO reference
     ObReferenceObjectByHandle()      YES - dereference it
     IoGetDeviceObjectPointer()       YES - two things to
                                      release, actually      */
```

Creating a device object

```
/* The classic WDM way. WDF wraps this (chapter 14), but you
   should see it once because it explains what WDF is doing. */

NTSTATUS
DriverEntry(_In_ PDRIVER_OBJECT DriverObject,
            _In_ PUNICODE_STRING RegistryPath)
{
        UNICODE_STRING devName, symLink;
        PDEVICE_OBJECT deviceObject;
        NTSTATUS status;

        RtlInitUnicodeString(&devName, L"\\Device\\MyDevice");

        status = IoCreateDevice(
                        DriverObject,
                        sizeof(MY_DEVICE_EXTENSION),  /* your
                                                         state */
                        &devName,
                        FILE_DEVICE_UNKNOWN,
                        FILE_DEVICE_SECURE_OPEN,      /* apply
                                                         ACLs to
                                                         opens  */
                        FALSE,          /* not exclusive */
                        &deviceObject);
        if (!NT_SUCCESS(status))
                return status;

        /* the extension is YOUR per-device data - the Windows
           equivalent of drvdata (Linux ch. 17)             */

   can open \Device\MyDevice\anything and BYPASS the device's
   ACL, because the security check is only applied to the
```

```
   exact device name. Set it unless you have a namespace of
   your own to parse.                                        */
```

Securing a device

```
/* By default, a device object created by a driver may be
   openable by any user. Decide deliberately who may open it. */

/* 1. AN SDDL STRING in the INF (chapter 19) - the normal way: */
        [MyDevice_AddReg]
        HKR,,DeviceCharacteristics,0x10001,0x0100  ; SECURE_OPEN
        HKR,,Security,,"D:P(A;;GA;;;SY)(A;;GA;;;BA)"

/*    D:P                     a protected DACL
      (A;;GA;;;SY)            Allow, Generic All, SYSTEM
      (A;;GA;;;BA)            Allow, Generic All, Builtin Admins
   Add (A;;GRGW;;;WD) to allow read+write for Everyone - and
   think hard before you do.

/* 2. IoCreateDeviceSecure, in code: */
        DECLARE_CONST_UNICODE_STRING(sddl,
                L"D:P(A;;GA;;;SY)(A;;GA;;;BA)(A;;GRGW;;;WD)");

        status = IoCreateDeviceSecure(DriverObject,
                        sizeof(MY_DEVICE_EXTENSION),
                        &devName, FILE_DEVICE_UNKNOWN,
                        FILE_DEVICE_SECURE_OPEN, FALSE,
                        &sddl, NULL, &deviceObject);

/* 3. IN WDF (chapter 14): */
        WdfDeviceInitAssignSDDLString(deviceInit, &sddl);

/* THE COMMON SDDL ACRONYMS:
        SY  Local System        BA  Builtin Administrators
        WD  Everyone            AU  Authenticated Users
        IU  Interactive Users   RC  Restricted Code
        GA  Generic All         GR  Generic Read
        GW  Generic Write       GX  Generic Execute

/* AND A CHECK INSIDE AN OPERATION, when a specific action
   needs more privilege than opening does: */
        if (!SeSinglePrivilegeCheck(SeLoadDriverPrivilege,
                                    Irp->RequestorMode))
                return STATUS_PRIVILEGE_NOT_HELD;

/* THE DESIGN QUESTION to answer explicitly: if any user can
   open this device, then every IOCTL you expose is reachable
   by every user, including from a sandboxed process. Size the
   ACL to the least privilege your device genuinely needs -
   this is the Windows form of the least-privilege argument
   from isolation chapter 19.                                */
```

Inspecting objects

```
# --- Tools on the running machine ---
    WinObj              (Sysinternals) browse the namespace
    Process Explorer    per-process handle list, lower pane
    handle.exe          command line: who has this file open?
        handle.exe MyDevice

# --- In WinDbg (chapter 22) ---
    !object \Device                 list a directory
    !object \Device\MyDevice        one object's header
    !object ffff8a0c12345678

      Object: ffff8a0c12345678  Type: (ffff8a0c00112233) Device
        ObjectHeader: ffff8a0c12345650
        HandleCount: 2  PointerCount: 5
        Directory Object: ffffc00012340000  Name: MyDevice

    !handle                         all handles, this process
    !handle 0x1c4 f                 full detail on one
    !devobj ffff8a0c12345678        device object detail
    !drvobj \Driver\MyDriver 7      the driver and its
                                    dispatch table
    !object \ObjectTypes            every type, with counts

# --- FINDING A HANDLE LEAK ---
    !htrace -enable                 (before reproducing)
    ... run the workload ...
    !htrace -diff
# Shows every handle opened since the enable, with the stack
# that opened it. This is the tool for "handles keep climbing".

# Or from user mode:
    Process Explorer -> the process -> lower pane -> Handles
    and watch the count climb.
```

How it shows up

Symptom	Cause
`CreateFile` fails with ERROR_FILE_NOT_FOUND	No symbolic link, or the wrong name — check WinObj
`CreateFile` fails with ACCESS_DENIED	The device's ACL excludes the caller
Any user can open a privileged device	No SDDL set — the default is permissive
ACL bypassed by opening a sub-path	`FILE_DEVICE_SECURE_OPEN` not set
Unprivileged caller operates on a kernel object	`KernelMode` passed to `ObReferenceObjectByHandle` — a real EoP bug
Handle count climbs forever	Missing `ZwClose` — use `!htrace`
Driver cannot be unloaded	Leaked object reference — `!object` shows PointerCount
Use-after-free on a FILE_OBJECT	Kept a pointer without taking a reference
Crash on the extra dereference	Unbalanced `ObDereferenceObject`
I/O refused right after `IoCreateDevice`	`DO_DEVICE_INITIALIZING` never cleared
Symbolic link left behind after unload	No `IoDeleteSymbolicLink` in the unload path

Check yourself

- ✓ Describe an object's header, body and type, and the two reference counts.
- ✓ Explain how a parse procedure lets file paths extend the object namespace.
- ✓ Explain why a driver needs a symbolic link for user mode to reach it.
- ✓ Explain what a handle is and when its access mask is checked.
- ✓ State exactly what `UserMode` versus `KernelMode` changes, and the bug the wrong choice creates.
- ✓ Explain when a driver must take a reference, and both failure modes of getting it wrong.
- ✓ Create a device object with a device extension and a symbolic link, with correct cleanup.
- ✓ Explain what `FILE_DEVICE_SECURE_OPEN` prevents.
- ✓ Write an SDDL string granting access to SYSTEM and Administrators only.
- ✓ Find a handle leak with `!htrace`.

The I/O manager and IRPs

Every I/O operation in Windows is an I/O Request Packet travelling down a stack of drivers. One data structure carries reads, writes, IOCTLs, power transitions and PnP events alike — and understanding its lifecycle is understanding Windows I/O.

What an IRP is

```
 +-----------------------------------------+
 |  IRP HEADER                             |
 |    MdlAddress        for DIRECT I/O     |
 |    AssociatedIrp.SystemBuffer  BUFFERED |
 |    UserBuffer        METHOD_NEITHER     |
 |    IoStatus.Status   the result         |
 |    IoStatus.Information  bytes transferred|
 |    RequestorMode     UserMode / KernelMode|
 |    Cancel, CancelRoutine                |
 |    CurrentLocation                      |
 +-----------------------------------------+
 |  IO_STACK_LOCATION  [n-1]  bottom driver  |
 |  IO_STACK_LOCATION  [n-2]               |
 |  ...                                    |
 |  IO_STACK_LOCATION  [0]    top driver     |
 +-----------------------------------------+

ONE STACK LOCATION PER DRIVER in the device stack. Each
holds THAT driver's view of the request:

   MajorFunction     IRP_MJ_READ, IRP_MJ_DEVICE_CONTROL, ...
   MinorFunction     for PnP and power
   Parameters        a union: Read, Write, DeviceIoControl,
                     QueryDeviceRelations, Power, ...
   DeviceObject      which device
   FileObject        which open instance
   CompletionRoutine to run when a lower driver finishes

YOU GET YOURS WITH:
      PIO_STACK_LOCATION sp = IoGetCurrentIrpStackLocation(irp);

AND THE ONE BELOW YOU WITH:
      IoGetNextIrpStackLocation(irp)

THE DESIGN IDEA: the IRP is a self-contained request that
can be queued, cancelled, passed between drivers, and
completed asynchronously from any context. Linux has no
single equivalent - it has bio for block, urb for USB, skb
for network, and ad-hoc structures elsewhere. Windows pays
more machinery for one uniform mechanism.
```

The major function codes

Code	From	Notes
`IRP_MJ_CREATE`	`CreateFile`	An open. Your chance to refuse.
`IRP_MJ_CLOSE`	Last handle closed	Tear down per-open state

Code	From	Notes
`IRP_MJ_CLEANUP`	Last handle in a process closed	**Cancel pending I/O here**
`IRP_MJ_READ` / `_WRITE`	`ReadFile` / `WriteFile`	The data path
`IRP_MJ_DEVICE_CONTROL`	`DeviceIoControl`	IOCTLs (ch. 16)
`IRP_MJ_INTERNAL_DEVICE_CONTROL`	Kernel callers only	Driver-to-driver
`IRP_MJ_PNP`	The PnP manager	Start, stop, remove, query (ch. 05)
`IRP_MJ_POWER`	The power manager	D-states, S-states
`IRP_MJ_SYSTEM_CONTROL`	WMI	Instrumentation
`IRP_MJ_FLUSH_BUFFERS`	`FlushFileBuffers`	
`IRP_MJ_QUERY_INFORMATION`	File size etc.	

> **`CLEANUP` VERSUS `CLOSE` — THE DISTINCTION THAT MATTERS**
>
> `IRP_MJ_CLEANUP` arrives when the *last handle in a process* is closed, while the file object still exists. `IRP_MJ_CLOSE` arrives when the *last reference* to the file object goes away, which may be much later. Cancel and complete pending requests in **CLEANUP**: if you wait for CLOSE, a process that exits with I/O outstanding hangs in termination, because the file object cannot be released while your driver still holds its IRPs.

A dispatch routine

```
NTSTATUS
MyRead(_In_ PDEVICE_OBJECT DeviceObject, _In_ PIRP Irp)
{
        PMY_DEVICE_EXTENSION ext = DeviceObject->DeviceExtension;
        PIO_STACK_LOCATION sp = IoGetCurrentIrpStackLocation(Irp);
        ULONG length = sp->Parameters.Read.Length;
        PVOID buffer;
        NTSTATUS status;
        ULONG_PTR info = 0;

        /* For METHOD_BUFFERED the I/O manager already copied
           the user buffer somewhere safe (chapter 07):     */
        buffer = Irp->AssociatedIrp.SystemBuffer;

        if (length < sizeof(ULONG)) {
                status = STATUS_BUFFER_TOO_SMALL;
                goto complete;
        }

        status = MyReadData(ext, buffer, length, &info);

complete:
        Irp->IoStatus.Status = status;
        Irp->IoStatus.Information = info;   /* BYTES
                                               TRANSFERRED  */
        IoCompleteRequest(Irp, IO_NO_INCREMENT);
        return status;
}

/* THREE RULES, and each has a specific consequence:

   1. SET BOTH IoStatus FIELDS. `Information` is what
      ReadFile reports as bytes read. Leaving it uninitialised
      makes userspace read uninitialised stack contents as a
      length - and act on it.

   2. THE RETURN VALUE MUST MATCH IoStatus.Status, except that
      you return STATUS_PENDING when you did not complete it.

   3. ONCE YOU CALL IoCompleteRequest, THE IRP IS GONE.
      Touching it afterwards is a use-after-free. Not "may
      be" - the I/O manager may have freed it before the call
      returns.                                              */

/* IO_NO_INCREMENT vs a priority boost: the second argument
   boosts the waiting thread's priority on completion. Use
   IO_NO_INCREMENT unless the request took long enough that
   the thread deserves to run promptly (IO_DISK_INCREMENT and
   friends). Getting it wrong is a performance issue, not a
   correctness one.                                         */
```

Asynchronous completion

```
/* The interesting case: you cannot complete now, so you queue
   the IRP and return.                                          */

NTSTATUS
MyRead(_In_ PDEVICE_OBJECT DeviceObject, _In_ PIRP Irp)
{
        PMY_DEVICE_EXTENSION ext = DeviceObject->DeviceExtension;

        /* 1. MARK IT PENDING BEFORE QUEUEING. If you queue it
              first, another thread can complete it before you
              mark it - and marking a completed IRP is a
              use-after-free.                                   */
        IoMarkIrpPending(Irp);

        /* 2. set a cancel routine, so the request can be
              abandoned (below)                                 */
        IoSetCancelRoutine(Irp, MyCancelRoutine);

        /* 3. queue it */
        ExInterlockedInsertTailList(&ext->PendingIrps,
                                    &Irp->Tail.Overlay.ListEntry,
                                    &ext->QueueLock);

        /* 4. return PENDING. The IRP now belongs to your
              queue; do NOT touch it after this point without
              the queue lock.                                   */
        return STATUS_PENDING;
}

/* LATER - in the DPC when the hardware finishes: */
        PIRP irp = DequeueNextIrp(ext);

        if (irp) {
                irp->IoStatus.Status = STATUS_SUCCESS;
                irp->IoStatus.Information = bytesRead;
                IoCompleteRequest(irp, IO_NO_INCREMENT);
        }

/* AND THE USER SEES: ReadFile returns FALSE with
   GetLastError() == ERROR_IO_PENDING if the handle was opened
   with FILE_FLAG_OVERLAPPED, and the OVERLAPPED event is
   signalled at completion. Without FILE_FLAG_OVERLAPPED, the
   I/O manager blocks the thread for them and ReadFile appears
   synchronous.

   THIS IS ALL THE MACHINERY WDF QUEUES REMOVE (chapter 15).
   You should understand it once; you should not write it. */
```

Cancellation

```
/* A queued IRP can be cancelled at any moment - the thread
   called CancelIo, the process is exiting, the handle closed.
   Getting this right in raw WDM is genuinely hard.         */

VOID
MyCancelRoutine(_In_ PDEVICE_OBJECT DeviceObject, _In_ PIRP Irp)
{
        PMY_DEVICE_EXTENSION ext = DeviceObject->DeviceExtension;
        KIRQL oldIrql;

        /* The I/O manager called us holding the GLOBAL cancel
           spinlock, at DISPATCH_LEVEL. RELEASE IT FIRST -
           holding it while taking our own lock is a lock
           ordering violation and a system-wide bottleneck. */
        IoReleaseCancelSpinLock(Irp->CancelIrql);

        KeAcquireSpinLock(&ext->QueueLock, &oldIrql);
        RemoveEntryList(&Irp->Tail.Overlay.ListEntry);
        KeReleaseSpinLock(&ext->QueueLock, oldIrql);

        Irp->IoStatus.Status = STATUS_CANCELLED;
        Irp->IoStatus.Information = 0;
        IoCompleteRequest(Irp, IO_NO_INCREMENT);
}

/* AND THE RACE, which is the whole difficulty:

     the cancel routine can fire at ANY time after
     IoSetCancelRoutine, including WHILE you are dequeuing the
     same IRP to complete it normally.

   THE PROTOCOL: whoever successfully clears the cancel
   routine owns the IRP.

        /* dequeuing normally: */
        KeAcquireSpinLock(&ext->QueueLock, &oldIrql);
        irp = DequeueOne(ext);
        if (irp && IoSetCancelRoutine(irp, NULL) == NULL) {
                /* the cancel routine ALREADY fired and owns
                   this IRP - do not touch it */
                irp = NULL;
        }
        KeReleaseSpinLock(&ext->QueueLock, oldIrql);

   Every raw-WDM driver must get this exactly right, on every
   queue, and most of the historical cancellation bugs in
   Windows drivers are here.                                */
```

> **THIS IS THE STRONGEST ARGUMENT FOR WDF**
>
> A WDF queue (chapter 15) handles pending, cancellation, the cancel-routine race, power-state stalling, and per-file-object cleanup — correctly, once, for everyone. The code above exists in this chapter so you can read and debug legacy drivers, and so that you understand what the framework is doing on your behalf. **Write new drivers in KMDF.**

Passing an IRP down

```
/* A filter driver, or any driver with something below it. */

/* --- pass it down and forget about it -------------------- */
NTSTATUS
MyPassThrough(_In_ PDEVICE_OBJECT DeviceObject, _In_ PIRP Irp)
{
        PMY_DEVICE_EXTENSION ext = DeviceObject->DeviceExtension;

        IoSkipCurrentIrpStackLocation(Irp);   /* reuse OUR slot -
                                                 we want no
                                                 completion
                                                 callback      */
        return IoCallDriver(ext->LowerDevice, Irp);
}

/* --- pass it down and see the result --------------------- */

        IoSetCompletionRoutine(Irp, MyCompletion, ext,
                               TRUE,    /* on success */
                               TRUE,    /* on error   */
                               TRUE);   /* on cancel  */
        return IoCallDriver(ext->LowerDevice, Irp);
}

NTSTATUS
MyCompletion(_In_ PDEVICE_OBJECT DeviceObject, _In_ PIRP Irp,
             _In_ PVOID Context)
{
        /* Runs at <= DISPATCH_LEVEL, in an ARBITRARY thread.
           Do not assume you are in the requesting process. */

        if (Irp->PendingReturned)
                IoMarkIrpPending(Irp);   /* propagate it up -
                                            REQUIRED         */

        /* inspect or modify Irp->IoStatus here */

        return STATUS_CONTINUE_COMPLETION;
        /* or STATUS_MORE_PROCESSING_REQUIRED to STOP the
           completion and take ownership of the IRP - then you
           must complete it yourself later.               */
}

/* THE SKIP vs COPY DISTINCTION:
     IoSkipCurrentIrpStackLocation   reuses your slot for the
                                     next driver. Cheaper. No
                                     completion routine
                                     possible.
     IoCopyCurrentIrpStackLocationToNext  gives the next
                                     driver its own copy, and
                                     leaves yours free for the
                                     completion routine.

   Using Skip and then setting a completion routine corrupts
```

```
   the stack - a classic filter-driver bug that bugchecks
   randomly.                                                  */
```

The full lifecycle

```
   ReadFile()
       |
   I/O manager: IoAllocateIrp / IoBuildSynchronousFsdRequest
       |  fills IoStatus, RequestorMode, the buffer fields
       |  sets up stack location [0] for the top driver
       v
   IoCallDriver(top)
       |
   +---v-------------------+
   | top driver            |  IoSkip/IoCopy, IoCallDriver
   +---+-------------------+
       |
   +---v-------------------+
   | function driver (you) |  complete now, or
   |                       |  IoMarkIrpPending + queue
   +---+-------------------+       |
       |                           | later, from a DPC
       v                           v
   IoCompleteRequest(irp, boost)
       |
       |  walk UP the stack, running each completion routine
       |  bottom-first
       v
   the I/O manager:
       · copies SystemBuffer back to the user buffer
         (METHOD_BUFFERED)
       · unlocks and frees the MDL (DIRECT)
       · sets the OVERLAPPED / event
       · wakes the waiting thread
       · FREES THE IRP
       v
   ReadFile returns

  THE INVARIANT: an IRP is completed EXACTLY ONCE, by exactly
  one driver. Completing twice is a bugcheck; never completing
  it hangs the caller forever.
```

Debugging IRPs

```
# In WinDbg (chapter 22):

    !irp ffff8a0c12345678
      Irp is active with 3 stacks, 2 is current
       cmd flg cl Device  File   Completion-Context
       [IRP_MJ_READ(3), N/A(0)]
         0  0  ffff8a0c...  ffff8a0c...   00000000-00000000
                \Driver\MyDriver
                Args: 00001000 00000000 00000000 00000000

    !irpfind                    every IRP in the system
    !irpfind -v 0 0 device ffff8a0c12345678
                                IRPs for one device
    !devstack ffff8a0c12345678  the whole device stack
    !devobj ffff8a0c12345678    one device object

# WHY !irpfind IS THE TOOL FOR A HANG: a thread stuck in
# ReadFile has an IRP that nobody completed. Find it, see
# which driver holds the current stack location, and you have
# named the culprit.

# LIVE TRACING: the I/O verifier option in Driver Verifier
# (chapter 21) checks IRP handling rules aggressively - double
# completion, touching a completed IRP, wrong IRQL at
# completion, missing PendingReturned propagation. Turn it on;
# these are exactly the bugs that are otherwise
# unreproducible.
```

How it shows up

Symptom	Cause
Bugcheck 0x44 MULTIPLE_IRP_COMPLETE_REQUESTS	Completed the same IRP twice
Application hangs in `ReadFile` forever	IRP queued and never completed — find it with `!irpfind`
Process will not terminate	Pending I/O not cancelled in `IRP_MJ_CLEANUP`
Crash after completing a request	Touched the IRP after `IoCompleteRequest`
`ReadFile` reports a wrong byte count	`IoStatus.Information` not set
Userspace acts on garbage length	Same — uninitialised `Information`
Random bugcheck in a filter driver	`IoSkipCurrentIrpStackLocation` plus a completion routine
Asynchronous request never signals	`PendingReturned` not propagated in the completion routine
Deadlock during cancellation	Cancel spinlock not released before taking your own
Cancelled IRP completed twice	Lost the cancel-routine race — the `IoSetCancelRoutine(NULL)` protocol
Verifier reports an IRP rule violation	A real bug it made deterministic

Check yourself

- ✓ Describe an IRP's header and stack locations, and how you get yours.
- ✓ Name eight major function codes and what triggers each.

- ✓ Explain the difference between CLEANUP and CLOSE, and which cancels pending I/O.
- ✓ Write a synchronous dispatch routine and state the three completion rules.
- ✓ Explain why `IoMarkIrpPending` must precede queueing.
- ✓ Write a cancel routine and explain the ownership protocol.
- ✓ Distinguish Skip from Copy and say what breaks if you mix them up.
- ✓ Explain why a completion routine must propagate `PendingReturned`.
- ✓ Trace an IRP's full lifecycle and state the completed-exactly-once invariant.
- ✓ Use `!irpfind` to diagnose a hung application.

The device stack and Plug and Play

Windows layers several drivers over one piece of hardware, and the PnP manager orchestrates their lifecycle. Understanding the stack explains filter drivers, why devices appear with a yellow bang, and what WDF is doing for you when it "just works".

One device, several drivers

```
For a single physical device:

+-----------------------------------+
|  UPPER FILTER   (optional, several)|  encryption, tracing,
|     e.g. a monitoring filter       |  policy
+-----------------------------------+
|  FUNCTION DRIVER (FDO)             |  <-- YOURS. Knows
|     the driver that knows the      |      how the hardware
|     hardware                       |      works.
+-----------------------------------+
|  LOWER FILTER   (optional, several)|
+-----------------------------------+
|  BUS DRIVER (PDO)                  |  pci.sys, acpi.sys,
|     enumerated this device,        |  usbhub.sys
|     owns its resources             |
+-----------------------------------+

NAMES YOU MUST KNOW:

  PDO   Physical Device Object. Created by the BUS driver
        to say "a device exists here". One per child.
  FDO   Functional Device Object. Created by YOUR driver
        and attached above the PDO.
  FiDO  Filter Device Object.

An IRP enters at the TOP and travels down (chapter 04).
Each layer may handle it, modify it, or pass it on.

WHY THIS EXISTS: it makes filtering universal. A disk
encryption filter, a keyboard logger, a USB analyser and a
power policy owner all attach the same way, to any device,
without the function driver knowing. Linux has no direct
equivalent - filtering there is per-subsystem or done with
stacked block devices.

SEE A REAL ONE:
     WinDbg:  !devstack ffff8a0c12345678
     Device Manager -> device -> Details -> "Upper filters"
```

The PnP state machine

```
BUS DRIVER enumerates hardware
     |  reports a new child in
     |  IRP_MN_QUERY_DEVICE_RELATIONS (BusRelations)
     v
PnP MANAGER creates a PDO, reads its HARDWARE IDs
     |     PCI\VEN_1234&DEV_5678&SUBSYS_...&REV_01
     |     ACPI\VEN0001
     v
matches against installed INFs (chapter 19)
     |
     v
loads the driver, calls DriverEntry (once per driver)
     |
     v
calls EvtDriverDeviceAdd / AddDevice (once PER DEVICE)
     |     you create the FDO and attach it to the stack
     v
IRP_MN_QUERY_RESOURCE_REQUIREMENTS
     |     "what does this device need?"
     v
PnP manager ASSIGNS resources (memory ranges, interrupts,
DMA channels) - arbitrating between all devices
     |
     v
IRP_MN_START_DEVICE                <-- the big one
     |     WDF: EvtDevicePrepareHardware  (map registers)
     |          EvtDeviceD0Entry          (power it up)
     |          interrupts connected
     v
===== DEVICE IS RUNNING; I/O flows =====
     |
     v
IRP_MN_QUERY_REMOVE_DEVICE     "may I remove it?"
     |     you may VETO this if you are busy
     v
IRP_MN_REMOVE_DEVICE
     |     WDF: EvtDeviceD0Exit
     |          EvtDeviceReleaseHardware
     |          EvtDeviceSelfManagedIoCleanup
     v
device object deleted

OTHER TRANSITIONS you must handle:
  IRP_MN_CANCEL_REMOVE_DEVICE   the remove was vetoed
  IRP_MN_QUERY_STOP / STOP      resource rebalance
  IRP_MN_SURPRISE_REMOVAL       the user yanked it out
  IRP_MN_QUERY_CAPABILITIES
  IRP_MN_QUERY_ID / QUERY_DEVICE_TEXT
```

> **SURPRISE REMOVAL IS NOT AN EDGE CASE**
> For anything on USB, PCIe hot-plug, or a removable bus, `SURPRISE_REMOVAL` is the *normal* path — the hardware is already gone when you are told. Every register read now returns `0xFFFFFFFF`, every pending request must be completed with an error, and any code that waits for the hardware to respond will hang forever. Write the driver so that "the device vanished mid-operation" is a handled case from the first day, not something retrofitted after a bug report.

Doing it in raw WDM

```
/* Shown so you can read legacy drivers and understand what
   WDF replaces. Do not write new code this way.           */

                        &GUID_DEVINTERFACE_MYDEVICE,
                        NULL);   /* an optional reference
                                    string, to distinguish
                                    several interfaces on one
                                    device                  */

/* 3. USER MODE FINDS IT by GUID, not by name: */

        HDEVINFO info;
        SP_DEVICE_INTERFACE_DATA ifData = { sizeof(ifData) };
        PSP_DEVICE_INTERFACE_DETAIL_DATA_W detail;
        DWORD needed;
        HANDLE h;

        info = SetupDiGetClassDevsW(&GUID_DEVINTERFACE_MYDEVICE,
                        NULL, NULL,
                        DIGCF_PRESENT | DIGCF_DEVICEINTERFACE);

        SetupDiEnumDeviceInterfaces(info, NULL,
                        &GUID_DEVINTERFACE_MYDEVICE, 0, &ifData);

        SetupDiGetDeviceInterfaceDetailW(info, &ifData, NULL, 0,
                                         &needed, NULL);
        detail = malloc(needed);
        detail->cbSize = sizeof(*detail);
        SetupDiGetDeviceInterfaceDetailW(info, &ifData, detail,
                                         needed, &needed, NULL);

        h = CreateFileW(detail->DevicePath, GENERIC_READ |
                        GENERIC_WRITE, 0, NULL, OPEN_EXISTING,
                        FILE_ATTRIBUTE_NORMAL, NULL);

/* THE PATH looks like:
     \\?\pci#ven_1234&dev_5678#4&1a2b3c4d&0&00e0#{a1b2c3d4-...}

   WHY THIS IS BETTER than a symbolic link:
     · several identical devices coexist, each with its own
       path
     · user mode can enumerate ALL of them
     · arrival and removal can be watched with
       CM_Register_Notification / RegisterDeviceNotification,
       so an application reacts to hot-plug
     · no name collisions between vendors            */
```

Debugging the stack

```
# --- Device Manager, first ---
#   View -> Show hidden devices
#   The device's Properties -> Details tab:
#       Hardware Ids           what the INF must match
#       Device Instance Path
#       Upper/Lower filters
#       "Problem code"         <-- the yellow bang's meaning
#
#   COMMON PROBLEM CODES:
#     Code 10  the driver failed IRP_MN_START_DEVICE
#     Code 12  resource conflict - PnP could not assign
#     Code 18  reinstall required
#     Code 28  no driver installed
#     Code 31  the driver failed to load
#     Code 39  driver corrupt or missing
#     Code 43  the driver reported a failure
#     Code 52  signature verification failed (chapter 20)

# --- WinDbg ---
    !devnode 0 1                    the whole PnP tree
    !devnode 0 1 mydriver           just yours
    !devstack ffff8a0c12345678      one device's stack
    !devobj  ffff8a0c12345678
    !drvobj \Driver\MyDriver 7

# --- The setup log, for install-time problems ---
    C:\Windows\INF\setupapi.dev.log
# It records every INF match attempt, every rank, and exactly
# why a driver was or was not selected. This is the file to
# read when a device shows Code 28.

# --- Live PnP tracing ---
    tracelog -start pnp -guid #B3A7...  -f pnp.etl
    # or use Windows Performance Recorder with the
    # "Device I/O" profile
```

How it shows up

Symptom	Cause
Yellow bang, Code 28	No matching INF — check the hardware IDs against the INF
Code 10, "device cannot start"	`START_DEVICE` failed — usually `PrepareHardware` or `D0Entry` returned an error
Code 12	Resource conflict; the device asked for something unavailable
Code 52	Signing (ch. 20)
Bugcheck on device removal	Touched the hardware in `ReleaseHardware` after surprise removal
Hang when unplugging	Waiting for hardware that is gone; no timeout
Registers read `0xFFFFFFFF`	The device was surprise-removed — detect and fail fast
Device stops working after sleep	State not restored in `D0Entry`
Two devices, only one works	Used a fixed symbolic link instead of a device interface
Buffering behaves oddly in a filter	Flags not inherited from the lower device (ch. 07)
Random bugcheck in a filter driver	PnP IRP forwarded with the wrong rules for that minor function

Check yourself

- ✓ Draw a device stack and name PDO, FDO and filter DOs.
- ✓ Explain what filters make possible and why Linux has no direct equivalent.
- ✓ Walk the PnP sequence from enumeration to `START_DEVICE`.
- ✓ Explain why surprise removal is a normal path, not an edge case.
- ✓ Say what WDM's PnP dispatch has to do and why WDF replaces it.
- ✓ Name the four PnP/power callbacks and what belongs in each.
- ✓ Explain why you must not touch hardware in `ReleaseHardware`.
- ✓ Distinguish raw from translated resources.
- ✓ Publish a device interface and open it from user mode by GUID.
- ✓ Decode five Device Manager problem codes and know which log explains Code 28.

Memory management for drivers

Two pools, one crucial distinction, and a tagging scheme that turns "the system is leaking memory" from a week of guesswork into a single command. Plus the lookaside lists that make per-request allocation cheap.

Paged and non-paged pool

```
 NON-PAGED POOL
    · always resident in physical memory
    · usable at ANY IRQL
    · a finite, system-wide resource
    · REQUIRED for anything touched at DISPATCH_LEVEL or
      above: DPC data, ISR data, spinlock-protected state,
      DMA buffers, anything in a completion path

 PAGED POOL
    · may be written to the page file
    · usable ONLY at IRQL <= APC_LEVEL
    · much larger
    · use for: configuration, per-open state touched only
      at PASSIVE_LEVEL, large infrequently-used buffers

THE RULE, and it is chapter 02 restated:
   if the memory can be touched at DISPATCH_LEVEL or above,
   it MUST be non-paged. No exceptions.

THE FAILURE if you get it wrong: bugcheck 0xA,
IRQL_NOT_LESS_OR_EQUAL - and it is LATENT, because the page
is usually resident. It fires weeks later, under memory
pressure, on a customer machine.

WHEN IN DOUBT, USE NON-PAGED. Then measure. A driver holding
a few hundred kilobytes of unnecessary non-paged pool is a
minor inefficiency; a driver bugchecking under load is a
recall.

COMPARE LINUX: kmalloc is always resident, vmalloc is too -
Linux does not page kernel memory at all. So this whole
distinction has no Linux counterpart, and it is the thing
Linux developers most often get wrong on their first Windows
driver.
```

Allocating

```
#include <ntddk.h>

/* THE MODERN API - use this. ExAllocatePoolWithTag is
   deprecated and ExAllocatePool is long gone.             */

        PVOID p = ExAllocatePool2(POOL_FLAG_NON_PAGED,
                                  size,
                                  'DYMx');   /* the TAG */
        if (p == NULL)
                return STATUS_INSUFFICIENT_RESOURCES;

        /* ExAllocatePool2 ZEROES the memory by default -
           unlike the old ExAllocatePoolWithTag, which did
           not. That change closed a large class of
           information-disclosure bugs.                    */

        ExFreePoolWithTag(p, 'DYMx');   /* tag must MATCH */

/* THE FLAGS: */
        POOL_FLAG_NON_PAGED          resident, any IRQL
        POOL_FLAG_PAGED              pageable, PASSIVE only
        POOL_FLAG_NON_PAGED_EXECUTE  rarely justified
        POOL_FLAG_UNINITIALIZED      skip the zeroing, if you
                                     will fill it all anyway
        POOL_FLAG_CACHE_ALIGNED      start on a cache line
        POOL_FLAG_RAISE_ON_FAILURE   raise an exception rather
                                     than returning NULL

/* THE TAG is four characters, written REVERSED because it is
   stored little-endian and displayed as a string: */
        'DYMx'   displays as  "xMYD"
        ' yMD'   displays as  "DMy "

   /* So pick it so the DISPLAY is readable: */
        #define MY_POOL_TAG  'DYMx'    /* shows as xMYD */

/* USE A DISTINCT TAG PER ALLOCATION SITE, or at least per
   purpose. This is the single most valuable habit in this
   chapter - see "finding leaks" below.                    */

/* CONTIGUOUS PHYSICAL MEMORY, for DMA (chapter 18): */
        PHYSICAL_ADDRESS low = {0}, high, boundary = {0};
        high.QuadPart = 0xFFFFFFFF;      /* 32-bit device */

        p = MmAllocateContiguousMemorySpecifyCacheNode(
                size, low, high, boundary, MmCached,
                MM_ANY_NODE_OK);
        ...
        MmFreeContiguousMemory(p);

/* But prefer WDF's DMA common buffers (chapter 18), which do
   the mapping as well as the allocation.                  */
```

ALWAYS CHECK THE RETURN

`ExAllocatePool2` returns NULL on failure and does not raise. An unchecked allocation is a NULL dereference at whatever IRQL you happen to be at, which is bugcheck 0xA with a confusing address near zero. Every allocation, every time — Driver Verifier's low-resource simulation exists specifically to find the ones you missed (chapter 21).

Lookaside lists

```
/* For many same-sized objects - one per request, one per
   packet. The Windows equivalent of a Linux slab cache
   (Linux ch. 05).                                          */

        LOOKASIDE_LIST_EX Lookaside;

        status = ExInitializeLookasideListEx(
                        &ctx->Lookaside,
                        NULL,          /* custom allocate  */
                        NULL,          /* custom free      */
                        NonPagedPoolNx,
                        0,             /* flags            */
                        sizeof(MY_REQUEST),
                        MY_POOL_TAG,
                        0);            /* depth: 0 = auto  */
        if (!NT_SUCCESS(status))
                return status;

        PMY_REQUEST req = ExAllocateFromLookasideListEx(
                                &ctx->Lookaside);
        if (req == NULL)
                return STATUS_INSUFFICIENT_RESOURCES;
        ...
        ExFreeToLookasideListEx(&ctx->Lookaside, req);

        ExDeleteLookasideListEx(&ctx->Lookaside);   /* unload */

/* WHY: the list keeps a small per-CPU cache of freed objects,
   so the common case is a pop off a list rather than a pool
   allocation with its locking. The system TUNES THE DEPTH
   automatically based on your hit rate.

   USE ONE when you allocate the same size repeatedly in a hot
   path. Do not bother for a handful of allocations at
   startup.

   NOTE NonPagedPoolNx - the NX (no-execute) variant. Plain
   NonPagedPool is executable and deprecated for that reason;
   always use the Nx form.                                  */
```

Finding pool leaks

```
# THIS IS WHY YOU TAG EVERY ALLOCATION.

# --- On the live machine ---
    poolmon.exe                    # from the WDK
    # sort by bytes with 'b', by allocation count with 'a'
    # Watch YOUR tag over time. A tag whose "Diff" column
    # climbs and never falls is your leak, named precisely.

     Tag  Type     Allocs      Frees      Diff   Bytes
     xMYD Nonp     104321     100002      4319   1105664  <--
     xMYB Nonp        512        512         0         0

# --- Enable pool tagging if it is off ---
    gflags /r +ptg
    # (on by default on checked builds and modern Windows)

# --- In WinDbg ---
    !poolused 2                    # sorted by non-paged usage
    !poolused /t 10 2              # top 10
    !poolfind xMYD                 # every allocation with
                                   # this tag
    !pool ffff8a0c12345678         # what is this address?
      Pool page ffff8a0c12345678 region is Nonpaged pool
       ffff8a0c12345670 size:   40 previous size:    0
                                   (Allocated) xMYD

# --- Track allocation STACKS, not just counts ---
    gflags /i mydriver.sys +ust    # user stack trace
    # or Driver Verifier's pool tracking (chapter 21), then:
    !verifier 3 mydriver.sys
    # shows the stack for every outstanding allocation

# THE WORKFLOW for "the system is running out of non-paged
# pool":
#   1. poolmon, sort by Diff, find the tag
#   2. the tag names the driver and the allocation site
#   3. verifier pool tracking gives you the stack
#   4. fix the missing free
# Steps 1 and 2 take about thirty seconds IF the tags are
# distinct. With every allocation using the same tag, or the
# default, you learn only "some driver is leaking".
```

Pool corruption

```
/* Writing past the end of an allocation corrupts the pool
   header of the NEXT block. The crash happens later, in an
   unrelated allocation, in someone else's driver.         */

/* BUGCHECKS THAT MEAN POOL CORRUPTION:
     0xC2  BAD_POOL_CALLER
             parameter 1 says what:
               0x07  freeing already-freed memory
               0x0D  freeing with the wrong tag
               0x99  freeing an invalid address
     0x19  BAD_POOL_HEADER
     0x1A  MEMORY_MANAGEMENT
     0xCD  DRIVER_PAGE_FAULT_BEYOND_END_OF_ALLOCATION
     0xC1  SPECIAL_POOL_DETECTED_MEMORY_CORRUPTION

/* SPECIAL POOL is the tool. It puts each allocation on its
   own page, with a GUARD PAGE immediately after (or before),
   so an overrun faults AT THE MOMENT IT HAPPENS rather than
   corrupting a neighbour.                                  */

         verifier /flags 0x1 /driver mydriver.sys
         # or, targeted at one tag, without full verifier:
         gflags /r +spp
         # then set the tag in
         # HKLM\SYSTEM\CCS\Control\Session Manager\Memory
         # Management\PoolTag

/* Special pool is the Windows equivalent of KASAN
   (Linux ch. 27): it converts a delayed, misattributed crash
   into an immediate, correctly-attributed one. Enable it
   whenever you are chasing corruption, and keep it on during
   development.

   COST: each allocation consumes a full page, so the system
   uses far more memory and runs slower. Target it at your
   driver, not the whole system.                           */
```

Touching user memory safely

```
/* A user-mode address is only valid:
     · in the context of THAT process
     · at IRQL <= APC_LEVEL (it can page-fault)
     · until the user changes it, which they can do at any
       moment from another thread                          */

/* THE MANDATORY PATTERN when you handle a raw user pointer -
   METHOD_NEITHER, or a pointer embedded in a buffer
   (chapter 07):                                            */

        __try {
                if (Irp->RequestorMode != KernelMode) {
                        ProbeForRead(userBuffer, length,
                                     __alignof(ULONG));
                        /* or ProbeForWrite for output */
                }

                /* COPY IT IN. Do not validate in place - the
                   user can change it between your check and
                   your use, from another thread. Same TOCTOU
                   argument as isolation chapter 09.       */
                RtlCopyMemory(localCopy, userBuffer, length);

        } __except (EXCEPTION_EXECUTE_HANDLER) {
                return GetExceptionCode();
        }

        /* now validate localCopy, and use ONLY localCopy */

/* WHAT ProbeForRead/Write CHECK:
     · the range lies entirely in user address space
     · the alignment is correct
     · nothing about whether it is mapped - a fault can still
       occur, which is why the __try is also required

/* THE THREE MISTAKES:
     1. no __try. A bad pointer becomes a bugcheck instead of
        an error return.
     2. probing but then using the ORIGINAL pointer. The probe
        proved nothing about what is there a microsecond
        later.
     3. probing at DISPATCH_LEVEL. Illegal - user memory is
        pageable.

/* THE GOOD NEWS: with METHOD_BUFFERED or METHOD_*_DIRECT
   (chapter 07), the I/O manager does all of this for you, and
   you never see a user pointer. That is why METHOD_NEITHER is
   discouraged.                                             */
```

A first look at MDLs

```
/* A Memory Descriptor List describes a buffer's PHYSICAL
   pages. Covered fully in chapter 08; here is why it exists.

   The problem: a user buffer is virtual, in one process's
   address space, and possibly paged out. A DMA engine needs
   physical addresses, and a DPC needs an address valid in any
   context. An MDL solves both: */

        PMDL mdl = IoAllocateMdl(buffer, length, FALSE, FALSE,
                                 NULL);
        if (!mdl)
                return STATUS_INSUFFICIENT_RESOURCES;

        __try {
                MmProbeAndLockPages(mdl, UserMode,
                                    IoWriteAccess);
        } __except (EXCEPTION_EXECUTE_HANDLER) {
                IoFreeMdl(mdl);
                return GetExceptionCode();
        }

        /* now: the pages are LOCKED IN MEMORY and cannot be
           paged out or freed. Get a kernel address valid in
           any context: */
        PVOID kva = MmGetSystemAddressForMdlSafe(mdl,
                        NormalPagePriority | MdlMappingNoExecute);
        if (!kva) {
                MmUnlockPages(mdl);
                IoFreeMdl(mdl);
                return STATUS_INSUFFICIENT_RESOURCES;
        }

        ... use kva at any IRQL, in any process context ...

        MmUnlockPages(mdl);
        IoFreeMdl(mdl);

/* USE MmGetSystemAddressForMdlSafe, NEVER the older
   MmGetSystemAddressForMdl - the latter raises a bugcheck on
   failure instead of returning NULL, which turns a resource
   shortage into a crash.                                    */
```

Pool limits and quotas

```
/* Non-paged pool is finite and shared. A driver that
   allocates without bound in response to user requests is a
   denial-of-service vector - any user can exhaust system
   memory.                                                  */

/* CHARGE IT TO THE CALLER'S PROCESS, so their quota limits
   them rather than the system: */
        p = ExAllocatePool2(POOL_FLAG_NON_PAGED |
                            POOL_FLAG_USE_QUOTA, size, TAG);

/* OR, better, BOUND IT YOURSELF: */
        if (requestedSize > MY_MAX_BUFFER)
                return STATUS_INVALID_PARAMETER;
        if (ctx->OutstandingRequests >= MY_MAX_REQUESTS)
                return STATUS_INSUFFICIENT_RESOURCES;

/* SEE THE LIMITS: */
        WinDbg:  !vm
                 Non-paged pool usage / maximum
        Perfmon: Memory \ Pool Nonpaged Bytes
        Task Manager -> Performance -> Memory ->
                        Non-paged pool

/* THE DESIGN RULE, and it is the same as the Linux one
   (ch. 06): preallocate what you need at start time, bound
   what you allocate per request, and never let an untrusted
   caller decide how much kernel memory to consume.        */
```

How it shows up

Symptom	Cause
Bugcheck 0xA under memory pressure only	Paged pool touched at DISPATCH_LEVEL — latent until the page is evicted
Bugcheck 0xC2, parameter 1 = 0x07	Double free
Bugcheck 0xC2, parameter 1 = 0x0D	Freed with the wrong tag
Bugcheck 0x19 or 0xCD	Pool overrun — enable special pool
Crash in an unrelated driver	You corrupted the pool; special pool will attribute it correctly
Non-paged pool climbs forever	Leak — `poolmon`, sort by Diff, read the tag
Leak found but the site is unknown	Same tag used everywhere — use distinct tags
Bugcheck at an address near zero	Unchecked allocation return
Bugcheck touching a user pointer	No `__try`, or probed at the wrong IRQL
User changes data after your validation	Validated in place instead of copying in
A user program exhausts system memory	Unbounded allocation driven by request parameters
Crash when `MmGetSystemAddressForMdl` fails	Use the `Safe` variant

Check yourself

- ✓ State the rule for choosing paged versus non-paged pool, and why the wrong choice is latent.
- ✓ Explain why this distinction has no Linux equivalent.

- ✓ Allocate and free with `ExAllocatePool2`, and explain the tag byte order.
- ✓ Explain why distinct tags per site are worth the effort.
- ✓ Use a lookaside list and say when it is justified.
- ✓ Find a leak with `poolmon` and `!poolused`.
- ✓ Explain what special pool does and what it corresponds to on Linux.
- ✓ Write the full safe pattern for touching a user pointer, and name the three mistakes.
- ✓ Explain what an MDL gives you and why the `Safe` variant matters.
- ✓ Explain why unbounded allocation from a request is a security bug.

User buffers: buffered, direct and neither

Three ways the I/O manager can hand you a user's buffer, with completely different performance, safety and access rules. Choosing correctly is a design decision made once per interface — and choosing `METHOD_NEITHER` by accident is how drivers get CVEs.

The three methods

	METHOD_BUFFERED	METHOD_IN/OUT_DIRECT	METHOD_NEITHER
What you get	A kernel copy	An MDL	The raw user pointer
Field	`Irp->AssociatedIrp.SystemBuffer`	`Irp->MdlAddress`	`Irp->UserBuffer`
Copy cost	Two copies	**Zero**	Zero
Safe at any IRQL	**Yes**	Yes, once mapped	**No**
Valid in any process	**Yes**	Yes	**No**
Probing done for you	Yes	Yes	**No**
Good for	Small transfers, control	Large transfers, DMA	Almost nothing
Typical size	< 4 KB	> 4 KB	—

THE DECISION, IN ONE LINE

Use **METHOD_BUFFERED** for control operations and small data. Use **METHOD_OUT_DIRECT** / **METHOD_IN_DIRECT** for bulk data and anything you will DMA. Use **METHOD_NEITHER** only when you have a specific, defensible reason — and then write the probing code with the care of someone who knows it is the most commonly botched thing in Windows drivers.

METHOD_BUFFERED

```
 WRITE:
   user buffer --copy--> SystemBuffer (non-paged pool)
                              |
                              v
                         your driver reads it

 READ:
   your driver writes SystemBuffer
                              |
   user buffer <--copy-- SystemBuffer
   (the I/O manager copies back AT COMPLETION)

ONE buffer serves BOTH directions in an IOCTL. It is sized
max(InputBufferLength, OutputBufferLength), so:

   · your input is available when you start
   · you overwrite it with output
   · the I/O manager copies OutputBufferLength bytes back

READ YOUR INPUT BEFORE WRITING YOUR OUTPUT. Writing output
first destroys the input you have not read yet - a bug that
works whenever input and output happen not to overlap, and
fails when they do.

THE SAFETY: the I/O manager probed the user buffer, copied
it in kernel space in the CALLER'S context at PASSIVE_LEVEL,
and the copy is in non-paged pool. So SystemBuffer is safe
to touch at any IRQL, in any thread, at any time - which is
exactly what you need for asynchronous completion from a
DPC.

THE COST: two copies. For a 4-byte control value that is
irrelevant. For a 4 MB frame it is not.
```

```
NTSTATUS
MyDeviceControl(_In_ PDEVICE_OBJECT DeviceObject, _In_ PIRP Irp)
{
        PIO_STACK_LOCATION sp = IoGetCurrentIrpStackLocation(Irp);
        ULONG inLen  = sp->Parameters.DeviceIoControl.
                           InputBufferLength;
        ULONG outLen = sp->Parameters.DeviceIoControl.
                           OutputBufferLength;
        PVOID buffer = Irp->AssociatedIrp.SystemBuffer;
        NTSTATUS status;
        ULONG_PTR info = 0;

        switch (sp->Parameters.DeviceIoControl.IoControlCode) {
        case IOCTL_MY_SET_CONFIG: {
                MY_CONFIG cfg;

                if (inLen < sizeof(MY_CONFIG)) {
                        status = STATUS_BUFFER_TOO_SMALL;
                        break;
                }
                /* SystemBuffer is a kernel copy already, but
                   copy again into a local if you will write
                   output into the same buffer               */
                RtlCopyMemory(&cfg, buffer, sizeof(cfg));

                status = MyValidateAndApply(&cfg);
                break;
        }

        case IOCTL_MY_GET_STATS: {
                MY_STATS stats;

                if (outLen < sizeof(MY_STATS)) {
                        status = STATUS_BUFFER_TOO_SMALL;
                        Irp->IoStatus.Information = sizeof(MY_STATS);
                        break;          /* tell them the size */
                }
                MyGatherStats(&stats);
                RtlCopyMemory(buffer, &stats, sizeof(stats));
                info = sizeof(stats);
                status = STATUS_SUCCESS;
                break;
        }

        default:
                status = STATUS_INVALID_DEVICE_REQUEST;
                break;
        }

        Irp->IoStatus.Status = status;
        Irp->IoStatus.Information = info;
        IoCompleteRequest(Irp, IO_NO_INCREMENT);
        return status;
}
```

METHOD_DIRECT

```
The I/O manager:
  1. probes the user buffer
  2. builds an MDL describing its physical pages
  3. LOCKS those pages in memory
  4. hands you Irp->MdlAddress

NO COPY happens. You either:
  · map the MDL to a kernel virtual address and touch it,
    or
  · hand the MDL straight to a DMA engine (chapter 18)

METHOD_IN_DIRECT   the buffer is INPUT to the driver
                   (despite "IN" - the user WRITES it, the
                   driver READS it)
METHOD_OUT_DIRECT  the buffer is OUTPUT from the driver

THE NAMING IS GENUINELY CONFUSING. Remember it from the
USER's point of view: OUT_DIRECT means data comes OUT of
the driver to the user, so the driver writes it. That is
the common case for a read.

AND FOR IOCTLs: only the OUTPUT buffer is described by the
MDL. The INPUT buffer of a DIRECT ioctl is still buffered,
in SystemBuffer. So a DIRECT ioctl gives you BOTH:

     input  -> Irp->AssociatedIrp.SystemBuffer
     output -> Irp->MdlAddress

That asymmetry catches everyone once.
```

```
        PVOID kva;
        ULONG length;

        if (Irp->MdlAddress == NULL) {
                status = STATUS_INVALID_PARAMETER;
                goto complete;
        }

        length = MmGetMdlByteCount(Irp->MdlAddress);

        /* map it to a kernel address valid in ANY context */
        kva = MmGetSystemAddressForMdlSafe(Irp->MdlAddress,
                        NormalPagePriority | MdlMappingNoExecute);
        if (kva == NULL) {
                status = STATUS_INSUFFICIENT_RESOURCES;
                goto complete;
        }

        RtlCopyMemory(kva, source, min(length, sourceLength));
        info = min(length, sourceLength);
        status = STATUS_SUCCESS;

/* NOTES:
     · MmGetSystemAddressForMdlSafe can FAIL under memory
       pressure - check it. The non-Safe variant bugchecks
       instead, which is why it is never the right call.
     · MdlMappingNoExecute is required on modern Windows;
       omitting it fails the mapping outright.
     · the I/O manager unlocks and frees the MDL at
       completion. Do NOT unlock it yourself.
     · for DMA you do not map at all - you pass the MDL to the
       DMA adapter (chapter 18). That is the real payoff:
       user pages go straight to the hardware with no copy and
       no kernel mapping.                                  */
```

METHOD_NEITHER

```
/* You get the RAW USER POINTERS:
        input  -> sp->Parameters.DeviceIoControl.Type3InputBuffer
        output -> Irp->UserBuffer

   NOTHING has been probed, nothing copied, nothing locked.
   These addresses are valid ONLY:
        · in the calling process's context
        · at IRQL <= APC_LEVEL
        · until the user changes the memory, which another
          thread can do at any instant                      */

/* THE ONLY CORRECT WAY TO USE IT: */

        PVOID userIn  = sp->Parameters.DeviceIoControl.
                            Type3InputBuffer;
        PVOID userOut = Irp->UserBuffer;
        MY_CONFIG local;

        if (inLen < sizeof(MY_CONFIG))
                return STATUS_BUFFER_TOO_SMALL;

        __try {
                if (Irp->RequestorMode != KernelMode) {
                        ProbeForRead(userIn, inLen,
                                     __alignof(MY_CONFIG));
                        ProbeForWrite(userOut, outLen,
                                      __alignof(ULONG));
                }

                /* COPY IN. Never validate in place. */
                RtlCopyMemory(&local, userIn, sizeof(local));

        } __except (EXCEPTION_EXECUTE_HANDLER) {
                return GetExceptionCode();
        }

        /* validate the COPY, use only the COPY */
        if (local.Rate == 0 || local.Rate > MAX_RATE)
                return STATUS_INVALID_PARAMETER;

        status = MyApply(&local);

        __try {
                RtlCopyMemory(userOut, &result, sizeof(result));
        } __except (EXCEPTION_EXECUTE_HANDLER) {
                return GetExceptionCode();
        }
```

WHY METHOD_NEITHER PRODUCES CVES

- **No `__try`.** A bad pointer becomes a bugcheck — a denial of service any user can trigger.
- **Probed, then used the original pointer.** Another thread rewrites the buffer between the probe and the use. Classic TOCTOU (the same argument as isolation chapter 09).
- **Validated in place.** Same problem: the value you checked is not the value you use.
- **Forgot `RequestorMode`.** Probing is skipped for kernel callers — but if you never check, a user-mode caller's kernel-looking address is used unprobed.
- **Touched the pointer from a DPC or another thread.** The address means nothing outside the caller's process context.
- **Trusted a length field inside the user buffer** to bound a copy.

Every one of these has shipped in real drivers. If you cannot state why `METHOD_BUFFERED` or `METHOD_DIRECT` is unacceptable for your case, do not use `METHOD_NEITHER`.

Choosing it, per interface

```
/* FOR READ/WRITE: the DEVICE OBJECT's flags decide, and it
   applies to every read and write on that device.        */

        /* WDM: */
        deviceObject->Flags |= DO_BUFFERED_IO;
        /* or */
        deviceObject->Flags |= DO_DIRECT_IO;
        /* neither flag set = METHOD_NEITHER */

        /* WDF: */
        WdfDeviceInitSetIoType(DeviceInit,
                               WdfDeviceIoBuffered);
        WdfDeviceInitSetIoType(DeviceInit,
                               WdfDeviceIoDirect);
        /* and per-queue, in newer versions: */
        WdfDeviceInitSetIoTypeEx(DeviceInit, &ioTypeConfig);

/* FOR IOCTLs: encoded in the CONTROL CODE itself
   (chapter 16), so it is per-operation: */

        #define IOCTL_MY_SET_CONFIG \
            CTL_CODE(FILE_DEVICE_UNKNOWN, 0x800, \
                     METHOD_BUFFERED, FILE_WRITE_ACCESS)

        #define IOCTL_MY_READ_BULK \
            CTL_CODE(FILE_DEVICE_UNKNOWN, 0x801, \
                     METHOD_OUT_DIRECT, FILE_READ_ACCESS)

/* SO A SINGLE DRIVER can use BUFFERED for its control IOCTLs
   and DIRECT for its bulk transfer IOCTL, which is exactly
   the right design: cheap safety where the data is small,
   zero copy where it is large.                           */

/* AND IN A FILTER DRIVER: inherit the method from the device
   below you, or reads and writes arrive in a form your lower
   driver does not expect:                                */
        fdo->Flags |= lowerDevice->Flags &
                      (DO_BUFFERED_IO | DO_DIRECT_IO);
```

In WDF, it is simpler

```
/* WDF hides the method behind one API. You ask for a buffer
   and the framework gives you a safe kernel pointer,
   whichever transfer method was used.                    */

VOID
MyEvtIoDeviceControl(_In_ WDFQUEUE Queue,
                     _In_ WDFREQUEST Request,
                     _In_ size_t OutputBufferLength,
                     _In_ size_t InputBufferLength,
                     _In_ ULONG IoControlCode)
{
        PVOID inBuf, outBuf;
        size_t inLen, outLen;
        NTSTATUS status;

        status = WdfRequestRetrieveInputBuffer(Request,
                        sizeof(MY_CONFIG),   /* MINIMUM size -
                                                checked FOR you */
                        &inBuf, &inLen);
        if (!NT_SUCCESS(status)) {
                WdfRequestComplete(Request, status);
                return;
        }

        status = WdfRequestRetrieveOutputBuffer(Request,
                        sizeof(MY_STATS), &outBuf, &outLen);
        ...

        WdfRequestCompleteWithInformation(Request, status,
                                          bytesWritten);
}

/* WdfRequestRetrieve*Buffer:
     · works for BUFFERED and DIRECT identically
     · CHECKS THE MINIMUM LENGTH and returns
       STATUS_BUFFER_TOO_SMALL if it is short - so the most
       common validation is done for you
     · for DIRECT, maps the MDL and handles the failure
     · refuses outright for METHOD_NEITHER unless you opted
       in

   AND for DMA, ask for the MDL instead:               */
        status = WdfRequestRetrieveOutputWdmMdl(Request, &mdl);

/* THIS IS THE ARGUMENT FOR WDF in miniature: the same code
   handles both transfer methods, the length check is not
   optional-and-forgotten, and METHOD_NEITHER is opt-in rather
   than the default you fall into.                        */
```

How it shows up

Symptom	Cause
Buffer is NULL	Wrong field for the method — `SystemBuffer` vs `MdlAddress` vs `UserBuffer`
Input data is garbage after writing output	METHOD_BUFFERED shares one buffer — read input first
Bugcheck touching the buffer in a DPC	METHOD_NEITHER pointer used outside the caller's context

Symptom	Cause
Bugcheck on a bad user pointer	No `__try` / `__except`
Validation passes, bad data used	Validated in place instead of copying in
Works for small buffers, fails for large	DIRECT MDL not mapped, or length taken from the wrong place
`MmGetSystemAddressForMdlSafe` returns NULL	Memory pressure — handle it, do not use the unsafe variant
DIRECT ioctl input buffer is NULL	Input is still in `SystemBuffer`, not the MDL
Filter driver corrupts data	Buffering flags not inherited from the lower device
Output not returned to the user	`IoStatus.Information` not set
Security review flags the driver	METHOD_NEITHER without justification

Check yourself

- ✓ Name the three methods, the field each uses, and their trade-offs.
- ✓ Explain why METHOD_BUFFERED is safe at any IRQL and in any process.
- ✓ Explain the shared input/output buffer and the ordering rule it implies.
- ✓ Explain what METHOD_DIRECT gives you and why the input buffer of a DIRECT ioctl is still buffered.
- ✓ Say why `MmGetSystemAddressForMdlSafe` is the only correct choice.
- ✓ Write the complete safe pattern for METHOD_NEITHER.
- ✓ List six ways METHOD_NEITHER is got wrong.
- ✓ Set the method for read/write and per-IOCTL, in both WDM and WDF.
- ✓ Explain what `WdfRequestRetrieveInputBuffer` does for you.
- ✓ Choose the right method for four different interfaces and justify each.

MDLs and locked memory

A Memory Descriptor List describes where a virtual buffer really lives in physical memory. It is how Windows hands user pages to a DMA engine, how a driver reaches a buffer from a DPC, and how one buffer gets two mappings — and it has a strict ownership protocol you must not violate.

What an MDL describes

```
A virtual buffer:

  0x00007ff6'12345678, length 12288 (3 pages)

is scattered in physical memory:

  +-------------+   page 1  -> PFN 0x1A2B3
  +-------------+   page 2  -> PFN 0x0C4D5   (not adjacent)
  +-------------+   page 3  -> PFN 0x39E10

THE MDL captures exactly that:

+---------------------------------------+
|  MDL HEADER                           |
|    Next          chain to another MDL |
|    Size                               |
|    MdlFlags      locked? mapped? ...  |
|    Process       whose address space  |
|    MappedSystemVa  the kernel mapping |
|    StartVa       page-aligned base    |
|    ByteCount     length               |
|    ByteOffset    offset into the first|
|                  page                 |
+---------------------------------------+
|  PFN ARRAY:  0x1A2B3 0x0C4D5 0x39E10  |
+---------------------------------------+

THE ACCESSORS - use these, never the fields directly:

  MmGetMdlVirtualAddress(mdl)   the original VA
  MmGetMdlByteCount(mdl)        length
  MmGetMdlByteOffset(mdl)       offset in the first page
  MmGetMdlPfnArray(mdl)         the page frame numbers
  MmGetSystemAddressForMdlSafe(mdl, priority)
                                a KERNEL VA, any context

NOTE ByteOffset: a buffer rarely starts on a page boundary,
so the first page is partial. Code that assumes
page-aligned data - a DMA descriptor builder, for example -
must account for it, and forgetting is a classic
off-by-a-few-bytes corruption.
```

Why they exist

Problem	What the MDL solves
A DMA engine needs physical addresses	The PFN array *is* the physical description
User pages can be paged out mid-transfer	`MmProbeAndLockPages` pins them

Problem	What the MDL solves
A user VA is meaningless in a DPC	Map it to a system VA valid in any context
A user VA is meaningless in another process	Same
Copying large buffers is expensive	No copy at all — describe, do not duplicate
The buffer is not physically contiguous	Scatter-gather, straight from the PFN array

The Linux analogue is roughly a `struct scatterlist` plus `get_user_pages()` (chapter 24): the same two jobs — pin the pages, describe them physically — combined into one object.

The ownership protocol

```
/* The steps, and every one of them must be undone. */

/* 1. ALLOCATE - describes the buffer, does nothing yet */
        PMDL mdl = IoAllocateMdl(buffer,        /* VA        */
                                 length,
                                 FALSE,         /* secondary */
                                 FALSE,         /* charge
                                                   quota     */
                                 NULL);         /* no IRP    */
        if (mdl == NULL)
                return STATUS_INSUFFICIENT_RESOURCES;

/* 2. PROBE AND LOCK - pins the pages, fills the PFN array.
      CAN RAISE. Must be at IRQL <= APC_LEVEL, in the
      process that owns the buffer.                        */
        __try {
                MmProbeAndLockPages(mdl,
                                    UserMode,   /* or KernelMode */
                                    IoWriteAccess);
                                    /* IoReadAccess, IoWriteAccess,
                                       IoModifyAccess       */
        } __except (EXCEPTION_EXECUTE_HANDLER) {
                IoFreeMdl(mdl);
                return GetExceptionCode();
        }

/* 3. MAP, if the CPU will touch it */
        PVOID kva = MmGetSystemAddressForMdlSafe(mdl,
                        NormalPagePriority | MdlMappingNoExecute);
        if (kva == NULL) {
                MmUnlockPages(mdl);
                IoFreeMdl(mdl);
                return STATUS_INSUFFICIENT_RESOURCES;
        }

/* 4. USE IT - kva is valid at ANY IRQL, in ANY process */
        RtlCopyMemory(kva, source, length);

/* 5. UNWIND, in exactly reverse order */
        MmUnlockPages(mdl);     /* unmaps too, if mapped */
        IoFreeMdl(mdl);

/* THE ACCESS ARGUMENT IS A SECURITY CONTROL. IoWriteAccess
   means "the driver will WRITE this buffer", and the memory
   manager verifies the caller has write permission to it.
   Requesting IoReadAccess and then writing corrupts a
   read-only mapping - possibly a shared code page.       */

/* AND `UserMode` versus `KernelMode`, exactly as in
   chapter 03: pass UserMode when the buffer came from a user
   request, so the access check is enforced.             */
```

> **LOCKED PAGES ARE A SYSTEM-WIDE RESOURCE**
>
> `MmProbeAndLockPages` removes pages from the pageable pool for as long as the MDL is locked. A driver that locks unbounded amounts, or fails to unlock on an error path, degrades the whole machine and eventually causes `STATUS_WORKING_SET_QUOTA` failures for everyone. Bound how much you lock, unlock on *every* path, and never hold a lock across an operation with no timeout.

MDLs the I/O manager gives you

```
/* With METHOD_DIRECT (chapter 07), the I/O manager has
   already done steps 1 and 2 for you.                     */

        PMDL mdl = Irp->MdlAddress;

        if (mdl == NULL)
                return STATUS_INVALID_PARAMETER;

        PVOID kva = MmGetSystemAddressForMdlSafe(mdl,
                        NormalPagePriority | MdlMappingNoExecute);
        if (kva == NULL)
                return STATUS_INSUFFICIENT_RESOURCES;

        ULONG len = MmGetMdlByteCount(mdl);

        ... use it ...

/* DO NOT UNLOCK OR FREE IT. IoCompleteRequest does that.
   Calling MmUnlockPages on an IRP's MDL is a double-unlock
   and bugchecks.

   THE RULE: whoever allocated the MDL frees it. If the I/O
   manager built it, the I/O manager tears it down.       */

/* IN WDF you rarely see the MDL at all: */
        status = WdfRequestRetrieveOutputBuffer(Request, minLen,
                                                &buffer, &len);
        /* the framework maps it and checks the length */

        /* unless you want the MDL, for DMA: */
        status = WdfRequestRetrieveOutputWdmMdl(Request, &mdl);
```

Double mapping

```
/* An MDL can describe pages that are ALSO mapped somewhere
   else. That gives you a second view of the same physical
   memory - and it is how a driver shares a buffer with user
   mode.                                                    */

/* --- kernel buffer, mapped into a user process ---------- */

        PVOID kernelBuf;
        PMDL  mdl;
        PVOID userVa = NULL;

        kernelBuf = ExAllocatePool2(POOL_FLAG_NON_PAGED,
                                    size, TAG);
        if (!kernelBuf)
                return STATUS_INSUFFICIENT_RESOURCES;

        mdl = IoAllocateMdl(kernelBuf, size, FALSE, FALSE, NULL);
        if (!mdl) { ... }

        MmBuildMdlForNonPagedPool(mdl);   /* non-paged pool is
                                             already resident -
                                             no probe needed  */

        __try {
                userVa = MmMapLockedPagesSpecifyCache(
                                mdl,
                                UserMode,
                                MmCached,
                                NULL,       /* let it choose */
                                FALSE,
                                NormalPagePriority);
        } __except (EXCEPTION_EXECUTE_HANDLER) {
                status = GetExceptionCode();
                goto err;
        }

        /* userVa is now valid IN THE CURRENT PROCESS ONLY.
           Return it to the caller; they see the same physical
           memory the driver writes.                        */

        /* teardown, IN THE SAME PROCESS: */
        MmUnmapLockedPages(userVa, mdl);
        IoFreeMdl(mdl);
        ExFreePoolWithTag(kernelBuf, TAG);

/* THE RULES for a shared mapping, and they are strict:
     · map and unmap in the SAME process context. Doing it
       from a system thread maps into the wrong address space.
     · unmap BEFORE the process exits, or in IRP_MJ_CLEANUP
       (chapter 04) - which is exactly what CLEANUP is for.
     · the user can write anything into it at any time. Treat
       every byte as hostile, exactly as with a shared TEE
       buffer (isolation chapter 09).
     · never share memory containing anything the user should
       not see - the whole page is exposed, not just your
       struct.

   THIS IS A REAL SECURITY BOUNDARY, and shared-memory
   interfaces are where driver security reviews concentrate.
```

```
   Prefer IOCTLs unless the throughput genuinely demands
   sharing.                                                */
```

Partial MDLs

```
/* Describe a SUB-RANGE of an existing MDL, without locking
   anything again. Used to split a large transfer into
   hardware-sized chunks.                                  */

        PMDL partial = IoAllocateMdl(
                        (PUCHAR)MmGetMdlVirtualAddress(sourceMdl)
                                + offset,
                        chunkLength,
                        FALSE, FALSE, NULL);
        if (!partial)
                return STATUS_INSUFFICIENT_RESOURCES;

        IoBuildPartialMdl(sourceMdl,        /* the parent   */
                          partial,
                          (PUCHAR)MmGetMdlVirtualAddress(sourceMdl)
                                  + offset,
                          chunkLength);

        ... use `partial` for one hardware transfer ...

        IoFreeMdl(partial);      /* free ONLY the partial -
                                    do NOT unlock; the parent
                                    owns the lock            */

/* THE OWNERSHIP RULE AGAIN: the partial MDL borrows the
   parent's locked pages. Unlocking through the partial
   corrupts the parent's state and bugchecks later.

   AND: the parent must outlive every partial derived from it.
   Completing the parent IRP while a partial is still in
   flight is a use-after-free with a DMA engine writing into
   it - about the worst failure mode available.           */
```

MDL chains

```
/* MDLs link through ->Next, describing a discontiguous
   logical buffer - used heavily by the network stack, where
   a packet is a header MDL plus a payload MDL.            */

        PMDL mdl;
        ULONG total = 0;

        for (mdl = firstMdl; mdl != NULL; mdl = mdl->Next) {
                PVOID va = MmGetSystemAddressForMdlSafe(mdl,
                                LowPagePriority |
                                MdlMappingNoExecute);
                if (va == NULL)
                        return STATUS_INSUFFICIENT_RESOURCES;

                ProcessChunk(va, MmGetMdlByteCount(mdl));
                total += MmGetMdlByteCount(mdl);
        }

/* ALWAYS WALK THE WHOLE CHAIN. Code that handles only the
   first MDL works perfectly for small transfers and silently
   truncates large ones - a data-loss bug that appears only
   under load, which is the hardest kind to attribute.    */
```

Debugging MDLs

```
# In WinDbg (chapter 22):

    dt nt!_MDL ffff8a0c12345678
       +0x000 Next             : (null)
       +0x008 Size             : 0n56
       +0x00a MdlFlags         : 0x2004
       +0x010 Process          : 0xffff8a0c`11223344 _EPROCESS
       +0x018 MappedSystemVa   : 0xffffcb01`23456000
       +0x020 StartVa          : 0x00007ff6`12345000
       +0x028 ByteCount        : 0x3000
       +0x02c ByteOffset       : 0x678

# DECODE MdlFlags - this tells you the MDL's state:
    0x0001  MDL_MAPPED_TO_SYSTEM_VA
    0x0002  MDL_PAGES_LOCKED
    0x0004  MDL_SOURCE_IS_NONPAGED_POOL
    0x0008  MDL_ALLOCATED_FIXED_SIZE
    0x0010  MDL_PARTIAL
    0x0020  MDL_PARTIAL_HAS_BEEN_MAPPED
    0x0040  MDL_IO_PAGE_READ
    0x0080  MDL_WRITE_OPERATION
    0x1000  MDL_IO_SPACE

# So 0x2004 = SOURCE_IS_NONPAGED_POOL | (0x2000 internal).
# No PAGES_LOCKED bit -> it was never probed and locked, which
# is a bug if you expected it to be.

    !pte 0xffff8a0c12345678         # is this VA mapped?
    !pfn 0x1a2b3                    # one physical page's state
    !process 0 7                    # locked pages per process

# DRIVER VERIFIER (chapter 21) checks MDL rules aggressively:
#   unlocking an MDL you did not lock
#   freeing a mapped MDL
#   using an MDL after completion
#   mapping in the wrong process
# Every one of these is otherwise an intermittent crash.
```

How it shows up

Symptom	Cause
Bugcheck in `MmUnlockPages`	Unlocked an MDL you did not lock, or unlocked twice
Bugcheck completing an IRP	Freed or unlocked the IRP's MDL yourself
`MmGetSystemAddressForMdlSafe` returns NULL	Memory pressure — a real case to handle
Mapping fails on modern Windows	Missing `MdlMappingNoExecute`
Data corrupt by a few bytes at the start	`ByteOffset` ignored — the first page is partial
Large transfers truncated	Only the first MDL of a chain processed
User mapping is invalid	Mapped in a different process than the one using it
Crash when the user process exits	Mapping not torn down in `IRP_MJ_CLEANUP`
DMA writes into freed memory	Parent MDL completed while a partial was still in flight
System degrades, working-set errors	Unbounded or leaked locked pages

Symptom	Cause
Read-only page corrupted	Locked with `IoReadAccess`, then written

Check yourself

- ✓ Describe an MDL's contents and name the accessor for each field.
- ✓ Explain why `ByteOffset` exists and what ignoring it breaks.
- ✓ List the six problems MDLs solve.
- ✓ Write the full allocate-lock-map-unmap-unlock-free sequence with correct error unwinding.
- ✓ Explain the access argument as a security control.
- ✓ Say who owns an IRP's MDL and what happens if you free it.
- ✓ Map a kernel buffer into user space and list the four rules for doing it safely.
- ✓ Explain partial MDLs and the ownership rule they impose.
- ✓ Walk an MDL chain and say what breaks if you do not.
- ✓ Decode `MdlFlags` in WinDbg and say what a missing `PAGES_LOCKED` bit means.

Synchronisation primitives

Windows offers a dozen locks, and choosing between them is decided almost entirely by one question: what IRQL will touch this data? Get that right and the rest follows mechanically.

The decision

```
 What is the HIGHEST IRQL at which this data is touched?
      |
      +-- DIRQL (an ISR touches it)
      |      -> the INTERRUPT SPINLOCK
      |         WdfInterruptAcquireLock / KeAcquireInterruptSpinLock
      |
      +-- DISPATCH_LEVEL (a DPC or timer touches it)
      |      -> SPINLOCK
      |         KeAcquireSpinLock / WdfSpinLockAcquire
      |
      +-- PASSIVE / APC only
             |
             +-- do I need to WAIT for something?
             |      -> KEVENT
             |
             +-- many readers, rare writers, long holds?
             |      -> ERESOURCE
             |
             +-- just mutual exclusion, short?
             |      -> FAST MUTEX
             |
             +-- a single counter or flag?
                    -> INTERLOCKED operations, no lock at all

AND THE OVERRIDING RULE: everything forbidden at
DISPATCH_LEVEL (chapter 02) is forbidden INSIDE A SPINLOCK,
because acquiring one raises you to DISPATCH_LEVEL. No
paged memory, no blocking, no paged-pool allocation, no
waiting.

This is the same shape as the Linux decision
(Linux ch. 11), with IRQL replacing "context".
```

Spinlocks

```
#include <ntddk.h>

        KSPIN_LOCK Lock;
        KeInitializeSpinLock(&Lock);

/* From PASSIVE or APC level - raises IRQL and saves the old */
        KIRQL oldIrql;

        KeAcquireSpinLock(&Lock, &oldIrql);
        /* ... at DISPATCH_LEVEL now ... */
        KeReleaseSpinLock(&Lock, oldIrql);

/* When you KNOW you are already at DISPATCH_LEVEL - in a DPC,
   a timer callback, or nested inside another spinlock: */
        KeAcquireSpinLockAtDpcLevel(&Lock);
        ...
        KeReleaseSpinLockFromDpcLevel(&Lock);
/* Cheaper: no IRQL change. Calling it below DISPATCH_LEVEL is
   a bug Driver Verifier catches immediately.              */

/* IN-STACK QUEUED - fairer under contention, and preferred
   on many-core systems because it avoids the cacheline
   stampede of a plain spinlock: */
        KLOCK_QUEUE_HANDLE handle;

        KeAcquireInStackQueuedSpinLock(&Lock, &handle);
        ...
        KeReleaseInStackQueuedSpinLock(&handle);

/* THE RULES:
     · SHORT. Microseconds. Other CPUs are spinning.
     · `oldIrql` must be a LOCAL variable. Sharing one between
       CPUs corrupts the IRQL restore - a subtle, devastating
       bug.
     · never acquire a lower-IRQL lock while holding a
       higher-IRQL one
     · define and document a lock ORDER, exactly as on Linux
     · a spinlock protects against OTHER CPUs; raising IRQL
       protects against PREEMPTION on THIS one. You almost
       always need both, which is why Windows combines them. */

/* IN WDF, an object with proper lifetime management: */
        WDFSPINLOCK lock;
        WDF_OBJECT_ATTRIBUTES attr;

        WDF_OBJECT_ATTRIBUTES_INIT(&attr);
        attr.ParentObject = device;      /* freed with it */
        status = WdfSpinLockCreate(&attr, &lock);

        WdfSpinLockAcquire(lock);
        ...
        WdfSpinLockRelease(lock);
```

Interrupt spinlocks

```
/* Data shared with an ISR needs a lock acquired at the
   DEVICE's IRQL - otherwise the ISR can interrupt you while
   you hold it, and spin forever waiting for code that cannot
   resume. Exactly the Linux self-deadlock (ch. 11).       */

/* WDM: */
        KIRQL oldIrql;

        KeAcquireInterruptSpinLock(interruptObject, &oldIrql);
        /* now at DIRQL - the ISR cannot run on this CPU */
        ...
        KeReleaseInterruptSpinLock(interruptObject, oldIrql);

/* WDF - simpler, and it knows the right IRQL: */
        WdfInterruptAcquireLock(interrupt);
        ...
        WdfInterruptReleaseLock(interrupt);

/* INSIDE the ISR itself, you already hold it - WDF acquires
   it before calling EvtInterruptIsr. Do not re-acquire.

/* OR, AVOID THE PROBLEM: use
   WdfInterruptSynchronize to run a small function AT DIRQL
   with the lock held, rather than holding it around a longer
   section:                                                 */

static BOOLEAN
MySyncRoutine(_In_ WDFINTERRUPT Interrupt, _In_ WDFCONTEXT Ctx)
{
        PMY_CONTEXT c = (PMY_CONTEXT)Ctx;

        /* runs at DIRQL with the interrupt lock held */
        c->Enabled = TRUE;
        WRITE_REGISTER_ULONG(c->Base + REG_INT_EN, 1);
        return TRUE;
}

        WdfInterruptSynchronize(interrupt, MySyncRoutine, ctx);

/* This is the idiomatic way to touch ISR-shared state from a
   normal path: a tiny function, at DIRQL, for the shortest
   possible time.                                           */
```

Events

```
/* KEVENT is the "wait for something to happen" primitive -
   the analogue of a Linux completion or wait queue.       */

        KEVENT Event;

        KeInitializeEvent(&Event,
                          NotificationEvent,  /* or Synchronization */
                          FALSE);             /* initial state */

/* NotificationEvent    stays signalled until manually reset.
                        ALL waiters wake. ("manual reset")
   SynchronizationEvent auto-resets when ONE waiter wakes.
                        ("auto reset")                       */

/* WAITING - at PASSIVE_LEVEL only: */
        LARGE_INTEGER timeout;
        NTSTATUS status;

        timeout.QuadPart = -10LL * 1000 * 1000 * 5;  /* 5 s */
        /* NEGATIVE = relative. POSITIVE = an absolute time in
           1601-epoch 100ns units. Getting the sign wrong
           gives you either an instant return or a wait until
           the far future - both common bugs.            */

        status = KeWaitForSingleObject(&Event,
                                       Executive,
                                       KernelMode,
                                       FALSE,     /* alertable */
                                       &timeout);
        if (status == STATUS_TIMEOUT)
                return STATUS_IO_TIMEOUT;

/* SIGNALLING - legal at any IRQL <= DISPATCH_LEVEL, which is
   why a DPC can wake a waiting thread: */
        KeSetEvent(&Event, IO_NO_INCREMENT, FALSE);
        KeClearEvent(&Event);
        KeResetEvent(&Event);        /* clear, return old state */

/* WAITING ON SEVERAL: */
        PVOID objects[2] = { &EventA, &EventB };

        status = KeWaitForMultipleObjects(2, objects,
                        WaitAny,        /* or WaitAll */
                        Executive, KernelMode, FALSE,
                        &timeout, NULL);
        /* returns STATUS_WAIT_0 or STATUS_WAIT_1 for WaitAny */

/* ALWAYS USE A TIMEOUT in a driver. An infinite wait on
   hardware that has stopped responding hangs the thread
   permanently, and if it is a system thread, it hangs
   shutdown. Same argument as the Linux
   wait_for_completion_timeout rule (ch. 11).             */
```

Fast mutexes and ERESOURCE

```
/* FAST MUTEX - simple exclusion at PASSIVE_LEVEL: */
        FAST_MUTEX Mutex;

        ExInitializeFastMutex(&Mutex);

        ExAcquireFastMutex(&Mutex);
        /* raises IRQL to APC_LEVEL - so APCs are blocked,
           which is what makes it "fast"                    */
        ...
        ExReleaseFastMutex(&Mutex);

        if (ExTryToAcquireFastMutex(&Mutex)) { ... }

/* NOT RECURSIVE. Acquiring twice on one thread deadlocks.
   NOT usable above APC_LEVEL.
   You MAY sleep while holding one - which is the whole point
   compared to a spinlock.                                  */

/* ERESOURCE - reader/writer, recursive, PASSIVE only: */
        ERESOURCE Resource;

        ExInitializeResourceLite(&Resource);

        KeEnterCriticalRegion();     /* disable normal APCs -
                                        REQUIRED, and forgetting
                                        it is the classic bug */
        ExAcquireResourceSharedLite(&Resource, TRUE);
        /* ... many readers concurrently ... */
        ExReleaseResourceLite(&Resource);
        KeLeaveCriticalRegion();

        KeEnterCriticalRegion();
        ExAcquireResourceExclusiveLite(&Resource, TRUE);
        /* ... one writer ... */
        ExReleaseResourceLite(&Resource);
        KeLeaveCriticalRegion();

        ExDeleteResourceLite(&Resource);

/* The TRUE argument means "wait". FALSE means "try", and
   returns FALSE if it would block.

   THE CRITICAL REGION requirement exists because a normal
   kernel APC could suspend the thread while it holds the
   resource, blocking every other waiter indefinitely. The
   Ex*ResourceLite functions ASSERT you are in one on checked
   builds.

   USE ERESOURCE when reads genuinely dominate AND the hold
   time is long. Otherwise a fast mutex is cheaper - the same
   advice as Linux's on rw_semaphores (ch. 11).          */

/* WDF WAIT LOCK - the framework's PASSIVE-level lock, and the
   one to reach for in WDF code: */
        WDFWAITLOCK lock;

        WdfWaitLockCreate(&attr, &lock);
        WdfWaitLockAcquire(lock, NULL);   /* NULL = wait
                                             forever; or a
                                             timeout          */
```

```
        ...
        WdfWaitLockRelease(lock);
```

Interlocked operations

```
/* No lock at all, for a single value. */

        LONG counter = 0;

        InterlockedIncrement(&counter);
        InterlockedDecrement(&counter);

   that is a use-after-free. Structure the code so a
   reference can only be taken from something that already
   holds one.                                               */
```

THE COMPARISON TABLE

Primitive	Max IRQL	Can wait	Recursive	Use for
Interlocked	Any	—	—	One counter or flag
Interrupt spinlock	DIRQL	No	No	Data shared with an ISR
Spinlock	DISPATCH	No	No	Data shared with a DPC
Fast mutex	APC	Yes	**No**	General PASSIVE exclusion
WDFWAITLOCK	PASSIVE	Yes	No	The WDF default
ERESOURCE	PASSIVE	Yes	**Yes**	Long reads, rare writes
KEVENT	Wait: PASSIVE Set: DISPATCH	Yes	—	"Wait until this happens"
KSEMAPHORE	Same	Yes	—	Counted resources
Rundown protection	DISPATCH	Yes	—	"Wait for all users to leave"

Rundown protection

```
/* The problem: you are tearing down an object, and other
   threads may be using it right now. You must wait for them
   all to finish, and prevent new ones from starting.
   Doing this with a refcount and an event is subtly racy;
   EX_RUNDOWN_REF does it correctly.                        */

        EX_RUNDOWN_REF RunRef;

        ExInitializeRundownProtection(&RunRef);

/* Every user, before touching the object: */
        if (!ExAcquireRundownProtection(&RunRef))
                return STATUS_DEVICE_REMOVED;   /* rundown has
                                                   started    */
        ... use the object ...
        ExReleaseRundownProtection(&RunRef);

/* The teardown path, once: */
        ExWaitForRundownProtectionRelease(&RunRef);
        /* returns when every acquirer has released, AND all
           future acquires fail. NOW it is safe to free.    */

        ... free the object ...

/* THIS IS EXACTLY the problem Linux solves with module
   refcounts and _sync cancellation (ch. 13/15). Windows gives
   it a name and a correct implementation.

   USE IT for anything with a lifetime shorter than the
   driver: a per-file context, a session, a queued operation
   the user can cancel.                                     */
```

Deadlock and how it is found

```
/* THE FOUR CLASSIC WAYS, same as Linux (ch. 11):
     1. AB-BA lock ordering
     2. self-deadlock on a non-recursive lock
     3. an ISR taking a lock its interrupted code holds
     4. waiting at DISPATCH_LEVEL

/* THE FIX FOR (1) IS ALWAYS THE SAME: a documented order. */

/*
 * Lock order:
 *      device->ConfigLock  (WDFWAITLOCK)
 *        -> device->QueueLock  (WDFSPINLOCK)
 *          -> interrupt lock
 * Never acquire in the reverse direction.
 */

/* AND LET DRIVER VERIFIER CHECK IT: */
        verifier /flags 0x20 /driver mydriver.sys
        /* 0x20 = deadlock detection */

/* Verifier's deadlock detector builds a lock ORDER GRAPH at
   runtime and bugchecks with 0xC4 (subcode 0x1000-series) the
   first time it sees an inconsistent acquisition - even if no
   deadlock actually occurred. This is the direct equivalent
   of Linux's lockdep (ch. 11), and it finds the same class of
   latent bug.

   ENABLE IT DURING DEVELOPMENT, ALWAYS. It is the single most
   valuable verifier flag for concurrency.               */

/* DEBUGGING A HANG in WinDbg (chapter 22): */
        !locks                  /* every ERESOURCE and its
                                   owner                    */
        !deadlock               /* verifier's graph */
        !stacks 2               /* every thread's stack */
        !thread ffff8a0c...     /* what is this one waiting on */
        !process 0 7            /* everything, verbose */
```

How it shows up

Symptom	Cause
Bugcheck 0xA in a spinlock section	Touched paged memory at DISPATCH_LEVEL
One CPU spins forever	ISR took a lock held by the code it interrupted — use the interrupt spinlock
Whole system hangs	AB-BA deadlock, or waiting while holding a spinlock
Bugcheck 0xC4 with a deadlock subcode	Verifier found an inconsistent lock order — a real bug
Random corruption after a lock release	`oldIrql` shared rather than local
Thread waits forever	Infinite timeout on hardware that stopped responding
Wait returns immediately	Timeout sign wrong — negative is relative
Deadlock on a fast mutex	Acquired recursively; it is not recursive
ERESOURCE assertion on a checked build	Missing `KeEnterCriticalRegion`
Counter drifts under load	Non-interlocked read-modify-write

Symptom	Cause
Use-after-free during teardown	No rundown protection — a user was still inside
Works on one core, fails on many	It was always racy; low core count hid it

Check yourself

- ✓ Walk the decision tree for four different pieces of driver data.
- ✓ Explain why acquiring a spinlock imposes every DISPATCH_LEVEL restriction.
- ✓ Say why data shared with an ISR needs an interrupt spinlock, and what `WdfInterruptSynchronize` is for.
- ✓ Distinguish notification from synchronisation events.
- ✓ Explain the sign convention for timeouts and why every driver wait needs one.
- ✓ Say why a fast mutex must not be acquired recursively.
- ✓ Explain what `KeEnterCriticalRegion` protects against.
- ✓ Use interlocked operations correctly, and state their limit.
- ✓ Explain what rundown protection solves and when to use it.
- ✓ Enable Verifier's deadlock detection and explain what it corresponds to on Linux.

ISRs, DPCs and work items

Windows splits interrupt handling into three tiers by IRQL: a tiny ISR at device level, a DPC at dispatch level, and a work item at passive level. Knowing which tier each piece of work belongs to is the core skill of interrupt-driven driver design.

The three tiers

```
  device raises its interrupt
       |
       v
  ISR                              at DIRQL
    · acknowledge the hardware, stop it re-asserting
    · read the minimum state you need
    · queue a DPC
    · RETURN. Target: under a few microseconds.
    · CANNOT: touch paged memory, allocate paged pool,
      wait, block, call most APIs
       |
       v
  DPC                              at DISPATCH_LEVEL
    · the real work: parse data, complete requests, start
      the next transfer
    · CAN: complete IRPs, use spinlocks, allocate non-paged
      pool, queue work items
    · CANNOT: touch paged memory, wait, block
    · Target: tens of microseconds. Over ~100us and you are
      hurting system latency; the DPC watchdog fires at
      around 20ms.
       |
       v
  WORK ITEM                        at PASSIVE_LEVEL
    · anything that must sleep: registry access, file I/O,
      waiting on an event, sending a request to another
      driver, allocating paged pool
    · runs on a system worker thread, so it may be delayed
       |
       v
  done

COMPARE LINUX (ch. 13):
   ISR        = the hard IRQ handler
   DPC        = a tasklet or softirq
   work item  = a workqueue item
   and WDF's passive-level interrupts = a threaded IRQ

THE SAME DESIGN PRESSURE produces the same three tiers in
both systems: something must be fast and constrained,
something must be deferred but prompt, and something must be
able to sleep.
```

The ISR

```
BOOLEAN
MyEvtInterruptIsr(_In_ WDFINTERRUPT Interrupt,
                  _In_ ULONG MessageID)
{
        PMY_CONTEXT ctx = MyInterruptGetContext(Interrupt);
        ULONG status;

        UNREFERENCED_PARAMETER(MessageID);

        /* WDF has ALREADY acquired the interrupt spinlock
           before calling us (chapter 09).                  */

        status = READ_REGISTER_ULONG(
                        (PULONG)(ctx->RegBase + REG_INT_STATUS));

        /* IS IT OURS? On a shared line this is mandatory -
           returning TRUE for someone else's interrupt breaks
           their driver.                                     */
        if ((status & INT_PENDING) == 0)
                return FALSE;

        /* ACKNOWLEDGE FIRST, so the device stops asserting */
        WRITE_REGISTER_ULONG(
                (PULONG)(ctx->RegBase + REG_INT_CLEAR), status);

        /* hand the minimum state to the DPC */
        ctx->LastStatus = status;

        /* queue the DPC and return */
        WdfInterruptQueueDpcForIsr(Interrupt);

        return TRUE;
}

/* THE RETURN VALUE:
     TRUE   this interrupt was mine and I handled it
     FALSE  not mine - let the next handler on the shared
            line try

   IF EVERY HANDLER RETURNS FALSE repeatedly, Windows
   eventually declares the interrupt unhandled and the system
   may bugcheck with 0x7A or hang in an interrupt storm - the
   equivalent of Linux's "nobody cared" (ch. 14).

/* WHAT NOT TO DO IN AN ISR:
     · a slow MMIO read (a PCIe config read can take
       microseconds - do it in the DPC)
     · a loop of unknown length
     · DbgPrint on a serial console (milliseconds!)
     · anything touching paged memory
     · acquiring any lock other than the interrupt lock     */
```

The DPC

```
VOID
MyEvtInterruptDpc(_In_ WDFINTERRUPT Interrupt,
                  _In_ WDFOBJECT AssociatedObject)
{
        PMY_CONTEXT ctx = MyInterruptGetContext(Interrupt);
        WDFREQUEST request;
        ULONG status;
        NTSTATUS s;

        UNREFERENCED_PARAMETER(AssociatedObject);

        /* read the state the ISR captured, under the
           interrupt lock (chapter 09) */
        WdfInterruptAcquireLock(Interrupt);
        status = ctx->LastStatus;
        ctx->LastStatus = 0;
        WdfInterruptReleaseLock(Interrupt);

        if (status & INT_ERROR) {
                ctx->Errors++;
                MyHandleError(ctx, status);
        }

        if (status & INT_DATA_READY) {
                /* complete a pending request (chapter 15) */
                s = WdfIoQueueRetrieveNextRequest(ctx->ReadQueue,
                                                  &request);
                if (NT_SUCCESS(s)) {
                        MyFillRequest(ctx, request);
                        WdfRequestCompleteWithInformation(
                                request, STATUS_SUCCESS, len);
                }
        }

        /* need PASSIVE_LEVEL? queue a work item */
        if (status & INT_NEEDS_RESET)
                WdfWorkItemEnqueue(ctx->ResetWorkItem);
}

/* DPC PROPERTIES worth knowing:

   · ONE DPC OBJECT runs at most once at a time, system-wide.
     Queueing it again while it is queued is a no-op - so a
     burst of interrupts produces ONE DPC run, not N. Your DPC
     must therefore handle "several things happened" in one
     pass, not assume a one-to-one mapping with interrupts.

   · It runs on the CPU that queued it, by default.
     WdfDpcCreate lets you request otherwise; on a
     multi-queue device, spreading DPCs across CPUs is how you
     scale.

   · It can be interrupted by any DIRQL interrupt, including
     your own ISR - so shared state still needs the interrupt
     lock.

   · DPCs from all drivers share one per-CPU queue. A long DPC
     delays everyone's. This is the single biggest source of
     system-wide latency spikes on Windows, and it is the
     direct analogue of the Linux argument for keeping
```

```
     softirqs short (ch. 10).                                */

/* A STANDALONE DPC, not tied to an interrupt: */
        WDF_DPC_CONFIG dpcConfig;
        WDF_OBJECT_ATTRIBUTES attr;

        WDF_DPC_CONFIG_INIT(&dpcConfig, MyDpcFunc);
        dpcConfig.AutomaticSerialization = TRUE;

        WDF_OBJECT_ATTRIBUTES_INIT(&attr);
        attr.ParentObject = device;

        status = WdfDpcCreate(&dpcConfig, &attr, &ctx->Dpc);
        ...
        WdfDpcEnqueue(ctx->Dpc);

        /* teardown - WAIT for it, like Linux's _sync forms */
        WdfDpcCancel(ctx->Dpc, TRUE);   /* TRUE = wait */
```

THE DPC WATCHDOG

Bugcheck `0x133 DPC_WATCHDOG_VIOLATION` fires when a single DPC runs for roughly 20 ms, or when the system stays at DISPATCH_LEVEL for around 10 seconds. It exists because a long DPC is invisible in normal testing but destroys interactive latency in the field. If you hit it, the fix is never to raise the timeout — it is to move work into a work item or split it across several DPC invocations.

Work items

```
/* For anything needing PASSIVE_LEVEL. */

VOID
MyEvtWorkItem(_In_ WDFWORKITEM WorkItem)
{
        PMY_WORKITEM_CONTEXT wc = MyWorkItemGetContext(WorkItem);
        PMY_CONTEXT ctx = wc->DeviceContext;

        PAGED_CODE();     /* asserts PASSIVE_LEVEL */

        /* we may sleep here: registry, files, waiting */
        MyResetHardwareSlowly(ctx);
        MyReadConfigFromRegistry(ctx);
}

/* creating one, in EvtDeviceAdd: */
        WDF_WORKITEM_CONFIG workConfig;
        WDF_OBJECT_ATTRIBUTES attr;

        WDF_WORKITEM_CONFIG_INIT(&workConfig, MyEvtWorkItem);

        WDF_OBJECT_ATTRIBUTES_INIT_CONTEXT_TYPE(&attr,
                        MY_WORKITEM_CONTEXT);
        attr.ParentObject = device;

        status = WdfWorkItemCreate(&workConfig, &attr,
                                   &ctx->WorkItem);

        wc = MyWorkItemGetContext(ctx->WorkItem);
        wc->DeviceContext = ctx;

/* enqueue from a DPC or anywhere: */
        WdfWorkItemEnqueue(ctx->WorkItem);

/* teardown: */
        WdfWorkItemFlush(ctx->WorkItem);   /* WAIT for it */

/* THE SAME COALESCING RULE as DPCs: enqueueing an already
   queued work item is a no-op. If each event needs its own
   handling, either create several work items, or maintain
   your own queue of pending events and have one work item
   drain it.

   THAT SECOND PATTERN is usually the right one:
        DPC: push an event onto a list, enqueue the work item
        work item: drain the list until empty
   It handles bursts correctly and needs only one work item. */

/* SYSTEM WORKER THREADS are a shared, limited resource. A
   work item that blocks for a long time occupies one. Do not
   use work items for long-running loops - create a dedicated
   system thread instead (chapter 11).                    */
```

Passive-level interrupts

```
/* Some devices are on a slow bus - I2C, SPI, or behind a
   USB transfer - where you CANNOT read the interrupt status
   register without sleeping. A DIRQL ISR cannot do that.

   WDF's answer: a passive-level interrupt.                */

        WDF_INTERRUPT_CONFIG config;

        WDF_INTERRUPT_CONFIG_INIT(&config,
                                  MyEvtInterruptIsr,
                                  MyEvtInterruptDpc);

        config.PassiveHandling = TRUE;    /* <-- the ISR runs
                                             at PASSIVE_LEVEL */
        config.AutomaticSerialization = FALSE;   /* required
                                                    with
                                                    passive   */

        status = WdfInterruptCreate(device, &config, &attr,
                                    &ctx->Interrupt);

/* NOW EvtInterruptIsr runs at PASSIVE_LEVEL, on a dedicated
   thread, and may sleep - so it can do an I2C read to find
   out what happened.

   This is EXACTLY Linux's threaded IRQ (ch. 13), including
   the reason it exists.

   CONSEQUENCES:
     · higher latency - a thread must be scheduled
     · the interrupt stays masked until your handler returns,
       so it is inherently one-shot
     · use WdfInterruptAcquireLock, which becomes a
       passive-level lock, not a spinlock
     · you may not need a DPC at all - do the work in the ISR

   USE IT for I2C/SPI/GPIO-connected devices, which on modern
   ARM64 Windows systems is most of them.                  */
```

Timers

```
/* WDFTIMER - the callback runs at DISPATCH_LEVEL by default. */

        WDF_TIMER_CONFIG timerConfig;

        WDF_TIMER_CONFIG_INIT_PERIODIC(&timerConfig,
                                       MyEvtTimer,
                                       100);   /* ms period */
        /* or one-shot: */
        WDF_TIMER_CONFIG_INIT(&timerConfig, MyEvtTimer);

        timerConfig.AutomaticSerialization = TRUE;
        timerConfig.TolerableDelay = 50;   /* ms - lets the
                                              system coalesce
                                              timers and save
                                              power           */

        WDF_OBJECT_ATTRIBUTES_INIT(&attr);
        attr.ParentObject = device;

        status = WdfTimerCreate(&timerConfig, &attr,
                                &ctx->Timer);

        WdfTimerStart(ctx->Timer,
                      WDF_REL_TIMEOUT_IN_MS(100));

        WdfTimerStop(ctx->Timer, TRUE);   /* TRUE = WAIT for
                                             any running
                                             callback         */

              WDF disconnects the interrupt for us AFTER this
              callback, but the device must stop asserting
              first or we take a spurious one.            */
        WRITE_REGISTER_ULONG(
                (PULONG)(ctx->RegBase + REG_INT_ENABLE), 0);

        /* 2. wait for anything already queued */
        WdfDpcCancel(ctx->Dpc, TRUE);        /* TRUE = wait */
        WdfWorkItemFlush(ctx->WorkItem);
        WdfTimerStop(ctx->Timer, TRUE);      /* TRUE = wait */

        /* 3. now nothing can touch our state */
        return STATUS_SUCCESS;
}

/* THE "TRUE" ARGUMENTS ARE NOT OPTIONAL. Without them these
   calls return immediately, the callback may still be
   running, and it will touch your context after
   EvtDeviceReleaseHardware has unmapped the registers -
   producing a bugcheck at an address that no longer maps.

   This is the exact Windows counterpart of forgetting
   cancel_work_sync() on Linux, with the same symptom and the
   same fix.                                             */
```

How it shows up

Symptom	Cause
Bugcheck 0x133 DPC_WATCHDOG_VIOLATION	A DPC doing far too much — move work to a work item
Bugcheck 0xA inside a DPC	Paged memory or paged pool at DISPATCH_LEVEL
Interrupt storm, system unresponsive	ISR not acknowledging the device
Another device stops working	Your ISR returned TRUE for an interrupt that was not yours
Bugcheck 0x7A or a hang	Nobody claimed the interrupt
Events lost during a burst	Assumed one DPC per interrupt — DPCs coalesce
Work items lost during a burst	Same coalescing rule — use a list plus one drainer
Bugcheck on device removal or sleep	DPC, timer or work item not cancelled with wait
System-wide latency spikes	A long DPC delaying everyone's
Cannot read the status register in the ISR	Slow bus — use `PassiveHandling`
Work item never runs	Enqueued while already queued, or the worker pool is exhausted
High CPU with nothing happening	`KeStallExecutionProcessor` for too long

Check yourself

- ✓ Name the three tiers, their IRQLs, and what each may and may not do.
- ✓ Map them onto Linux's equivalents.
- ✓ Write an ISR and explain both return values.
- ✓ Explain what happens if every handler on a shared line returns FALSE.
- ✓ Explain DPC coalescing and how to write a DPC that handles bursts.
- ✓ Say what bugcheck 0x133 means and what the correct fix is.
- ✓ Explain why a long DPC harms the whole system.
- ✓ Use a work item, and give the pattern for handling many events with one.
- ✓ Say when a passive-level interrupt is needed and what it costs.
- ✓ Write the teardown sequence and explain why the wait arguments are mandatory.

Threads and scheduling

System threads, thread priorities, APCs, and the context rules that decide whether a user-mode address means anything to your code. Shorter than the Linux equivalent, because most drivers should not create threads at all — but you need to know when they should.

Priorities

```
31  ┐
...  │  REAL-TIME range (16-31)
16  ┘  Fixed. NEVER boosted, never decayed.
       A runaway thread here starves everything below.

15  ┐
...  │  DYNAMIC range (1-15)
 1  ┘  Boosted on I/O completion, decayed over time.
 0     the zero-page thread only

THREAD PRIORITY = process priority class + thread relative
priority, for user threads. Kernel threads set an absolute
value.

FOR DRIVER THREADS the useful constants:

  LOW_REALTIME_PRIORITY     16
  HIGH_PRIORITY             31
  LOW_PRIORITY               0
  THREAD_PRIORITY_NORMAL     8   (dynamic)

A driver's worker thread usually wants LOW_REALTIME_PRIORITY
(16) if it services hardware with timing requirements, or
simply the default 8 if it does background work.

THE RULE: raising priority is almost never the fix for a
latency problem. If a driver thread is not running promptly
the usual causes are a long DPC somewhere (chapter 10), a
lock it is waiting on, or too much work in the wrong tier.
Raising priority moves the problem onto someone else.
```

System threads

```
#include <ntddk.h>

VOID
MyThreadRoutine(_In_ PVOID Context)
{
        PMY_CONTEXT ctx = (PMY_CONTEXT)Context;
        NTSTATUS status;

        /* PASSIVE_LEVEL. May sleep. No user address space -
           we are in the SYSTEM process.                    */

        KeSetPriorityThread(KeGetCurrentThread(),
                            LOW_REALTIME_PRIORITY);

        for (;;) {
                status = KeWaitForSingleObject(&ctx->WorkEvent,
                                Executive, KernelMode, FALSE,
                                NULL);   /* or a timeout */

                if (ctx->Stopping)
                        break;

                MyDoLongRunningWork(ctx);
        }

        PsTerminateSystemThread(STATUS_SUCCESS);
}

/* CREATING one: */
        HANDLE threadHandle;
        NTSTATUS status;

        status = PsCreateSystemThread(&threadHandle,
                                      THREAD_ALL_ACCESS,
                                      NULL,     /* attributes */
                                      NULL,     /* process:
                                                   NULL = the
                                                   system one  */
                                      NULL,     /* client id  */
                                      MyThreadRoutine,
                                      ctx);
        if (!NT_SUCCESS(status))
                return status;

        /* Take a REFERENCE so we can wait for it later, then
           close the handle - we do not need it. */
        status = ObReferenceObjectByHandle(threadHandle,
                        THREAD_ALL_ACCESS, *PsThreadType,
                        KernelMode, &ctx->ThreadObject, NULL);
        ZwClose(threadHandle);

/* STOPPING it - and this must be exactly right: */
        ctx->Stopping = TRUE;
        KeSetEvent(&ctx->WorkEvent, IO_NO_INCREMENT, FALSE);

        KeWaitForSingleObject(ctx->ThreadObject, Executive,
                              KernelMode, FALSE, NULL);
        /* the thread has now RETURNED - it is safe to free its
           context and to unload                              */
```

```
        ObDereferenceObject(ctx->ThreadObject);

/* WITHOUT THAT WAIT, the driver can unload while the thread
   is still executing its code, and the next instruction it
   runs is in freed memory. Exactly the Linux kthread_stop()
   requirement (ch. 09).                                    */
```

> **WHEN TO CREATE A THREAD — RARELY**
>
> Use a **work item** (chapter 10) for short deferred work; it shares the system worker pool and costs nothing when idle. Create a dedicated system thread only when you need a long-lived loop that blocks — a polling loop, a thread servicing a hardware queue, a watchdog. A thread per device that mostly sleeps is wasted memory and a scheduler entry; a work item that blocks for seconds starves the shared pool. Match the tool to the duration.

Thread and process context

```
/* WHICH PROCESS AM I IN? It determines whether a user-mode
   address means anything.                                    */

        PEPROCESS process = IoGetCurrentProcess();
        PETHREAD  thread  = PsGetCurrentThread();
        HANDLE    pid     = PsGetCurrentProcessId();
        HANDLE    tid     = PsGetCurrentThreadId();

/* THE THREE CONTEXTS a driver routine can run in:

   1. THE CALLER'S CONTEXT
        A dispatch routine called synchronously from a
        syscall. `IoGetCurrentProcess()` is the requesting
        process, and user-mode addresses are valid.
        -> only reliable for synchronous, non-queued requests

   2. AN ARBITRARY THREAD CONTEXT
        A DPC, a completion routine, a timer callback. You are
        on whatever thread happened to be interrupted. User
        addresses are MEANINGLESS.
        -> this is why METHOD_BUFFERED and MDLs exist
           (chapter 07)

   3. A SYSTEM THREAD CONTEXT
        Your own thread, or a work item. In the System
        process. No user address space at all.

/* THE ONE-LINE RULE: unless you are certain you are in case
   1, never touch a user-mode address. Use SystemBuffer or a
   mapped MDL, which are valid everywhere.

/* IF YOU MUST reach a specific process's address space: */
        KAPC_STATE apcState;

        KeStackAttachProcess(targetProcess, &apcState);
        /* now user addresses in targetProcess are valid */
        __try {
                ProbeForRead(userVa, len, 1);
                RtlCopyMemory(local, userVa, len);
        } __except (EXCEPTION_EXECUTE_HANDLER) {
                status = GetExceptionCode();
        }
        KeUnstackDetachProcess(&apcState);

/* ATTACHING IS EXPENSIVE and constrained: PASSIVE_LEVEL only,
   no nesting across other attaches, and you must detach on
   every path. Treat it as a last resort - the existence of
   MDLs means you almost never need it.                   */
```

APCs

```
/* An Asynchronous Procedure Call runs a function IN THE
   CONTEXT OF A SPECIFIC THREAD. It is the mechanism behind
   asynchronous I/O completion, thread suspension, and
   termination.                                          */

   KERNEL APCs      run at APC_LEVEL, in the target thread.
                    Used by the I/O manager to copy results
                    back into the caller's buffer at
                    completion - which is why METHOD_BUFFERED
                    output lands in the right process without
                    you doing anything.

   SPECIAL KERNEL APCs  a higher-priority variant, used for
                    I/O completion and thread termination.
                    Cannot be disabled by a critical region.

   USER APCs        run at PASSIVE_LEVEL in user mode, when
                    the thread enters an ALERTABLE wait.
                    QueueUserAPC, and the completion routine
                    of ReadFileEx.

/* WHY A DRIVER CARES:

   1. KeEnterCriticalRegion() disables normal kernel APCs.
      Required around ERESOURCE (chapter 09), because an APC
      could otherwise suspend a thread holding the resource.

   2. An ALERTABLE wait can be interrupted by a user APC:
        KeWaitForSingleObject(..., TRUE, ...)   /* alertable */
      returns STATUS_USER_APC. Handle it, or use FALSE.

   3. Thread termination is delivered as a special kernel APC.
      A thread that never enters an alertable wait can be hard
      to terminate - which is why driver threads should use an
      explicit stop flag plus an event, as above, rather than
      relying on termination.

/* QUEUEING ONE yourself is possible but rarely right - the
   APC structures are undocumented in detail and the lifetime
   rules are unforgiving. If you think you need an APC, you
   probably want a work item.                            */
```

Cancellation and thread exit

```
/* When a thread exits with I/O outstanding, the I/O manager
   cancels its pending IRPs. Your driver must cooperate or the
   process hangs in termination.                              */

/* THE OBLIGATIONS:
     1. every queued request must have a cancel path
        (chapter 04, or WDF queues in chapter 15)
     2. IRP_MJ_CLEANUP must cancel everything belonging to
        that file object
     3. no wait without a timeout

/* WDF DOES ALL OF THIS if you use queues:
     · WdfIoQueuePurgeSynchronously cancels and waits
     · the framework cancels per-file-object requests on
       cleanup automatically
     · EvtIoCanceledOnQueue lets you clean up device state

/* SEEING A HUNG TERMINATION in WinDbg (chapter 22): */
        !process 0 7               /* find the process */
        !thread ffff8a0c...        /* what is it waiting on */
        !irpfind -v 0 0 device ...  /* which IRP is stuck */

/* THE PATTERN: a process stuck in "Terminated" state with a
   non-zero thread count almost always means a driver holds an
   IRP it never completes and never cancels. The Linux
   equivalent is a task stuck in D state (ch. 09), and it is
   diagnosed the same way: find the request, find the driver
   holding it.                                                */
```

Observing

```
# --- On the machine ---
    Process Explorer           per-thread CPU, priority,
                               start address, stack
    Process Monitor            I/O by thread
    Performance Monitor        Thread \ Priority Current
    xperf / WPA                scheduling traces, wait
                               analysis - the best tool for
                               "why was my thread not running"

# --- In WinDbg ---
    !process 0 0               every process, brief
    !process ffff8a0c... 7     one process, all threads,
                               all stacks
    !thread ffff8a0c...        one thread: priority, state,
                               wait reason, stack
    !ready                     threads ready to run, by
                               priority
    !running                   what each CPU is running now
    !stacks 2                  every thread's stack, filtered
    ~*k                        all stacks in the current
                               process

# WAIT REASONS worth recognising in !thread output:
    Executive        waiting on a dispatcher object
    UserRequest      a user-mode wait
    WrQueue          waiting on a work queue
    Suspended
    WrLpcReceive     an ALPC call

# THE QUESTION !thread ANSWERS: "what is this thread blocked
# on, and who owns it?" That is usually the whole diagnosis
# for a hang.
```

How it shows up

Symptom	Cause
Bugcheck after driver unload	Thread not waited for — `KeWaitForSingleObject` on the thread object is mandatory
Driver will not unload	Thread never exits; the stop flag is not checked, or the event is never signalled
Process stuck in "Terminated"	A driver holds an IRP it never completes or cancels
User buffer is garbage in a DPC	Arbitrary thread context — the address means nothing there
Works synchronously, fails when queued	Same cause; the request completed in a different context
Wait returns `STATUS_USER_APC`	An alertable wait was interrupted — handle it or pass FALSE
System-wide starvation	A real-time-priority driver thread that never blocks
ERESOURCE assertion	Missing `KeEnterCriticalRegion` (ch. 09)
Worker pool exhausted	Work items blocking for a long time — use a dedicated thread
Crash in `KeUnstackDetachProcess`	Attach/detach not paired on every path

Check yourself

✓ Explain the real-time and dynamic priority ranges and why raising priority rarely fixes latency.

- ✓ Create a system thread and stop it correctly, including the reference and the wait.
- ✓ Say when a work item is right and when a dedicated thread is.
- ✓ Name the three contexts a driver routine can run in and which allows user addresses.
- ✓ Explain why `KeStackAttachProcess` is a last resort.
- ✓ Explain what APCs are used for and the three reasons a driver cares.
- ✓ Explain why `IRP_MJ_CLEANUP` matters to process termination.
- ✓ Use `!thread` to determine what a blocked thread is waiting on.
- ✓ Map each of these onto its Linux equivalent.

Driver models: WDM, KMDF and UMDF

Three ways to write a Windows driver, with a clear answer about which to choose. This chapter explains what each is, what WDF actually does for you, and the narrow cases where the older model is still required.

The three models

	WDM	KMDF	UMDF
Runs in	Kernel	Kernel	**User mode**
Introduced	1999	2005	2006 (v2 in 2013)
A bug means	Bugcheck	Bugcheck	**A crashed process**
Lines for a simple driver	~2000	~600	~600
PnP/power state machine	**You write it**	Framework	Framework
Request cancellation	**You write it**	Framework	Framework
Direct hardware access	Yes	Yes	Limited
Interrupts	Yes	Yes	Yes (passive only)
DMA	Yes	Yes	**No**
Debuggable with	WinDbg (kernel)	WinDbg (kernel)	**Visual Studio**
Language	C	C	C++ (COM-based)

THE DECISION, IN ORDER

1. **Can it be UMDF?** If your device needs no DMA, no DIRQL interrupt handling, and no kernel-only API, write it in user mode. A bug becomes a restarted service, not a blue screen — and you debug it in Visual Studio with a normal debugger.
2. **Otherwise, KMDF.** This is the answer for essentially every kernel driver written today.
3. **WDM only if forced.** Some device classes have their own port/miniport models that are WDM-based, and some filter positions are not expressible in WDF. Those are the real exceptions; "we have always used WDM" is not one.

What WDF actually gives you

```
THE WDM DRIVER MUST IMPLEMENT:

  · ~25 PnP minor functions, each with its own forwarding
    and completion rules (chapter 05)
  · a PnP state machine with roughly 15 states, including
    surprise removal, query-remove veto, and resource
    rebalance
  · power IRP handling, correctly serialised, including
    the notorious rule that power IRPs must not be
    completed out of order
  · queue management for pending requests
  · cancellation, with the cancel-routine ownership race
    (chapter 04)
  · request stalling across power transitions
  · per-file-object request tracking, for cleanup
  · reference counting for safe removal
  · synchronisation between all of the above

ALL OF THAT IS THE FRAMEWORK'S JOB IN WDF. What remains
yours:

  · EvtDriverDeviceAdd            create the device
  · EvtDevicePrepareHardware      map registers
  · EvtDeviceD0Entry / D0Exit     power the device
  · EvtDeviceReleaseHardware      unmap
  · EvtIoRead / Write / DeviceControl   the actual work
  · EvtInterruptIsr / Dpc         the interrupt

That is why a KMDF driver is roughly a third the size, and
why the parts that shrink are exactly the parts that were
historically buggy. The framework is not hiding the
hardware from you - it is hiding the OS protocol.
```

The WDF object model in outline

```
/* Everything is a WDF object, with a handle, a parent, an
   optional context, and cleanup callbacks. Covered fully in
   chapter 13; the shape:                                    */

   WDFDRIVER          one per driver
     WDFDEVICE        one per device
       WDFQUEUE       request queues
       WDFINTERRUPT
       WDFDMAENABLER
       WDFTIMER, WDFDPC, WDFWORKITEM
       WDFSPINLOCK, WDFWAITLOCK
       WDFMEMORY
       WDFREQUEST     one per in-flight request
       WDFFILEOBJECT  one per open handle

/* PARENTING IS THE KEY IDEA: destroying a parent destroys its
   children, in order. Set ParentObject and most of your
   cleanup disappears - the Windows counterpart of Linux's
   devm_ (ch. 26).                                           */

        WDF_OBJECT_ATTRIBUTES attr;

        WDF_OBJECT_ATTRIBUTES_INIT(&attr);
        attr.ParentObject = device;      /* dies with it */
        WdfSpinLockCreate(&attr, &lock);
```

A KMDF driver, complete

```
#include <ntddk.h>
#include <wdf.h>

typedef struct _MY_CONTEXT {
        WDFDEVICE     Device;
        WDFQUEUE      DefaultQueue;
        WDFINTERRUPT  Interrupt;
        PUCHAR        RegBase;
        ULONG         RegLength;
        ULONG         LastStatus;
} MY_CONTEXT, *PMY_CONTEXT;

   framework destroys the partially-built device for you.

   That is the same guarantee Linux's devm_ gives (ch. 26),
   and it removes the same class of bug.                  */
```

UMDF

```
/* Same object model, same callback names, C++ and COM instead
   of C. A UMDF v2 driver's EvtDeviceAdd looks almost
   identical: */

NTSTATUS
MyEvtDeviceAdd(_In_ WDFDRIVER Driver,
               _Inout_ PWDFDEVICE_INIT DeviceInit)
{
        WDFDEVICE device;
        NTSTATUS status;

        status = WdfDeviceCreate(&DeviceInit,
                                 WDF_NO_OBJECT_ATTRIBUTES,
                                 &device);
        ...
}

/* WHAT UMDF CAN DO:
     · USB devices (through WinUSB)
     · HID devices
     · serial, sensors, biometrics
     · anything reachable through another driver's interface
     · MMIO, on modern versions, with restrictions
     · interrupts, at passive level only

   WHAT IT CANNOT:
     · DMA
     · DIRQL interrupt handling
     · kernel-only APIs
     · being anything other than a leaf or near-leaf in the
       stack

   HOW IT RUNS: the driver is a DLL hosted in
   WUDFHost.exe, a service process. The reflector - a small
   kernel component - forwards IRPs to it.

   THE PAYOFF is large and worth taking seriously:
     · a bug crashes WUDFHost, which RESTARTS. No blue screen,
       no lost user work.
     · debug it in Visual Studio, with breakpoints, watch
       windows and edit-and-continue - not WinDbg on a second
       machine.
     · it runs with restricted privileges, so a compromised
       driver is far less valuable to an attacker.
     · the whole class of IRQL and paged-pool bugs simply does
       not exist.

   IF YOUR DEVICE QUALIFIES, USE IT. The reflexive assumption
   that "real drivers are kernel drivers" costs teams months
   of debugging that user-mode development would not have
   required.                                                */
```

Framework versions

```
; The framework ships as a library BOUND INTO your driver's
; INF, not as a fixed OS component. You target a version.

    [MyDriver_Install.Wdf]
    KmdfService = MyDriver, MyDriver_wdfsect

    [MyDriver_wdfsect]
    KmdfLibraryVersion = 1.15

; VERSION -> MINIMUM WINDOWS:
;   1.9   Windows 7
;   1.11  Windows 8
;   1.13  Windows 8.1
;   1.15  Windows 10 1507
;   1.17  Windows 10 1607
;   1.21  Windows 10 1809
;   1.31  Windows 10 2004
;   1.33  Windows 11

; PICK THE LOWEST VERSION that has the features you need -
; it maximises the range of systems your driver installs on.
; The build knows, and Code Analysis will tell you if you call
; an API newer than your declared version:

;   in the project properties, or the .vcxproj:
;     <KMDF_VERSION_MAJOR>1</KMDF_VERSION_MAJOR>
;     <KMDF_VERSION_MINOR>15</KMDF_VERSION_MINOR>

/* AND IN CODE, for a feature that may not be present: */
        if (WdfDriverIsVersionAvailable(driver, &versionInfo)) {
                ...
        }
```

Reading a WDM driver

WDM	KMDF
`IoCreateDevice` + `IoAttachDeviceToDeviceStack`	`WdfDeviceCreate`
`DeviceExtension`	A context, via `WDF_DECLARE_CONTEXT_TYPE`
`MajorFunction[IRP_MJ_READ]`	`EvtIoRead` on a queue
`IRP_MN_START_DEVICE`	`EvtDevicePrepareHardware` + `EvtDeviceD0Entry`
`IRP_MN_REMOVE_DEVICE`	`EvtDeviceD0Exit` + `EvtDeviceReleaseHardware`
Hand-written queue + cancel routine	`WDFQUEUE`
`IoCompleteRequest`	`WdfRequestComplete`
`IoConnectInterrupt`	`WdfInterruptCreate`
`KeInitializeDpc` + `KeInsertQueueDpc`	`WdfDpcCreate` + `WdfDpcEnqueue`
`IoAllocateMdl` + `MmProbeAndLockPages`	`WdfRequestRetrieveOutputBuffer`
`KSPIN_LOCK`	`WDFSPINLOCK`
Manual cleanup on every path	Object parenting

How it shows up

Symptom	Cause
Driver installs but never starts	KMDF version in the INF is newer than the OS supports
`WdfDriverCreate` fails	Called twice, or the co-installer/INF section is wrong
Bugcheck on removal in a WDM driver	PnP state machine implemented incorrectly — the reason WDF exists
Requests never complete after resume	Queue not restarted — WDF does this for you
Cancellation races	Hand-written queue instead of a WDFQUEUE
Context accessor returns garbage	`WDF_OBJECT_ATTRIBUTES_INIT_CONTEXT_TYPE` not used at creation
Objects leak across device removal	`ParentObject` not set
UMDF driver cannot do DMA	By design — it needs to be KMDF
Code Analysis flags an unavailable API	Calling something newer than your declared framework version

Check yourself

- ✓ Compare the three models across ten dimensions.
- ✓ State the decision order and the real reasons to choose WDM.
- ✓ List nine things WDF implements that WDM leaves to you.
- ✓ Write a complete `DriverEntry` and `EvtDeviceAdd` from memory.
- ✓ Explain object parenting and its Linux counterpart.
- ✓ Say what UMDF can and cannot do, and list four benefits of using it.
- ✓ Explain how framework versioning works and how to choose a version.
- ✓ Translate ten WDM constructs into their KMDF equivalents.

The WDF object model

Handles, contexts, parenting and cleanup callbacks. Once you understand these four ideas, every WDF API follows the same shape — and most of your cleanup code disappears.

Objects and handles

```
/* A WDF object is an opaque HANDLE, not a pointer: */

        WDFDEVICE     device;
        WDFQUEUE      queue;
        WDFREQUEST    request;
        WDFMEMORY     memory;
        WDFSPINLOCK   lock;
        WDFTIMER      timer;
        WDFINTERRUPT  interrupt;
        WDFDMAENABLER dmaEnabler;
        WDFCHILDLIST  childList;
        WDFFILEOBJECT fileObject;
        WDFCOLLECTION collection;
        WDFKEY        registryKey;
        WDFSTRING     string;
        WDFIOTARGET   ioTarget;

/* EVERY CREATION FUNCTION HAS THE SAME SHAPE: */

        NTSTATUS Wdf<Type>Create(
                <parent or config>,
                <type-specific config>,
                PWDF_OBJECT_ATTRIBUTES Attributes,
                <Type> *Handle);

/* AND EVERY OBJECT HAS: */
        a TYPE
        a PARENT              <-- the important one
        an optional CONTEXT   your data, attached to it
        a reference count
        optional EvtCleanupCallback and EvtDestroyCallback

/* YOU NEVER FREE AN OBJECT DIRECTLY in normal code. It is
   destroyed when its parent is. WdfObjectDelete exists but
   is needed only for objects you deliberately parented to
   something long-lived.                                    */
```

Parenting

```
WDFDRIVER
   |
   +-- WDFDEVICE                (parent: the driver)
          |
          +-- WDFQUEUE          (parent: the device)
          |      |
          |      +-- WDFREQUEST (parent: the queue)
          |             |
          |             +-- WDFMEMORY
          |
          +-- WDFINTERRUPT
          +-- WDFDMAENABLER
          |      +-- WDFDMATRANSACTION
          +-- WDFTIMER
          +-- WDFWORKITEM
          +-- WDFSPINLOCK
          +-- WDFFILEOBJECT     (one per open handle)

DESTROYING A PARENT DESTROYS ITS CHILDREN, depth-first,
in reverse creation order.

SO: parent everything to your WDFDEVICE and device removal
cleans up the entire tree, in the correct order, on every
path - including a failed EvtDeviceAdd.

THE DEFAULT PARENT is usually sensible: WdfSpinLockCreate
with WDF_NO_OBJECT_ATTRIBUTES parents to the DRIVER, which
is almost never what you want. SET IT EXPLICITLY:

     WDF_OBJECT_ATTRIBUTES_INIT(&attr);
     attr.ParentObject = device;
     WdfSpinLockCreate(&attr, &lock);

THIS IS EXACTLY Linux's devm_ (ch. 26) with a tree instead
of a flat list - and the same payoff: correct unwinding
that you did not have to write, on the error path you did
not test.
```

Contexts

```
/* A context is YOUR structure attached to a WDF object. It
   replaces WDM's DeviceExtension, and unlike it, you can
   attach one to ANY object.                                  */

/* 1. DECLARE the type and its accessor: */

typedef struct _MY_DEVICE_CONTEXT {
        WDFDEVICE     Device;
        WDFQUEUE      ReadQueue;
        WDFINTERRUPT  Interrupt;
        PUCHAR        RegBase;
        ULONG         RegLength;
        WDFSPINLOCK   StateLock;
        ULONG         SampleRate;
        LONG64        InterruptCount;
} MY_DEVICE_CONTEXT, *PMY_DEVICE_CONTEXT;

WDF_DECLARE_CONTEXT_TYPE_WITH_NAME(MY_DEVICE_CONTEXT,
                                   MyGetDeviceContext)
/* generates:
     PMY_DEVICE_CONTEXT MyGetDeviceContext(WDFOBJECT);
   plus the type information WDF needs to size the
   allocation.                                                */

/* 2. REQUEST it at creation: */
        WDF_OBJECT_ATTRIBUTES attributes;

        WDF_OBJECT_ATTRIBUTES_INIT_CONTEXT_TYPE(&attributes,
                                        MY_DEVICE_CONTEXT);
        status = WdfDeviceCreate(&DeviceInit, &attributes,
                                 &device);

/* 3. USE it: */
        PMY_DEVICE_CONTEXT ctx = MyGetDeviceContext(device);
        ctx->SampleRate = 48000;

/* SEVERAL CONTEXT TYPES ON ONE OBJECT is allowed, with
   different accessors - useful when a shared library and your
   driver both need private data on the same device.       */

/* PER-REQUEST CONTEXT, the common second use: */
typedef struct _MY_REQUEST_CONTEXT {
        WDFMEMORY  Memory;
        ULONG      Channel;
        LARGE_INTEGER StartTime;
} MY_REQUEST_CONTEXT, *PMY_REQUEST_CONTEXT;

WDF_DECLARE_CONTEXT_TYPE_WITH_NAME(MY_REQUEST_CONTEXT,
                                   MyGetRequestContext)

        /* attach it to requests arriving on a queue: */
        WDF_OBJECT_ATTRIBUTES_INIT_CONTEXT_TYPE(&attr,
                                        MY_REQUEST_CONTEXT);
        queueConfig.  /* ... */;
        WdfIoQueueCreate(device, &queueConfig, &attr, &queue);
        /* now every request on this queue has your context */

/* THE CONTEXT MEMORY IS NON-PAGED and ZEROED at creation, so
```

```
    you do not allocate or free it - it lives inside the
    object's own allocation.                              */
```

> **THE MOST COMMON WDF MISTAKE**
>
> Calling `MyGetDeviceContext()` on an object created *without* `WDF_OBJECT_ATTRIBUTES_INIT_CONTEXT_TYPE`. The accessor returns garbage or NULL, and you get a crash with no obvious cause. If a context pointer looks wrong, check the creation call first — the attributes must name the same context type the accessor expects.

Cleanup and destroy callbacks

```
/* Two callbacks, at different points in an object's death. */

        WDF_OBJECT_ATTRIBUTES_INIT_CONTEXT_TYPE(&attr,
                                        MY_DEVICE_CONTEXT);
        attr.EvtCleanupCallback = MyEvtDeviceCleanup;
        attr.EvtDestroyCallback = MyEvtDeviceDestroy;
        attr.ParentObject       = parent;

VOID
MyEvtDeviceCleanup(_In_ WDFOBJECT Object)
{
        PMY_DEVICE_CONTEXT ctx = MyGetDeviceContext(Object);

        /* CLEANUP: the object is being deleted, but its
           children still exist and its context is still
           valid. This is where you release things you
           acquired yourself.

           IRQL: <= DISPATCH_LEVEL by default, or PASSIVE if
           you asked for WdfExecutionLevelPassive.        */

        if (ctx->MyOwnAllocation) {
                ExFreePoolWithTag(ctx->MyOwnAllocation, TAG);
                ctx->MyOwnAllocation = NULL;
        }
}

VOID
MyEvtDeviceDestroy(_In_ WDFOBJECT Object)
{
        /* DESTROY: the last reference is gone, all children
           are destroyed, and the memory is about to be
           freed. Very little belongs here.

           IRQL: <= DISPATCH_LEVEL. Do not touch children -
           they no longer exist.                          */
}

/* THE ORDER on deletion:
     1. EvtCleanupCallback on the object
     2. children are deleted (each with its own cleanup)
     3. EvtDestroyCallback on the object
     4. memory freed

/* WHICH TO USE: almost always Cleanup. Destroy is for the
   rare case where you must know the object is truly gone -
   for example, signalling that a device's memory can now be
   reused.

/* AND THE POINT: if everything you allocate is either a WDF
   object parented correctly, or a WDFMEMORY, you need
   NEITHER callback. Reach for them only for raw resources
   the framework does not know about.                     */
```

WDFMEMORY

```
/* A WDF object wrapping a buffer, so allocation participates
   in parenting and lifetime management.                    */

        WDFMEMORY memory;
        PVOID buffer;
        WDF_OBJECT_ATTRIBUTES attr;

        WDF_OBJECT_ATTRIBUTES_INIT(&attr);
        attr.ParentObject = request;    /* dies with the
                                           request           */

        status = WdfMemoryCreate(&attr,
                                 NonPagedPoolNx,
                                 MY_POOL_TAG,
                                 size,
                                 &memory,
                                 &buffer);   /* optional out */
        if (!NT_SUCCESS(status))
                return status;

        /* no free needed - the request's completion destroys
           it                                                 */

/* GETTING AT IT LATER: */
        size_t length;
        PVOID p = WdfMemoryGetBuffer(memory, &length);

/* WRAPPING A BUFFER YOU ALREADY HAVE, without copying: */
        status = WdfMemoryCreatePreallocated(&attr,
                         existingBuffer, size, &memory);
        /* WDF does NOT free the buffer in this case - you
           still own it. Use this to hand an existing buffer
           to an API that wants a WDFMEMORY.               */

/* COPYING, with bounds checking done for you: */
        WdfMemoryCopyFromBuffer(memory, offset, src, length);
        WdfMemoryCopyToBuffer(memory, offset, dst, length);
/* These return STATUS_BUFFER_TOO_SMALL rather than
   overrunning - which is the argument for using them instead
   of RtlCopyMemory on a raw pointer.                      */
```

Synchronisation scope

```
/* WDF can AUTOMATICALLY serialise your callbacks, so you may
   not need locks at all.                                      */

        WDF_OBJECT_ATTRIBUTES attr;

        WDF_OBJECT_ATTRIBUTES_INIT(&attr);
        attr.SynchronizationScope = WdfSynchronizationScopeDevice;
        attr.ExecutionLevel       = WdfExecutionLevelPassive;

/* SYNCHRONIZATION SCOPE:

   WdfSynchronizationScopeDevice
        ALL callbacks for this device, and its queues, timers
        and DPCs, are serialised against one another with a
        single device lock. Simplest to reason about; limits
        parallelism.

   WdfSynchronizationScopeQueue
        callbacks for one queue are serialised with each
        other, but different queues run in parallel.

   WdfSynchronizationScopeNone
        no automatic serialisation. YOU do the locking.
        The default for a parallel queue, and the right choice
        for a high-throughput device.

   WdfSynchronizationScopeInheritFromParent
        the default for most objects.

/* EXECUTION LEVEL:

   WdfExecutionLevelPassive
        every callback runs at PASSIVE_LEVEL, so it may touch
        paged memory and sleep. The framework uses work items
        to arrange it.
        NOTE: cannot be combined with a queue that must run at
        DISPATCH_LEVEL, and it adds latency.

   WdfExecutionLevelDispatch
        callbacks may run at DISPATCH_LEVEL.

   WdfExecutionLevelInheritFromParent   the default.

/* THE TRADE, stated plainly:
     ScopeDevice + LevelPassive is the EASIEST model to write
     correctly - one lock, everything sleepable, no IRQL
     puzzles. It is also the slowest, because every callback
     serialises against every other.

     ScopeNone + parallel dispatch is the FASTEST and requires
     you to get the locking right yourself (chapter 09).

   START with the simple model. Move to the parallel one when
   you have measured a reason to.                            */
```

Collections and child lists

```
/* WDFCOLLECTION - an ordered set of WDF objects: */
        WDFCOLLECTION collection;

        WdfCollectionCreate(&attr, &collection);
        WdfCollectionAdd(collection, someObject);

        ULONG count = WdfCollectionGetCount(collection);
        for (ULONG i = 0; i < count; i++) {
                WDFOBJECT obj = WdfCollectionGetItem(collection, i);
                ...
        }
        WdfCollectionRemove(collection, someObject);

/* Holds a REFERENCE on each item, so an object in a
   collection outlives its parent's deletion attempt until
   removed. Convenient, and a source of "the device will not
   go away" bugs if you forget to empty it.               */

/* WDFCHILDLIST - for a BUS DRIVER that enumerates children: */
        WDF_CHILD_LIST_CONFIG config;

        WDF_CHILD_LIST_CONFIG_INIT(&config,
                        sizeof(MY_CHILD_ID),
                        MyEvtChildListCreateDevice);
        WdfFdoInitSetDefaultChildListConfig(DeviceInit,
                        &config, WDF_NO_OBJECT_ATTRIBUTES);

        /* when you discover a child: */
        WdfChildListBeginScan(list);
        WdfChildListAddOrUpdateChildDescriptionAsPresent(

        /* anything not re-reported during the scan is
           automatically reported as REMOVED - which handles
           hot-unplug without you tracking it            */

/* This is how a driver for a bus, a multi-function device, or
   a device with dynamically appearing endpoints reports its
   children to PnP (chapter 05).                          */
```

Debugging WDF objects

```
# The WDF debugger extension - load it first:
    .load wdfkd.dll
    !wdfkd.wdfhelp

# THE ESSENTIAL COMMANDS:
    !wdfdriverinfo mydriver         everything about the driver
    !wdfdevicequeues <WDFDEVICE>    every queue and its
                                    contents
    !wdfobjectdump                  every WDF object
    !wdfhandle <handle>             one object: type, parent,
                                    context, refcount
    !wdfobject <handle>
    !wdfqueue <WDFQUEUE>            requests in a queue
    !wdfrequest <WDFREQUEST>        one request's state
    !wdflogdump mydriver            THE FRAMEWORK'S OWN LOG

# !wdflogdump IS THE ONE TO REMEMBER. WDF keeps an internal
# trace of every state transition, every request, and every
# error it detected. On a crash, it usually tells you what the
# framework thought was happening - which is often the whole
# answer.

# ENABLE VERBOSE FRAMEWORK LOGGING during development:
#   in the registry, under the driver's Parameters\Wdf key:
    VerboseOn      = 1
    VerifierOn     = 1     ; WDF VERIFIER - see below
    DbgBreakOnError = 1

# Or via the WDF verifier settings in the WDK's
# "WDF Verifier Control Application" (wdfverifier.exe).

# WDF VERIFIER checks framework-specific rules: object
# lifetime, handle validity, IRQL for each API, correct
# request completion. It is separate from Driver Verifier
# (chapter 21) and catches a different, WDF-specific class of
# bug. Turn BOTH on.
```

How it shows up

Symptom	Cause
Context accessor returns NULL or garbage	Object created without the matching context type
Objects leak across device removal	`ParentObject` not set — they parented to the driver
Crash in a cleanup callback	Touched a child that was already destroyed — use Cleanup, not Destroy
Device will not go away	A reference held by a collection, or an object parented too high
Callbacks race with each other	`SynchronizationScopeNone` without your own locking
Callback bugchecks touching paged memory	Execution level is Dispatch, not Passive
Buffer freed while still in use	WDFMEMORY parented to something shorter-lived than its use
Preallocated memory double-freed	`WdfMemoryCreatePreallocated` does not take ownership
Child devices never removed	Not re-scanned — WDFCHILDLIST reports absence by omission
WDF verifier bugcheck	A framework rule violation it made deterministic

Check yourself

- ✓ Name ten WDF object types and the common shape of their creation functions.
- ✓ Draw the parenting tree and explain what destroying a device does.
- ✓ Explain why the default parent is often wrong and what to set instead.
- ✓ Declare a context type, request it at creation, and use the accessor.
- ✓ Explain the most common context mistake and how to spot it.
- ✓ Distinguish Cleanup from Destroy and say which to use.
- ✓ Use WDFMEMORY, including the preallocated form and its ownership rule.
- ✓ Explain synchronisation scope and execution level, and the trade between them.
- ✓ Explain how a WDFCHILDLIST reports removal.
- ✓ Use `!wdflogdump` and say why it is the first command to try.

The WDF device lifecycle

Which callback runs when, what belongs in each, and what the framework guarantees about the order. Get this table right and PnP, power management and surprise removal all work without you writing a state machine.

The order

```
DriverEntry                        once, per driver load
     |
     v
EvtDriverDeviceAdd                 once PER DEVICE
     |   create the WDFDEVICE, queues, interrupt objects
     |   NO HARDWARE ACCESS - resources are not assigned
     v
EvtDevicePrepareHardware           resources assigned
     |   map registers, find the interrupt's descriptor
     |   PASSIVE_LEVEL
     v
EvtDeviceD0Entry                   powering up
     |   initialise the hardware, restore state
     |   PASSIVE_LEVEL
     v
EvtDeviceD0EntryPostInterruptsEnabled
     |   interrupts are now live; safe to start the device
     v
===== RUNNING: queues dispatch requests, ISR/DPC fire =====
     |
     v
EvtDeviceD0ExitPreInterruptsDisabled
     |   stop the device generating interrupts
     v
EvtDeviceD0Exit                    powering down
     |   quiesce, save state. THE DEVICE IS STILL THERE.
     v
EvtDeviceReleaseHardware           resources revoked
     |   unmap. DO NOT TOUCH THE HARDWARE.
     v
EvtCleanupCallback / EvtDestroyCallback
     |
     v
DriverUnload / EvtDriverUnload     once

AND THE POWER CYCLE, which happens repeatedly WITHOUT
PrepareHardware/ReleaseHardware:

     D0Entry -> running -> D0Exit -> (sleep) -> D0Entry ...

THAT IS THE KEY ASYMMETRY: PrepareHardware runs once per
resource assignment; D0Entry runs on every power-up. So
MAPPING goes in PrepareHardware and INITIALISATION goes in
D0Entry - and putting initialisation in PrepareHardware
produces a device that works until the first sleep.
```

What belongs where

Callback	Do	Do not
`DriverEntry`	`WdfDriverCreate`, global state	Anything per-device
`EvtDriverDeviceAdd`	Create device, queues, interrupts, locks, timers; publish the interface	Touch hardware — there is none yet
`EvtDevicePrepareHardware`	Map MMIO, read resource descriptors, allocate buffers sized from resources	Program the device
`EvtDeviceD0Entry`	Reset, configure, restore registers, verify the ID	Enable interrupts (use the Post callback)
`EvtDeviceD0Exit`	Stop the device, save state, flush	Unmap
`EvtDeviceReleaseHardware`	Unmap, free what PrepareHardware allocated	**Touch the hardware**
`EvtDeviceSelfManagedIoInit`	Start self-managed I/O — timers, polling threads	
`EvtDeviceSelfManagedIoSuspend`	Stop them, and **wait**	
`EvtDeviceSelfManagedIoCleanup`	Final teardown of self-managed I/O	

> **THE RULE THAT PREVENTS THE WORST BUG**
>
> `EvtDeviceReleaseHardware` can run *after the device has physically been removed*. A register read then returns `0xFFFFFFFF`; a write may hang the bus or bugcheck. All hardware quiescing belongs in `EvtDeviceD0Exit`, which is guaranteed to run while the device is still present in the normal path — and which the framework *skips the hardware-touching parts of* on surprise removal.

   IF YOU HAVE NO TIMERS OR THREADS OF YOUR OWN, you do not
   need these callbacks at all. That is the common case - and
   another reason to prefer queues over self-started work. */
```

Surprise removal

```
/* The user unplugged it. The hardware is GONE.

   WHAT THE FRAMEWORK DOES:
     · fails all new requests with STATUS_DEVICE_REMOVED
     · calls EvtDeviceSurpriseRemoval if you registered one
     · SKIPS D0Exit's hardware access expectations - but it
       still CALLS D0Exit, so your code must tolerate a
       missing device
     · calls ReleaseHardware
     · destroys the device

   WHAT YOU MUST DO:
     · detect the "all ones" read and stop rather than
       retrying forever
     · never wait for hardware without a timeout
     · complete every pending request                    */

static BOOLEAN
MyDeviceIsPresent(PMY_CONTEXT ctx)
{
        ULONG id = READ_REGISTER_ULONG(

                return;
        }

/* TESTING IT: in Device Manager, disable the device while I/O
   is in flight. Or, for USB, unplug it during a transfer. Or
   use the WDK's "Device Fundamentals" tests, which do exactly
   this automatically - and which you must pass for
   certification anyway (chapter 21).                  */
```

How it shows up

Symptom	Cause
Works until the first sleep, then dead	Initialisation in `PrepareHardware` instead of `D0Entry`
Bugcheck on unplug	Hardware touched in `ReleaseHardware`
Hang on unplug	Polling for hardware that is gone, with no timeout
Spurious interrupt during power-down	Device not silenced in `D0ExitPreInterruptsDisabled`
Crash after resume in a timer callback	Timer not stopped-and-waited in self-managed I/O suspend
Device never idles	No S0 idle policy assigned

Symptom	Cause
Device sleeps mid-operation	Work started outside a queue, so the framework does not know it is busy
State lost on resume	`D0Entry` does not restore configuration
Freed something needed after resume	Did not check for `D3Final` in `D0Exit`
Device Manager shows Code 10	`PrepareHardware` or `D0Entry` returned an error
Registers read `0xFFFFFFFF`	Surprise removal — detect and fail fast

Check yourself

- ✓ Write out the callback order from `DriverEntry` to unload.
- ✓ Explain the asymmetry between `PrepareHardware` and `D0Entry`.
- ✓ Say what belongs in each of the nine callbacks, and what does not.
- ✓ Explain why hardware access is forbidden in `ReleaseHardware`.
- ✓ Explain the purpose of the Pre/Post interrupt callbacks.
- ✓ Distinguish `D3` from `D3Final` and say why it matters.
- ✓ Assign an S0 idle policy and compare it with Linux runtime PM.
- ✓ Say when self-managed I/O callbacks are needed and what they must guarantee.
- ✓ Write a device-present check and explain the all-ones read.
- ✓ Test surprise removal deliberately.

WDF request queues

Queues are where WDF earns its keep. They handle dispatch, cancellation, power stalling and per-handle cleanup — the four things that made raw WDM I/O so error-prone — and they reduce your driver to a handful of callbacks.

Dispatch types

```
SEQUENTIAL
   One request at a time. The next is not delivered until
   the current one COMPLETES.
   -> simplest to write; no concurrency to reason about
   -> correct for hardware that can only do one thing
   -> the default choice for a first driver

PARALLEL
   Requests delivered as they arrive, from any CPU,
   concurrently.
   -> you must handle concurrency yourself
   -> correct for hardware with multiple channels, or when
      you queue internally

MANUAL
   Nothing is delivered. You call
   WdfIoQueueRetrieveNextRequest when you are ready.
   -> a holding pen for pending requests
   -> THE standard pattern for asynchronous I/O: the
      default queue receives, hands to a manual queue, and
      the DPC retrieves and completes

THE COMMON ARCHITECTURE, and the one to learn:

   default queue (parallel)   receives every request
         |
         +-- a read arrives, no data yet
         |         -> WdfRequestForwardToIoQueue(manual)
         |
         v
   manual queue               holds pending reads
         ^
         |  interrupt -> DPC
         |         -> WdfIoQueueRetrieveNextRequest
         |         -> fill it, complete it

That structure gives you asynchronous, cancellable,
power-aware I/O in about forty lines - versus several
hundred in WDM (chapter 04).
```

Creating queues

```
/* THE DEFAULT QUEUE - receives anything not routed elsewhere */

        WDF_IO_QUEUE_CONFIG queueConfig;
        NTSTATUS status;

        WDF_IO_QUEUE_CONFIG_INIT_DEFAULT_QUEUE(&queueConfig,
                        WdfIoQueueDispatchParallel);

        queueConfig.EvtIoRead          = MyEvtIoRead;
        queueConfig.EvtIoWrite         = MyEvtIoWrite;
        queueConfig.EvtIoDeviceControl = MyEvtIoDeviceControl;
        queueConfig.EvtIoStop          = MyEvtIoStop;

        status = WdfIoQueueCreate(device, &queueConfig,
                                  WDF_NO_OBJECT_ATTRIBUTES,
                                  &ctx->DefaultQueue);

/* A MANUAL QUEUE, for holding pending requests: */

        WDF_IO_QUEUE_CONFIG_INIT(&queueConfig,
                                 WdfIoQueueDispatchManual);
        queueConfig.PowerManaged = WdfFalse;   /* see below */

        status = WdfIoQueueCreate(device, &queueConfig,
                                  WDF_NO_OBJECT_ATTRIBUTES,
                                  &ctx->PendingReadQueue);

/* ROUTING a specific request type to its own queue: */

        status = WdfDeviceConfigureRequestDispatching(device,
                        ctx->WriteQueue,
                        WdfRequestTypeWrite);
/* now every IRP_MJ_WRITE goes to WriteQueue instead of the
   default one - useful when reads and writes have completely
   different handling and concurrency needs.              */

/* POWER MANAGED (the default for the default queue):
     the framework STOPS the queue when the device leaves D0
     and RESTARTS it on return. Requests wait rather than
     failing. This is what makes S0 idle transparent to
     userspace (chapter 14).

   NOT POWER MANAGED:
     the queue keeps delivering regardless of power state.
     Required for a manual queue used from a DPC, and for any
     queue that must work while powering down.

   GETTING THIS WRONG produces "requests hang after the device
   idles" (power-managed manual queue that nobody restarts) or
   "requests arrive while the device is off" (not power
   managed when it should be).                            */
```

The callbacks

```
VOID
MyEvtIoRead(_In_ WDFQUEUE Queue, _In_ WDFREQUEST Request,
            _In_ size_t Length)

        }
}
```

THE OWNERSHIP RULE

A request belongs to exactly one place at a time: the queue, or you. `WdfIoQueueRetrieveNextRequest` transfers ownership to you and guarantees it cannot be cancelled behind your back. Once you own it, you **must** complete it, forward it, or requeue it — dropping it hangs the caller forever. This single guarantee is what removes the cancel-routine race that dominates WDM queue code (chapter 04).

Cancellation

```
/* A request sitting on a queue is cancellable automatically.
   The framework completes it with STATUS_CANCELLED and you
   write nothing.

   IF YOU NEED TO KNOW - to abort a hardware operation, for
   example - mark it cancellable explicitly after taking
   ownership: */

        status = WdfRequestMarkCancelableEx(request,
                                            MyEvtRequestCancel);
        if (status == STATUS_CANCELLED) {
                /* it was ALREADY cancelled - complete it and
                   do not use it                              */
                WdfRequestComplete(request, STATUS_CANCELLED);
                return;
        }

VOID
MyEvtRequestCancel(_In_ WDFREQUEST Request)
{
        WDFDEVICE device = WdfIoQueueGetDevice(
                        WdfRequestGetIoQueue(Request));
        PMY_CONTEXT ctx = MyGetContext(device);

        /* abort the hardware operation */
        MyAbortTransfer(ctx);

        WdfRequestComplete(Request, STATUS_CANCELLED);
}

/* AND BEFORE COMPLETING IT NORMALLY, take it back: */
        status = WdfRequestUnmarkCancelable(request);
        if (status == STATUS_CANCELLED) {
                /* the cancel routine is running or has run -
                   it owns the request. DO NOT complete it. */
                return;
        }
        WdfRequestComplete(request, STATUS_SUCCESS);

/* THIS IS THE SAME OWNERSHIP PROTOCOL as WDM's
   IoSetCancelRoutine(NULL) dance (chapter 04) - but it is
   three lines with a clear return code, rather than a
   spinlock-protected sequence you must get exactly right on
   every path.                                              */

/* PURGING a queue - cancel everything on it: */
        WdfIoQueuePurgeSynchronously(queue);

                /* "can you pause this?" - acknowledge that we
                   will not complete it soon, and let the
                   framework proceed                        */
                WdfRequestStopAcknowledge(Request, FALSE);

        } else if (ActionFlags & WdfRequestStopActionPurge) {
                /* "cancel it" */
                WdfRequestCancelSentRequest(Request);
        }
}

/* WHAT HAPPENS IF YOU DO NOT IMPLEMENT IT: the framework
   waits for the request to complete before allowing the power
   transition. For a request waiting on hardware that will not
   respond until the device is powered - which is exactly the
   case during a suspend - that is a DEADLOCK, and it appears
   as "the machine will not sleep".

   IMPLEMENT EvtIoStop for any queue that can hold a request
   for an unbounded time. That is most manual queues.     */
```

Getting at a request

```
/* BUFFERS - method-independent (chapter 07): */
        status = WdfRequestRetrieveInputBuffer(request,
                        minLength, &buffer, &actualLength);
        status = WdfRequestRetrieveOutputBuffer(request,
                        minLength, &buffer, &actualLength);
/* both CHECK the minimum length for you and return
   STATUS_BUFFER_TOO_SMALL - so the most commonly forgotten
   validation is not optional.                              */

/* AS WDFMEMORY, if you want to pass it on: */

/* THE FRAMEWORK AUTOMATICALLY completes requests belonging to
   a closing file object with STATUS_CANCELLED - which is the
   IRP_MJ_CLEANUP obligation from chapter 04, handled for
   you.                                                      */
```

Debugging queues

```
# The single most useful command for "requests are stuck":
    !wdfkd.wdfdevicequeues <WDFDEVICE>

      Queue: 0x0000... State: Accepting Requests, Dispatching
      Type: Parallel, PowerManaged: TRUE
      Requests: 0

      Queue: 0x0000... State: Accepting Requests, NOT Dispatching
      Type: Manual, PowerManaged: FALSE
      Requests: 3               <-- three pending reads
        WDFREQUEST 0x0000...
        WDFREQUEST 0x0000...

# READ THE STATE:
#   "NOT Dispatching" on a power-managed queue -> the device
#     is not in D0. Expected while idle; a bug if it never
#     resumes.
#   Requests climbing on a manual queue -> nothing is
#     retrieving them. Your DPC is not running, or the
#     hardware stopped.
#   Requests on the default queue -> your callback is not
#     completing or forwarding them.

    !wdfqueue <WDFQUEUE>            one queue in detail
    !wdfrequest <WDFREQUEST>        one request's state,
                                    owner, and IRP
    !wdflogdump mydriver            the framework's own trace

# AND FROM USER MODE, the symptom to correlate: a thread stuck
# in ReadFile. Find its IRP with !irpfind (chapter 04), then
# !wdfrequest on the corresponding WDFREQUEST.
```

How it shows up

Symptom	Cause
Application hangs in `ReadFile`	Request retrieved and never completed — you own it
Requests pile up on a manual queue	Nothing retrieving them; the DPC is not firing
Requests hang after the device idles	Power-managed manual queue with nothing to restart it
Requests arrive while the device is off	Queue not power-managed when it should be
Machine will not sleep	No `EvtIoStop`; the framework waits for an in-flight request
Bugcheck completing a cancelled request	Ignored the return of `WdfRequestUnmarkCancelable`
Corruption with a parallel queue	Concurrency not handled — use sequential or add locking
Byte count is zero in userspace	`Information` not set — use `CompleteWithInformation`
Two handles interfere with each other	Per-handle state kept in the device context
Requests leak on handle close	Holding a request outside a queue without cleanup handling
`WdfRequestRetrieveOutputBuffer` fails	Buffer shorter than your minimum — that check is the point

Check yourself

- ✓ Compare the three dispatch types and say when each is right.
- ✓ Draw the default-plus-manual-queue architecture and explain what it buys.
- ✓ Explain what "power managed" changes, and both failure modes of choosing wrong.
- ✓ State the request ownership rule and its consequence.
- ✓ Write a read callback that completes immediately or parks the request.
- ✓ Retrieve and complete a request from a DPC.
- ✓ Use the cancellable protocol correctly, including both return codes.
- ✓ Explain what `EvtIoStop` prevents and when it is required.
- ✓ Keep per-handle state and say what the framework does on cleanup.
- ✓ Diagnose stuck requests with `!wdfdevicequeues`.

IOCTLs and `DeviceIoControl`

The control interface between your driver and user mode. The control code encodes the device type, the access required and the buffering method — and because it is a permanent ABI reachable by whoever can open your device, it is where driver security is won or lost.

The control code

```
#define CTL_CODE(DeviceType, Function, Method, Access) ( \
        ((DeviceType) << 16) | ((Access) << 14) |         \
        ((Function) << 2)    | (Method) )

/* 32 bits, four fields:

     31..16  DeviceType   FILE_DEVICE_UNKNOWN (0x22) for a
                          custom device
     15..14  Access       FILE_ANY_ACCESS
                          FILE_READ_ACCESS
                          FILE_WRITE_ACCESS
                          FILE_READ_ACCESS|FILE_WRITE_ACCESS
     13..2   Function     YOURS. 0x800-0xFFF is the range
                          reserved for third parties.
                          Below 0x800 is Microsoft's.
      1..0   Method       METHOD_BUFFERED     0
                          METHOD_IN_DIRECT    1
                          METHOD_OUT_DIRECT   2
                          METHOD_NEITHER      3   */

/* A realistic set: */

#define MY_DEVICE_TYPE  0x8000    /* >= 0x8000 for vendors */

#define IOCTL_MY_GET_VERSION \
    CTL_CODE(MY_DEVICE_TYPE, 0x800, METHOD_BUFFERED, \
             FILE_ANY_ACCESS)

#define IOCTL_MY_GET_CONFIG \
    CTL_CODE(MY_DEVICE_TYPE, 0x801, METHOD_BUFFERED, \
             FILE_READ_ACCESS)

#define IOCTL_MY_SET_CONFIG \
    CTL_CODE(MY_DEVICE_TYPE, 0x802, METHOD_BUFFERED, \
             FILE_WRITE_ACCESS)

#define IOCTL_MY_READ_BULK \
    CTL_CODE(MY_DEVICE_TYPE, 0x803, METHOD_OUT_DIRECT, \
             FILE_READ_ACCESS)

#define IOCTL_MY_RESET \
    CTL_CODE(MY_DEVICE_TYPE, 0x804, METHOD_BUFFERED, \
             FILE_WRITE_ACCESS)
```

THE ACCESS FIELD IS ENFORCED BY THE I/O MANAGER

An IOCTL declared `FILE_WRITE_ACCESS` is **rejected before your driver sees it** if the handle was not opened with write access. This is free, automatic, correct access control — and it is why `FILE_ANY_ACCESS` should be reserved for genuinely harmless queries. Marking a "reconfigure the device" IOCTL as `FILE_ANY_ACCESS` means any process that can open the device read-only can reconfigure it, which is precisely the bug Linux chapter 21 warns about — except here the platform would have prevented it for free.

The handler

```
VOID
MyEvtIoDeviceControl(_In_ WDFQUEUE Queue,
                     _In_ WDFREQUEST Request,

```

Internal IOCTLs

```
/* IRP_MJ_INTERNAL_DEVICE_CONTROL is reachable ONLY from
   kernel mode. Use it for driver-to-driver interfaces.    */

        queueConfig.EvtIoInternalDeviceControl =
                        MyEvtIoInternalDeviceControl;

/* WHY IT MATTERS FOR SECURITY: an internal IOCTL cannot be
   invoked by a user-mode program at all - the I/O manager
   refuses. So a privileged operation exposed only as an
   internal IOCTL has no user-mode attack surface.

   USE IT for anything a peer driver needs but userspace must
   never reach: raw register access, firmware update entry
   points, diagnostic modes.

/* AND THE TRAP: an internal IOCTL's buffers come from a
   kernel caller, so RequestorMode is KernelMode and probing
   is skipped. That is correct - but it means you are
   trusting the calling driver completely. Do not expose an
   internal IOCTL that a user-mode-reachable driver simply
   forwards, because you have then re-opened the surface you
   were closing.                                            */
```

The user-mode side

```
#include <windows.h>

   STATUS_PENDING. That is SUCCESS, not failure - a mistake
   almost every first async client makes.                */
```

Designing the interface

RULES, IN ORDER OF HOW MUCH DAMAGE BREAKING THEM CAUSES

1. **Validate every field of every input.** The caller is untrusted, always, even if today only your own application calls it.
2. **Use the Access field.** Free enforcement; use it rather than checking by hand.
3. **Fixed-width types, explicit padding.** `UINT32`, not `ULONG` or `int`; pad so the layout is identical for 32- and 64-bit callers.
4. **Version the interface** from day one, with a `GET_VERSION` IOCTL that never changes.
5. **Reserved fields, required to be zero.** They cost nothing and are the only way to extend a struct later.
6. **Never embed a pointer** in a buffer. It breaks 32-on-64 and it is a confused-deputy invitation.
7. **Bound every length.** A size field that drives an allocation is a denial-of-service vector.
8. **Return** `STATUS_INVALID_DEVICE_REQUEST` for unknown codes, so callers can probe for support.
9. **Keep the surface small.** Every IOCTL is an entry point into kernel mode from whoever can open the device.

```
/* THE 32-ON-64 PROBLEM, and why fixed-width types matter: */

/* WRONG - different layout for a 32-bit caller: */
typedef struct {
        ULONG   Count;
        PVOID   Buffer;     /* 4 bytes on Win32, 8 on Win64 */
        SIZE_T  Length;     /* same problem                 */
} BAD_REQUEST;

/* RIGHT: */
typedef struct {
        UINT32  Count;
        UINT32  Reserved;   /* explicit padding */
        UINT64  BufferOffset;   /* an OFFSET, not a pointer */
        UINT32  Length;
        UINT32  Reserved2[3];
} GOOD_REQUEST;

/* AND IF YOU MUST support both layouts, detect the caller: */
        if (IoIs32bitProcess(NULL)) {
                /* the request came from a 32-bit process -
                   parse the 32-bit layout                  */
        }

/* THE BETTER ANSWER: design so there is only one layout.
   Fixed-width types and no pointers achieves it, exactly as
   in Linux chapter 21.                                     */
```

Testing

```
# NEGATIVE TESTS - these find the bugs:
    · an unknown control code       -> STATUS_INVALID_DEVICE_REQUEST
    · a zero-length input buffer     -> STATUS_BUFFER_TOO_SMALL
    · an input buffer one byte short -> same
    · a NULL output buffer           -> handled, not a crash
    · out-of-range field values      -> STATUS_INVALID_PARAMETER
    · a huge length field            -> refused, not a hang
    · SET_CONFIG on a read-only handle -> refused by the I/O
                                          manager
    · concurrent calls from many threads -> no corruption
    · a 32-bit client, if you support one

# TOOLS:
    devcon.exe                  install, enable, disable
    Device Fundamentals tests   in the WDK - includes
                                fuzzing of your IOCTL
                                interface. REQUIRED for
                                certification anyway, so run
                                them early (chapter 21).
    IoSpy / IoAttack            the WDK's IOCTL fuzzer

# IoAttack sends malformed buffers, wrong lengths and random
# control codes at your device. With Driver Verifier enabled
# it finds unvalidated input in minutes. Run it before anyone
# else does.
```

How it shows up

Symptom	Cause
`DeviceIoControl` fails with ERROR_ACCESS_DENIED	Handle lacks the access the control code requires — usually correct
Fails with ERROR_INVALID_FUNCTION	Control code mismatch between client and driver headers
Fails with ERROR_IO_PENDING	Not a failure — asynchronous completion
Output buffer unchanged	`Information` not set on completion
Input corrupted mid-handler	METHOD_BUFFERED shares one buffer — copy input to a local first
Bugcheck from a user-mode call	Unvalidated field — a security bug, not just a crash
Works from a 64-bit client, garbage from 32-bit	Pointer or `SIZE_T` in the struct
Double-completion bugcheck	Completed a request already forwarded to another queue
Read-only handle reconfigures the device	`FILE_ANY_ACCESS` on a privileged operation
Kernel memory exhausted by a user program	Unbounded length field
Cannot extend the struct in v2	No reserved fields in v1

Check yourself

- ✓ Decode a control code into its four fields.
- ✓ Explain what the Access field enforces and who enforces it.
- ✓ Write a handler with correct validation, completion and forwarding.
- ✓ Explain why a forwarded request must not be completed.
- ✓ Say what internal IOCTLs are for and the trap they carry.
- ✓ Open a device by interface GUID from user mode.
- ✓ Issue a synchronous and an asynchronous IOCTL, handling `ERROR_IO_PENDING` correctly.
- ✓ List the nine interface design rules.
- ✓ Explain the 32-on-64 layout problem and design a struct that avoids it.
- ✓ Run the negative test list and the WDK's IOCTL fuzzer.

Hardware resources and interrupts in WDF

How your driver learns where its registers are and which interrupt is its own, how to map and access them safely, and the WDF interrupt object that connects the ISR and DPC from chapter 10 to real silicon.

The resource list

```
/* PnP assigns resources and hands you two lists in
   EvtDevicePrepareHardware (chapter 14):

     ResourcesRaw         bus-relative addresses, as the
                          device sees them
     ResourcesTranslated  system addresses the CPU can use

   USE THE TRANSLATED LIST for mapping. Use the RAW list only
   when you must program a bus-relative value into the device
   itself - which is rare on modern systems.              */

NTSTATUS

           info.Vector, info.Irql, info.TargetProcessorSet  */
```

MSI REMOVES THE SHARED-LINE PROBLEM

A line-based interrupt may be shared, so every ISR must read a status register to ask "is this mine?" — and that read can cost microseconds on PCIe. An MSI is by definition yours, and the message number tells you what happened. On any device where you control the hardware design or the interrupt count, MSI-X with one message per queue is both faster and simpler.

Synchronising with the ISR

```
/* Data shared between the ISR and everything else needs the
   interrupt lock (chapter 09).                              */

/* Option 1: acquire it around a section */
        WdfInterruptAcquireLock(ctx->Interrupt);
        ctx->SharedState = newValue;
        MyWr(ctx, REG_CONFIG, newValue);
        WdfInterruptReleaseLock(ctx->Interrupt);

/* Option 2 - PREFERRED: run a small function at DIRQL with
   the lock held: */
static BOOLEAN
MySetEnableSync(_In_ WDFINTERRUPT Interrupt,
                _In_ WDFCONTEXT Context)

   Set from the INF, not from code - it is a system policy
   decision, and the administrator may override it.        */

        [MyDevice_AddReg]
        HKR,"Interrupt Management\Affinity Policy",\
            DevicePolicy,0x00010001,5    ; IrqPolicySpreadMessagesAcrossAllProcessors
        HKR,"Interrupt Management\Affinity Policy",\
            DevicePriority,0x00010001,3  ; IrqPriorityHigh

/* THE POLICIES:
     0  MachineDefault
     1  AllCloseProcessors
     2  OneCloseProcessor
     3  AllProcessorsInMachine
     4  SpecifiedProcessors
     5  SpreadMessagesAcrossAllProcessors   <-- for MSI-X

/* SPREADING MSI-X MESSAGES across CPUs is what lets a
   multi-queue device scale: each message's DPC runs on a
   different core, so DPC processing is parallel rather than
   serialised on one CPU (chapter 10).

/* FROM CODE, if you must: */
        WdfInterruptSetPolicy(ctx->Interrupt,
                        WdfIrqPolicySpecifiedProcessors,
                        WdfIrqPriorityNormal,
                        1 << 2);        /* CPU 2 */

/* And read what you got: */
        WdfInterruptGetInfo(interrupt, &info);
        /* info.TargetProcessorSet */
```

Debugging resources and interrupts

```
# --- Device Manager ---
#   Properties -> Resources tab: exactly what was assigned.
#   If a range or IRQ you expect is missing, the problem is in
#   the firmware or the INF, not your driver.

# --- WinDbg ---
    !devnode 0 1 mydriver           the PnP node
    !devobj ffff8a0c...             the device object
    !arbiter 4                      the resource arbiters -
                                    who owns which ranges
    !idt                            the interrupt dispatch
                                    table: which vector goes
                                    where
    !wdfkd.wdfdriverinfo mydriver 0x10   WDF's view of the
                                    interrupt objects

# --- Is my interrupt firing at all? ---
#   Add a counter in the ISR and expose it in a debug IOCTL or
#   read it with WinDbg. If it never increments:
#     · the device is not enabled - check REG_INT_ENABLE
#     · the interrupt was never connected - check the
#       WdfInterruptCreate return
#     · the resource descriptor was absent - check
#       PrepareHardware
#     · the device is not clocked or not out of reset
#     · MSI was requested but not granted, and you assumed it
#
#   THE SAME CHECKLIST as Linux chapter 14, in a different
#   dialect.

# --- ETW tracing of interrupts and DPCs ---
    wpr -start GeneralProfile -start DeviceIO
    ... reproduce ...
    wpr -stop trace.etl
    wpa trace.etl
# The "DPC/ISR" graph shows every ISR and DPC with durations.
# It is the tool for "why is this system's latency bad", and
# it will show your DPC's cost next to everyone else's.
```

How it shows up

Symptom	Cause
Code 10 at start	`PrepareHardware` returned an error — usually a missing expected resource
Registers read `0xFFFFFFFF`	Wrong range mapped, device not powered, or surprise-removed
Mapped the wrong range	Assumed descriptor order — match on type and index deliberately
Interrupt never fires	Device's interrupt enable not set, or the resource was absent
Interrupt storm	ISR not acknowledging the device
Spurious interrupt during power-down	Device not silenced before disconnect — use `EvtInterruptDisable`
Only message 0 ever fires	Fewer MSI messages granted than requested
All DPCs on one CPU	No affinity policy — MSI-X messages not spread
Corruption between ISR and normal code	Interrupt lock not used

Symptom	Cause
Bugcheck 0xA in the ISR	Paged memory or a paged-pool allocation at DIRQL
Works on one machine, Code 12 on another	Resource conflict — the arbiter could not satisfy the request

Check yourself

- ✓ Distinguish raw from translated resources and say which to map.
- ✓ Walk a resource list and handle five descriptor types.
- ✓ Explain why you must not assume descriptor order or count.
- ✓ Use the register access macros and say why a raw dereference is wrong.
- ✓ Create a WDF interrupt object with enable and disable callbacks, and explain the ordering they give.
- ✓ Explain what MSI changes about ISR design.
- ✓ Request MSI-X from an INF and handle getting fewer messages than asked.
- ✓ Use `WdfInterruptSynchronize` and say why it beats an acquire/release pair.
- ✓ Set an interrupt affinity policy and explain why spreading MSI-X matters.
- ✓ Work the checklist for an interrupt that never fires.

DMA in WDF

Giving a Windows device direct memory access: the DMA enabler, transactions, common buffers and scatter-gather. The same problem as Linux chapter 24, with a framework that manages the state machine for you.

The model

```
WDFDMAENABLER          created once, in PrepareHardware.
     |                 describes the device's DMA
     |                 capabilities: direction, maximum
     |                 transfer length, alignment,
     |                 address width
     |
     +-- WDFDMATRANSACTION   one per logical transfer
     |        |              May be split into several
     |        |              hardware transfers if the
     |        |              buffer exceeds what the device
     |        |              can do in one go.
     |        |
     |        +-- SCATTER/GATHER LIST
     |               the physical fragments, ready to
     |               program into the device
     |
     +-- WDFCOMMONBUFFER    memory the CPU and device both
                            access continuously - rings,
                            descriptors, status blocks

THE THREE ADDRESS SPACES are the same as Linux's
(ch. 24): virtual, physical, and LOGICAL (Windows' name
for the device-visible address). The DMA enabler is what
knows the mapping, including any IOMMU translation - so you
program the device with the LOGICAL address the framework
gives you, never a physical one you computed.
```

Creating the enabler

```
NTSTATUS
MyPrepareHardware(_In_ WDFDEVICE Device,
                  _In_ WDFCMRESLIST ResourcesRaw,
                  _In_ WDFCMRESLIST ResourcesTranslated)
{
        PMY_CONTEXT ctx = MyGetContext(Device);
        WDF_DMA_ENABLER_CONFIG dmaConfig;
        NTSTATUS status;

        ... map registers (chapter 17) ...

        /* 1. DECLARE THE ADDRESS WIDTH. This is the single
              most consequential call: get it wrong and the
              hardware silently drops the high address bits.
              Same failure as a wrong dma_set_mask on Linux -
              works on a small-memory machine, corrupts
              random memory on a large one.               */
        status = WdfDeviceSetAlignmentRequirement(Device,
                        FILE_LONG_ALIGNMENT);   /* 4-byte */
        if (!NT_SUCCESS(status))
                return status;

        WDF_DMA_ENABLER_CONFIG_INIT(&dmaConfig,
                        WdfDmaProfileScatterGather64,
                        MY_MAX_TRANSFER_LENGTH);

        dmaConfig.WdmDmaVersionOverride = 3;

        status = WdfDmaEnablerCreate(Device, &dmaConfig,
                        WDF_NO_OBJECT_ATTRIBUTES,
                        &ctx->DmaEnabler);
        if (!NT_SUCCESS(status))
                return status;

        return STATUS_SUCCESS;
}

/* THE PROFILES:

   WdfDmaProfilePacket           single contiguous buffer,
                                 32-bit addresses
   WdfDmaProfileScatterGather    scattered, 32-bit
   WdfDmaProfilePacket64         contiguous, 64-bit
   WdfDmaProfileScatterGather64  scattered, 64-bit   <-- the
                                 usual modern choice
   WdfDmaProfileSystem           uses a system DMA controller
                                 rather than bus mastering
   WdfDmaProfileSystemDuplex

   PICK 64-BIT ONLY IF THE DEVICE REALLY IS. Declaring 64 on a
   32-bit device is the classic silent corruption; declaring
   32 on a 64-bit device merely costs you bounce buffering,
   which is safe but slow.

/* AND THE MAXIMUM LENGTH: if a request exceeds it, the
   framework splits the transaction into several transfers
   automatically - which is why you must handle
   EvtProgramDma being called more than once per
   transaction.                                          */

           hardware transfers. DmaCompleted returns TRUE if
           the whole transaction is finished, FALSE if it
           queued the next transfer - in which case
           EvtProgramDma is called again and we must NOT
           complete the request.                          */
        more = !WdfDmaTransactionDmaCompleted(transaction,
                                              &status);
        if (more)
                return;

        transferred = WdfDmaTransactionGetBytesTransferred(
                                transaction);
```

```
        request = WdfDmaTransactionGetRequest(transaction);

        ctx->CurrentTransaction = NULL;
        WdfObjectDelete(transaction);   /* releases the SG list
                                           and unmaps        */

        if (request)
                WdfRequestCompleteWithInformation(request,
                                status, transferred);
}

/* THE MULTI-TRANSFER RULE IS THE ONE PEOPLE MISS. A driver
   that completes the request on the first DPC works
   perfectly for small buffers and truncates large ones -
   exactly the Linux scatter-gather coalescing trap
   (ch. 24), in a different form.                       */
```

DELETING THE TRANSACTION IS NOT OPTIONAL

`WdfObjectDelete` on the transaction is what releases the scatter-gather list, unmaps the buffer and returns the map registers to the system pool. Map registers are a finite, shared resource; leaking them degrades DMA for every device on the machine and eventually makes `WdfDmaTransactionExecute` fail with `STATUS_INSUFFICIENT_RESOURCES` — for someone else's driver.

Common buffers

```
/* For memory the CPU and device both touch continuously:
   descriptor rings, command queues, status blocks. The
   Windows equivalent of dma_alloc_coherent (Linux ch. 24). */

        WDFCOMMONBUFFER commonBuffer;
        PVOID va;
        PHYSICAL_ADDRESS la;

        status = WdfCommonBufferCreate(ctx->DmaEnabler,
                        MY_RING_SIZE,
                        WDF_NO_OBJECT_ATTRIBUTES,
                        &commonBuffer);
        if (!NT_SUCCESS(status))
                return status;

        va = WdfCommonBufferGetAlignedVirtualAddress(
                        commonBuffer);
        la = WdfCommonBufferGetAlignedLogicalAddress(
                        commonBuffer);

        RtlZeroMemory(va, MY_RING_SIZE);

        /* program the device with the LOGICAL address */
        MyWr(ctx, REG_RING_BASE_LO, la.LowPart);
        MyWr(ctx, REG_RING_BASE_HI, la.HighPart);

        /* the CPU uses `va` normally, at any IRQL */
        ring = (PMY_DESCRIPTOR)va;
        ring[0].Address = dataLa.QuadPart;
        ring[0].Length  = len;
        ring[0].Flags   = DESC_OWN;

        KeMemoryBarrier();
        MyWr(ctx, REG_DOORBELL, 0);

/* WITH SPECIFIC ALIGNMENT: */
        status = WdfCommonBufferCreateWithConfig(
                        ctx->DmaEnabler, size, &config,
                        &attributes, &commonBuffer);
        /* config.AlignmentRequirement = 4096 - 1; */

/* PROPERTIES:
     · physically contiguous
     · cache-coherent with the device, or mapped uncached if
       the platform is not coherent - so no explicit flushing
     · allocated at PrepareHardware time, so no runtime
       fragmentation risk
     · freed automatically when its parent dies

   USE IT FOR SMALL CONTROL STRUCTURES. On a non-coherent
   platform it is uncached, so CPU access is slow - bulk data
   belongs in a transaction, not a common buffer. Exactly the
   Linux coherent-versus-streaming trade (ch. 24).       */
```

Direct-programmed DMA

```
/* Some devices need the driver to manage the buffer
   lifecycle itself - a continuous capture ring, for example,
   where there is no per-request transaction.             */

        /* build a transaction from an MDL you own */
        status = WdfDmaTransactionInitialize(transaction,
                        MyEvtProgramDma,
                        WdfDmaDirectionReadFromDevice,
                        mdl,
                        virtualAddress,
                        length);

        /* or, for a buffer you will reuse indefinitely,
           allocate a common buffer and manage it yourself */

/* AND FOR "I just need the logical address of this buffer": */
        status = WdfDmaTransactionGetTransferInfo(transaction,
                        &mapRegisters, &sgElements);

/* THE HONEST ADVICE: if the framework's transaction model
   fits your device, use it - it handles splitting, map
   register allocation, cache flushing and cleanup. Reach for
   direct programming only when the device's model genuinely
   does not match request-oriented DMA, which in practice
   means continuous streaming devices: audio, video capture,
   and network receive rings.                             */
```

The IOMMU

```
/* Modern Windows enables DMA remapping (VT-d / SMMU) for
   kernel DMA protection. The consequences for your driver are
   the same as the Linux ones (isolation ch. 03-07):

   · the LOGICAL address the framework gives you is an IOVA,
     not a physical address. Programming a physical address
     you computed yourself will FAULT.

   · a transfer longer than what you mapped faults, rather
     than reading a neighbour's memory. That is a feature: it
     turns silent corruption into an attributable error.

   · using a logical address after deleting the transaction
     faults, because the mapping is gone.

   · the device must be correctly identified to the IOMMU by
     firmware. On a machine where it is not, DMA either
     bypasses protection entirely or fails outright.

/* SEEING IT: */
        WinDbg:  !iommu                (on supported builds)
        Event Viewer -> Microsoft-Windows-Kernel-IoTrace
        System event log: DMA remapping faults are logged

/* KERNEL DMA PROTECTION also affects HOT-PLUGGABLE buses
   (Thunderbolt): a device may be blocked from DMA entirely
   until the user authorises it. A driver must handle
   STATUS_DEVICE_NOT_READY gracefully rather than assuming
   DMA will always be permitted.                          */
```

Debugging DMA

```
# DRIVER VERIFIER's DMA checking (chapter 21) is the primary
# tool - the Windows counterpart of CONFIG_DMA_API_DEBUG:
    verifier /flags 0x10 /driver mydriver.sys
# It validates:
#   · map register accounting
#   · buffer alignment against the declared requirement
#   · transfers exceeding the declared maximum
#   · use after completion
#   · flushing rules
#   · adapter object misuse
# and bugchecks with 0xE6 DRIVER_VERIFIER_DMA_VIOLATION,
# naming the rule.

# --- WinDbg ---
    !wdfkd.wdfdriverinfo mydriver 0x20    DMA enabler state
    !dma                                  adapter objects and
                                          map register usage
    dt nt!_SCATTER_GATHER_LIST <address>

# --- The classic symptoms ---
#   data lands in the wrong place  -> you programmed a
#                                     physical rather than a
#                                     logical address
#   large transfers truncated      -> completed the request on
#                                     the first DPC
#   works on 4 GB, fails on 32 GB  -> declared 64-bit DMA on a
#                                     32-bit device
#   intermittent under load        -> missing memory barrier
#                                     before the doorbell
#   DMA fails for other drivers    -> you are leaking map
#                                     registers
```

How it shows up

Symptom	Cause
Data written to the wrong memory	Programmed a physical address instead of the logical one
IOMMU fault logged	Same — the physical address is not a valid IOVA
Works with 4 GB RAM, corrupts with more	Declared a 64-bit profile on a 32-bit device
Large transfers truncated	Request completed on the first DPC — check `DmaCompleted`
Device reads stale descriptors	Missing `KeMemoryBarrier()` before the doorbell
Bugcheck 0xE6	Verifier caught a DMA rule violation
`WdfDmaTransactionExecute` fails with insufficient resources	Map registers exhausted — usually your own leak
Other drivers' DMA starts failing	Leaked transactions — delete them
Alignment fault or corruption at buffer start	Alignment requirement not declared or not honoured
Common buffer access is very slow	Non-coherent platform maps it uncached — use it only for control structures
DMA blocked on a Thunderbolt device	Kernel DMA protection pending user authorisation

Check yourself

- ✓ Name the WDF DMA objects and what each is for.
- ✓ Choose a DMA profile and explain the consequence of declaring the wrong address width.
- ✓ Write the full transaction flow: create, initialise, execute, program, complete.
- ✓ Explain why `EvtProgramDma` may be called several times per transaction.
- ✓ Explain what `WdfDmaTransactionDmaCompleted` returns and why it matters.
- ✓ Say what deleting the transaction releases, and what leaking it costs the system.
- ✓ Use a common buffer and say when it is the right choice.
- ✓ Explain what the IOMMU changes and why a computed physical address now faults.
- ✓ Enable Verifier's DMA checking and name five rules it enforces.
- ✓ Map each concept onto its Linux counterpart.

INF files and installation

The INF tells Windows which hardware your driver serves, what to copy, and what registry state to create. It plays the role the device tree plays on Linux — describing this particular device — but applied once at install time rather than parsed at every boot.

Anatomy of an INF

```
;
; mydriver.inf - Vendor MyDevice
;

[Version]
Signature   = "$WINDOWS NT$"
Class       = System                ; or a custom class
ClassGuid   = {4d36e97d-e325-11ce-bfc1-08002be10318}
Provider    = %ManufacturerName%
CatalogFile = mydriver.cat          ; the signature catalog
DriverVer   = 03/15/2026,1.0.0.0    ; DATE,VERSION
PnpLockdown = 1                     ; REQUIRED on modern
                                    ; Windows - protects the
                                    ; driver's files

[DestinationDirs]
DefaultDestDir = 13                 ; 13 = the DRIVER STORE.
                                    ; Not System32\drivers.

[SourceDisksNames]
1 = %DiskName%,,,""

[SourceDisksFiles]
mydriver.sys = 1,,

; ---- which hardware, on which architectures ----

[Manufacturer]
%ManufacturerName% = Standard,NTamd64,NTarm64

[Standard.NTamd64]

HKR,"Interrupt Management\MessageSignaledInterruptProperties",\
    MSISupported,0x00010001,1
HKR,"Interrupt Management\MessageSignaledInterruptProperties",\
    MessageNumberLimit,0x00010001,4

; ---- strings, localisable ----

[Strings]
ManufacturerName    = "Vendor Corporation"
DiskName            = "MyDevice Installation Disk"
MyDevice.DeviceDesc = "Vendor MyDevice Controller"
MyDevice.SvcDesc    = "Vendor MyDevice Driver"
```

DESTINATION 13 IS NOT OPTIONAL

`DefaultDestDir = 13` means the driver store, and it is required for a modern, universal INF. Copying to `%windir%\System32\drivers` (destination 12) directly is the legacy pattern; it breaks driver store integrity, prevents proper rollback, and fails certification. Let Windows manage the files.

Hardware IDs and ranking

```
The PnP manager asks the bus driver for a list of IDs, most
specific first, and picks the BEST-RANKED matching INF.

  For a PCI device, the bus reports:

    HARDWARE IDs, most specific first:
      PCI\VEN_1234&DEV_5678&SUBSYS_9ABCDEF0&REV_01
      PCI\VEN_1234&DEV_5678&SUBSYS_9ABCDEF0
      PCI\VEN_1234&DEV_5678&REV_01
      PCI\VEN_1234&DEV_5678
    COMPATIBLE IDs, less specific:
      PCI\VEN_1234&DEV_5678&CC_010601
      PCI\VEN_1234&CC_0106
      PCI\CC_010601

  RANK, lower is better:
    0x0000  a signed INF matching a HARDWARE id
    0x1000  a signed INF matching a COMPATIBLE id
    0x8000+ unsigned equivalents

  So a driver matching the full subsystem ID beats a generic
  class driver - which is how a vendor driver replaces
  Microsoft's inbox one, and how a generic driver still works
  when no vendor driver is installed.

  THE PRACTICAL RULE: match the MOST SPECIFIC id your driver
  genuinely supports. Matching PCI\VEN_1234&DEV_5678 claims
  every board with that chip, including ones with different
  wiring - and if yours behaves differently, use the SUBSYS
  form.

  FIND THE IDs: Device Manager -> Properties -> Details ->
  "Hardware Ids". Copy them exactly; a single wrong character
  means Code 28 and no explanation.
```

Universal INFs

```
; A "universal" (or "declarative") INF is required for
; Windows 10+ certification and for anything shipping on
; Windows on ARM, HoloLens or IoT Core. The rules:

; MUST:
;   · DefaultDestDir = 13 (the driver store)
;   · use only DECLARATIVE directives - no co-installers, no
;     RunOnce, no custom setup code
;   · AddReg only under HKR (relative) - no absolute HKLM
;     paths
;   · no [DDInstall.CoInstallers] section
;   · no calls out to external programs

; MUST NOT:
;   · RegisterDlls, UnregisterDlls
;   · AddService for a user-mode service that runs setup code
;   · absolute file paths
;   · legacy WDF co-installers (WdfCoInstaller*.dll) -
;     modern KMDF is inbox and needs none

; CHECK IT:
    InfVerif.exe /u mydriver.inf
    ; /u = universal check. Also:
    InfVerif.exe /v /w mydriver.inf

; The Windows Driver Kit's build already runs InfVerif in
; recent versions. Failures here block certification, so fix
; them as you write rather than at submission time.

; IF YOU NEED SETUP LOGIC - to install a user-mode service or
; a control panel applet - ship it as a separate DCH-compliant
; component package or a Windows app, not as a co-installer.
; That separation is the whole point of the universal model:
; the driver package is pure data.
```

Installing and testing

```
# --- Prepare a test machine (chapter 01) ---
    bcdedit /set testsigning on
    shutdown /r /t 0

# --- Install ---
    pnputil /add-driver mydriver.inf /install
    ; /install also updates matching devices

    ; or, the older tool, still useful for testing:
    devcon install mydriver.inf "PCI\VEN_1234&DEV_5678"

    ; for a device with no physical hardware - a software
    ; device or a test device:
    devcon install mydriver.inf "root\mydevice"

# --- Inspect ---
    pnputil /enum-drivers                ; every third-party
                                         ; driver in the store
    pnputil /enum-devices /connected
    devcon status "PCI\VEN_1234*"
    devcon driverfiles "PCI\VEN_1234*"

# --- Update and remove ---
    pnputil /add-driver mydriver.inf /install    ; upgrade
    devcon update mydriver.inf "PCI\VEN_1234&DEV_5678"

    pnputil /delete-driver oem12.inf /uninstall /force
    devcon remove "PCI\VEN_1234&DEV_5678"
    devcon rescan

# --- The development loop ---
    devcon disable "PCI\VEN_1234*"
    pnputil /delete-driver oem12.inf /uninstall
    ; rebuild
    pnputil /add-driver mydriver.inf /install
    devcon enable "PCI\VEN_1234*"

# Script this. You will run it several hundred times.
```

setupapi.dev.log

```
# THE FILE THAT ANSWERS "why did my driver not install":
    C:\Windows\INF\setupapi.dev.log

# It records every INF considered, its rank, and the decision:

        /* VALIDATE - the registry is user-writable by an
           administrator, so treat the values as input       */
        if (ctx->FifoDepth == 0 || ctx->FifoDepth > MY_MAX_FIFO)
                ctx->FifoDepth = MY_DEFAULT_FIFO;

        return STATUS_SUCCESS;
}

/* THE TWO KEYS:
     PLUGPLAY_REGKEY_DEVICE  the device's "Device Parameters"
                             subkey - per-instance settings.
                             THIS is where HKR from the .HW
                             section lands.
     PLUGPLAY_REGKEY_DRIVER  the driver's software key -
                             per-driver settings.

/* ALWAYS HAVE A DEFAULT. A missing value must not be fatal -
   the driver may be loaded on a device whose INF section did
   not run, or the value may have been deleted.          */
```

How it shows up

Symptom	Cause
Code 28, "drivers not installed"	Hardware ID mismatch — compare against setupapi.dev.log
A different driver was chosen	Your rank was worse; match a more specific ID
Code 52, signature	Test signing off, or the catalog is missing (ch. 20)
Code 10 after a successful install	Installation worked; `START_DEVICE` failed — a driver bug
Code 39, driver corrupt	File not copied, or the service entry is wrong
Driver installs but no service is created	Missing `SPSVCINST_ASSOCSERVICE` (0x2) on `AddService`
Registry settings absent	`AddReg` in the wrong section — device settings go under `.NT.HW`
InfVerif fails	Non-universal directives — fix before certification, not after
Works on x64, no match on ARM64	Missing `NTarm64` in `[Manufacturer]`
Old driver keeps coming back	Still in the driver store — `pnputil /delete-driver`
Device opens for any user	No SDDL in the INF (ch. 03)
KMDF version error at load	`KmdfLibraryVersion` newer than the OS supports

Check yourself

- ✓ Write a complete INF for a PCI and an ACPI device.
- ✓ Explain what destination 13 means and why it is required.
- ✓ Explain hardware versus compatible IDs, and how ranking picks a driver.
- ✓ List the rules a universal INF must follow, and run `InfVerif`.
- ✓ Install, update and remove a driver with `pnputil` and `devcon`.
- ✓ Use setupapi.dev.log to distinguish an install failure from a start failure.
- ✓ Write device settings from the INF and read them back with validation.
- ✓ Explain why every setting needs a default.
- ✓ Set the device's security descriptor from the INF.
- ✓ Script the full uninstall-rebuild-install loop.

Driver signing

On 64-bit Windows, an unsigned kernel driver does not load. This chapter covers why, the difference between test signing and production signing, and the attestation and HLK paths to a driver that installs on someone else's machine.

Why it is mandatory

```
A kernel driver runs at ring 0 with full access to memory,
hardware and every other driver. There is no sandbox, no
privilege boundary, and no way to contain a malicious one
after it loads.

  SO WINDOWS ENFORCES CODE INTEGRITY at load time:

     x64 and ARM64        signing REQUIRED, always
     Secure Boot on       the boot chain is verified too
     HVCI enabled         additional requirements: no
                          W+X memory, no dynamic code
     Windows 10 1607+     new kernel drivers must be signed by
                          MICROSOFT, not merely by a
                          certificate you bought

  THAT LAST POINT IS THE ONE THAT SURPRISES PEOPLE. Buying an
  EV code-signing certificate is no longer sufficient by
  itself for a new kernel-mode driver on a clean, Secure-Boot
  system - the driver must carry a Microsoft signature
  obtained through the Partner Center.

  THIS IS THE SAME ARGUMENT as isolation chapter 14's chain of
  trust: the boot ROM verifies firmware, firmware verifies the
  kernel, and the kernel verifies drivers. Break any link and
  the ones above it are decoration.
```

Test signing

```
# For development, you self-sign and tell the machine to
# accept it.

# --- 1. Enable test mode on the TARGET machine ---
    bcdedit /set testsigning on
    shutdown /r /t 0
# A "Test Mode" watermark appears on the desktop. Expected.

# On a Secure Boot machine you must first DISABLE Secure Boot
# in firmware, or testsigning is refused.

# --- 2. Create a test certificate ---
    makecert -r -pe -ss PrivateCertStore -n "CN=MyTestCert" \
             mytestcert.cer
# The WDK's Visual Studio template does this for you and
# stores it as "WDKTestCert".

# --- 3. Sign the driver and the catalog ---
    inf2cat /driver:. /os:10_x64,10_ARM64
    ; produces mydriver.cat from the INF

    signtool sign /v /s PrivateCertStore /n MyTestCert \
             /t http://timestamp.digicert.com mydriver.cat
    signtool sign /v /s PrivateCertStore /n MyTestCert \
             /t http://timestamp.digicert.com mydriver.sys

# --- 4. Install the certificate on the target ---
    certmgr /add mytestcert.cer /s /r localMachine root
    certmgr /add mytestcert.cer /s /r localMachine \
            trustedpublisher

# --- 5. Verify ---
    signtool verify /v /kp mydriver.sys
    signtool verify /v /c mydriver.cat mydriver.sys

# THE VISUAL STUDIO PROJECT does steps 2, 3 and part of 4
# automatically when "Sign Mode" is set to "Test Sign".
# Configuration Properties -> Driver Signing.

# --- The alternative for quick experiments ---
    bcdedit /set nointegritychecks on
# Disables enforcement entirely. Works, but it also disables
# it for malware, and it masks signature problems you will hit
# later. Prefer test signing.
```

> **NEVER SHIP A MACHINE IN TEST MODE**
>
> Test signing disables the guarantee the whole mechanism exists to provide. It is a development convenience on a machine you control. A product that requires `testsigning on` or `nointegritychecks` to run is a product with no code integrity, and it will fail every security review it meets.

Production signing

```
THE MODERN PATH, for a new kernel driver:

1. GET AN EV CODE SIGNING CERTIFICATE
     from a CA Microsoft recognises (DigiCert, Sectigo,
     GlobalSign...). "EV" means extended validation: a
     hardware token, and identity verification of your
     organisation. Weeks, and a real cost.

2. REGISTER ON THE MICROSOFT PARTNER CENTER
     for the Hardware Program. The EV certificate is what
     establishes your identity there.

3. SIGN YOUR PACKAGE with the EV certificate.

4. SUBMIT IT to the Partner Center as a driver package
     (a .cab or .hlkx).

5. MICROSOFT SIGNS IT and returns the signed package.
     THAT signature is what makes it load.

6. OPTIONALLY, distribute via Windows Update.

TWO SUBMISSION ROUTES:

  ATTESTATION SIGNING
     · you attest that the driver is safe
     · NO test results required
     · fast: often under an hour
     · limited to Windows 10/11, and NOT for drivers that
       need to run on older releases
     · NOT eligible for Windows Update distribution of
       some classes
     -> the right route for most in-house and niche
        hardware

  HLK / WHQL CERTIFICATION
     · run the Hardware Lab Kit test suite
     · produces an .hlkx package with results
     · required for the "Certified for Windows" logo, for
       Windows Update distribution, and for some device
       classes
     · days to weeks of test running and fixing
     -> required for consumer hardware sold at scale
```

The HLK

```
# The Hardware Lab Kit is the certification test suite. Even
# if you use attestation signing, RUN THE RELEVANT TESTS -
# they find real bugs.

# SETUP:
#   an HLK Controller machine (with SQL Server)
#   an HLK Studio (the UI)
#   one or more TEST SYSTEMS running the HLK Client, with your
#   driver installed
#
# The controller drives the clients, runs tests, and collects
# results into a submission package.

# THE TESTS THAT MATTER MOST for a typical driver:

    Device Fundamentals
      · DF - PNP Disable and Enable
      · DF - PNP Remove and Restart
      · DF - PNP Surprise Remove       <-- chapter 14
      · DF - Sleep and PNP (with IO Before and After)
      · DF - Reboot Restart
      · DF - Concurrent Hardware and Operating System
      · DF - Fuzz tests (IoSpy/IoAttack)  <-- chapter 16
      · DF - Driver Verifier tests        <-- chapter 21

    Static Tools Logo
      · Code Analysis with driver-specific rules
      · Static Driver Verifier              <-- chapter 21
      Both must pass with zero defects.

# RUN THESE EARLY. A driver that fails "PNP Surprise Remove"
# at certification time usually needs architectural changes -
# whereas the same test on day three costs an afternoon.

# THE DEVICE FUNDAMENTALS TESTS ALONE, run with Driver
# Verifier enabled, catch the majority of the bugs this whole
# track has been warning about: IRQL violations, leaked
# resources, unhandled removal, unvalidated IOCTL input.
# They are, in effect, a free test suite for your driver -
# use them as one.
```

HVCI and additional requirements

```
/* Hypervisor-protected Code Integrity runs the code integrity
   check inside a VM-isolated environment, so a compromised
   kernel cannot disable it. It is DEFAULT ON for many
   Windows 11 configurations.

   HVCI IMPOSES EXTRA RULES on drivers: */

   1. NO WRITABLE AND EXECUTABLE MEMORY. A driver may not
      allocate memory that is both.
        -> use POOL_FLAG_NON_PAGED, never
           POOL_FLAG_NON_PAGED_EXECUTE unless truly required
        -> no self-modifying code, no dynamically generated
           trampolines

   2. NO SECTION ALIGNMENT SMALLER THAN 4 KB.
        the linker flag /ALIGN:4096, which the WDK templates
        already set

   3. NO EXECUTABLE SECTIONS THAT ARE ALSO WRITABLE.

   4. IMPORT TABLES MUST BE VALID and resolvable.

/* CHECK YOUR DRIVER: */
        Device Guard / HVCI readiness test in the HLK
        DGReadiness.ps1 (the Device Guard readiness tool)

/* THE SYMPTOM if you fail: the driver silently does not load
   on an HVCI system, with an event log entry about code
   integrity. It works perfectly on your development machine
   with HVCI off - which is why testing on an HVCI-enabled
   system is a required part of the matrix, not an
   afterthought.                                          */

/* AND THE DEEPER POINT, which connects to the isolation
   track: HVCI is Windows applying the same reasoning as
   TrustZone (isolation ch. 09) - move the enforcement to a
   more privileged, smaller, separately-verified component,
   so that compromising the large component does not
   compromise the check.                                  */
```

Verifying a signature

```
# --- Is this file signed, and by whom? ---
    signtool verify /v /kp mydriver.sys
      Verifying: mydriver.sys
      Signature Index: 0 (Primary Signature)
      Hash of file (sha256): 3A2B...
      Signing Certificate Chain:
          Issued to: Microsoft Windows Third Party Component CA
          ...
      Successfully verified: mydriver.sys

    ; /kp = check against KERNEL POLICY, which is stricter
    ; than the default. Use it - a driver can pass plain
    ; verification and still be refused at load.

# --- Against the catalog ---
    signtool verify /v /c mydriver.cat mydriver.sys

# --- What is actually loaded ---
    WinDbg:  lm                 ; loaded modules
             !chkimg mydriver   ; image integrity
             .imgscan

# --- WHY DID IT NOT LOAD? ---
    Event Viewer ->
      Applications and Services Logs ->
        Microsoft -> Windows -> CodeIntegrity -> Operational

# Event 3004: "Windows is unable to verify the image integrity
# of the file ... because file hash could not be found on the
# system."  -> the catalog is missing or does not cover the
# file.
# Event 3033: "... did not meet the Microsoft signing level
# requirements."  -> signed, but not by an authority this
# policy accepts.

# THESE TWO EVENTS distinguish "no signature" from "wrong
# signature", which is the first thing to establish.
```

A signing pipeline

```
# What a real build should do, in order:

# 1. BUILD
    msbuild mydriver.sln /p:Configuration=Release \
            /p:Platform=x64

# 2. STATIC ANALYSIS - must be clean before signing
    msbuild /p:RunCodeAnalysis=true
    ; and Static Driver Verifier (chapter 21)

# 3. BUILD THE CATALOG
    inf2cat /driver:.\output /os:10_x64,10_ARM64 /verbose

# 4. VERIFY THE INF
    InfVerif /u .\output\mydriver.inf

# 5. SIGN, with a timestamp
    signtool sign /v /fd sha256 /a \
             /tr http://timestamp.digicert.com /td sha256 \
             .\output\mydriver.cat
    signtool sign /v /fd sha256 /a \
             /tr http://timestamp.digicert.com /td sha256 \
             .\output\mydriver.sys

# THE TIMESTAMP MATTERS: without it, the signature becomes
# invalid when the certificate expires - typically in one to
# three years. With it, the signature remains valid because
# the timestamp proves it was signed while the certificate
# was live. Never sign without /tr.

# 6. VERIFY
    signtool verify /v /kp .\output\mydriver.sys

# 7. PACKAGE for submission
    makecab /f driver.ddf     ; -> mydriver.cab
    ; sign the cab with the EV certificate, then submit

# KEEP THE EV PRIVATE KEY IN ITS HARDWARE TOKEN. It is the
# identity of your organisation to Microsoft; a stolen one
# signs malware in your name, and revoking it invalidates
# every driver you have shipped.
```

How it shows up

Symptom	Cause
Code 52, "cannot verify the digital signature"	Unsigned, or test signing not enabled
CodeIntegrity event 3004	Catalog missing, or it does not cover the file's hash
CodeIntegrity event 3033	Signed, but not to the required level — needs a Microsoft signature
Works on your machine, not on a clean one	Your test certificate is installed locally only
Works, then stops after a rebuild	The catalog was not regenerated — hashes no longer match
Loads with HVCI off, not with it on	Writable-and-executable memory, or bad section alignment
Signature invalid after a year	Signed without a timestamp
`bcdedit /set testsigning on` refused	Secure Boot is enabled — disable it in firmware first

Symptom	Cause
Attestation submission rejected	The driver class is not eligible; HLK certification is required
HLK Surprise Remove test fails	A real removal-handling bug (ch. 14)
Static Tools Logo fails	Code Analysis or SDV findings — fix them (ch. 21)

Check yourself

- ✓ Explain why kernel driver signing is mandatory and what it protects.
- ✓ Set up test signing end to end, including the certificate on the target.
- ✓ Explain why an EV certificate alone is no longer sufficient.
- ✓ Compare attestation signing with HLK certification and say when each applies.
- ✓ Name six Device Fundamentals tests and the bug class each finds.
- ✓ List HVCI's four requirements and the symptom of failing them.
- ✓ Verify a signature against kernel policy, and read the CodeIntegrity event log.
- ✓ Distinguish event 3004 from 3033.
- ✓ Write a signing pipeline and explain why the timestamp is required.
- ✓ Relate this chapter to the chain of trust in the isolation track.

Static analysis and Driver Verifier

Windows ships the best driver verification tooling of any operating system, and most of it is free and automatic. Static analysis finds bugs at build time; Driver Verifier turns latent runtime bugs into immediate, attributable bugchecks. Use both, from day one.

Why these matter more here

```
A driver bug on Linux is found by the community, because the
source is in the tree and everyone builds it (Linux ch. 30).

A Windows driver ships as a signed binary that Microsoft never
sees the source of. So the verification burden moves to
TOOLING, and Microsoft has invested accordingly:

   BUILD TIME              Code Analysis (PREfast)
                           Static Driver Verifier (SDV)
                           SAL annotations (chapter 02)
                           InfVerif (chapter 19)

   RUN TIME                Driver Verifier
                           WDF Verifier (chapter 13)
                           Application Verifier (user mode)
                           Special pool (chapter 06)

   CERTIFICATION           HLK Device Fundamentals
                           Static Tools Logo test

  THE PAYOFF: these tools find, mechanically, most of the bug
  classes this entire track has described - IRQL violations,
  leaked resources, unvalidated input, incorrect IRP handling,
  DMA misuse, lock ordering. A driver that passes all of them
  clean is in far better shape than one that merely works.
```

Code Analysis

```
# PREfast for Drivers - runs during the build, understands
# SAL annotations (chapter 02) and driver-specific rules.

    msbuild mydriver.sln /p:RunCodeAnalysis=true
    ; or: Visual Studio -> Analyze -> Run Code Analysis

# In the project: use the "Recommended driver rules" ruleset,
# which adds the driver-specific checks to the general C/C++
# ones.

# WHAT IT CATCHES:
#   · calling a function at the wrong IRQL, per its
#     _IRQL_requires_max_ annotation
#   · ignoring a _Must_inspect_result_ return
#   · buffer sizes inconsistent with _In_reads_bytes_
#   · using an uninitialised variable
#   · leaking a resource on an error path
#   · dereferencing a possibly-NULL pointer
#   · a lock acquired and not released on some path
#   · incorrect WDF object usage

# A TYPICAL FINDING:
    warning C28118: The current IRQL was too high. Prior
    function calls indicate IRQL was DISPATCH_LEVEL, but the
    function MmMapIoSpaceEx requires PASSIVE_LEVEL.

# FIX IT. Do not suppress it. If a warning is genuinely a
# false positive, suppress it NARROWLY and with a comment:
    #pragma warning(suppress: 28118)  // IRQL is checked by
                                      // the caller; see the
                                      // header contract

# THE HIGHEST-VALUE HABIT in Windows driver development is
# annotating your own functions with SAL as you write them.
# The analyser then checks your CALLERS against your
# contract - which is the difference between finding an IRQL
# bug at build time and finding it in a customer's crash
# dump.
```

Static Driver Verifier

```
# SDV is different from Code Analysis: it does symbolic model
# checking against a set of RULES that describe how the driver
# framework must be used. It explores paths, not just
# expressions.

    msbuild /p:Configuration="Win8.1 Release" \
            /p:Platform=x64 /t:sdv /p:Inputs="/check:*"
    ; or: Visual Studio -> Driver -> Launch Static Driver
    ;     Verifier

# THE PROCESS:
#   1. scan - identify entry points and roles
#   2. verify - run each rule against the model
#   3. produce a report, with a COUNTEREXAMPLE TRACE for each
#      violation

# EXAMPLE RULES:
    IrqlKeApcLte1        KeXxx APC functions at the right IRQL
    IrqlIoPassive1       Io functions requiring PASSIVE_LEVEL
    SpinLockRelease      every acquire has a release
    LowerDriverReturn    completion routines return correctly
    PnpIrpCompletion     PnP IRPs completed per the rules
    RequestCompleted     every WDF request is completed exactly
                         once
    MarkIrpPending2      IoMarkIrpPending used correctly
    WdfSpinlock          WDF spinlock usage
    DoubleCompletion     no IRP completed twice

# READING A DEFECT: SDV shows the exact path through your code
# that violates the rule, step by step. It is a proof, not a
# heuristic - so a reported defect on a reachable path is a
# real bug.

# CAVEATS, stated honestly:
#   · SDV can time out on complex drivers. Increase the limit,
#     or simplify the function it struggles with.
#   · it can report defects on paths that cannot actually
#     occur, because it does not know a hardware invariant you
#     rely on. Those need review, not blind fixing.
#   · it must be run on the whole driver, not one file.

# BUT: the Static Tools Logo certification test REQUIRES a
# clean SDV run and a clean Code Analysis run. So this is not
# optional if you intend to certify - run it early, when the
# fixes are cheap.
```

> **RUN BOTH BEFORE YOU EVER LOAD THE DRIVER**
>
> A bug caught by Code Analysis costs a minute. The same bug caught by Driver Verifier costs an hour of crash-dump analysis. The same bug found by a customer costs a support case, a hotfix, and a re-certification. The ordering of these tools is also the ordering of their cost.

Driver Verifier

```
# The runtime tool. It instruments your driver's interaction
# with the kernel and BUGCHECKS at the moment a rule is
# violated, rather than letting the consequence appear later
# somewhere else.

# --- Enable it ---
    verifier /standard /driver mydriver.sys
    ; or a specific flag set:
    verifier /flags 0x209BB /driver mydriver.sys
    ; then reboot

    verifier /querysettings        ; what is enabled
    verifier /volatile /flags 0x1 /adddriver mydriver.sys
                                   ; some flags, no reboot
    verifier /reset                ; turn it all off
    ; or the GUI: verifier.exe

# --- THE FLAGS, and what each finds ---

    0x00001  Special pool
             each allocation on its own page with a guard
             page. Catches overruns AT THE MOMENT they happen.
             The equivalent of Linux's KASAN (ch. 27).

    0x00002  Force IRQL checking
             makes pageable code and data non-resident, so
             touching it at DISPATCH_LEVEL faults IMMEDIATELY
             instead of weeks later (chapter 02). THE most
             valuable flag.

    0x00004  Low resources simulation
             randomly fails allocations, so untested error
             paths execute. Linux's fault injection (ch. 26).

    0x00008  Pool tracking
             detects allocations still outstanding at unload,
             with the stack that made them (chapter 06).

    0x00010  I/O verification
             IRP rule checking: double completion, use after
             completion, wrong IRQL, missing PendingReturned
             (chapter 04).

    0x00020  Deadlock detection
             builds a lock-order graph and reports
             inconsistent acquisition. Linux's lockdep
             (ch. 09).

    0x00080  DMA verification
             map register accounting, alignment, overruns
             (chapter 18).

    0x00100  Security checks
             insecure object creation, missing access checks

    0x00800  Miscellaneous checks
             freeing an object with references, incorrect
             string usage

    0x02000  Invariant MDL checking (stack)
```

```
    0x04000  Invariant MDL checking (driver)

    0x20000  DDI compliance checking
             the KMDF framework rules

# --- START HERE ---
    verifier /flags 0x209BB /driver mydriver.sys
# = special pool, IRQL checking, pool tracking, I/O
# verification, deadlock detection, DMA, security, misc, DDI
# compliance. This is the standard development set.

# --- AND FOR A HARDER PASS, add low resources ---
    verifier /flags 0x209BF /driver mydriver.sys
# Expect to find unchecked allocations. That is the point.
```

The cost, and when to enable what

Flag	Cost	When
Special pool	High memory, moderate speed	Development, and any corruption hunt
Force IRQL checking	Moderate	**Always** during development
Low resources	Causes failures by design	A dedicated error-path testing pass
Pool tracking	Low	Always
I/O verification	Moderate	Always
Deadlock detection	Moderate	Always
DMA verification	Low	Any driver doing DMA
DDI compliance	Low	Always, for WDF drivers
Everything at once	Very slow	An overnight soak run

```
/* THE PRACTICAL SCHEDULE:

   EVERY DEVELOPMENT BUILD
        the standard set, always on. You will catch bugs the
        day you write them.

   BEFORE EACH MILESTONE
        add low resources simulation and run the full
        functional test suite. Every crash is an unchecked
        allocation.

   BEFORE SUBMISSION
        the full flag set, plus the HLK Device Fundamentals
        tests (chapter 20), running overnight.

   ON A TEST MACHINE, NOT YOUR DEVELOPMENT BOX. Verifier
   bugchecks, by design.                                  */
```

Reading a Verifier bugcheck

```
DRIVER_VERIFIER_DETECTED_VIOLATION (c4)
A device driver attempting to corrupt the system has been
caught.
Arguments:
Arg1: 0000000000000062, A driver has forgotten to free its
                        pool allocations prior to unloading.
Arg2: ffff8a0c11223344, name of the driver having the issue
Arg3: 0000000000000004, number of allocations leaked
Arg4: 0000000000000000

/* THE FIRST ARGUMENT IS THE RULE. Common ones:

     0x62  pool allocations not freed at unload
     0x81  freeing memory that contains active timers
     0xE6  DMA violation (also bugcheck 0xE6 itself)
     0xF6  a driver referenced a freed object
     0x91  a thread holding a spinlock at exit
     0x1000-series  deadlock detection

/* AND THE INVESTIGATION, in WinDbg (chapter 22): */

        !analyze -v
        !verifier 3 mydriver.sys
          /* every outstanding allocation, WITH THE STACK that
             made it - which names the leak directly */
        !verifier 0x80 mydriver.sys
          /* IRP log */
        !verifier 1
          /* the enabled flags */

/* THE OTHER VERIFIER BUGCHECKS:
     0xC4  DRIVER_VERIFIER_DETECTED_VIOLATION
     0xC6  DRIVER_CAUGHT_MODIFYING_FREED_POOL
     0xC9  DRIVER_VERIFIER_IOMANAGER_VIOLATION
     0xE6  DRIVER_VERIFIER_DMA_VIOLATION
     0xC1  SPECIAL_POOL_DETECTED_MEMORY_CORRUPTION

/* EACH ONE NAMES YOUR DRIVER AND THE RULE. That is the whole
   value: the crash is at the point of the mistake, attributed
   to the code that made it, rather than a random later
   consequence in someone else's driver.                  */
```

WDF Verifier

```
# Separate from Driver Verifier, and it checks a different
# thing: framework contract violations.

# Enable via the WDK's tool:
    wdfverifier.exe
# or in the registry, under the driver's Parameters\Wdf key:
    VerifierOn        = 1
    VerboseOn         = 1
    DbgBreakOnError   = 1
    TrackHandles      = 1     ; find handle leaks
    VerifyDownLevel   = 1

# WHAT IT CATCHES:
#   · using a WDF handle after deletion
#   · completing a request twice
#   · completing a request you forwarded
#   · calling a WDF API at the wrong IRQL
#   · object hierarchy violations (chapter 13)
#   · lock misuse
#   · queue state violations (chapter 15)

# WHEN IT FIRES, with DbgBreakOnError it breaks into the
# debugger with a message naming the rule:
    *** WDFVERIFIER: WdfRequestComplete called on a request
        that is not owned by the driver.

# THEN:
    !wdflogdump mydriver
# gives the framework's own trace of what led there.

# TURN BOTH VERIFIERS ON. They overlap very little.
```

The workflow

```
# A realistic development cycle:

# EVERY BUILD
    msbuild /p:RunCodeAnalysis=true
    ; zero warnings, or a documented suppression

# EVERY TEST RUN, on the test machine
    verifier /flags 0x209BB /driver mydriver.sys
    wdfverifier: VerifierOn=1
    ; both enabled, always

# WEEKLY
    SDV full run
    low resources simulation pass
    100 install/uninstall cycles
    100 disable/enable cycles
    sleep/resume cycles with I/O in flight

# BEFORE SUBMISSION
    full verifier flags, overnight soak
    HLK Device Fundamentals (chapter 20)
    HLK Static Tools Logo (Code Analysis + SDV, clean)
    IoAttack fuzzing of the IOCTL interface (chapter 16)

# THE THINGS THAT MOST OFTEN FIND REAL BUGS, in order:
#   1. Force IRQL checking - the paged-memory-at-DISPATCH bug
#   2. Low resources simulation - unchecked allocations
#   3. PNP Surprise Remove - unhandled removal
#   4. Deadlock detection - latent lock ordering
#   5. IoAttack - unvalidated IOCTL input
#
# All five are free, automated, and take an afternoon to set
# up once.
```

How it shows up

Symptom	Cause
Bugcheck 0xC4 Arg1 = 0x62	Pool leaked at unload — `!verifier 3` names the site
Bugcheck 0xC1	Special pool caught an overrun at the moment it happened
Bugcheck 0xC6	Wrote to freed pool
Bugcheck 0xC9	I/O manager rule — usually double completion
Bugcheck 0xE6	DMA rule (ch. 18)
Driver crashes only with Verifier on	A real latent bug Verifier made deterministic — not a false alarm
Crashes with low resources simulation	Unchecked allocation return
WDFVERIFIER message about request ownership	Completed a forwarded request (ch. 15)
SDV reports an unreachable defect	A path it cannot rule out — review, annotate, or accept
SDV times out	Function too complex; simplify or raise the limit
Static Tools Logo fails	Code Analysis or SDV not clean — required for certification
Everything is very slow	Too many Verifier flags for routine use — trim to the standard set

Check yourself

- ✓ Explain why Windows invests more in tooling than Linux does, and what that follows from.
- ✓ Run Code Analysis and fix a finding rather than suppressing it.
- ✓ Explain what SAL annotations let the analyser check about your callers.
- ✓ Explain how SDV differs from Code Analysis and what a counterexample trace is.
- ✓ Name eight Driver Verifier flags and the bug class each finds.
- ✓ Map five of them onto their Linux equivalents.
- ✓ Choose a flag set for daily use and one for a milestone pass.
- ✓ Read a 0xC4 bugcheck and use `!verifier 3` to locate the leak.
- ✓ Enable WDF Verifier and say what it catches that Driver Verifier does not.
- ✓ Write the weekly and pre-submission verification schedule.

WinDbg for driver developers

Setting up kernel debugging, reading a crash dump, and the two dozen commands that cover almost everything you will need. Unlike Linux, Windows expects you to use a real debugger — and the tooling is correspondingly good.

Setting up a connection

```
# You need TWO machines: the HOST running WinDbg, and the
# TARGET running your driver. A VM is ideal.

# --- On the TARGET: choose a transport ---

# NETWORK (fastest, and the modern default):
    bcdedit /debug on
    bcdedit /dbgsettings net hostip:192.168.1.10 \
            port:50000 key:1.2.3.4.5.6.7.8
    ; the key can be anything; note it for the host
    shutdown /r /t 0

# SERIAL (works on anything, including physical boards):
    bcdedit /debug on
    bcdedit /dbgsettings serial debugport:1 baudrate:115200

# For a Hyper-V VM, the simplest option:
    bcdedit /dbgsettings serial debugport:1 baudrate:115200
    ; and configure the VM's COM1 as a named pipe:
    ;   \\.\pipe\mydebug

# BREAK INTO THE DEBUGGER AT BOOT, to catch DriverEntry:
    bcdedit /set bootdebug on

# --- On the HOST: connect ---
    windbg -k net:port=50000,key=1.2.3.4.5.6.7.8
    windbg -k com:pipe,port=\\.\pipe\mydebug,resets=0,reconnect

# --- SYMBOLS - do this first, always ---
    .sympath srv*C:\symbols*https://msdl.microsoft.com/download/symbols
    .sympath+ C:\myproject\x64\Debug
    .reload /f

    ; or set _NT_SYMBOL_PATH as an environment variable so
    ; every tool picks it up:
    setx _NT_SYMBOL_PATH "srv*C:\symbols*https://msdl.microsoft.com/download/symbols"

# WITHOUT SYMBOLS, every command prints hex addresses and you
# learn nothing. This is the single most common reason a
# newcomer finds WinDbg useless.

# --- Source-level debugging ---
    .srcpath C:\myproject\src
    l+t          ; source line mode
    .lines       ; enable line number information
```

Reading a crash dump

```
# CONFIGURE DUMPS on the target, before you need them:
#   System Properties -> Advanced -> Startup and Recovery
#   "Kernel memory dump" is the right choice for driver work -
#   a minidump often lacks the pool data you need.
#   -> C:\Windows\MEMORY.DMP

# Open it:
    windbg -z C:\Windows\MEMORY.DMP

# THE FIRST COMMAND, ALWAYS:
    !analyze -v

# It gives you:
#   the bugcheck code and its four parameters, decoded
#   the faulting module and function
#   the stack trace
#   often, a plain-English "PROCESS_NAME" and
#   "FAILURE_BUCKET_ID" that names the bug class
#   and a "MODULE_NAME" - which, if it is yours, is the answer

# THEN, IN ORDER:
    .bugcheck                 ; the code and parameters again
    kb                        ; the stack with arguments
    kv                        ; verbose - includes frame
                              ; pointers and trap frames
    kP                        ; with full parameter names
    lm                        ; loaded modules
    lmvm mydriver             ; details of yours - version,
                              ; timestamp, symbol status
    !irql                     ; the IRQL at the time
    !process                  ; the current process
    !thread                   ; the current thread
    r                         ; registers
    .trap <address>           ; switch to a trap frame's
                              ; context, from the kv output

# IF THE STACK IS CORRUPT:
    dps @rsp L100             ; dump the stack as symbols -
                              ; often reveals return addresses
                              ; the unwinder missed
    !stackusage
    .thread /r /p <ethread>   ; switch thread context
```

> **`!ANALYZE -V` IS RIGHT MORE OFTEN THAN YOU EXPECT**
>
> It applies a large body of heuristics about known bug patterns and frequently names the exact module and reason. Read its whole output before doing anything else — including the "STACK_COMMAND" and "FOLLOWUP_NAME" lines, which tell you what it thinks and why. Then verify its conclusion rather than trusting it blindly; it is a very good first hypothesis, not a proof.

The commands worth memorising

Command	Does
`!analyze -v`	Automated crash analysis
`kb` / `kv` / `kP`	Stack trace, increasingly verbose

Command	Does
`lm` / `lmvm mod`	Loaded modules; details of one
`x mydriver!*`	Symbols matching a pattern
`dt nt!_IRP addr`	Display a typed structure
`dt -r mydriver!_MY_CONTEXT addr`	Recursively, your own type
`db` / `dw` / `dd` / `dq addr`	Dump memory, by width
`dps addr`	Dump pointers with symbol names
`u addr`	Disassemble
`bp mydriver!MyRead`	Breakpoint
`ba w4 addr`	Break on write to an address — invaluable for corruption
`g` / `p` / `t`	Go, step over, step into
`!process 0 0`	All processes, brief
`!thread addr`	One thread: state, wait reason, stack
`!irp addr` / `!irpfind`	One IRP; find all IRPs
`!devobj` / `!devstack` / `!drvobj`	Device and driver objects
`!devnode 0 1`	The PnP tree
`!pool addr` / `!poolused 2`	Pool allocation; usage by tag
`!poolfind Tag`	Every allocation with a tag
`!verifier 3 mydriver`	Verifier's outstanding allocations, with stacks
`!locks` / `!deadlock`	Held resources; the deadlock graph
`!stacks 2`	Every thread's stack
`!vm`	Memory usage summary
`!error 0xc0000001`	Decode an NTSTATUS or Win32 error
`.reload /f`	Force symbol reload

The WDF extension

```
    .load wdfkd.dll
    !wdfkd.wdfhelp                  ; the full list

# THE ONES THAT MATTER:
    !wdfdriverinfo mydriver         ; everything: version,
                                    ; devices, queues
    !wdfdriverinfo mydriver 0xff    ; maximum verbosity
    !wdfdevicequeues <WDFDEVICE>    ; every queue and its
                                    ; pending requests
                                    ; (chapter 15)
    !wdfhandle <handle>             ; type, parent, context,
                                    ; refcount (chapter 13)
    !wdfobject <handle>
    !wdfrequest <WDFREQUEST>        ; state, owner, IRP
    !wdfqueue <WDFQUEUE>
    !wdfobjectdump                  ; the whole object tree

# AND THE MOST VALUABLE ONE:
    !wdflogdump mydriver
    !wdflogdump mydriver -d         ; include the IFR (in-flight
                                    ; recorder) detail

# The framework keeps a circular trace of every state
# transition, request, and error it detected - IN MEMORY, at
# all times, with no configuration. After a crash it usually
# tells you what the framework thought was happening, which is
# frequently the entire diagnosis.

# YOUR OWN TRACES appear there too, if you use WPP or
# TraceEvents - see below.
```

Tracing from your driver

```
/* THREE OPTIONS, in increasing order of quality: */

/* 1. DbgPrint / KdPrint - simplest, slowest */
        KdPrint(("MyRead: length %lu\n", length));
        /* compiled out in release builds */

        DbgPrintEx(DPFLTR_IHVDRIVER_ID, DPFLTR_INFO_LEVEL,
                   "MyRead: length %lu\n", length);

        /* enable output on the target: */
        ; registry: HKLM\SYSTEM\CCS\Control\Session Manager\Debug
        ;           Print Filter -> IHVDRIVER = 0xF
        ; or in WinDbg:
        ed nt!Kd_IHVDRIVER_Mask 0xF

/* DbgPrint IS SLOW - it serialises to the debugger connection
   and can take milliseconds with interrupts disabled. Never
   in a hot path or an ISR (chapter 10).                    */

/* 2. WPP TRACING - the standard for production drivers.
      Compiled to a binary format with a message GUID; the
      strings live in a PDB, not in the driver.             */

        /* trace.h */
        #define WPP_CONTROL_GUIDS \
            WPP_DEFINE_CONTROL_GUID( \
                MyDriverTraceGuid, \
                (A1B2C3D4,1234,5678,9ABC,DEF012345678), \
                WPP_DEFINE_BIT(TRACE_DEVICE)  \
                WPP_DEFINE_BIT(TRACE_QUEUE)   \
                WPP_DEFINE_BIT(TRACE_DPC)     \
                )

        /* in the driver: */
        WPP_INIT_TRACING(DriverObject, RegistryPath);
        ...
        TraceEvents(TRACE_LEVEL_INFORMATION, TRACE_QUEUE,
                    "Read request, length %lu", length);
        ...
        WPP_CLEANUP(DriverObject);

/* WPP IS FAST - a few dozen cycles per event, safe at any
   IRQL. And the messages land in the WDF log, so
   !wdflogdump shows them interleaved with the framework's
   own trace, which is exactly the correlation you want.  */

        /* capture live: */
        tracelog -start MyTrace -guid #A1B2C3D4-1234-5678-9ABC-DEF012345678 \
                 -f mytrace.etl -flag 0xF -level 5
        tracelog -stop MyTrace
        tracefmt -o output.txt mytrace.etl
        ; or traceview.exe for a GUI

/* 3. ETW TRACE EVENTS - for anything you want correlated with
      system-wide traces in WPA. More setup, best integration.
      Use it when latency or performance is the question
      rather than correctness.                              */
```

Live debugging techniques

```
# --- Break in whenever you like ---
    Ctrl+Break in WinDbg, or on the target:
    ; SysRq equivalent: the debugger breaks on demand over the
    ; connection

# --- Break on your driver loading ---
    sxe ld mydriver.sys
    g
    ; stops the moment it loads, before DriverEntry

# --- Breakpoint on a function, with a condition ---
    bp mydriver!MyEvtIoRead ".if (@rdx == 0) {} .else {gc}"
    ; break only when the second argument is zero

# --- Breakpoint that just logs and continues ---
    bp mydriver!MyEvtIoRead "dt mydriver!_MY_CONTEXT @rcx; gc"

# --- BREAK ON MEMORY WRITE - the corruption finder ---
    ba w8 ffff8a0c12345678
    ; breaks when 8 bytes at that address are written.
    ; THE tool for "who is corrupting my structure?" - set it
    ; on the field that gets clobbered and the culprit
    ; identifies itself.
    ; Limited to four hardware breakpoints.

# --- Watch a value change over time ---
    .while (1) { dd mydriver!g_Counter L1; .sleep 1000; g }

# --- Call a function in the target ---
    .call mydriver!MyDumpState(0)
    g
    ; requires private symbols and a compatible calling
    ; convention. Powerful, and occasionally the fastest way
    ; to interrogate driver state.

# --- Scripting ---
    $$>a< C:\scripts\myscript.txt
    dx @$curprocess.Threads     ; the NatVis/dx data model
    dx -g @$curprocess.Threads.Where(t => t.Id > 100)
```

Diagnosing the common failures

```
# --- "My driver bugchecked" ---
    !analyze -v
    ; then verify its conclusion with kb and the bugcheck
    ; parameters (chapter 02 for 0xA/0xD1)

# --- "The system hangs, no bugcheck" ---
    Ctrl+Break
    !running                  ; what is each CPU doing?
    !stacks 2                 ; every thread
    !locks                    ; who holds what
    !deadlock                 ; if verifier's flag is on
    !irql                     ; are we stuck at high IRQL?

# --- "An application hangs on my device" ---
    !process 0 7              ; find the process and thread
    !thread <ethread>         ; what is it waiting on
    !irpfind -v 0 0 device <devobj>     ; which IRP is stuck
    !wdfdevicequeues <wdfdevice>        ; and which queue
                                        ; holds it

# --- "Memory is leaking" ---
    !poolused 2               ; sorted by non-paged usage
    !poolfind xMYD            ; your tag (chapter 06)
    !verifier 3 mydriver.sys  ; with stacks, if pool tracking
                              ; is enabled

# --- "Something is corrupting my structure" ---
    ba w8 <address of the field>
    ; or enable special pool and let it fault at the moment of
    ; the overrun (chapter 21)

# --- "The driver will not load" ---
    !devnode 0 1 mydriver
    ; and read setupapi.dev.log (chapter 19) and the
    ; CodeIntegrity event log (chapter 20) on the target

# --- "It works with the debugger attached" ---
    ; a timing bug. The debugger changes timing enormously.
    ; Use WPP tracing instead of breakpoints, and enable
    ; Driver Verifier - which perturbs timing differently and
    ; often makes the race deterministic.
```

How it shows up

Symptom	Cause
Every command prints hex, no names	Symbols not configured — fix `.sympath` first
Your driver's symbols missing	PDB not in the path, or a different build than the one running
`lmvm` shows "export symbols only"	Same — you need the private PDB
Stack trace makes no sense	Corrupt stack — try `dps @rsp`, or a trap frame with `.trap`
Minidump lacks the data you need	Configure a kernel memory dump instead
Cannot connect over the network	Firewall, wrong key, or the NIC is not debug-capable
Bug disappears under the debugger	A timing-dependent race — use tracing and Verifier
`DbgPrint` output missing	Print filter mask not set for your component

Symptom	Cause
Driver is slow only in debug builds	`DbgPrint` in a hot path — switch to WPP
Four breakpoints, the fifth fails	Hardware breakpoint limit

Check yourself

- ✓ Set up a network or serial kernel debugging connection to a VM.
- ✓ Configure symbols so both Microsoft's and your own resolve.
- ✓ Read a crash dump with `!analyze -v` and verify its conclusion.
- ✓ Use fifteen of the core commands from memory.
- ✓ Use the WDF extension to inspect queues, requests and the framework log.
- ✓ Add WPP tracing and explain why it beats `DbgPrint`.
- ✓ Set a conditional breakpoint and a data breakpoint.
- ✓ Diagnose a hang using only `!running`, `!stacks` and `!locks`.
- ✓ Find a hung application's stuck IRP and the queue holding it.
- ✓ Locate a pool leak with `!poolused` and `!verifier 3`.

Project: the KMDF ring-buffer driver

A complete, working Windows driver you build, sign, install and break yourself. It needs no hardware — it installs as a software device — and it exercises queues, IOCTLs, asynchronous completion, timers, locking and the full PnP lifecycle. Deliberately the same problem as the Linux project in chapter 28, so the comparison teaches as much as the code.

What you are building

```
   \\.\RingBuf                    a software device

   WriteFile()                    push bytes into a ring
   ReadFile()                     pop bytes; BLOCKS if empty,
                                  completing asynchronously
   IOCTL_RB_GET_STATS             counters
   IOCTL_RB_RESET                 empty it
   IOCTL_RB_SET_CONFIG            capacity policy

   A periodic timer generates synthetic data, standing in for
   an interrupt - so the asynchronous completion path is real
   even without hardware.

  WHAT IT EXERCISES:
     WDF object model and contexts       (chapter 13)
     the device lifecycle                (chapter 14)
     default and manual queues           (chapter 15)
     asynchronous completion from a DPC  (chapter 10)
     IOCTL design and validation         (chapter 16)
     spinlocks and IRQL discipline       (chapters 02, 09)
     an INF and installation             (chapter 19)
     Driver Verifier and WinDbg          (chapters 21, 22)

  That is most of the track, in about 600 lines.
```

The files

```
ringbuf\
  ringbuf.h          shared with user mode - the ABI
  driver.h           internal definitions
  driver.c           DriverEntry, EvtDeviceAdd
  queue.c            the I/O callbacks
  ring.c             the buffer itself
  ringbuf.inf
  ringbuf.vcxproj
  test\
    rbtest.c         the client (chapter 24)
```

ringbuf.h — the shared ABI

```
#pragma once

#include <initguid.h>

Building and installing

```
# --- On the DEVELOPMENT machine ---
    msbuild ringbuf.vcxproj /p:Configuration=Debug \
            /p:Platform=x64
    ; the WDK template signs it with a test certificate

# --- On the TEST machine (a VM), once ---
    bcdedit /set testsigning on
    bcdedit /debug on
    bcdedit /dbgsettings serial debugport:1 baudrate:115200
    shutdown /r /t 0

# --- Install ---
    certmgr /add ringbuf.cer /s /r localMachine root
    certmgr /add ringbuf.cer /s /r localMachine trustedpublisher

    pnputil /add-driver ringbuf.inf /install
    devcon install ringbuf.inf root\ringbuf

# --- Verify it started ---
    devcon status root\ringbuf
      root\ringbuf\0000
          Name: RingBuf Test Device
          Driver is running.

    ; and in Device Manager, under System devices

# --- The development loop, scripted ---
    devcon remove root\ringbuf
    pnputil /delete-driver oem12.inf /uninstall /force
    ; rebuild, copy over
    pnputil /add-driver ringbuf.inf /install
    devcon install ringbuf.inf root\ringbuf

# --- Turn the verifiers on immediately (chapter 21) ---
    verifier /flags 0x209BB /driver ringbuf.sys
    shutdown /r /t 0
```

Exercises

BREAK IT DELIBERATELY. EACH OF THESE PRODUCES A SPECIFIC, DIAGNOSABLE FAILURE.

1. **Remove the spinlock** from `RbEvtIoWrite`. Run several writers and a reader. Watch the counters drift. Then re-add it.
2. **Allocate the buffer from paged pool.** Enable Verifier's force-IRQL flag. The timer DPC now bugchecks with 0xA immediately, rather than in three weeks (chapter 02).
3. **Complete a forwarded request.** In `RbEvtIoRead`, call `WdfRequestComplete` after `WdfRequestForwardToIoQueue`. WDF Verifier catches it (chapter 13).
4. **Make the pending queue power-managed.** Let the device idle, then read. The request never completes — and `!wdfdevicequeues` shows the queue not dispatching (chapter 15).
5. **Drop** `WdfTimerStop(..., TRUE)` from cleanup. Uninstall while the timer is running. With special pool on, you get a use-after-free bugcheck naming your driver.
6. **Skip the** `RtlZeroMemory` in `GET_STATS`. The reserved fields now leak whatever was in the buffer — an information disclosure, in one deleted line.
7. **Remove the validation** from `SET_CONFIG` and pass a huge `TimerPeriodMs`. Then run the WDK's IoAttack fuzzer against it and see what else it finds.
8. **Change** `IOCTL_RB_RESET` **to** `FILE_ANY_ACCESS` and reset the buffer from a read-only handle. Observe that the platform was preventing this for free (chapter 16).
9. **Leak pool:** remove the `ExFreePoolWithTag`. Install and uninstall ten times with pool tracking on. Bugcheck 0xC4, Arg1 = 0x62, with the allocation stack.
10. **Add a feature:** support several concurrent readers, each with an independent read position. This requires per-file-object state (chapter 15) and changes the ring's semantics — think carefully about what "consumed" means with several readers.
11. **Add an** `EvtIoStop` **handler** and verify the machine can now sleep with a read pending.
12. **Convert to a real interrupt.** If you have any PCIe device with a documented register map, replace the timer with a `WDFINTERRUPT` (chapter 17). The queue and completion logic does not change at all — which is the point.

The review pass

```
# Before you call it finished:

# 1. Static analysis, clean (chapter 21)
    msbuild /p:RunCodeAnalysis=true
    ; and Static Driver Verifier

# 2. Driver Verifier, standard flags, through a full test run

# 3. Low resources simulation
    verifier /flags 0x209BF /driver ringbuf.sys
    ; expect to find unchecked allocations; there is at least
    ; one obvious candidate in EvtDeviceAdd

# 4. 50 install/uninstall cycles
# 5. 50 disable/enable cycles
    for /L %i in (1,1,50) do devcon disable root\ringbuf & \
                             devcon enable root\ringbuf

# 6. Sleep and resume with a read pending
    pwrtest /sleep /c:5

# 7. The HLK Device Fundamentals tests (chapter 20)

# 8. IoAttack against the IOCTL interface (chapter 16)

# STEPS 3, 5 AND 8 find the most. Step 6 finds the
# EvtIoStop omission specifically.
```

Check yourself

- ✓ Explain why the ring buffer must be in non-paged pool.
- ✓ Justify the choice of buffered I/O and the SDDL string.
- ✓ Explain why the pending queue is not power-managed.
- ✓ State the request ownership rule and find every place the code honours it.
- ✓ Explain why `RbCompletePendingReads` is called outside the lock.
- ✓ Explain the requeue-on-zero path and what bug it prevents.
- ✓ Justify the Access field on each IOCTL.
- ✓ Explain why `RtlZeroMemory` on the output struct is a security control.
- ✓ Complete exercises 1 through 9 and describe each symptom.
- ✓ Complete at least one of exercises 10 to 12.
- ✓ Pass the eight-step review with no findings.

> **NEXT**
> Chapter 24 builds the user-mode client: device discovery by interface GUID, synchronous and overlapped I/O, and a benchmark that shows what the asynchronous path actually buys.

Project: the user-mode client

The other half of the Windows project: finding the device by interface GUID, driving it synchronously and with overlapped I/O, watching for arrival and removal, and measuring what the asynchronous path is actually worth.

Finding the device

```
/* rbtest.c - build with:
     cl /W4 /Zi rbtest.c setupapi.lib cfgmgr32.lib   */

#include <windows.h>
#include <setupapi.h>
#include <cfgmgr32.h>
#include <stdio.h>
#include <stdlib.h>
#include "../ringbuf.h"

/* Open by INTERFACE GUID, not by a hard-coded name
   (chapter 05). This works for any number of instances and
   survives the device moving.                              */

}
```

WIN32 ERRORS, NOT NTSTATUS

User mode sees Win32 error codes; the I/O manager translates. `STATUS_INVALID_PARAMETER` becomes `ERROR_INVALID_PARAMETER` (87), `STATUS_BUFFER_TOO_SMALL` becomes `ERROR_INSUFFICIENT_BUFFER` (122), `STATUS_INVALID_DEVICE_REQUEST` becomes `ERROR_INVALID_FUNCTION` (1). When a test asserts on an error code, assert on the Win32 one — and use `!error` in WinDbg to translate either direction.

Overlapped I/O

```
static void TestOverlapped(void)
{

/* THIS IS HOW A REAL APPLICATION handles hot-plug: it
   registers for the interface class, opens the device on
   arrival, and closes its handles on query-remove. An
   application that keeps a handle open through a removal
   attempt is what makes "Windows cannot stop this device"
   dialogs appear.                                       */
```

Measuring the difference

```
static void Benchmark(void)
{
        HANDLE h;
        BYTE buf[64];
        DWORD read;
        LARGE_INTEGER freq, start, end;
        int i;
        const int N = 2000;

        QueryPerformanceFrequency(&freq);

        /* --- synchronous --- */
        h = RbOpen(FALSE);
        if (h == INVALID_HANDLE_VALUE)
                return;

        QueryPerformanceCounter(&start);
        for (i = 0; i < N; i++) {
                if (!ReadFile(h, buf, sizeof(buf), &read, NULL))
                        break;
        }
        QueryPerformanceCounter(&end);
        CloseHandle(h);

        printf("sync:  %d reads in %.1f ms (%.1f us each)\n",
               i,
               (end.QuadPart - start.QuadPart) * 1000.0
                       / freq.QuadPart,
               (end.QuadPart - start.QuadPart) * 1e6
                       / freq.QuadPart / (i ? i : 1));

        /* --- the completion-port version, for comparison --- */
        TestCompletionPort(2);
}

/* WHAT YOU WILL SEE: with the driver's 100 ms timer, the
   synchronous loop is limited to roughly one read per timer
   tick, because each read blocks until data arrives. The
   completion-port version keeps eight requests outstanding
   and drains a whole tick's data at once.

   THE LESSON, and it is the reason asynchronous I/O exists:
   the bottleneck is not CPU time, it is the round trip. Depth
   hides latency. Exactly the argument for batching across any
   expensive boundary - the same one as SMC calls in isolation
   chapter 11.                                                */

int main(int argc, char **argv)
{
        const char *what = (argc > 1) ? argv[1] : "all";

        if (!strcmp(what, "all") || !strcmp(what, "sync")) {
                printf("--- round trip ---\n");  TestRoundTrip();
                printf("--- config ---\n");      TestConfig();
        }
        if (!strcmp(what, "all") || !strcmp(what, "async")) {
                printf("--- overlapped ---\n");  TestOverlapped();
                printf("--- iocp ---\n");        TestCompletionPort(3);
        }
        if (!strcmp(what, "all") || !strcmp(what, "bench")) {
```

```
                printf("--- benchmark ---\n");   Benchmark();
        }
        if (!strcmp(what, "watch"))
                WatchDevice();

        return 0;
}
```

Running it

```
# Build (from a Developer Command Prompt):
    cl /W4 /Zi rbtest.c setupapi.lib cfgmgr32.lib

# With the driver installed (chapter 23):
    rbtest.exe
      opening \\?\root#system#0000#{8f3a2b1c-...}
      --- round trip ---
      wrote 256
      read 256
      cap=4096 used=0 written=256 read=256 drops=0 ticks=41 pending=0
      --- config ---
      bad config refused: 87 (expect 87)
      --- overlapped ---
      issuing an async read...
      pending - doing other work
      ...other work done, now waiting
      async read completed: 64 bytes
      --- iocp ---
      152 completions, 9728 bytes in 3 s (50.7 completions/s)

# NOTE the completion rate tracks the driver's timer period -
# 50 ms in the config test means ~20 ticks/second, times the
# bytes per tick divided by the read size. If your numbers do
# not line up, work out why: that arithmetic is a good check
# that you understand what the driver is doing.

# Hot-plug behaviour:
    rbtest.exe watch
    ; then, in another window:
    devcon disable root\ringbuf
    devcon enable root\ringbuf

# ACCESS CONTROL - confirm the SDDL works (chapter 23):
    ; as a standard user, not an administrator:
    rbtest.exe
      CreateFile: 5           ; ERROR_ACCESS_DENIED - correct
```

Exercises

CLIENT-SIDE EXERCISES

1. **Handle removal properly.** Extend `WatchDevice` to close its handle on query-remove and reopen on arrival. Verify the device can then be disabled without a "device in use" dialog.
2. **Vary the queue depth** in the completion-port test from 1 to 32 and plot completions per second. Find where it stops improving, and explain why.
3. **Cancel deliberately.** Issue ten reads, then `CancelIoEx` them all. Confirm each completes with `ERROR_OPERATION_ABORTED`, and check the driver's stats for consistency.
4. **Kill the process** with reads outstanding. Confirm the process terminates promptly — this exercises the driver's cleanup path (chapter 04).
5. **Two processes at once.** Run two clients reading concurrently. Observe how the ring's single read position makes them compete — then decide whether that is the semantics you want, which is exercise 10 of chapter 23.
6. **Fuzz it yourself.** Send random control codes, random buffer sizes, and NULL pointers. With Driver Verifier on, anything that bugchecks is a driver bug.
7. **Add a 32-bit build** of the client and run it against the 64-bit driver. Confirm the structs still work — that is what the fixed-width types in `ringbuf.h` bought you (chapter 16).

Linux and Windows, side by side

Task	Linux (ch. 28)	Windows (ch. 23)
Find the device	Fixed path `/dev/ringbuf`	Enumerate by interface GUID
Open	`open()`	`CreateFileW`
Blocking read	`wait_event_interruptible`	Forward to a manual queue
Wake the reader	`wake_up_interruptible`	`WdfIoQueueRetrieveNextRequest` + complete
Readiness notification	`poll()` / `.poll`	Overlapped I/O + completion port
Control interface	`ioctl` with `_IOR` / `_IOW`	`DeviceIoControl` with `CTL_CODE`
Access control	udev rule on the node	SDDL in the INF + the IOCTL Access field
Per-open state	`file->private_data`	WDFFILEOBJECT context
Cancellation	Signal interrupts the wait	`CancelIoEx`, handled by the queue
Cleanup on exit	`release()`	`IRP_MJ_CLEANUP`, automatic in WDF
Install	`insmod`	INF + `pnputil` + signing
Verification	KASAN, lockdep, sparse	Driver Verifier, SDV, Code Analysis

The two drivers solve an identical problem, and the differences are almost entirely about *who is responsible for what*: Linux gives you primitives and expects the driver to compose them; Windows gives you a framework that owns the protocol and calls you at the right moments. Neither is better in the abstract — but knowing both makes the trade-offs in each visible, which is exactly what the next chapter is about.

Check yourself

- ✓ Open a device by interface GUID, using the two-call idiom correctly.
- ✓ Explain why Win32 error codes differ from NTSTATUS and how to translate.
- ✓ Issue an overlapped read and handle `ERROR_IO_PENDING` correctly.
- ✓ Build a completion-port loop that keeps N requests outstanding.
- ✓ Explain `CONTAINING_RECORD` and why `OVERLAPPED` comes first.
- ✓ Register for device arrival and removal, and respond to query-remove correctly.
- ✓ Measure synchronous versus asynchronous throughput and explain the gap.
- ✓ Verify the driver's access control from a non-administrator account.
- ✓ Complete at least four of the seven exercises.
- ✓ Fill in the Linux/Windows comparison table from memory.

Linux and Windows drivers compared

Two operating systems solving identical problems with opposite philosophies. Having built a driver in each, the comparison is now concrete — and it is the fastest way to see what each design actually costs and buys.

The root difference

```
ONE DECISION EXPLAINS ALMOST EVERYTHING ELSE:

LINUX: NO STABLE INTERNAL ABI.
   The kernel may refactor any interface at any time,
   because it can fix every in-tree driver in the same
   commit.

   -> drivers must be UPSTREAM to survive
   -> therefore the source is public
   -> therefore review is by humans reading code
   -> therefore no signing requirement, no certification
   -> therefore no framework is needed: the core can be
      changed to suit the drivers
   -> and an out-of-tree driver is a permanent maintenance
      liability (Linux ch. 30)

WINDOWS: A STABLE DRIVER ABI, FOR DECADES.
   A driver from 2015 often still loads.

   -> drivers ship as closed binaries
   -> therefore Microsoft never sees the source
   -> therefore review must be MECHANICAL: static
      analysis, Driver Verifier, HLK
   -> therefore signing is mandatory - identity is the only
      accountability available
   -> therefore a FRAMEWORK (WDF) is needed, because the
      protocol cannot be simplified by changing the core
   -> and installation needs a declarative package (the
      INF) rather than "copy the file"

NEITHER IS WRONG. They are consistent answers to: who is
responsible for keeping drivers working?
  Linux says: the kernel community, for code it can see.
  Windows says: the vendor, for code it cannot.
```

Concept map

Concept	Linux	Windows
Execution constraint	Context (process / softirq / hardirq / atomic)	IRQL, an explicit number
"Can I sleep?"	Am I in atomic context?	Is IRQL ≤ APC_LEVEL?
Deferred work tiers	hardirq → softirq/tasklet → workqueue	ISR → DPC → work item
Threaded interrupt	`request_threaded_irq`	`PassiveHandling`
Allocation	`kmalloc(size, GFP_*)`	`ExAllocatePool2(flags, size, tag)`
Pageable kernel memory	**None**	Paged pool — the extra rule
Object cache	`kmem_cache`	Lookaside list

Concept	Linux	Windows
Managed cleanup	`devm_*`	WDF object parenting
Per-device data	`drvdata`	Device context / DeviceExtension
Per-open data	`file->private_data`	WDFFILEOBJECT context
Request object	Per-subsystem (bio, urb, skb)	The IRP, universally
Layering	Per-subsystem	The device stack, universally
Hardware description	Device tree	ACPI + registry, written by the INF
Binding	`compatible` string	Hardware ID + INF rank
User interface	char dev, sysfs, or a subsystem	Device interface GUID + IOCTLs
Readiness	`poll()`	Overlapped I/O
Memory safety tool	KASAN	Special pool
Lock checking	lockdep	Verifier deadlock detection
Fault injection	`CONFIG_FAILSLAB`	Low resources simulation
Sleeping-in-atomic check	`DEBUG_ATOMIC_SLEEP`	Force IRQL checking
Static analysis	sparse, coccinelle, smatch	Code Analysis, SDV
Debugger	printk, ftrace, kgdb (rarely)	WinDbg (routinely)
Tracing	ftrace, trace events	WPP, ETW

Where each is genuinely easier

Task	Easier on	Why
Getting a first driver running	**Linux**	`insmod`, no signing, no INF, no reboot
The edit–build–test loop	**Linux**	Module reload in a second; QEMU for free
Reading how something works	**Linux**	The source of every driver in the tree is a worked example
Asking for help	**Linux**	Public archives of every design discussion
PnP, hot-plug, surprise removal	**Windows**	WDF implements the whole state machine
Request cancellation	**Windows**	Queues own it; the WDM-era race is gone
Power management	**Windows**	S0 idle policy is declarative
Layering and filtering	**Windows**	Universal, not per-subsystem
Finding your own bugs	**Windows**	Verifier + SDV + HLK are unmatched
Post-mortem debugging	**Windows**	WinDbg on a real dump beats reading a printk log
Keeping a driver working for ten years	**Windows** if out-of-tree, **Linux** if upstream	The ABI decision, from both directions
Shipping to a closed hardware ecosystem	**Windows**	The model was designed for exactly that
Shipping an embedded product you control	**Linux**	No signing gate, full source control

> **THE HONEST SUMMARY**
> Linux is easier to *start* with and easier to *learn from*, because everything is readable and the loop is fast. Windows is better at *keeping you correct*, because the framework owns the hard protocols and the verification tooling finds the bugs mechanically. A developer who has done both tends to want Linux's iteration speed and Windows' verifiers — and, in practice, to bring habits from each into the other: annotating invariants like SAL, and running the negative-test discipline that the HLK enforces.

What is the same everywhere

```
Strip away the APIs and the same problems remain, because
they come from the HARDWARE, not the OS:

  · an interrupt handler must be short, because it blocks
    everything else
  · deferred work needs a tier that can sleep and one that
    cannot
  · shared data needs a lock chosen by the highest-priority
    context that touches it
  · a lock held too long is a latency bug for the whole system
  · DMA needs the device's address, not the CPU's, and the
    pages must be pinned
  · caches must be maintained, or coherent hardware must do it
  · the power-up sequence in the datasheet is a specification
  · resources must be acquired in order and released in
    reverse
  · teardown must stop the source before waiting for what is
    in flight
  · every input crossing a trust boundary must be validated,
    copied in, and bounded
  · hardware that stops responding must produce a timeout,
    never an infinite wait
  · error paths are the least-tested code and need mechanical
    exercise

  THAT LIST is what this whole track has actually been about.
  The two dialects are how you say it; the list is what you
  say.
```

Porting between them

```
/* If you must support both - which is common for a chip
   vendor - structure the driver so the shared part is real. */

   +-----------------------------------------------+
   |  HARDWARE LOGIC - shared, portable C          |
   |    register definitions                       |
   |    the state machine                          |
   |    protocol encoding and decoding             |
   |    NO OS calls at all                         |
   +-----------------------------------------------+
              |                       |
   +----------v---------+   +---------v-----------+
   |  LINUX SHIM        |   |  WINDOWS SHIM       |
   |   readl/writel     |   |   READ_REGISTER_*   |
   |   spin_lock        |   |   WdfSpinLockAcquire|

   +--------------------+   +---------------------+

/* DEFINE A THIN OS ABSTRACTION and implement it twice: */

         osal_reg_read32(dev, offset)
         osal_reg_write32(dev, offset, value)
         osal_lock_acquire(lock)
         osal_alloc(size)
         osal_delay_us(n)
         osal_log(level, fmt, ...)

/* WHAT PORTS WELL:  register access, hardware sequences,
   protocol logic, data formats, error decoding.

   WHAT DOES NOT:    everything about the OS - PnP, power,
   queueing, buffering, cancellation, installation, security.
   Do NOT try to abstract those; the models are too different
   and the abstraction becomes worse than either.

/* THE REALISTIC SPLIT on a typical device driver: 30-40% of
   the code is hardware logic and shareable; the rest is OS
   integration, written twice. That is still a large saving,
   and more importantly it means the hardware behaviour is
   defined in ONE place, so a silicon erratum workaround is
   applied once rather than diverging.                    */
```

Which to learn

```
EMBEDDED LINUX dominates:
  · phones, tablets, TVs, set-top boxes
  · automotive infotainment and increasingly ADAS
  · networking equipment, from home routers to core
  · industrial control, robotics, drones
  · almost everything running on an ARM SoC that is not a
    microcontroller
  -> if "embedded" is your field, Linux is the default and
     this is where the jobs are

WINDOWS DRIVERS dominate:
  · PC peripherals of every kind
  · enterprise storage and networking hardware
  · specialised industrial and medical equipment on
    Windows
  · anything sold into a Windows-first ecosystem
  -> a smaller field, with fewer people who know it well,
     and correspondingly good demand

LEARNING BOTH is worth more than the sum: each makes the
other's design decisions visible. You cannot really see
why Linux has no stable ABI until you have felt what a
stable one costs, and you cannot appreciate what WDF does
until you have hand-written a cancellation path.

AND THE HARDWARE KNOWLEDGE - the ARM architecture,
isolation, memory ordering, DMA, caches, interrupts, power -
TRANSFERS COMPLETELY. That is the durable part, and it is
why the tracks before these two are the foundation rather
than the preamble.
```

A driver review checklist, either OS

Check	Linux	Windows
Every allocation checked	Fault injection	Low resources simulation
No sleeping in atomic context	`DEBUG_ATOMIC_SLEEP`	Force IRQL checking
No unbounded waits	`wait_event_*_timeout`	Timeouts on every wait
Locks consistent and ordered	lockdep	Verifier deadlock detection
All input validated	Review + fuzzing	IoAttack + Code Analysis
Teardown stops the source first	`_sync` everywhere	`TRUE` wait arguments
Removal handled	unbind/bind loop	HLK Surprise Remove
No resource leaks	kmemleak, 100 cycles	Pool tracking, 50 cycles
Memory errors	KASAN	Special pool
DMA correct	`DMA_API_DEBUG`	Verifier DMA checking
Power cycle survives	suspend/resume loop	`pwrtest /sleep`
Static analysis clean	sparse, `W=1`, checkpatch	Code Analysis, SDV

Every row is the same requirement expressed twice. A driver that passes the whole column on either system is a genuinely solid driver — and the tools that verify it are free on both.

Check yourself

- ✓ State the root difference between the two systems and derive four consequences from it.
- ✓ Translate fifteen concepts from one dialect to the other.
- ✓ Say which system is easier for six specific tasks, with the reason.
- ✓ List twelve problems that are identical on both, and explain why.
- ✓ Design a portable driver split and say what should not be abstracted.
- ✓ Estimate what fraction of a real driver is shareable.
- ✓ Say which system dominates in which markets, and what transfers between them.
- ✓ Run the twelve-row review checklist against a driver you have written.

END OF THE WINDOWS TRACK

Twenty-five chapters, from NT architecture to a signed, verified driver and its client. With the Linux track before it, you have now built the same device twice on two operating systems — which is the point at which driver development stops being a set of recipes and becomes a set of principles. Next: compilers and toolchains, which explains what has been turning all of this code into instructions.

Project: a TrustZone-backed crypto driver in C++

A Windows KMDF driver on ARM64 that hashes with CNG in the normal world, sends only the digest across a transport into the secure world, and returns a signature made by a key it has never seen. This chapter builds the Windows half; chapter 27 builds the trusted application and runs the whole thing on QEMU.

Read this before you start

Windows on ARM does not talk to OP-TEE. That is not a gap in your knowledge; it is the actual state of the world, and the project is designed around it rather than pretending otherwise.

Claim	Reality
"Windows uses OP-TEE for TrustZone"	**No.** Windows reaches the secure world through **TrEE** (Trusted Execution Environment), a class-extension driver model. The secure-side implementation is the silicon vendor's — QSEE/QTEE on Qualcomm parts, not OP-TEE
"A KMDF driver can issue an SMC"	**No.** There is no documented SMC API for ordinary Windows drivers. The world switch belongs to the TrEE provider, which is firmware-adjacent and vendor-supplied
"Windows and OP-TEE can run together under TF-A"	In principle. In practice no public TrEE provider speaks the OP-TEE SMC ABI, so nothing bridges them
"Windows ARM64 runs under QEMU"	**Yes**, via UEFI, slowly but usably. That part is real

SO WHAT ARE WE ACTUALLY BUILDING?

A driver whose *transport is a seam*. Above the seam — the IOCTL surface, the CNG hashing, the command ABI, the trusted application, the user-mode client — everything is real and production-shaped. Below it there are two implementations: **TrEE**, which is what you would ship on hardware, and a **shared-memory mailbox**, which is what actually runs on QEMU. The driver does not know or care which one it has.

```
WINDOWS ARM64 GUEST                          THE SECURE SIDE

+--------------------------------------+
| secteectl.exe   (user mode, C++)     |
|   CreateFile on the device interface |

|  * SHA-256 with CNG (ksecdd)  <--- the "crypto driver"
|  * ECDSA verify with CNG           part: normal-world
|  * marshals a command              crypto stays here
|  * ITeeTransport::Invoke()         |
+------------------+-------------------+
                   |
     +-------------+--------------+
     |                            |
ON HARDWARE                   ON QEMU
TreeTransport                 MailboxTransport
TrEE class extension          ivshmem BAR2 + doorbell
     |                            |
     v                            v
TrustZone, S-EL1              a second VM running
vendor trusted OS             OP-TEE, bridged by a
                              host daemon (chapter 27)
                                    |
                                    v
                         +--------------------------+
                         | sectee_ta  (S-EL0, C++)  |
                         |   P-256 key, made and    |
                         |   kept inside            |
                         |   ECDSA sign             |
                         +--------------------------+

WHAT IS HONEST ABOUT THE QEMU PATH:
  the isolation you get is VM isolation between two QEMU
  instances, NOT TrustZone isolation. It exercises every
  line of software and proves the protocol; it does not
  prove the security property. Chapter 27 says so again,
  louder.
```

C++ in a Windows kernel driver

The WDK compiles C++ perfectly well. What it does not give you is a C++ *runtime*: there is no CRT startup to run your global constructors, no exception unwinder, and no heap behind `new`. You get the language, and you supply the plumbing.

```
// SecTee/Kernel/CppSupport.h
//
// Everything C++ needs from us before the language works in
// kernel mode. About forty lines, written once, reused for ever.

#pragma once
#include <ntddk.h>

#define SECTEE_POOL_TAG 'eeTS'   // "STee" reversed, as WinDbg
                                 // displays tags little-endian

// ---------------------------------------------------------------
// operator new / delete
//
// We deliberately do NOT define a global parameterless `new`.
// Every allocation must name its pool, because getting NonPaged
// vs Paged wrong is a bugcheck at DISPATCH_LEVEL, and a default
// makes it easy to not think about it.
// ---------------------------------------------------------------
_IRQL_requires_max_(DISPATCH_LEVEL)
inline void* __cdecl operator new(size_t size, POOL_FLAGS flags,
                                  ULONG tag)
{
    if (size == 0) size = 1;
    // ExAllocatePool2 zeroes by default and is the modern spelling;
    // ExAllocatePoolWithTag is deprecated and fails WDK analysis.
    return ExAllocatePool2(flags, size, tag);
}

inline void __cdecl operator delete(void* p, size_t)
{
    if (p) ExFreePoolWithTag(p, SECTEE_POOL_TAG);
}
inline void __cdecl operator delete(void* p)
{
    if (p) ExFreePoolWithTag(p, SECTEE_POOL_TAG);
}

// Placement new, for constructing into memory WDF already owns
// (a WDFDEVICE context, for instance).
inline void* __cdecl operator new(size_t, void* where) { return where; }
inline void  __cdecl operator delete(void*, void*) {}

// ---------------------------------------------------------------
// The compiler emits a reference to this for any file-scope object
// with a destructor. We never rely on static destruction, but the
// symbol must exist to link.
// ---------------------------------------------------------------
extern "C" int __cdecl atexit(void (__cdecl*)(void)) { return 0; }
extern "C" void* __dso_handle = nullptr;

// ---------------------------------------------------------------
// A scope guard. This is most of the reason to use C++ here: it
// replaces the goto-cleanup ladder that every C driver grows.
// ---------------------------------------------------------------
template <typename F>
class ScopeExit
{
public:
    explicit ScopeExit(F f) : m_f(f), m_armed(true) {}
    ~ScopeExit() { if (m_armed) m_f(); }
    void Dismiss() { m_armed = false; }
```

```
    ScopeExit(const ScopeExit&)            = delete;
    ScopeExit& operator=(const ScopeExit&) = delete;
private:
    F    m_f;
    bool m_armed;
};

template <typename F>
ScopeExit<F> MakeScopeExit(F f) { return ScopeExit<F>(f); }

#define SECTEE_CONCAT2(a, b) a##b
#define SECTEE_CONCAT(a, b)  SECTEE_CONCAT2(a, b)
#define SECTEE_ON_EXIT(code) \
    auto SECTEE_CONCAT(guard_, __LINE__) = MakeScopeExit([&]() { code; })
```

THE FOUR PROJECT SETTINGS THAT MAKE THIS LEGAL

In the `.vcxproj`: `<CompileAs>CompileAsCpp</CompileAs>`, `<RuntimeTypeInfo>false</RuntimeTypeInfo>` (`/GR-`), `<ExceptionHandling>false</ExceptionHandling>` (`/EHs-c-`), and the `/kernel` switch, which makes the compiler *reject* constructs that need a runtime rather than letting them link and fail at load. Turn `/kernel` on first, not last — it tells you immediately which C++ you are not allowed to have.

```
   WHAT YOU MAY USE          WHAT YOU MAY NOT

   classes, members          exceptions (try/catch/throw)
   constructors/destructors  RTTI (dynamic_cast, typeid)
   RAII and scope guards     the STL - all of it
   templates                 std::string, std::vector, ...
   references                global objects with constructors
   overloading               new/delete without a pool
   constexpr, enum class     virtual inheritance games
   lambdas (no captures      thread_local
     that allocate)          floating point (without
   nullptr, auto               KeSaveFloatingPointState)

   The STL exclusion is not snobbery: every container allocates
   from a heap that does not exist here, and throws on failure
   in a context with no unwinder. Write the two or three small
   containers you need, or use WDF's collections.
```

The ABI

```
// SecTee/Common/SecTeeAbi.h
//
// Shared verbatim by the driver, the user-mode client and (via a
// C-compatible subset) the trusted application. One file, three
// consumers, no numbers written twice.

#pragma once

#ifdef _KERNEL_MODE
#include <ntddk.h>
#else
#include <windows.h>
#endif

#include <initguid.h>

// The device interface the client opens. A GUID, not a fixed
// symbolic-link name, so several instances can coexist and
// SetupDi can enumerate them (chapter 19).
// {6F1A2B3C-4D5E-4F60-9A1B-2C3D4E5F6071}
DEFINE_GUID(GUID_DEVINTERFACE_SECTEE,

} SECTEE_COUNTER_INOUT;

#include <poppack.h>

// Commands on the far side of the transport. Deliberately NOT the
// same numbers as the IOCTLs: the driver is a translator, and the
// two interfaces are allowed to version independently.
#define TA_CMD_GET_PUBKEY 0u
#define TA_CMD_SIGN       1u
#define TA_CMD_COUNTER    2u
```

WHY THE DRIVER HASHES AND THE TA ONLY SIGNS

The same split as the Rust project, for the same reason: bulk data is not secret, and pushing 64 KB through a transport into a secure world with a few hundred kilobytes of heap is slow and pointless. Only the 32-byte digest crosses. The private key is the one thing that must not leak, so it is the one thing that lives on the far side.

The transport seam

```
// SecTee/Kernel/ITeeTransport.h
#pragma once
#include "CppSupport.h"
#include "..\Common\SecTeeAbi.h"

// A pure interface. This is where C++ earns its place a second
// time: two wildly different mechanisms behind one vtable, chosen
// at PrepareHardware, with no #ifdefs sprayed through the driver.
class ITeeTransport
{
public:
    virtual ~ITeeTransport() {}

    // Called at PASSIVE_LEVEL from EvtDevicePrepareHardware.
    virtual NTSTATUS Start(WDFDEVICE Device,
                           WDFCMRESLIST Raw,
                           WDFCMRESLIST Translated) = 0;

    virtual void Stop() = 0;

    // One request into the secure world and back.
    //   Command  - TA_CMD_*
    //   In/InLen - marshalled input, may be null
    //   Out      - buffer for the reply
    //   InOutLen - in: capacity of Out; out: bytes produced
    //
    // PASSIVE_LEVEL only. Every implementation may block.
    _IRQL_requires_(PASSIVE_LEVEL)
    virtual NTSTATUS Invoke(ULONG Command,
                            const void* In,  ULONG InLen,
                            void* Out, ULONG* InOutLen) = 0;
};

// Factories. Exactly one is compiled in, selected by the INF's
// hardware ID match - see the two INF sections at the end.
NTSTATUS CreateMailboxTransport(ITeeTransport** Out);   // QEMU
NTSTATUS CreateTreeTransport(ITeeTransport** Out);      // hardware
```

The production transport: TrEE

```
// SecTee/Kernel/TreeTransport.cpp
//
// The shape of the production path. Windows exposes the secure
// world to drivers through the Trusted Execution Environment class
// extension: your driver is a "TrEE service driver", it links
// against the TrEE ClassExtension, and it addresses a trusted
// application by GUID.
//
// HONEST CAVEAT: the exact class-extension entry points and the
// structures they take differ between WDK releases, and the
// interface is thinly documented compared with the rest of WDF.
// The sequence below is correct in SHAPE - open a session to a TA
// by GUID, marshal parameters, send, read the reply, close - and
// you should take the precise spellings from the
// TrustedRuntime headers in the WDK you are building against.
//
// Everything above this file is unaffected either way, which is
// the whole argument for the ITeeTransport seam.

#include "ITeeTransport.h"

class TreeTransport : public ITeeTransport
{
public:
    NTSTATUS Start(WDFDEVICE Device, WDFCMRESLIST, WDFCMRESLIST) override
    {
        m_Device = Device;

        // 1. Attach to the TrEE class extension for this device.
        //    The platform's TrEE provider - vendor firmware glue -
        //    is what actually performs the world switch.
        //
        // 2. Open a session to our trusted application, addressed
        //    by its GUID. On Windows a TA is identified by a GUID
        //    rather than the 16-byte UUID OP-TEE uses; they are
        //    the same 128 bits in a different textual convention.
        //
        // 3. Cache the session handle for the driver's lifetime,
        //    exactly as the mailbox transport caches its mapping.

        return STATUS_NOT_IMPLEMENTED;   // see caveat above
    }

    void Stop() override
    {
        // Close the session, then detach from the class extension.
        // Reverse order of Start, always.
    }

    NTSTATUS Invoke(ULONG Command,
                    const void* In, ULONG InLen,
                    void* Out, ULONG* InOutLen) override
    {
        UNREFERENCED_PARAMETER(Command);
        UNREFERENCED_PARAMETER(In);
        UNREFERENCED_PARAMETER(InLen);
        UNREFERENCED_PARAMETER(Out);
        UNREFERENCED_PARAMETER(InOutLen);

        // Marshal into the TrEE parameter list - the same
        // four-slot value/memref model GlobalPlatform uses
```

```
        // (chapter 12), because both descend from the same
        // TEE Client API specification.
        //
        // Then issue the command and map the returned status
        // onto an NTSTATUS with the table below.
        return STATUS_NOT_IMPLEMENTED;
    }

private:
    WDFDEVICE m_Device = nullptr;
};

    if (!t) return STATUS_INSUFFICIENT_RESOURCES;
    *Out = t;
    return STATUS_SUCCESS;
}
```

The transport that runs: a shared-memory mailbox

```
// SecTee/Kernel/MailboxTransport.cpp
//
// Runs on QEMU against an ivshmem device, which gives us a PCI
// function with:
//   BAR0  256 bytes of registers, including a doorbell
//   BAR2  a shared memory window, visible to another VM
//
// The far end is a daemon in a second VM that owns the same
// memory and calls into OP-TEE. Chapter 27 builds it.
//
// No QEMU patching is required: ivshmem is a stock device.

#include "ITeeTransport.h"

The crypto half: CNG in kernel mode

This is the part that makes it a *crypto driver* rather than a pipe. Windows exposes CNG to kernel drivers through `ksecdd.sys`; the API is the same `BCrypt*` surface user mode gets, with two extra rules.

```
// SecTee/Kernel/Crypto.cpp
//
// RULE 1: pass BCRYPT_PROV_DISPATCH when opening an algorithm
//         provider in kernel mode. Without it the call fails.
// RULE 2: PASSIVE_LEVEL only. CNG allocates and may page.
//
// Link against ksecdd.lib.

    // STATUS_INVALID_SIGNATURE on mismatch, STATUS_SUCCESS on match.
}
```

TWO ECOSYSTEMS, TWO SIGNATURE ENCODINGS

The TA produces raw `r || s`, 64 fixed bytes. **CNG takes that directly. OpenSSL does not** — it wants an ASN.1 `SEQUENCE` of two `INTEGER`s, which is why the Rust project needed a conversion step and this one does not. Neither is more correct; they are different conventions with the same mathematics underneath, and knowing which side wants which saves an afternoon every single time.

```

THE OVERREAD THIS CODE IS WRITTEN TO AVOID

`SECTEE_SIGN_IN::DataLength` is a number the caller chose. The buffer size is a number the I/O manager measured. Hashing `DataLength` bytes without checking it against `InputBufferLength - FIELD_OFFSET(...)` reads past the system buffer into whatever pool follows — a kernel information disclosure straight back to the caller, since the digest goes in the output. Check the claim against the measurement, every time, for every variable-length field.

The user-mode client

```
// SecTee/Client/secteectl.cpp
//
// Finds the device by interface GUID rather than by a hard-coded
// name, which is what lets the driver be installed more than once
// and is what SetupDi exists for (chapter 24).

REM Building. From an ARM64 Developer Command Prompt for the WDK.

msbuild SecTee.sln /p:Configuration=Release /p:Platform=ARM64

REM Test-sign it, because an unsigned driver will not load
REM (chapter 20). On the TARGET machine, once:
bcdedit /set testsigning on
shutdown /r /t 0

REM Then, on the target, as Administrator:
certmgr /add SecTee.cer /s /r localMachine root
certmgr /add SecTee.cer /s /r localMachine trustedpublisher
pnputil /add-driver SecTee.inf /install

REM Confirm:
pnputil /enum-devices /class System /connected
sc query SecTee
```

How it shows up

Symptom	Cause
Link error: unresolved `operator new`	`CppSupport.h` not included, or a parameterless `new` used somewhere
Link error: `_purecall`, `__CxxFrameHandler`, `atexit`	Exceptions or RTTI still enabled, or a global object with a constructor
Driver loads, then bugchecks on first IOCTL	CNG called above PASSIVE_LEVEL — set `ExecutionLevel = WdfExecutionLevelPassive` on the queue
`BCryptOpenAlgorithmProvider` returns `STATUS_INVALID_PARAMETER`	`BCRYPT_PROV_DISPATCH` not passed
Unresolved `BCrypt*` at link	`ksecdd.lib` not in the linker inputs
`STATUS_DEVICE_NOT_READY` from PrepareHardware	Mailbox magic absent — the far-end daemon is not running (chapter 27)
Every request times out after 5 s	Doorbell going to the wrong peer, or the daemon is not watching the doorbell
Ack never observed although the daemon says it replied	Shared memory mapped cached — must be `PAGE_NOCACHE`
`STATUS_REVISION_MISMATCH`	Client and driver built against different `SecTeeAbi.h`
Signature verifies with CNG, fails with OpenSSL	Expected — OpenSSL needs DER, CNG needs raw r‖s
Public key rejected by CNG	The `0x04` SEC1 prefix was included; CNG's `BCRYPT_ECCKEY_BLOB` does not take it
Driver will not install: "third-party INF does not contain digital signature information"	Not test-signed, or test signing is off on the target
Verifier flags a pool leak on unload	`ReleaseHardware` not deleting the transport, or an early-return path in `PrepareHardware` without the scope guard

Check yourself

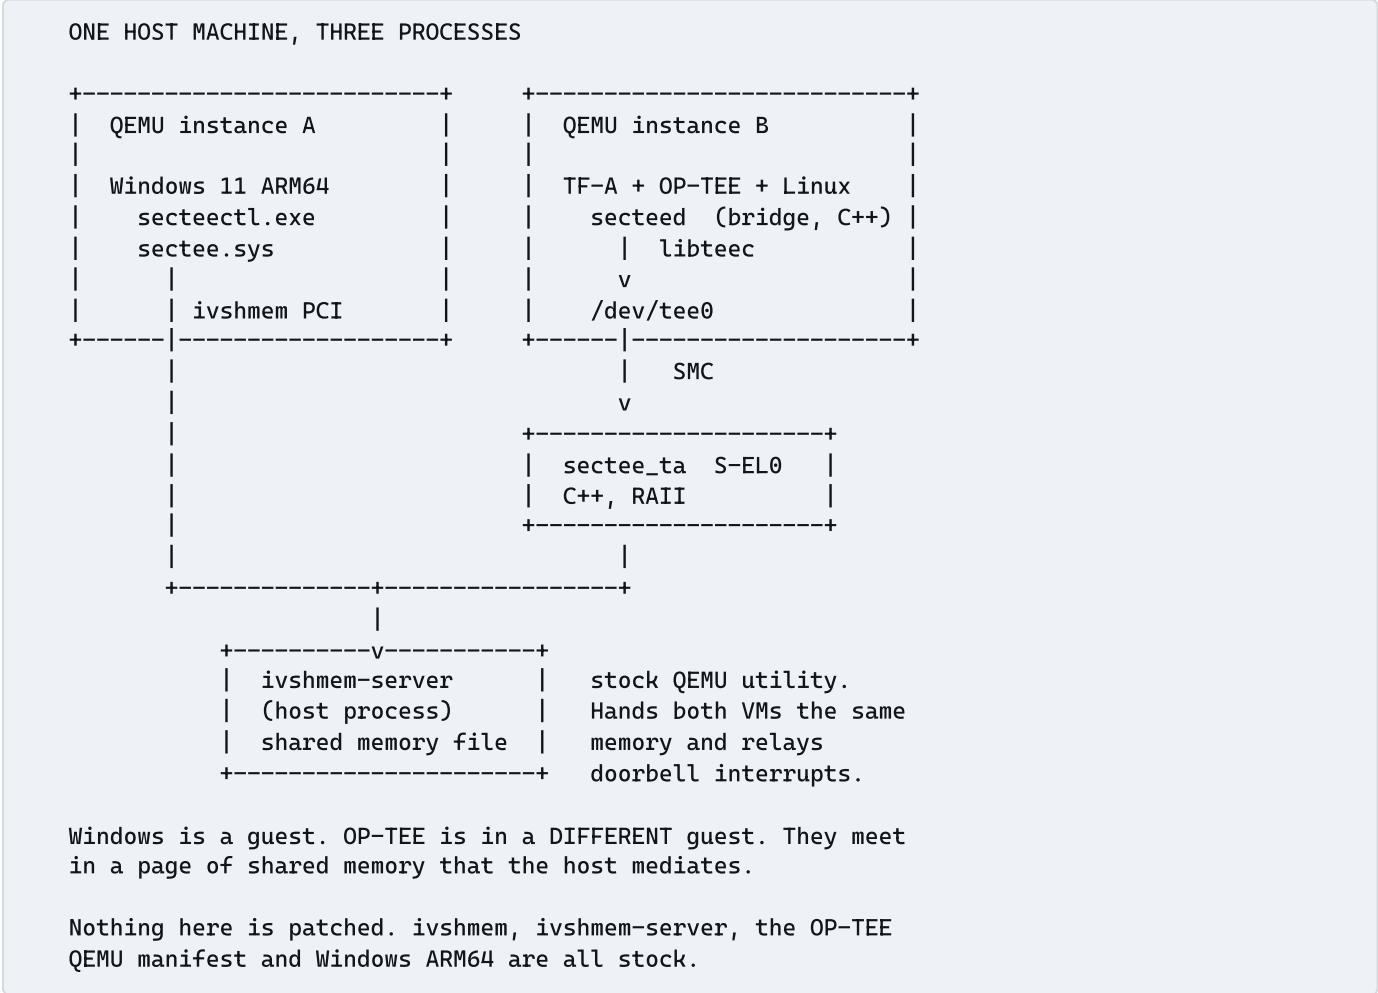
- ✓ State what Windows actually uses to reach the secure world on ARM, and why this project needs a transport seam.
- ✓ Say precisely which security property the QEMU configuration does *not* demonstrate.

- ✓ List four things C++ gives you in a kernel driver and four it forbids, with the reason for each prohibition.
- ✓ Explain why `operator new` here takes a pool type instead of defaulting.
- ✓ Justify `METHOD_BUFFERED` for this ABI and say when you would switch.
- ✓ Explain why `DataLength` must be checked against `InputBufferLength`, and what leaks if it is not.
- ✓ Give the two extra rules for calling CNG from kernel mode.
- ✓ Explain why the driver hashes but the TA signs.
- ✓ State the difference between CNG's and OpenSSL's ECDSA signature encodings, and which one the TA emits.
- ✓ Explain why the shared memory must be mapped non-cached.
- ✓ Point to the memory barrier before the sequence increment and say what it prevents.
- ✓ Trace one `secteectl sign` from `DeviceIoControl` to the transport and back, naming every buffer the data occupies.

Project: the trusted application, and running it on QEMU

The secure half of the project: an OP-TEE trusted application written in C++, a bridge daemon that connects it to the Windows guest, and the two-VM QEMU topology that lets you run the whole thing on a laptop. Plus an honest accounting of which security properties this configuration demonstrates and which it only simulates.

The topology



WHAT THIS CONFIGURATION DOES AND DOES NOT PROVE

Does: that the driver, the ABI, the marshalling, the trusted application and the client are all correct; that a key generated inside OP-TEE signs digests the Windows guest computes; that CNG in the Windows kernel accepts those signatures. Every line of software is exercised for real.

Does not: demonstrate TrustZone isolation. The Windows guest is separated from the TA by *VM boundaries*, not by the NS bit. On production hardware the same driver reaches the same TA through TrEE and the isolation is real; here it is a development harness. Never quote a QEMU run as evidence of a security property.

Why write a TA in C++

Not for templates or the STL — neither is available. For one thing only, and it is worth the whole chapter: **destructors**. Compare the C key-store TA of OP-TEE chapter 21 with what follows.

```
   THE C SHAPE, from chapter 21          THE C++ SHAPE

   TEE_ObjectHandle  obj = NULL;         {
   TEE_OperationHandle op = NULL;            PersistentKey key(id);
   res = open(&obj);                         if (!key) return key.Error();
   if (res) goto out;
   res = TEE_AllocateOperation(&op...);      SignOperation op(key);
   if (res) goto out;                        if (!op) return op.Error();
   res = TEE_SetOperationKey(op, obj);
   if (res) goto out;                        return op.Sign(digest, sig);
   res = TEE_AsymmetricSignDigest(...);  }   // both freed here, on
   out:                                      // EVERY path, in reverse
       TEE_FreeOperation(op);                // order, including the
       TEE_CloseObject(obj);                 // early returns
       return res;

   A leaked TEE_OperationHandle is not a tidiness problem. The
   secure heap is a few tens of kilobytes (chapter 6); leak one
   per request and the TA panics after a few thousand
   operations, in production, weeks later, under load.

   The goto ladder works. It also breaks the moment someone adds
   a fourth resource in the middle and forgets one branch. RAII
   makes that class of bug unrepresentable.
```

THREE C++ TRAPS SPECIFIC TO A TA

Globals with constructors. There is no CRT to run them. Anything at file scope must be `constexpr` or a POD, which is why the constants above are `constexpr` and every stateful object is a local. **Function-local statics.** They emit `__cxa_guard_acquire` unless you pass `-fno-threadsafe-statics`. **Double-free.** `TEE_CloseAndDeletePersistentObject1` closes the handle itself, so an RAII wrapper must `Release()` first — closing a TEE handle twice panics the TA, and the panic appears on the secure console with a stack you will have to decode by hand (OP-TEE chapter 19).

The bridge daemon

```
// bridge/secteed.cpp
//
// Runs in the OP-TEE Linux guest. Owns the same shared memory the
// Windows driver mapped, watches the sequence number, and turns
// each request into a TEEC_InvokeCommand.
//
// Build:
//   aarch64-linux-gnu-g++ -std=c++17 -O2 -o secteed secteed.cpp \
//       -I$TEEC_EXPORT/include -L$TEEC_EXPORT/lib -lteec

04a91f3c...e7b2
```

```
# And on instance B's SECURE console, at that moment:
I/TA: sectee TA loaded
I/TA: generating a new P-256 keypair

C:\> echo hello from windows > C:\msg.txt
C:\> secteectl.exe sign C:\msg.txt
digest 9f2a7c...41
sig    4b7d2e...91

C:\> secteectl.exe verify C:\msg.txt
VALID

C:\> secteectl.exe counter
0
C:\> secteectl.exe counter inc
1
C:\> secteectl.exe counter inc
2
# Reboot instance B (not Windows) and the counter is still 2:
# it lives in OP-TEE secure storage, not in the Windows guest.
```

Proving it independently

```
# Everything above trusted our own code to check our own code.
# Take the artefacts out and verify with stock OpenSSL, which has
# never heard of OP-TEE, ivshmem or Windows.

# In Windows, capture the public key and a signature:
C:\> secteectl.exe pubkey > C:\pub.hex
C:\> secteectl.exe sign C:\msg.txt > C:\sig.txt

# Copy them out, then on any Linux box:
$ xxd -r -p pub.hex > pub.raw          # 65 bytes: 04 || X || Y
$ printf '3059301306072a8648ce3d020106082a8648ce3d030107034200' \
    | xxd -r -p > spki.der
$ cat spki.der pub.raw > pubkey.der
$ openssl ec -pubin -inform DER -in pubkey.der -out pubkey.pem
read EC key
writing EC key

# The TA emits raw r||s; OpenSSL wants DER. (CNG in the Windows
# driver took the raw form directly - chapter 26.)
$ python3 - "$(cat sig.txt)" <<'EOF' > sig.der
import sys, binascii
raw = binascii.unhexlify(sys.argv[1].strip())
r, s = raw[:32], raw[32:]
def der_int(b):
    b = b.lstrip(b'\x00') or b'\x00'
    if b[0] & 0x80: b = b'\x00' + b
    return b'\x02' + bytes([len(b)]) + b
body = der_int(r) + der_int(s)
sys.stdout.buffer.write(b'\x30' + bytes([len(body)]) + body)
EOF

$ printf 'hello from windows\r\n' > msg.txt   # note CRLF - Windows echo
$ openssl dgst -sha256 -verify pubkey.pem -signature sig.der msg.txt
Verified OK

# THAT is the result. A signature over a digest computed by CNG in
# a Windows ARM64 kernel driver, made by a key generated inside an
# OP-TEE trusted application written in C++, verified by an
# unrelated tool on a third machine.
```

> **THE CRLF TRAP**
>
> `echo hello from windows > C:\msg.txt` writes `hello from windows\r\n`, and `echo` also keeps any trailing space before the `>`. If OpenSSL says `Verification Failure`, compare the digest the driver printed with `sha256sum msg.txt` before suspecting the crypto. Nine times out of ten the bytes differ, not the mathematics.

Extensions worth doing

Exercise	What it teaches
Take the ivshmem MSI-X vector and complete requests from a DPC instead of polling	Interrupts and asynchronous request completion in WDF (chapter 17)
Make the queue parallel and give the mailbox four slots	Concurrency against a fixed-size resource, and OP-TEE's thread limit

Exercise	What it teaches
Add `IOCTL_SECTEE_SIGN_FILE` using `METHOD_OUT_DIRECT` and an MDL	Why buffered I/O stops paying at scale (chapter 18)
Run Driver Verifier with pool tracking and IRQL checking against the driver	Every latent lifetime bug at once (chapter 21)
Register the driver as a CNG key-storage provider (KSP)	How a TEE-backed key becomes usable by CertEnroll, TLS and Windows Hello rather than only by your own client
Have the TA sign the counter alongside the digest	Replay resistance (OP-TEE chapter 17)
Point the driver at a real TrEE provider on Qualcomm silicon	Whether the transport seam was honestly abstract
Run the hostile client from OP-TEE chapter 20 against the TA	Whether the validation is real
Kill `secteed` mid-request and see what the driver does	Timeout handling, and why `STATUS_IO_TIMEOUT` beats hanging for ever

How it shows up

Symptom	Cause
TA will not build: `undefined reference to __cxa_guard_acquire`	A function-local static with a constructor; add `-fno-threadsafe-statics`
TA will not build: `__gxx_personality_v0`	Exceptions still enabled — add `-fno-exceptions`
TA loads then panics immediately	A global object with a constructor that never ran; make it `constexpr` or move it into a function
TA panics on the second request	Double-close — an RAII wrapper and `TEE_CloseAndDeletePersistentObject1` both released the same handle
`TEEC_OpenSession` returns `0xFFFF0008`	The `.ta` is not in `/lib/optee_armtz`, or its filename does not match the UUID
`secteed`: cannot open `/dev/uio0`	No uio driver bound to the ivshmem PCI function; check `lspci -k`
Windows driver: `STATUS_DEVICE_NOT_READY`	`secteed` not started, so the magic was never written
Both sides running, every request times out	The two VMs connected to different `ivshmem-server` sockets, or `-n` too small for the vectors requested
Ack seen but the reply is garbage	`MailboxHeader` layout differs between the two sources — check the `static_assert`
Works once, then never again	Sequence and Ack out of step after an error path that did not write Ack
Signature verifies in CNG, fails in OpenSSL	Raw r‖s not converted to DER
Verification fails about 1 time in 128	ECC coordinates not left-padded to 32 bytes
Counter resets when the OP-TEE guest reboots	Secure storage in `/data/tee` on a volatile rootfs — persist it, or enable RPMB
Everything is unbearably slow	Windows under TCG. Use `-accel kvm` or `-accel hvf` on an ARM64 host

Check yourself

- ✓ Draw the two-VM topology and name what crosses each boundary.
- ✓ State plainly which security property this configuration demonstrates and which it only simulates.

- ✓ Give the single strongest reason to write a TA in C++, with a concrete failure it prevents.
- ✓ Name three C++ features that need a runtime a TA does not have, and the flag that disables each.
- ✓ Explain why the RAII wrapper needs a `Release()` method.
- ✓ Point to the single-fetch copy and the `paramTypes` check in the TA source.
- ✓ Explain the left-padding of ECC coordinates and the failure rate without it.
- ✓ Explain why the bridge publishes the magic value last.
- ✓ Identify both memory barriers in the mailbox protocol and say what each orders.
- ✓ Explain why the bridge copies the input out of shared memory before using it.
- ✓ Verify a signature end to end with stock OpenSSL and say what it proves about the driver, the transport and the TA.
- ✓ Describe what you would change to move this driver onto real Qualcomm silicon.

TRACK

GPU architecture & programming

How a processor built for throughput rather than latency actually works, the graphics and compute pipelines that ride on it, and DX12 in enough depth to draw a triangle and know why every line is there.

20 chapters

What a GPU is and why it exists

A CPU is built to finish one instruction stream as fast as possible. A GPU is built to have so much work outstanding that it never has to wait. Almost everything that seems strange about GPU programming follows from that one difference in objective.

Latency versus throughput

```
THE SAME PROBLEM: memory is ~300 cycles away.

A CPU SOLVES IT BY NOT WAITING
  huge caches                    keep data close
  out-of-order execution         run later instructions now
  branch prediction + speculation
  prefetchers
  deep pipelines, high clocks

  -> most of the transistor budget is spent on CONTROL and
     CACHE. Perhaps 1-5% is arithmetic.

A GPU SOLVES IT BY HAVING SOMETHING ELSE TO DO
  thousands of threads resident at once
  a scheduler that switches between them EVERY CYCLE,
    at zero cost, because every thread's registers stay in
    the register file
  small caches, enormous register files
  in-order, simple cores, modest clocks

  -> most of the budget is ARITHMETIC. Latency is not
     reduced at all; it is HIDDEN behind other work.

THE CONSEQUENCE, and it is the whole chapter:

  a CPU is fast at ONE thing.
  a GPU is fast only if you give it TEN THOUSAND things.

  A GPU running one thread is far slower than a CPU running
  one thread. There is no configuration in which a GPU wins
  on a serial problem.
```

	Modern CPU core	Modern GPU
Cores	8–128	Thousands of ALUs, in dozens of SMs / CUs
Threads in flight	1–2 per core (SMT)	Tens of thousands
Clock	3–5 GHz	1–2.5 GHz
Registers per core	~180 physical	65,536 ×*32-bit* per SM
L1 per core	32–64 KB	~128 KB, shared by many threads
Context switch	~1–5 µs	**Free**, every cycle
Memory bandwidth	50–200 GB/s	500 GB/s – 3 TB/s (HBM)
Branch cost	~15 cycles if mispredicted	Divergence — *both* paths execute (chapter 3)
FP32 throughput	~1 TFLOP/s	20–100 TFLOP/s

THE REGISTER FILE IS THE SURPRISING NUMBER

A GPU SM has *more register storage than L1 cache* — commonly 256 KB of registers against 128 KB of L1. That inversion is the whole latency-hiding trick: every resident thread keeps its full register state live, so switching between them costs nothing. It also explains why "using too many registers" is a real performance problem (chapter 5): registers are the budget that decides how many threads fit.

How it became a general-purpose processor

```
1990s   FIXED FUNCTION
          transform, light, rasterise, texture. All in
          silicon, configured by a few registers. You did
          not program it; you set state.

2001    PROGRAMMABLE SHADERS
          vertex and pixel shaders. Tiny assembly programs,
          no branches, no loops, 128 instructions.

2004    people notice the pixel shader is a parallel
          floating-point machine, and start smuggling
          physics and linear algebra through it as
          textures. "GPGPU" - genuinely by abusing the
          graphics API.

2006    UNIFIED SHADERS. One pool of cores runs vertex,
          pixel and geometry work. The hardware stops
          caring which is which.

2007    CUDA. You may now write C. The graphics API is no
          longer in the way.

2010s   compute shaders in every graphics API; OpenCL;
          GPUs enter supercomputers.

2017    TENSOR CORES. Fixed-function matrix-multiply units
          bolted back on - because the general machine was
          not fast enough for deep learning.

2018    RT CORES. Fixed-function ray-triangle intersection,
          for the same reason.

NOTE THE ARC: fixed function -> programmable -> general ->
fixed function again, for the workloads that matter enough.
That cycle is the most reliable pattern in hardware, and it
is worth expecting the next turn of it.
```

The execution model, in one picture

```
You write a KERNEL: one function, describing what ONE
thread does. You then launch millions of them.

  __global__ void add(float *a, float *b, float *c, int n)
  {
          int i = blockIdx.x * blockDim.x + threadIdx.x;
          if (i < n) c[i] = a[i] + b[i];
  }
  add<<<(n + 255) / 256, 256>>>(a, b, c, n);

THE HIERARCHY (CUDA names / portable names)

  thread          one lane. Has its own registers.
    |
  warp / wavefront    32 (NVIDIA) or 32-64 (AMD) threads
    |                 that execute IN LOCKSTEP. The real
    |                 unit of execution - chapter 2.
    |
  block / workgroup   up to 1024 threads. Share fast
    |                 on-chip memory and can barrier with
    |                 each other. Runs entirely on ONE SM.
    |
  grid / NDRange      all the blocks of one launch. Blocks
                      may run in ANY order, on any SM, and
                      cannot synchronise with each other.

THE RULE THAT SHAPES EVERYTHING:
  threads within a block can cooperate.
  blocks cannot. If your algorithm needs global
  synchronisation, you need a SECOND KERNEL LAUNCH.
```

What it costs to use one

```
/* The numbers that decide whether a GPU is worth it. */

  kernel launch overhead ..............   5-20 us
  PCIe transfer, host to device ........   ~25 GB/s (PCIe 4 x16)
  PCIe latency, one way ................   1-2 us
  device memory bandwidth ..............   500-3000 GB/s
  device memory latency ................   400-800 cycles
  shared memory latency ................   ~20-30 cycles

/* THE ARITHMETIC THAT MATTERS

   Copying 1 MB to the GPU:      ~40 us
   Adding 1 MB of floats there:  ~2 us

   -> the transfer costs twenty times the compute. A kernel
      that is only worth running if the data is ALREADY on the
      device is the normal case, not the exception.

   THE COMPUTE-TO-COMMUNICATION RATIO is the first thing to
   estimate. Arithmetic intensity - FLOPs per byte moved -
   tells you whether you are compute-bound or bandwidth-bound
   before you write a line:

        vector add       0.08 FLOP/byte   hopelessly
                                          bandwidth-bound
        SGEMM (large)    ~50 FLOP/byte    compute-bound
        LLM inference,
          batch size 1   ~2 FLOP/byte     bandwidth-bound,
                                          which is why it is
                                          slow (AI chapter 25)

   Integrated GPUs (phones, Apple Silicon, consoles) share
   DRAM with the CPU, so there is no copy at all - but also no
   HBM, so bandwidth is much lower. Different trade, same
   analysis.                                                  */
```

> **NOT EVERYTHING BELONGS ON A GPU**
>
> Good fits are *uniform* (every element does the same work), *independent* (no ordering between elements), *arithmetic-heavy* relative to bytes moved, and *large* (millions of items, not thousands). Bad fits: pointer chasing, branch-heavy logic, small problems where launch overhead dominates, anything sequentially dependent, and anything needing frequent CPU coordination. A "GPU rewrite" of an unsuitable algorithm typically lands between two and ten times *slower*.

The landscape

	NVIDIA	AMD	ARM Mali / Adreno	Apple
Compute unit	SM	CU / WGP	Shader core	GPU core
Lockstep group	Warp (32)	Wavefront (32 or 64)	Warp (4–16)	SIMD group (32)
Compute API	CUDA	HIP / ROCm	OpenCL, Vulkan	Metal
Graphics API	DX12, Vulkan		Vulkan, GLES	Metal
Memory	Discrete, GDDR/HBM		Unified with CPU	Unified

	NVIDIA	AMD	ARM Mali / Adreno	Apple
Architecture	Immediate mode		Tile-based (chapter 10)	

This track uses **DX12** as the worked API from chapter 11 onward, because it pairs with the Windows track and because Vulkan and Metal are close enough that the concepts transfer directly. Where they differ meaningfully, the chapters say so.

How it shows up

Symptom	Cause
GPU version slower than the CPU one	Transfer cost, launch overhead, or a problem too small
GPU sits at 5% utilisation	Not enough parallelism resident — too few threads
Speed-up far below the FLOPs ratio	Bandwidth-bound; compute throughput was never the limit
Scales to 1000 elements, then stops improving	Launch overhead dominates below a few tens of thousands
Fast on the desktop, slow on the phone	Tile-based architecture, and much lower bandwidth
Profile shows most time in `memcpy`	Data is crossing PCIe every frame; keep it resident
A branch-heavy kernel is 10× slower than expected	Divergence — both sides of the branch run
Works with 256 threads, fails with 1024	Register or shared-memory budget exceeded per block

Check yourself

- ✓ State the difference in objective between a CPU and a GPU in one sentence.
- ✓ Explain how a GPU hides memory latency without reducing it.
- ✓ Say why a GPU SM has more register storage than L1, and what that enables.
- ✓ Trace the arc from fixed-function to programmable and back, with an example of the return.
- ✓ Name the four levels of the execution hierarchy and what can synchronise at each.
- ✓ Explain why global synchronisation requires a second kernel launch.
- ✓ Compare the cost of copying 1 MB to a GPU against computing on it.
- ✓ Define arithmetic intensity and classify vector-add, SGEMM and batch-1 LLM inference.
- ✓ Give four properties of a workload that suits a GPU and four that do not.
- ✓ Name the vendor terms for a compute unit and a lockstep group across three vendors.

SIMT: how a GPU really executes

You write code for one thread. The hardware runs thirty-two of them from a single instruction pointer. That gap between the programming model and the execution model is where GPU performance lives, and pretending it is not there is why most first kernels are slow.

SIMD wearing a disguise

```
SIMD — what the hardware does
  one instruction, one register file of N lanes, N results.
  The programmer sees vectors and writes vector code.

     vaddps  ymm0, ymm1, ymm2      ; 8 floats at once

SIMT — what the GPU shows you
  one instruction, N THREADS each with their own registers
  and their own view of memory. The programmer writes
  SCALAR code for one thread.

     c[i] = a[i] + b[i];           // "one thread"

UNDERNEATH THEY ARE THE SAME MACHINE. The GPU groups your
threads into WARPS of 32 and issues one instruction for the
whole warp, every cycle.

  warp = 32 threads
         ONE program counter
         32 sets of registers
         a 32-bit ACTIVE MASK saying which lanes are live

WHAT SIMT ADDS OVER SIMD

  1. per-lane addressing. Each thread computes its own
     address, so gather and scatter are free at the
     programming level (though not at the memory level —
     chapter 4).
  2. per-lane control flow, via the mask. You may write an
     `if` and it will behave correctly — at a cost
     (chapter 3).

WHAT IT DOES NOT CHANGE

  the 32 threads still share ONE program counter. They are
  not independent. Anything that makes them want to be in
  different places costs you.
```

THE WARP IS THE UNIT OF EVERYTHING

Scheduling, instruction issue, memory coalescing, divergence and most synchronisation all operate on warps, not threads. "How many threads" is almost never the useful question; "how many warps, and are their lanes doing the same thing on adjacent data" is. A block of 100 threads occupies four warps and wastes 28 lanes of the fourth — which is why block sizes are always multiples of 32.

Inside an SM

```
One Streaming Multiprocessor, roughly (NVIDIA Ampere-ish):

+-----------------------------------------------------------+
|  INSTRUCTION CACHE                                        |
+-----------------------------------------------------------+
|  WARP SCHEDULERS  x4                                      |
|    each holds up to 16 resident warps and picks ONE       |
|    ready warp per cycle to issue                          |
+-----------------------------------------------------------+
|  REGISTER FILE   65,536 x 32-bit  =  256 KB               |
|    partitioned among resident warps. THIS is the budget   |
|    that decides how many fit (chapter 5).                 |
+-----------------------------------------------------------+
|  EXECUTION UNITS                                          |
|    32x INT32/FP32 lanes    (the main array)               |
|    16x FP64                (few, on consumer parts)       |
|     4x SFU     sin, cos, rsqrt - slow, low throughput     |
|     4x LD/ST   address generation                         |
|     4x TENSOR  matrix-multiply-accumulate                 |
+-----------------------------------------------------------+
|  128 KB, split between L1 CACHE and SHARED MEMORY         |
|    the split is configurable per kernel                   |
+-----------------------------------------------------------+

THE KEY OBSERVATION: there are 32 FP32 lanes and up to 64
RESIDENT WARPS. The hardware can only execute a few warps
per cycle, but it KEEPS dozens ready. When one stalls on
memory, the scheduler issues from another - in the same
cycle, at no cost, because every warp's registers are
already live in the file.

That is latency hiding, and it is why occupancy matters.
```

One cycle in the life of a scheduler

```
/* A warp scheduler holds N resident warps. Every cycle it
   picks one that is READY and issues its next instruction. */

  cycle 1:  warp 3  -> LDG   R4, [R2]     ; global load, ~500
                                            cycles. warp 3 is
                                            now STALLED.
  cycle 2:  warp 7  -> FMA   R1, R2, R3   ; ready, issue it
  cycle 3:  warp 12 -> LDG   R8, [R6]     ; stalls too
  cycle 4:  warp 7  -> FMA   R5, R1, R4   ; still ready
  cycle 5:  warp 19 -> IADD  R0, R0, 1
  ...
  cycle 500: warp 3's load returns -> warp 3 is READY again

/* WITH ENOUGH WARPS the ALUs never idle, and the 500-cycle
   memory latency is completely invisible.

   WITH TOO FEW WARPS - say 4 resident - all four issue a load
   and then everyone waits. The SM sits idle for hundreds of
   cycles with nothing to do.

   THE ARITHMETIC:
     to hide 500 cycles of latency with an SM that issues 4
     instructions per cycle, you need roughly
         500 x 4 / (instructions between loads)
     warps in flight. For memory-heavy code that is dozens.

   THIS IS WHY "more parallelism" is the answer to almost
   every GPU performance question, and why a kernel with
   perfect arithmetic and no occupancy is slow.            */
```

Independent thread scheduling

```
/* PRE-VOLTA (before 2017): one PC per warp. Threads within a
   warp could NOT make independent progress. This was legal:  */

        /* the "warp-synchronous" idiom - once ubiquitous */
        shared[tid] = value;
        /* no __syncthreads() needed if tid < 32, because the
           warp is in lockstep by construction */
        if (tid < 16) shared[tid] += shared[tid + 16];

/* VOLTA AND LATER: each thread has its own PC and call stack.
   Threads in a warp may diverge and RECONVERGE independently,
   and the hardware may interleave them.

   That broke every warp-synchronous program in existence,
   silently and intermittently.

   THE FIX: state your assumption explicitly. */

        __syncwarp();                    /* barrier the warp    */
        val = __shfl_down_sync(0xffffffff, val, 16);
        /*                     ^^^^^^^^^^ the mask of lanes you
                               are synchronising with. The _sync
                               suffix is mandatory now; the old
                               unsuffixed __shfl is removed.   */

/* WHY THE CHANGE WAS WORTH IT: it makes this correct, which
   it was not before: */

        while (!atomicCAS(&lock, 0, 1)) ;   /* lane 0 wins ...  */
        /* critical section */
        atomicExch(&lock, 0);
/* Pre-Volta, the winning lane could not proceed to release
   the lock while the losing lanes spun - the whole warp
   deadlocked. Per-thread PCs fixed a genuine footgun.       */
```

NEVER ASSUME IMPLICIT LOCKSTEP

If your code relies on threads in a warp being at the same instruction, it is wrong on modern hardware — even though it will usually appear to work. Every intra-warp operation now takes an explicit mask: `__shfl_sync`, `__ballot_sync`, `__any_sync`, `__syncwarp`. In HLSL and Vulkan the equivalents are the wave intrinsics (`WaveActiveSum`, `WaveReadLaneFirst`), which were designed after this lesson and require no mask.

Warp-level operations

```
/* Because a warp shares an instruction stream, the hardware
   can offer cross-lane operations that cost almost nothing -
   no shared memory, no barrier, just wires in the register
   file. They are the single best optimisation available. */

/* CUDA */
  __shfl_sync(mask, var, srcLane)      /* read another lane   */
  __shfl_down_sync(mask, var, delta)   /* shift within warp   */
  __shfl_xor_sync(mask, var, lanemask) /* butterfly exchange  */
  __ballot_sync(mask, pred)            /* 32-bit vote bitmap  */
  __all_sync / __any_sync(mask, pred)  /* reductions on bools */
  __activemask()                       /* who is live now     */
  __reduce_add_sync(mask, val)         /* Ampere+: one insn   */

/* HLSL / DX12 wave intrinsics (SM 6.0+) */
  WaveActiveSum(v)      WaveActiveMax(v)
  WaveActiveBallot(p)   WaveActiveAllTrue(p)
  WaveGetLaneIndex()    WaveReadLaneFirst(v)
  WavePrefixSum(v)

/* A WARP REDUCTION - 5 instructions, no memory, no barrier: */
__device__ float warp_sum(float v)
{
        for (int off = 16; off > 0; off /= 2)
                v += __shfl_down_sync(0xffffffff, v, off);
        return v;      /* lane 0 holds the total              */
}

/* Compare with the shared-memory version: allocate shared
   memory (which costs occupancy), write, __syncthreads(),
   tree-reduce with more barriers, read back. The warp version
   is several times faster and uses no shared memory at all.

   THE PATTERN FOR A FULL BLOCK REDUCTION:
     1. warp_sum within each warp        (no barrier)
     2. lane 0 of each warp writes to shared    (32 floats max)
     3. __syncthreads()                          (one barrier)
     4. the first warp reduces those 32 values with warp_sum
   Two barriers total, whatever the block size.             */
```

How it shows up

Symptom	Cause
Kernel uses 3% of peak FLOPs	Too few resident warps to hide memory latency
Block size 100 performs like block size 128	Warps are 32 wide; the remainder wastes lanes
Code works on Pascal, fails intermittently on Volta+	Warp-synchronous programming without explicit sync
`__shfl` does not compile	The unsuffixed forms were removed; use `_sync`
Deadlock in an intra-warp spinlock on old hardware	Single PC per warp — the winner could not proceed
Reduction is slower than expected	Using shared memory where warp shuffles would do
Occupancy is low despite small blocks	Register pressure — the file is the limit (chapter 5)
Adding one variable halved performance	It pushed register count over a threshold, evicting warps
Wave intrinsics return odd results on AMD	Wavefront is 32 or 64 depending on the part; do not hardcode 32

Check yourself

- ✓ Distinguish SIMD from SIMT and say what SIMT adds.
- ✓ State what a warp shares and what each thread in it owns privately.
- ✓ Explain why block sizes should be multiples of 32.
- ✓ Draw an SM and name the resource that limits how many warps are resident.
- ✓ Walk through several cycles of warp scheduling and explain how latency is hidden.
- ✓ Estimate how many warps are needed to hide a 500-cycle load.
- ✓ Explain what independent thread scheduling changed and which idiom it broke.
- ✓ Say why every intra-warp intrinsic now takes a mask.
- ✓ Write a warp-level sum reduction and say why it beats the shared-memory version.
- ✓ Give the four steps of an efficient block-wide reduction and count its barriers.

Warps, wavefronts and divergence

Thirty-two threads share one program counter. When an `if` sends them different ways the hardware does not pick one — it runs *both* sides, masking off the lanes that should not be there. Understanding exactly when that costs you, and when it does not, is the difference between a fast kernel and a correct one.

Execution masking

```
if (threadIdx.x % 2 == 0)  even_work();
else                       odd_work();

ONE warp, 32 lanes. 16 want each branch.

  mask 11111111111111111111111111111111   all active
     |
     +-- evaluate the condition -> a 32-bit predicate
     |
  mask 10101010101010101010101010101010   even lanes
     run even_work()          <-- 16 lanes idle, burning
                                  the same cycles
     |
  mask 01010101010101010101010101010101   odd lanes
     run odd_work()           <-- the other 16 idle
     |
  mask 11111111111111111111111111111111   reconverge

TIME TAKEN = time(even_work) + time(odd_work)
WORK DONE  = half of it

The branch was not mispredicted. It was not slow. BOTH
SIDES SIMPLY RAN, and half your lanes were switched off for
each. That is divergence.

THE COST IS THE SUM OF ALL TAKEN PATHS. A switch with 8
cases hit by different lanes of one warp costs 8x.
```

DIVERGENCE IS PER-WARP, NOT PER-THREAD

If *every* lane of a warp takes the same branch, there is **no cost at all** — the hardware skips the untaken side entirely. A branch on `blockIdx.x`, or on data that is uniform across 32 consecutive elements, is free. It is only divergence *within* a warp that hurts. So the question is never "does my kernel branch" but "do adjacent threads branch differently".

Divergent and uniform, side by side

```
/* DIVERGENT - alternate lanes disagree. Worst case. */
        if (threadIdx.x % 2 == 0) { ... }

/* UNIFORM - the whole warp agrees. FREE. */
        if (blockIdx.x == 0)      { ... }
        if (N > 1024)             { ... }    /* same for all   */

/* UNIFORM BY CONSTRUCTION - the standard trick: branch on
   something that changes only every 32 threads. */
        if ((threadIdx.x / 32) % 2 == 0) { ... }   /* per-warp  */

/* THE BOUNDS CHECK - technically divergent, and free anyway,
   because only the LAST warp of the grid diverges. */
        int i = blockIdx.x * blockDim.x + threadIdx.x;
        if (i < n) c[i] = a[i] + b[i];

/* DATA-DEPENDENT - the real problem, because you cannot see
   it in the source. */
        if (particle[i].alive) simulate(i);
/* If alive/dead are scattered randomly, every warp diverges
   and you pay 2x for ever. If particles are SORTED by
   liveness, whole warps agree and it is free. Same code, same
   data, ten times the difference.                          */

/* A LOOP WITH A DATA-DEPENDENT TRIP COUNT - divergence that
   lasts as long as the longest lane. */
        while (x > threshold) { x = step(x); }
/* The warp runs until the SLOWEST lane finishes. 31 lanes
   idle while one iterates 400 more times.                  */
```

Removing divergence

```
/* 1. PREDICATION - for tiny branches, the compiler does it
      for you: compute both, select. No branch at all. */
        y = (x > 0) ? f(x) : g(x);
/* becomes: compute f, compute g, select. Costs both, but no
   branch overhead and no reconvergence. Good when both sides
   are one or two instructions; bad when one side is
   expensive - you now always pay for it.                    */

/* 2. SORT THE DATA so lanes agree. Usually the biggest win
      available. */
        /* before: particles in creation order, alive scattered
           after:  partition alive to the front               */
        int n_alive = partition_by_alive(particles);
        simulate<<<grid(n_alive), 256>>>(particles);
/* Now the whole grid is alive and the branch disappears. The
   sort costs a kernel; the divergence cost every frame.    */

/* 3. STREAM COMPACTION - build a dense index list of the
      items that need work, then launch over that. */
        // pass 1: ballot + prefix sum to compact indices
        // pass 2: kernel over the compacted list
/* This is the general form of (2) and the standard answer for
   ray tracing, sparse grids and particle systems.          */

/* 4. SEPARATE KERNELS per case, when the cases are big and
      known in advance. Two uniform kernels beat one divergent
      one, even with two launches.                            */

/* 5. RESTRUCTURE INDEXING so that consecutive lanes handle
      consecutive similar work. Often as simple as swapping
      which dimension maps to threadIdx.x.                    */

/* 6. PERSISTENT THREADS + a work queue. Each warp pulls the
      next item when it finishes, so a long-running lane does
      not stall a whole block. Complex, but the standard answer
      for highly irregular workloads.                         */
```

> **DO NOT FIGHT DIVERGENCE YOU DO NOT HAVE**
>
> A branch that every lane of a warp takes together is free, and branch-free tricks (bit twiddling, arithmetic selects) cost real instructions. Measure the divergence first — Nsight Compute reports *branch efficiency* and *warp execution efficiency* directly. Rewriting a uniform branch into branch-free arithmetic is a pure loss, and it happens constantly.

Reconvergence, and the deadlock it used to cause

```
The hardware must know where diverged lanes rejoin. It
tracks this with a stack of (mask, reconvergence-PC) pairs.

  push  (else-mask, PC-after-if)
  run   the if-body with the if-mask
  pop   -> restore else-mask, jump to else
  run   the else-body
  pop   -> full mask, continue at PC-after-if

PRE-VOLTA this stack was PER WARP, and reconvergence was
forced at the immediate post-dominator. Consequence:

     if (lane == 0) {
             while (atomicCAS(&lock, 0, 1) != 0) ;   /* spin */
             critical();
             atomicExch(&lock, 0);
     }
Lane 0 acquires the lock. The other 31 lanes are masked off
at the SAME PC, waiting to reconverge. Lane 0 proceeds,
releases - fine. But reverse it:

     while (atomicCAS(&lock, 0, 1) != 0) ;
with several lanes competing: one lane wins and wants to
move on; the losers are still in the loop. The warp cannot
be in two places, so the winner is held back at the loop,
which means it never releases the lock. DEADLOCK, in code
that is obviously correct on a CPU.

VOLTA+ gives each thread its own PC, so the winner really
can proceed. That is why the change was made, and why any
intra-warp locking on old hardware is a trap.

The trade: reconvergence is no longer guaranteed at the
post-dominator, so you must call __syncwarp() where you
need it.
```

Measuring it

```
# Nsight Compute - the two metrics that matter.
$ ncu --metrics \
    smsp__thread_inst_executed_per_inst_executed.ratio,\
    smsp__sass_average_branch_targets_threads_uniform.pct \
    ./app

  smsp__thread_inst_executed_per_inst_executed.ratio   18.4
# "average active threads per issued instruction", out of 32.
# 32.0 = perfect. 18.4 means you are wasting ~43% of every
# instruction issue.

  ...branch_targets_threads_uniform.pct                61.2%
# fraction of branches where the whole warp agreed.

# Source-level attribution, which is what you actually want:
$ ncu --set full --import-source yes -o report ./app
$ ncu-ui report.ncu-rep
# the source view colours each line by divergence.

# AMD:
$ rocprof --stats ./app

# DX12 / HLSL: PIX and RenderDoc both show wave occupancy and
# divergence per draw. Nsight Graphics does the same for
# Vulkan and DX12.

# THE CHEAP ESTIMATE, if you have no profiler: comment out the
# divergent branch (take one side unconditionally, accept the
# wrong answer) and time it. The gap is your divergence cost.
```

Warp width is not always 32

Vendor	Width	Note
NVIDIA	32	Stable since 2006; `warpSize` is still a variable, do not hardcode
AMD GCN	64	Divergence costs twice as much per branch
AMD RDNA	32 or 64	Wave32 by default for graphics, wave64 available; the compiler chooses
Intel Xe	8, 16 or 32	Chosen per shader by the compiler — SIMD8 for register-heavy shaders
ARM Mali	4–16	Much narrower, so divergence is far cheaper; older Mali is effectively scalar
Apple	32	SIMD group

Write portable code with `WaveGetLaneCount()` (HLSL), `gl_SubgroupSize` (Vulkan) or `warpSize` (CUDA), and never assume 32 in a loop bound. A reduction hardcoded to five shuffle steps is silently wrong on a 64-wide wavefront.

How it shows up

Symptom	Cause
Kernel is 2× slower than the instruction count suggests	A two-way branch diverging in every warp
Performance depends on input data ordering	Data-dependent divergence — sort or compact

Symptom	Cause
Warp execution efficiency well below 32	Divergence, or a partially-filled last warp
A loop takes as long as its worst element	Divergent trip count; consider persistent threads
Branch-free rewrite made it slower	The branch was uniform and therefore already free
Deadlock in intra-warp locking	Pre-Volta forced reconvergence
Reduction gives wrong results on AMD	Wavefront is 64; the shuffle loop assumed 32
Fast on mobile, slow on desktop for the same branchy code	Mali's narrow warps make divergence cheap
Ray tracer slows as the scene gets complex	Rays in a warp hit different materials — the canonical divergence problem

Check yourself

- ✓ Explain what the hardware does when lanes of a warp take different branches.
- ✓ State the cost rule for a divergent branch, and for a switch with eight cases.
- ✓ Explain why divergence is per-warp and give two branches that are free.
- ✓ Explain why a bounds check `if (i < n)` costs essentially nothing.
- ✓ Give six techniques for removing divergence, and when each applies.
- ✓ Explain why sorting data can be faster than the divergence it removes.
- ✓ Say when predication is a win and when it is a loss.
- ✓ Describe the pre-Volta intra-warp deadlock and what fixed it.
- ✓ Name the two profiler metrics that quantify divergence and what perfect looks like.
- ✓ Give warp widths for three vendors and say what breaks if you hardcode 32.

The GPU memory hierarchy

Most GPU kernels are limited by memory, not arithmetic. The hierarchy has more levels than a CPU's, several of them are explicitly managed by you, and the single most important rule — coalescing — has no CPU equivalent at all.

The levels

```
                                latency   bandwidth   scope
REGISTERS                        ~1 cyc   ~20 TB/s    thread
  256 KB per SM. Private per thread. The fastest storage in
  the machine, and the budget that caps occupancy.
     |
SHARED MEMORY / LDS             ~20-30    ~10 TB/s    block
  up to 164 KB per SM, split with L1. SOFTWARE MANAGED -
  you decide what lives here. Banked (see below).
     |
L1 / TEXTURE CACHE              ~30       ~10 TB/s    SM
  automatic. Small per thread once you divide by occupancy.
     |
L2 CACHE                        ~200      ~2 TB/s     device
  2-100 MB. Shared by all SMs. Where atomics resolve.
     |
GLOBAL MEMORY (VRAM/HBM)        ~400-800  0.5-3 TB/s  device
  GB. Everything else lives here. THE BOTTLENECK.
     |
HOST MEMORY over PCIe           ~1-2 us   ~25 GB/s    system
  100x less bandwidth than VRAM. Avoid crossing it.

PLUS TWO READ-ONLY PATHS:
  CONSTANT MEMORY   64 KB, broadcast-optimised. One value
                    to all lanes in a cycle; serialised if
                    lanes read different addresses.
  TEXTURE/__ldg     read-only path with its own cache,
                    spatial (2D) locality, free filtering
                    and border handling.

THE RATIO THAT MATTERS: registers are ~40x the bandwidth of
global memory. Every byte you keep in registers or shared
memory instead of re-reading is the highest-value
optimisation available.
```

Coalescing: the rule with no CPU analogue

```
Memory is served in 32-byte SECTORS (four per 128-byte
line). A warp issues 32 addresses AT ONCE, and the hardware
merges them into as few transactions as it can.

PERFECT - consecutive lanes, consecutive floats

  lane:   0  1  2  3  ...           31
  addr: 000 004 008 012 ...        124
                                -> ONE 128-byte transaction
                                   128 bytes requested,
                                   128 used. 100%.

STRIDED BY 2 - c[i*2]

  lane:   0    1    2   ...          31
  addr: 000  008  016  ...          248
                                -> TWO transactions
                                   256 fetched, 128 used.
                                   50% of bandwidth wasted.

STRIDED BY 32 - a column of a row-major matrix

  lane:   0     1     2  ...         31
  addr: 000   128   256  ...       3968
                                -> 32 SEPARATE transactions
                                   4096 fetched, 128 used.
                                   3% efficiency.
                                   THIRTY-TWO TIMES SLOWER
                                   than the perfect case,
                                   for the same code.

RANDOM - a gather

  32 transactions, and no prefetcher can help.

THE RULE: adjacent THREADS should touch adjacent MEMORY.
Not adjacent iterations - adjacent threads. Getting this
backwards is the single most common GPU performance bug.
```

```
/* THE CLASSIC MISTAKE - each thread handles a contiguous
   chunk, "like a CPU would". */

__global__ void bad(float *a, int n, int per_thread)
{
        int t = blockIdx.x * blockDim.x + threadIdx.x;
        int base = t * per_thread;                 /* lane 0 -> 0
                                                      lane 1 -> 64
                                                      lane 2 -> 128 */
        for (int i = 0; i < per_thread; i++)
                a[base + i] *= 2.0f;               /* stride 64
                                                      between
                                                      lanes!    */
}

/* THE FIX - grid-stride loop. Lanes stay adjacent; the WHOLE
   GRID strides. */
__global__ void good(float *a, int n)
{
        int stride = blockDim.x * gridDim.x;
        for (int i = blockIdx.x * blockDim.x + threadIdx.x;
             i < n; i += stride)
                a[i] *= 2.0f;              /* lanes 0..31 touch
                                              adjacent floats,
                                              every iteration   */
}
/* Same work, same instruction count, typically 5-20x faster.
   And the grid-stride form is independent of grid size, so
   the same kernel is correct for any launch configuration. */
```

STRUCTURE OF ARRAYS, NOT ARRAY OF STRUCTURES

An AoS layout (`struct Particle { float x, y, z; }; Particle p[N];`) means lane 0 reads offset 0 and lane 1 reads offset 12 — a stride of 12 bytes, so reading just `x` wastes two-thirds of every transaction. SoA (`float px[N], py[N], pz[N];`) makes each field perfectly coalesced. This is the same transformation that helps SIMD on a CPU, but on a GPU the penalty for getting it wrong is far larger.

Shared memory and bank conflicts

```
/* Shared memory is divided into 32 BANKS, 4 bytes wide,
   interleaved. Bank = (address / 4) % 32.

   The 32 lanes of a warp can each access a DIFFERENT bank in
   one cycle. Two lanes hitting the SAME bank at DIFFERENT
   addresses serialise.                                    */

__shared__ float tile[32][32];

/* CONFLICT-FREE - row access. Lane i reads tile[k][i], which
   is bank i. All 32 banks, one cycle.                      */
        float v = tile[k][threadIdx.x];

/* 32-WAY CONFLICT - column access. Lane i reads tile[i][k],
   at address (i*32 + k)*4, so bank = (i*32 + k) % 32 = k for
   EVERY lane. All 32 lanes hit bank k. 32x serialisation. */
        float v = tile[threadIdx.x][k];

/* THE FIX - PAD THE ROW. One extra column shifts each row by
   one bank. */
__shared__ float tile[32][33];      /* <-- 33, not 32          */
        float v = tile[threadIdx.x][k];
        /* address = (i*33 + k)*4, bank = (i*33 + k) % 32
                                        = (i + k) % 32
           every lane a different bank. Conflict-free.        */

/* Four bytes of waste per row buys a 32x speed-up on the
   transpose. It is the best-known trick in GPU programming
   and it is one character.

   BROADCAST IS FREE: if every lane reads the SAME address,
   the hardware broadcasts in one cycle. Same-bank same-address
   is not a conflict; same-bank different-address is.       */
```

Tiling: the reason shared memory exists

```
/* Naive matrix multiply: every thread reads a whole row and a
   whole column from global memory. Each element of A is read
   N times.                                                    */

__global__ void matmul_naive(float *C, const float *A,
                             const float *B, int N)
{
        int r = blockIdx.y * blockDim.y + threadIdx.y;
        int c = blockIdx.x * blockDim.x + threadIdx.x;
        float sum = 0;
        for (int k = 0; k < N; k++)
                sum += A[r * N + k] * B[k * N + c];   /* B is
                                                         strided! */
        C[r * N + c] = sum;
}
/* Global traffic: 2 * N^3 * 4 bytes. Bandwidth-bound, and B's
   access pattern is a column walk. Perhaps 5% of peak.     */

#define T 32
__global__ void matmul_tiled(float *C, const float *A,
                             const float *B, int N)
{
        __shared__ float As[T][T + 1];      /* +1: no conflicts */
        __shared__ float Bs[T][T + 1];

        int r = blockIdx.y * T + threadIdx.y;
        int c = blockIdx.x * T + threadIdx.x;
        float sum = 0;

        for (int t = 0; t < N / T; t++) {
                /* COALESCED loads: adjacent lanes (threadIdx.x)
                   read adjacent floats. */
                As[threadIdx.y][threadIdx.x] =
                        A[r * N + t * T + threadIdx.x];
                Bs[threadIdx.y][threadIdx.x] =
                        B[(t * T + threadIdx.y) * N + c];

                __syncthreads();            /* tile is loaded   */

                for (int k = 0; k < T; k++)
                        sum += As[threadIdx.y][k] * Bs[k][threadIdx.x];

                __syncthreads();            /* before OVERWRITING
                                               the tile - this
                                               second barrier is
                                               the one people
                                               forget           */
        }
        C[r * N + c] = sum;
}
/* Global traffic: 2 * N^3 / T * 4 bytes - THIRTY-TWO TIMES
   LESS. Each element is loaded once per tile instead of once
   per output. Typically 10-20x faster.

   THE PRINCIPLE: load a tile cooperatively into fast memory,
   reuse it many times, move on. It is the same blocking
   transformation as a cache-oblivious CPU algorithm, except
   you write it explicitly.                                  */
```

BOTH `__syncthreads()` ARE LOAD-BEARING

The first ensures the tile is fully written before anyone reads it. The second ensures everyone has finished reading before the next iteration overwrites it. Omitting the second is a classic bug: it works at small sizes where warps happen to stay in step, and corrupts results once the block spans enough warps that they drift apart. Also note `__syncthreads()` must be reached by *every* thread in the block — putting one inside a divergent branch hangs the block.

How it shows up

Symptom	Cause
Kernel achieves 3% of peak bandwidth	Uncoalesced access — check the stride between adjacent lanes
Transpose is 30× slower than a copy	Bank conflicts; pad the shared tile
Reading one field of a struct is slow	AoS layout; switch to SoA
Matrix multiply far below peak	Not tiled — every element re-read from global
Results wrong only for large blocks	Missing the second `__syncthreads()`
Kernel hangs	`__syncthreads()` inside a divergent branch
Occupancy drops when you add shared memory	Shared memory per block limits resident blocks per SM
Constant memory is slow	Lanes reading different addresses — it serialises, it only broadcasts well
Most of the profile is `cudaMemcpy`	Crossing PCIe every iteration; keep data resident
Atomics are the bottleneck	They serialise at L2; use warp aggregation or a per-block partial

Check yourself

- ✓ List the memory levels with their scope and rough latency.
- ✓ State the coalescing rule and explain why stride 32 is thirty-two times worse.
- ✓ Explain why "each thread takes a contiguous chunk" is wrong on a GPU.
- ✓ Write a grid-stride loop and say why it is launch-configuration independent.
- ✓ Explain AoS versus SoA and why the GPU penalty exceeds the CPU one.
- ✓ Compute the bank for a shared-memory address and construct a 32-way conflict.
- ✓ Explain why `[32][33]` removes the conflict.
- ✓ Say when same-bank access is free.
- ✓ Explain what tiling saves in matrix multiply, quantitatively.
- ✓ Justify both `__syncthreads()` calls and describe the bug from omitting the second.

Occupancy and latency hiding

Occupancy is how many warps are resident on an SM as a fraction of the maximum. It is the knob everyone tunes first and the one most often misunderstood: more is not always better, and 100% occupancy is frequently the wrong target.

Three budgets, and the smallest wins

```
An SM has fixed resources. A block consumes some of each.
The number of resident blocks is the MINIMUM across all
limits.

Typical modern SM:
  max warps resident ....... 64      (2048 threads)
  max blocks resident ...... 16-32
  register file ............ 65,536 x 32-bit
  shared memory ............ up to 164 KB

WORKED EXAMPLE
  block = 256 threads = 8 warps
  registers per thread = 40
  shared memory per block = 8 KB

  by warps:      64 / 8            = 8 blocks
  by registers:  65536 / (256*40)  = 6.4  -> 6 blocks
  by shared mem: 164 KB / 8 KB     = 20 blocks
  by block limit:                    16 blocks

  LIMIT = 6 blocks = 48 warps = 48/64 = 75% occupancy
  and REGISTERS are the binding constraint.

NOW ADD ONE VARIABLE that pushes registers to 48:
  by registers: 65536 / (256*48)   = 5.3  -> 5 blocks
  = 40 warps = 62% occupancy

One local variable cost you 13% of your occupancy. This is
why GPU performance is famously sensitive to trivial code
changes, and why "register pressure" is a phrase you will
hear constantly.
```

```
# Find out which budget binds, before guessing.
$ nvcc -Xptxas -v --generate-line-info kernel.cu
ptxas info : Compiling entry function '_Z6kernelPfS_i'
ptxas info : Function properties for _Z6kernelPfS_i
             0 bytes stack frame, 0 bytes spill stores,
             0 bytes spill loads                <-- WATCH THIS
ptxas info : Used 40 registers, 8192 bytes smem, 380 bytes cmem[0]

# Non-zero spill stores/loads means registers overflowed into
# LOCAL memory - which is global memory with a friendly name,
# 400+ cycles away. A spilling kernel is usually far worse
# than a lower-occupancy one that does not spill.

$ ncu --set full ./app          # reports achieved occupancy,
                                # not just theoretical

# Cap registers to raise occupancy - and measure, because it
# may cause spills that cost more than the occupancy gained:
$ nvcc -maxrregcount=32 kernel.cu
  __launch_bounds__(256, 4)     /* 256 threads, want 4 blocks
                                   per SM - lets the compiler
                                   budget registers itself   */
```

How much is enough

```
Occupancy exists to hide latency. Once latency is hidden,
more occupancy buys NOTHING.

THE LITTLE'S LAW VIEW
  needed parallelism = latency x throughput

  to hide a 500-cycle memory latency on an SM that issues
  4 instructions/cycle, you need ~2000 instructions in
  flight. If each warp has 10 independent instructions
  between dependent loads, that is 200 warp-instructions -
  roughly 25 warps.

TYPICAL SHAPE OF THE CURVE

  performance
     |             ....------------------  flat
     |          ..
     |        .
     |      .
     |    .
     |  .
     +------------------------------------ occupancy
     0%   25%   50%   75%   100%

  The knee is usually between 25% and 50%. Past it you are
  tuning a number that does not affect the outcome.

AND THE CURVE CAN GO DOWN:
  * more warps share the same L1 and L2, so each gets less
    cache. A tiled kernel with a working set that fits at
    50% occupancy may thrash at 100%.
  * fewer registers per thread means less data kept close,
    so more memory traffic.

INSTRUCTION-LEVEL PARALLELISM SUBSTITUTES FOR OCCUPANCY.
Volkov's well-known result: a kernel where each thread
processes 4 independent elements can hit peak at 25%
occupancy, because the 4 loads are in flight simultaneously
from one warp. Fewer, fatter threads often beat more,
thinner ones.
```

> **THE RIGHT QUESTION**
> Not "how do I get to 100% occupancy" but "am I latency-bound, bandwidth-bound or compute-bound?" Occupancy only helps the first. If you are already at 80% of peak memory bandwidth, no amount of extra occupancy matters — you need to move fewer bytes (chapter 4). Nsight's Speed-of-Light section answers this in one screen and should be the first thing you look at.

Trading occupancy for work per thread

```
/* ONE ELEMENT PER THREAD - maximum occupancy, minimum ILP.
   Each thread issues one load and then waits.              */
__global__ void v1(float *out, const float *a, const float *b, int n)
{
        int i = blockIdx.x * blockDim.x + threadIdx.x;
        if (i < n) out[i] = a[i] * b[i];
}

/* FOUR ELEMENTS PER THREAD - fewer warps, but four
   INDEPENDENT loads in flight per thread. The scheduler can
   overlap them without needing another warp.               */
__global__ void v4(float4 *out, const float4 *a, const float4 *b, int n4)
{
        int i = blockIdx.x * blockDim.x + threadIdx.x;
        if (i < n4) {
                float4 x = a[i];        /* ONE 16-byte load -
                                           wider transactions,
                                           fewer of them      */
                float4 y = b[i];
                out[i] = make_float4(x.x*y.x, x.y*y.y,
                                     x.z*y.z, x.w*y.w);
        }
}
/* Two wins at once:
     - vectorised loads (float4 = 16 bytes) use the memory
       system better than four separate 4-byte loads
     - more independent work per thread, so lower occupancy
       still hides the latency

   Requires 16-byte alignment. cudaMalloc guarantees 256-byte
   alignment, so the base is fine; an offset into the middle
   of an array may not be.

   THE GENERAL TECHNIQUE is called THREAD COARSENING, and it
   is usually worth trying 2 or 4 elements per thread before
   any other optimisation.                                  */
```

Choosing a block size

Size	Warps	Notes
32	1	Too small — the block limit (16–32 blocks) caps you at 32 warps before any other resource does
128	4	Good default. Divides evenly into most SM limits, flexible for the scheduler
256	8	The most common choice. Good balance of granularity and overhead
512	16	Fine if register use is low; coarse granularity wastes an SM on the tail
1024	32	Maximum. Only one or two blocks fit, so a single barrier stalls half the SM. Rarely best
Not a multiple of 32	—	Always wrong. The final warp runs with idle lanes

```
/* Do not guess - ask the runtime. */
int block, grid;
cudaOccupancyMaxPotentialBlockSize(&grid, &block, my_kernel, 0, 0);
my_kernel<<<grid, block>>>(...);

/* Or query for a specific choice: */
int blocks_per_sm;
cudaOccupancyMaxActiveBlocksPerMultiprocessor(
        &blocks_per_sm, my_kernel, 256, 0);

/* AND SIZE THE GRID FOR THE MACHINE, not for the data, when
   using a grid-stride loop (chapter 4): */
int nsm;
cudaDeviceGetAttribute(&nsm, cudaDevAttrMultiProcessorCount, 0);
int grid = nsm * blocks_per_sm;     /* fill the GPU exactly    */

/* THE TAIL EFFECT, worth knowing:
     108 SMs, 110 blocks -> the last 2 blocks run alone while
     106 SMs idle. The kernel takes twice as long as the work
     requires. Either round the grid to a multiple of the SM
     count with a grid-stride loop, or use many small blocks
     so the imbalance is proportionally tiny.               */
```

REGISTER SPILLING BEATS OCCUPANCY EVERY TIME

Forcing `-maxrregcount=32` to reach 100% occupancy, and thereby spilling ten registers to local memory, is a large net loss: each spill is a global-memory round trip in the inner loop. Always check the `ptxas` spill counters after changing register limits. Zero spills at 50% occupancy is almost always better than heavy spilling at 100%.

How it shows up

Symptom	Cause
Low achieved occupancy, low performance	Register or shared-memory pressure — check `-Xptxas -v`
Adding a variable halved throughput	Crossed a register threshold, evicting a resident block
Raising occupancy changed nothing	You were bandwidth- or compute-bound, not latency-bound
Raising occupancy made it slower	Cache thrashing, or spills introduced by the register cap
Achieved occupancy far below theoretical	Load imbalance, or the tail effect — some SMs finish early
Kernel time does not scale with grid size	The tail: a partial final wave of blocks
Block size 1024 is slower than 256	Coarse granularity and barrier cost across 32 warps
Non-zero spill stores in the build log	Registers exhausted — reduce live values or raise the cap
Four elements per thread beat one	ILP substituting for occupancy, plus wider transactions

Check yourself

- ✓ Define occupancy and name the four budgets that limit it.
- ✓ Work an example and identify the binding constraint.
- ✓ Explain why one extra variable can cost 13% occupancy.
- ✓ Use Little's law to estimate the warps needed to hide a 500-cycle latency.

- ✓ Draw the occupancy-versus-performance curve and mark the knee.
- ✓ Give two reasons more occupancy can reduce performance.
- ✓ Explain how ILP substitutes for occupancy, with an example.
- ✓ Say why block sizes must be multiples of 32 and why 1024 is rarely best.
- ✓ Describe the tail effect and two ways to avoid it.
- ✓ Explain why zero spills at 50% occupancy usually beats spilling at 100%.

The graphics pipeline, stage by stage

Triangles in, pixels out. Every graphics API is a way of configuring the same fixed sequence of stages, some programmable and some not — and knowing which is which tells you exactly what you can and cannot change.

The pipeline

```
[P] = programmable    [F] = fixed function, configurable

INPUT ASSEMBLER                                          [F]
  reads vertex + index buffers, assembles primitives.
  Decides what a "triangle" is: list, strip, or fan.
     |  vertices
     v
VERTEX SHADER                                            [P]
  runs ONCE PER VERTEX. Transforms object space -> clip
  space. Must output SV_Position. Whatever else you emit is
  interpolated for the pixel shader.
     |
     v
[ HULL / TESSELLATOR / DOMAIN ]              [P][F][P]
  optional. Subdivide patches into more triangles on the
  GPU. Used for terrain and smooth surfaces; less popular
  now that mesh shaders exist.
     |
[ GEOMETRY SHADER ]                                      [P]
  optional, runs per PRIMITIVE, can emit 0..N primitives.
  Famously slow on most hardware - it serialises. Avoid.
     |
     v
CLIPPING + PERSPECTIVE DIVIDE + VIEWPORT                  [F]
  clip to the frustum, divide xyz by w, map to pixels.
     |
     v
RASTERISER                                               [F]
  triangles -> fragments. Also does back-face culling and
  the early-Z test. Generates 2x2 QUADS, always
  (chapter 8).
     |  fragments
     v
PIXEL / FRAGMENT SHADER                                  [P]
  runs ONCE PER FRAGMENT. Computes a colour. This is where
  nearly all your shading cost lives.
     |
     v
OUTPUT MERGER                                            [F]
  depth test, stencil test, blending, write to the render
  target. Blending is fixed-function because it must be
  ORDER-DEPENDENT and atomic per pixel.
     |
     v
RENDER TARGET

NOTE WHAT IS FIXED: rasterisation, clipping, depth test and
blending. These are fixed because they are done billions of
times per frame and because they need guarantees
(ordering, atomicity) that general code cannot give
cheaply. You configure them; you do not write them.
```

> **THE TWO COUNTS THAT DECIDE YOUR FRAME TIME**
>
> Vertex shaders run per *vertex* — perhaps a million per frame. Pixel shaders run per *fragment* — at 4K with any overdraw, tens of millions. A pixel shader is typically 10–100× more invocations than the vertex shader, which is why "move work to the vertex shader" is the oldest optimisation in real-time graphics, and why overdraw matters so much.

The coordinate spaces

```
/* A vertex is transformed through five spaces. Every graphics
   bug that renders "nothing at all" is a matrix in the wrong
   place in this chain.                                        */

  OBJECT / MODEL SPACE    the mesh as the artist made it,
                          origin at its own centre
        | x World matrix          (position, rotate, scale)
        v
  WORLD SPACE             everything in one shared frame
        | x View matrix           (the inverse of the camera's
        v                          transform)
  VIEW / CAMERA SPACE     camera at the origin, looking down
                          -Z (GL) or +Z (D3D)
        | x Projection matrix     (frustum -> a cube)
        v
  CLIP SPACE              homogeneous. -w <= x,y <= w and
                          0 <= z <= w (D3D) or -w <= z <= w (GL)
        | divide by w             (the PERSPECTIVE DIVIDE)
        v
  NDC                     the canonical cube
        | viewport transform
        v
  SCREEN SPACE            pixels, plus a depth in [0,1]

/* The vertex shader's job is object -> clip. Everything after
   is fixed function.                                          */

float4 VSMain(float3 pos : POSITION) : SV_Position
{
        float4 world = mul(float4(pos, 1.0), World);
        float4 view  = mul(world, View);
        return mul(view, Projection);          /* CLIP space   */
        /* Do NOT divide by w yourself - the hardware does it,
           and it also uses w for perspective-correct
           interpolation.                                       */
}

/* D3D vs GL DIFFERENCES that cause upside-down or clipped
   output when porting:
     clip-space Z range   D3D [0,1]      GL [-1,1]
     texture origin       D3D top-left   GL bottom-left
     matrix convention    D3D row-major, row-vector by default
                          GL  column-major, column-vector
   Vulkan follows D3D on Z and GL on Y, which catches
   everyone exactly once.                                      */
```

Perspective-correct interpolation

```
The rasteriser interpolates your vertex outputs across the
triangle. Doing that LINEARLY IN SCREEN SPACE is wrong for
anything in perspective.

A wall receding into the distance, with a checker texture:

  LINEAR interpolation of u:
    the checks stay evenly spaced -> the wall looks like
    it is BENDING. This is the classic PlayStation 1 look;
    that hardware had no perspective correction.

  PERSPECTIVE-CORRECT:
    interpolate u/w and 1/w linearly, then divide:
          u = (u/w interpolated) / (1/w interpolated)
    checks compress with distance. Correct.

The hardware does this for you, per attribute, which is
why the vertex shader must output w and must NOT divide.

YOU CAN TURN IT OFF, and occasionally should:

  noperspective float2 screenUV : TEXCOORD0;
    for screen-space effects, where you want the value to
    vary linearly in pixels.

  nointerpolation uint materialID : TEXCOORD1;
    "flat" - takes the value from the provoking vertex.
    MANDATORY for integers: interpolating an ID gives you
    fractional nonsense.
```

Hidden surface removal

```
/* Drawing a pixel you cannot see costs the same as one you
   can. Four mechanisms remove that work, at different
   stages.                                                  */

/* 1. BACK-FACE CULLING - rasteriser, free.
      Discards triangles facing away, based on winding order.
      Removes ~50% of a closed mesh for nothing.           */
        rasterizerDesc.CullMode = D3D12_CULL_MODE_BACK;
        rasterizerDesc.FrontCounterClockwise = FALSE;
/* If your model renders inside-out, this is the setting. */

/* 2. FRUSTUM CULLING - your code, on the CPU or in a compute
      shader. Do not submit what is off-screen.            */

/* 3. EARLY-Z - rasteriser, before the pixel shader.
      Tests depth BEFORE shading. The single biggest saving
      in a typical scene.

      IT IS DISABLED, silently, if the pixel shader:
        * writes SV_Depth
        * uses `discard` / `clip()`
        * writes to a UAV
      because in each case the hardware cannot know the final
      depth or whether the pixel survives before running the
      shader.

      So a single alpha-test material can cost far more than
      its pixel count suggests: it forces late-Z for those
      draws. If you must discard, mark it:                 */
        [earlydepthstencil]           /* HLSL: "test anyway,
        void PSMain(...) { ... }         I promise it is safe" */

/* 4. HIERARCHICAL-Z - a low-resolution depth pyramid, so
      whole tiles can be rejected at once. Automatic, but it
      is INVALIDATED by depth writes from the pixel shader
      and by changing the depth comparison direction
      mid-frame. Pick one direction and keep it.           */

/* THE STANDARD CONSEQUENCE: sort opaque geometry FRONT TO
   BACK. Near objects fill the depth buffer first, so far
   ones fail early-Z and never shade. Then draw transparent
   geometry BACK TO FRONT, because blending is order
   dependent - and that is why transparency is expensive and
   why it cannot use early-Z at all.                        */
```

OVERDRAW IS MEASURED IN SHADED FRAGMENTS, NOT PIXELS

A 4K frame is 8.3 million pixels. With an average overdraw of 3 — perfectly normal for a scene with foliage, particles and UI — the pixel shader runs 25 million times. Halving the shader cost saves less than eliminating one layer of overdraw. Every profiler has an overdraw visualisation; it is usually the first place to look when a frame is slow and the geometry count is modest.

Mesh shaders: the pipeline being replaced

```
The front of the pipeline is a 1998 design: fixed input
assembly, one vertex in and one vertex out, optional
tessellation stages nobody enjoys.

MESH SHADERS (DX12 Ultimate, Vulkan, Metal) replace
IA + VS + hull/domain/GS with two compute-like stages:

  AMPLIFICATION / TASK SHADER
    runs first, decides HOW MANY mesh shader groups to
    launch. This is where you do GPU-side culling.
     |
  MESH SHADER
    a workgroup cooperatively produces a MESHLET - a small
    batch of vertices and primitives (typically up to 64
    vertices, 126 triangles) - and writes them straight
    into the rasteriser.

WHY IT IS BETTER
  * you control the data layout; no fixed input assembler
  * culling per meshlet, on the GPU, before any vertex work
  * no serialisation bottleneck like the geometry shader
  * one workgroup can share vertex work across triangles

WHY IT IS NOT UNIVERSAL YET
  * needs newer hardware (Turing+, RDNA2+)
  * the asset pipeline must build meshlets offline
  * the classic path still works fine for most content

Worth knowing exists; the rest of this track uses the
classic pipeline because that is what you will meet.
```

How it shows up

Symptom	Cause
Nothing renders at all	Matrix order wrong, or the object is behind the camera or outside the frustum
Model appears inside-out	Winding order versus cull mode
Textures swim or bend on receding surfaces	Interpolation not perspective-correct — usually because `w` was divided too early
Image is upside down after a port	D3D/GL texture origin or clip-space Y
Geometry clipped at the wrong distance	D3D [0,1] versus GL [-1,1] clip Z
An integer varying comes through as garbage	Needs `nointerpolation`
Frame time collapses when foliage appears	`discard` disabled early-Z for those draws
Depth pre-pass made it slower	The scene was not overdraw-bound; you doubled the geometry cost
Transparent objects render in the wrong order	Blending is order-dependent; sort back to front
Geometry shader is unexpectedly slow	It serialises on most hardware — use instancing or mesh shaders

Check yourself

- ✓ List the pipeline stages in order and mark which are programmable.
- ✓ Say why rasterisation and blending are fixed function.

- ✓ Give the ratio of pixel-shader to vertex-shader invocations in a typical frame.
- ✓ Name the five coordinate spaces and the matrix between each pair.
- ✓ Explain why the vertex shader must not divide by `w`.
- ✓ Explain perspective-correct interpolation and what it looks like when absent.
- ✓ Say when to use `noperspective` and when `nointerpolation` is mandatory.
- ✓ Name three things that disable early-Z and why each does.
- ✓ Explain the sort order for opaque and for transparent geometry, and why they differ.
- ✓ Describe what mesh shaders replace and the main advantage they bring.

Shaders and the programmable stages

A shader is a small program run millions of times a frame with no memory of the last invocation. Learning the language takes an afternoon; learning what it may and may not do — and how it gets from source to silicon — is the part that matters.

The languages, and the IRs beneath them

```
HLSL   ---> DXBC        DX11 and earlier
       ---> DXIL        DX12 Shader Model 6+, LLVM-based
       ---> SPIR-V      via DXC, for Vulkan

GLSL   ---> SPIR-V      OpenGL 4.6, Vulkan
MSL    ---> AIR         Metal
WGSL   ---> whatever    WebGPU
Slang  ---> all of them a newer language that targets
                        everything; increasingly common

THE TWO-STAGE COMPILE, and it explains a lot:

  OFFLINE     your HLSL -> DXIL/SPIR-V.  Portable IR, but
              still not machine code. Ships in your app.
  AT RUNTIME  the DRIVER compiles IR -> the actual ISA of
              the installed GPU.

CONSEQUENCES

  * you cannot ship machine code: the ISA differs per
    vendor, per generation, and is often undocumented.
  * the FIRST use of a shader triggers a driver compile,
    which is why games stutter on new effects and why
    "shader pre-caching" screens exist.
  * a driver update can change your shader's performance
    without you rebuilding anything.
  * two GPUs disagreeing about your shader is usually two
    different back-end compilers, not a spec violation.

PIPELINE STATE OBJECTS (chapter 15) exist largely to give
the driver everything it needs to do this compile ONCE, at
a time you choose, instead of mid-frame.
```

```
// HLSL, the whole language you need for a first shader.

cbuffer PerObject : register(b0)      // constant buffer
{
    float4x4 WorldViewProj;
    float4   Tint;
};

Texture2D    Albedo  : register(t0);  // SRV
SamplerState Linear  : register(s0);  // sampler

struct VSIn {
    float3 pos    : POSITION;         // SEMANTICS bind these
    float3 normal : NORMAL;           // to vertex buffer
    float2 uv     : TEXCOORD0;        // elements
};

struct VSOut {
    float4 pos    : SV_Position;      // SV_ = SYSTEM VALUE,
    float3 normal : NORMAL;           // meaningful to the
    float2 uv     : TEXCOORD0;        // fixed-function stages
};

VSOut VSMain(VSIn i)
{
    VSOut o;
    o.pos    = mul(float4(i.pos, 1.0), WorldViewProj);
    o.normal = i.normal;
    o.uv     = i.uv;
    return o;
}

float4 PSMain(VSOut i) : SV_Target       // -> render target 0
{
    float3 n = normalize(i.normal);      // renormalise: linear
                                         // interpolation of
                                         // unit vectors does
                                         // NOT preserve length
    float  ndl = saturate(dot(n, float3(0, 1, 0)));
    float4 base = Albedo.Sample(Linear, i.uv);
    return base * Tint * (ndl * 0.8 + 0.2);
}
```

> **SEMANTICS ARE THE WIRING**
>
> There are no linkers between shader stages. `TEXCOORD0` out of the vertex shader connects to `TEXCOORD0` in the pixel shader *by name*, and the input layout binds `POSITION` to a byte offset in the vertex buffer *by name*. A mismatched or missing semantic is the commonest reason a mesh renders as garbage, and it usually produces no error — just wrong data.

Types and what is actually fast

Type	Cost	Notes
`float`, `float2/3/4`	1 lane-op	The native type. A `float4` is *not* a SIMD vector on modern GPUs — it is four scalar ops
`half` / `min16float`	Often 2× throughput	Real win on mobile and on tensor-heavy work; on desktop often just converted

Type	Cost	Notes
`double`	1/32 to 1/64 rate on consumer parts	Effectively unusable outside compute-focused hardware
`int` / `uint`	~same as float	Integer division and modulo are *very* slow — use bit ops for powers of two
`rcp`, `rsqrt`, `exp2`, `log2`, `sin`	1 SFU op, ~4× slower issue rate	Still cheap. `rsqrt` is faster than `1.0/sqrt()`
`pow(x, y)`	`exp2(y * log2(x))`	Two SFU ops; and it is *wrong* for negative `x`
`normalize`	`rsqrt` + 3 muls	Cheap. Do it in the pixel shader after interpolation
Branching	See chapter 3	Free if the whole wave agrees
Texture sample	~100s of cycles, latency-hidden	The dependent-sample chain is what actually costs you

```
/* Things that are slower than they look. */

  a / b            -> reciprocal + multiply. Fine.
  a % b   (int)    -> genuinely slow. If b is a power of two,
                      use a & (b-1).
  a / b   (int)    -> same. Use a >> log2(b).
  pow(x, 2)        -> use x * x. The compiler often catches
                      this; do not rely on it.
  length(v) < r    -> compare SQUARED lengths and skip the
                      sqrt entirely: dot(v,v) < r*r
  sin/cos of the
    same angle     -> sincos(x, s, c) computes both at once

/* Things that are faster than they look. */

  saturate(x)      -> FREE. It is an output modifier on the
                      preceding instruction, not an operation.
                      Prefer it to clamp(x, 0, 1).
  mad / fma        -> a*b+c is ONE instruction. Write your
                      arithmetic so it factors that way.
  lerp(a, b, t)    -> one mad.
  swizzles         -> free. v.xyzw, v.wwww, v.xz cost nothing.
  abs and negate   -> free input modifiers.

/* The general rule: the ALU is nearly free; MEMORY and
   DIVERGENCE are what cost. Optimising arithmetic in a shader
   that is texture-bound is wasted effort - measure first. */
```

What a shader may not do

```
NO recursion            the stack is finite and tiny.
                        (Ray-tracing shaders are the one
                        exception, with a bounded depth.)

NO function pointers    everything is inlined. There is no
                        call in the final ISA.

NO dynamic allocation   no malloc, no new. All storage is
                        declared up front.

NO pointers, mostly     buffers are indexed, not chased.
                        (DX12 has descriptor indexing, and
                        newer models add buffer pointers.)

NO cross-invocation
  communication         except within a wave (chapter 2) or
                        a compute workgroup via groupshared.
                        Two pixels cannot talk.

NO guaranteed order     pixel shader invocations complete in
                        any order. Blending is ordered by
                        fixed-function hardware, not by you.

LOOPS must be bounded   or the compiler unrolls until it
                        gives up. An unbounded while loop
                        driven by a texture value will
                        either fail to compile or produce a
                        multi-megabyte shader.

[loop]     forces a real loop (smaller code, more
           divergence)
[unroll]   forces unrolling (bigger code, more registers,
           often much faster)
[branch]   real branch
[flatten]  evaluate both sides and select

These attributes matter: a [unroll] on a 4-iteration loop
is usually a clear win, and a missing [loop] on a long one
can blow your register budget and destroy occupancy
(chapter 5).
```

Derivatives, and why pixels come in quads

```
/* The rasteriser ALWAYS shades 2x2 quads, even for a triangle
   covering one pixel. The other three lanes are "helper
   invocations": they run, they compute, their output is
   discarded.

   WHY: mip level selection needs to know how fast the texture
   coordinate is changing across the screen, and the only way
   to know that is to compare with your neighbour.          */

        float2 dx = ddx(uv);       /* difference with the pixel
                                      to the right             */
        float2 dy = ddy(uv);       /* ... and below            */
        /* Texture.Sample() calls these implicitly to pick a
           mip level.                                          */

/* THREE CONSEQUENCES

   1. SMALL TRIANGLES ARE EXPENSIVE. A triangle covering one
      pixel still costs four pixel-shader invocations - 4x
      the shading for the same coverage. This is why dense
      meshes tank performance long before the vertex cost
      matters, and the main problem meshlets and variable-rate
      shading exist to address.

   2. YOU CANNOT SAMPLE WITH IMPLICIT MIPS IN DIVERGENT FLOW.
      If half the quad took the other branch, its derivative
      is undefined. The compiler will either hoist the sample
      out of the branch or warn you. Use SampleLevel() or
      SampleGrad() to supply the mip yourself:             */
        if (someCondition)
                c = tex.Sample(s, uv);         /* UNDEFINED    */
        c = tex.SampleLevel(s, uv, 0);         /* fine anywhere */

   3. DERIVATIVES ARE PER-QUAD, so ddx of a value that varies
      per-pixel is a 2x2 approximation, not a true gradient.
      Screen-space effects built on ddx are blocky at 2x2
      granularity by construction.                         */
```

> **THE DENSE-MESH TRAP**
>
> Quad overshading means a mesh tessellated to sub-pixel triangles can cost *four times* the pixel shading of the same silhouette drawn with larger triangles — while every profiler tells you the pixel shader is the bottleneck, which it is, for a reason that has nothing to do with the shader. Check triangle size before optimising shader code on a highly detailed asset.

How it shows up

Symptom	Cause
Mesh renders as garbage, no errors	Semantic mismatch between input layout and vertex shader
Lighting is subtly wrong across a triangle	Normal not renormalised after interpolation
First frame with a new effect stutters	Driver compiling the shader on demand — pre-warm the PSOs
Works on NVIDIA, artefacts on AMD	Different back-end compilers; often uninitialised values or undefined behaviour you got away with

Symptom	Cause
Shader compile takes minutes	An unrolled loop with a large or unbounded trip count
Occupancy collapses after a small edit	Register pressure from unrolling
Blurry or aliased textures in a branch	Implicit-mip sample inside divergent flow
High-poly model far slower than expected	Quad overshading on sub-pixel triangles
`pow` returns NaN	Negative base — `pow` is `exp2(y*log2(x))`
Integer modulo dominates the profile	Use a bitmask if the divisor is a power of two

Check yourself

- ✓ Describe the two-stage shader compile and name three consequences.
- ✓ Explain what semantics do and why a mismatch produces no error.
- ✓ Say why a `float4` is not a SIMD vector on modern GPUs.
- ✓ Name four operations that are slower than they look and four that are free.
- ✓ Explain why `saturate` costs nothing.
- ✓ List five things a shader may not do.
- ✓ Explain what `[unroll]` and `[loop]` trade against each other.
- ✓ Explain why pixels are shaded in 2×2 quads.
- ✓ Give the three consequences of quad shading, including the one about dense meshes.
- ✓ Say why `Sample` is undefined in divergent flow and what to use instead.

Rasterisation, depth and blending

The fixed-function stages nobody writes and everybody has to configure. Getting the rules wrong here produces cracks between triangles, z-fighting, transparency in the wrong order, and shadow acne — a catalogue of artefacts that all look like bugs in your shader and are not.

Rasterisation is a coverage test

```
For each pixel, is its CENTRE inside the triangle?

     +-------+-------+-------+
     |       |   *   |       |    * = pixel centre
     |   *   |  / \  |   *   |
     +-------+-/---\-+-------+
     |     */|      \|       |
     |     / |   *   |\  *   |
     +----/--+-------+-\-----+

Not "does the triangle overlap the pixel". The CENTRE.
That single rule gives you everything below.

THE TOP-LEFT RULE
  A pixel centre exactly on an edge belongs to exactly one
  triangle: the one for which that edge is a top or left
  edge. Without a tie-break rule, two triangles sharing an
  edge would either both draw that pixel (double-blending
  -> a visible seam in transparent geometry) or neither
  (a crack -> a one-pixel gap you can see through).

  This is why watertight meshes rasterise watertight. It is
  also why "gaps between adjacent triangles" is almost
  never a rasterisation bug and almost always your vertices
  not being bit-for-bit identical: compute a shared vertex
  ONCE and reuse it, do not recompute it per triangle.

SUB-PIXEL PRECISION
  Vertices snap to a fixed-point grid, typically 1/256 of a
  pixel (8 sub-pixel bits). Very large coordinates lose
  precision and wobble; this is one reason to keep world
  coordinates near the origin, or to use camera-relative
  rendering for large worlds.
```

Multisampling

```
/* The trick: decouple COVERAGE from SHADING.

   Supersampling  = shade every sample.  4x SSAA = 4x cost.
   Multisampling  = shade ONCE per pixel, test coverage and
                    depth per SAMPLE, resolve at the end.
                    4x MSAA costs ~1.2x shading and 4x memory
                    bandwidth on the render target.          */

  1 sample                4 samples (4x MSAA)
   +-------+               +-------+
   |       |               |  x  x |    each sample gets its
   |   *   |               |   *   |    own coverage bit and
   |       |               |  x  x |    depth value; all four
   +-------+               +-------+    share ONE shaded colour

/* WHY IT ONLY FIXES GEOMETRIC ALIASING

   MSAA antialiases EDGES, because that is where coverage
   varies. It does nothing for:
     * shader aliasing - a specular highlight that flickers,
       a high-frequency normal map. The shader ran once.
     * alpha-tested foliage - coverage is decided inside the
       shader by `discard`, after MSAA has done its work.
       ALPHA-TO-COVERAGE converts alpha into a coverage mask
       and restores MSAA's usefulness there.

   THIS IS WHY MSAA FELL OUT OF FASHION with deferred
   rendering: a G-buffer stores per-sample data, so MSAA
   multiplies its already-large memory cost, and the lighting
   pass has to run per sample to benefit. Post-process
   antialiasing (FXAA, SMAA) and temporal methods (TAA, DLSS,
   FSR) took over - they are cheaper and they also catch
   shader aliasing, at the cost of blur and ghosting.       */

/* Per-sample shading, when you do want it: */
        float4 PSMain(VSOut i, uint sample : SV_SampleIndex)
        /* declaring SV_SampleIndex forces the shader to run
           PER SAMPLE - i.e. supersampling. Know that you are
           asking for 4x the shading.                        */
```

Depth: precision, and where the artefacts come from

```
Z-FIGHTING: two surfaces at nearly the same depth flicker
between each other as the camera moves. It is a precision
failure, and the cause is almost always the near plane.

THE PROBLEM: the perspective divide makes depth
NON-LINEAR. With a 24-bit depth buffer, near=0.1,
far=1000:

     distance     depth values available
     0.1 - 0.2    ~8,000,000     (half the buffer!)
     1   - 2      ~800,000
     10  - 20     ~80,000
     100 - 200    ~8,000
     900 - 1000   ~200            <-- z-fighting lives here

PRECISION IS PROPORTIONAL TO near/far. Moving the near
plane from 0.1 to 1.0 gains you TEN TIMES the precision
everywhere else. Pushing the far plane out costs you almost
nothing by comparison.

THE FIXES, in order of effectiveness:

1. RAISE THE NEAR PLANE. Free, and usually enough.

2. REVERSED-Z. Map near->1.0, far->0.0, clear to 0, and
   use GREATER_EQUAL. Floating-point has most of its
   precision near 0, and the perspective divide puts most
   depth range near 1 - so reversing them CANCELS OUT.
   With a 32-bit float depth buffer this is close to
   uniform precision across the whole range, for free.
   It is the modern default and there is no reason not to
   use it.

3. A 32-bit float depth buffer instead of 24-bit unorm.

4. Depth bias / polygon offset, for coplanar geometry like
   decals - but this is a patch, not a fix.
```

```
/* Reversed-Z, in DX12. Three changes, no shader edits. */

  /* 1. Build the projection with near and far swapped. */
     XMMatrixPerspectiveFovLH(fov, aspect, farZ, nearZ);

  /* 2. Clear depth to 0 instead of 1. */
     cmd->ClearDepthStencilView(dsv, D3D12_CLEAR_FLAG_DEPTH,
                                0.0f, 0, 0, nullptr);

  /* 3. Reverse the comparison. */
     dsDesc.DepthFunc = D3D12_COMPARISON_FUNC_GREATER_EQUAL;

/* Use a DXGI_FORMAT_D32_FLOAT buffer to get the full benefit.
   Note hierarchical-Z may need a depth-buffer "resummarise"
   if you change the comparison direction mid-frame - so pick
   one direction and stay with it (chapter 6).             */

/* SHADOW ACNE is the same family of problem: a shadow map
   samples depth at a different resolution than the receiving
   surface, so a surface shadows itself.
     depth bias        - shift the comparison; causes PETER
                         PANNING (shadows detach) if too large
     slope-scaled bias - scale the bias by the surface angle;
                         much better, and what you want
     normal offset     - move the sample position along the
                         normal instead of the depth; best
     front-face culling when rendering the shadow map - cheap
                         and effective for closed meshes    */
```

RAISE THE NEAR PLANE BEFORE ANYTHING ELSE

Depth precision is dominated by the ratio near:far, and the relationship is roughly linear in `near`. A team fighting z-fighting with bias tweaks and 32-bit buffers can often fix it entirely by changing `0.01f` to `0.5f` in one line — assuming nothing legitimately gets that close to the camera. Check that number first, every time.

Blending, and why order matters

```
/* Blending is fixed function because it must be atomic per
   pixel and applied in DRAW ORDER. The general form:      */

        result = src * SrcBlend  BlendOp  dst * DestBlend

/* The ones you actually use: */

  OPAQUE            src=ONE  dst=ZERO
                    (or just disable blending)

  ALPHA BLEND       src=SRC_ALPHA  dst=INV_SRC_ALPHA  op=ADD
                    result = s.rgb*s.a + d.rgb*(1-s.a)
                    ORDER DEPENDENT. Must sort back to front.

  PREMULTIPLIED     src=ONE  dst=INV_SRC_ALPHA
                    the colour already has alpha baked in.
                    Better: it composites correctly, filters
                    correctly, and makes "additive" and
                    "alpha" the same blend state with
                    different data. Prefer it.

  ADDITIVE          src=ONE  dst=ONE
                    ORDER INDEPENDENT - addition commutes.
                    Fire, sparks, glow. No sorting needed.

  MULTIPLY          src=DEST_COLOR  dst=ZERO

/* THE TRANSPARENCY PROBLEM

   Alpha blending needs back-to-front order. But:
     * sorting per object fails when objects intersect
     * sorting per triangle is expensive and still fails for
       a single self-intersecting mesh
     * you cannot use early-Z, so overdraw is fully paid

   MITIGATIONS
     depth PRE-PASS then depth-write-off for transparents:
       stops transparent surfaces occluding each other wrongly
     alpha test instead of blend where the edges allow it:
       restores Z, at the cost of hard edges
     WEIGHTED BLENDED OIT: an order-independent approximation
       that is cheap and looks acceptable for particles
     per-pixel linked lists / ROVs: exact, expensive, rarely
       worth it outside CAD

   Transparency remains genuinely unsolved in real-time
   graphics. Every game ships with a compromise.          */
```

> **ALPHA-BLENDED GEOMETRY MUST NOT WRITE DEPTH**
>
> If a transparent surface writes to the depth buffer, later transparent surfaces behind it fail the depth test and vanish — a very common "my particles disappear behind glass" bug. The standard setup is: depth *test* on, depth *write* off, sorted back to front. Opaque geometry writes depth; transparent geometry only reads it.

How it shows up

Symptom	Cause
One-pixel cracks between adjacent triangles	Shared vertices computed twice and not bit-identical
Dark seams in transparent geometry	Double-blending along a shared edge — usually a duplicated vertex
Surfaces flicker between each other	Z-fighting — raise the near plane, or use reversed-Z
Geometry wobbles far from the origin	Sub-pixel precision loss; use camera-relative coordinates
Shadows have stripes on lit surfaces	Shadow acne — use slope-scaled bias or normal offset
Shadows detached from their casters	Depth bias too large — peter panning
MSAA does nothing for foliage	Alpha test decides coverage after MSAA — use alpha-to-coverage
MSAA does nothing for shimmering highlights	Shader aliasing; MSAA only fixes edges
Particles vanish behind glass	Transparent geometry writing depth
Transparent objects pop as the camera moves	Per-object sorting with intersecting geometry
Everything is dark after switching to premultiplied	Textures not converted — the colour must be multiplied by alpha

Check yourself

- ✓ State the coverage rule and explain what the top-left rule prevents.
- ✓ Explain why cracks between triangles are usually a vertex problem, not a rasteriser one.
- ✓ Distinguish supersampling from multisampling and give the cost of each.
- ✓ Name two kinds of aliasing MSAA does not fix, and what does.
- ✓ Explain why depth precision is concentrated near the camera.
- ✓ Explain reversed-Z and why it works, and list the three changes it needs.
- ✓ Say which single parameter most affects z-fighting.
- ✓ Name three shadow-acne mitigations and rank them.
- ✓ Give the blend factors for alpha, premultiplied and additive, and say which is order-independent.
- ✓ Explain why transparent geometry must not write depth.

Textures, samplers and compression

Textures are the largest thing in memory and the largest source of bandwidth in most frames. The hardware gives you filtering, mip selection and decompression for free — provided you set up half a dozen things correctly, each of which has a characteristic artefact when you do not.

What a sample actually does

```
Texture.Sample(sampler, uv) is not a memory read. It is a
fixed-function unit doing five things:

1. ADDRESS      apply the wrap mode to uv
                (wrap / clamp / mirror / border)

2. MIP SELECT   from ddx(uv), ddy(uv) - the derivatives
                from the 2x2 quad (chapter 7) - compute how
                many texels fall in one pixel, and pick the
                level where that ratio is ~1.

3. FETCH        read 4 texels (bilinear) from level N, and
                4 more from level N+1 if trilinear

4. DECOMPRESS   BC/ASTC blocks are decoded in hardware, for
                free, at full rate

5. FILTER       blend the 4 (or 8) samples

A trilinear anisotropic 16x sample can read 128 texels. It
is one instruction in your shader and a great deal of work
in the texture unit - which is why texture-bound is such a
common state, and why the SAMPLER settings matter as much
as the shader.
```

Mipmaps

```
/* A chain of half-size images. Level 0 is full resolution,
   level 1 is half, and so on to 1x1.

   COST: +33% memory.        1 + 1/4 + 1/16 + ... = 4/3
   BENEFIT: enormous, and in two ways.                    */

/* 1. CORRECTNESS. Without mips, a surface at a distance where
      one pixel covers 16 texels samples ONE of those 16 at
      random. As the camera moves, WHICH one changes -> the
      texture crawls and shimmers. This is the single most
      visible aliasing artefact in real-time graphics.

   2. PERFORMANCE. Without mips, adjacent pixels sample texels
      far apart, so the texture cache misses constantly. WITH
      mips, a distant surface reads a small image that fits in
      cache. Mips often make distant geometry SEVERAL TIMES
      faster, not just prettier.

   MIP SELECTION uses the derivatives, which is why:
     - implicit-mip sampling in divergent flow is undefined
       (chapter 7)
     - a shader that computes uv from a branch may pick the
       wrong level and produce a visible seam
     - SampleLevel() with a hardcoded 0 disables all of this,
       reintroducing shimmer AND the cache misses. Use it only
       when you genuinely want level 0.                    */

/* MIP BIAS: nudge the selection. */
        tex.SampleBias(s, uv, -0.5);   /* sharper, more aliased */
        tex.SampleBias(s, uv, +1.0);   /* blurrier, cheaper     */
/* A slight negative bias is standard when using TAA, because
   temporal accumulation restores the detail while suppressing
   the aliasing.                                              */
```

> **GENERATE MIPS OFFLINE, NOT AT LOAD TIME**
>
> A proper offline chain uses a good filter (Kaiser or similar), can be gamma-correct, and handles normal maps specially — renormalising after downsampling, because averaging unit vectors does not produce a unit vector. Runtime `GenerateMips` is a box filter in linear space applied to whatever you give it, which makes normal maps flatten and sRGB textures darken as they recede. It is fine for a prototype and wrong for a product.

Filtering and anisotropy

Filter	Taps	Use for
Point / nearest	1	Pixel art, index/ID lookups, any texture where interpolating between values is meaningless
Bilinear	4	Within one mip level. The baseline
Trilinear	8	Bilinear on two mip levels, blended. Removes the visible band where the mip changes
Anisotropic *N*×	up to 8*N*	Surfaces seen at a glancing angle — floors, roads, terrain. The single best quality-per-cost setting there is

```
/* WHY ANISOTROPIC EXISTS

   A floor stretching to the horizon: one pixel covers a
   footprint that is 1 texel wide and 16 texels long.

   Isotropic mip selection must pick ONE level. It picks based
   on the LONGEST axis, so it chooses a level 16x too blurry -
   and the floor turns to mush in the distance. Choose by the
   shortest axis instead and it shimmers violently.

   Anisotropic filtering takes several samples ALONG the long
   axis at the sharper mip level. Correct in both directions.

   16x anisotropic typically costs a few percent of frame time
   and is the most visible quality setting in any game. Enable
   it.                                                        */

D3D12_SAMPLER_DESC s = {};
s.Filter         = D3D12_FILTER_ANISOTROPIC;
s.MaxAnisotropy  = 16;
s.AddressU       = D3D12_TEXTURE_ADDRESS_MODE_WRAP;
s.AddressV       = D3D12_TEXTURE_ADDRESS_MODE_WRAP;
s.AddressW       = D3D12_TEXTURE_ADDRESS_MODE_WRAP;
s.MipLODBias     = 0.0f;
s.MinLOD         = 0.0f;
s.MaxLOD         = D3D12_FLOAT32_MAX;    /* NOT 0 - a very
                                            common typo that
                                            disables mips
                                            entirely          */

/* COMPARISON SAMPLERS - for shadow maps. The hardware does
   the depth compare AND the bilinear filter in one go, giving
   free 2x2 percentage-closer filtering: */
s.Filter         = D3D12_FILTER_COMPARISON_MIN_MAG_LINEAR_MIP_POINT;
s.ComparisonFunc = D3D12_COMPARISON_FUNC_LESS_EQUAL;
        /* HLSL: shadowMap.SampleCmpLevelZero(cmpSampler, uv, z) */
```

Block compression

```
Textures are stored compressed and decoded IN THE TEXTURE
UNIT, for free, on every sample. This is not a load-time
decompression - the compressed data stays compressed in
VRAM, so it saves memory AND bandwidth AND cache space, all
at once. It is the highest-leverage decision in your asset
pipeline.

Fixed 4x4 blocks, fixed bits per block -> random access.

DESKTOP (BC / DXT / S3TC)
  BC1   0.5 B/texel  RGB + 1-bit alpha   8:1   albedo
  BC3   1.0 B/texel  RGBA               4:1   albedo+alpha
  BC4   0.5 B/texel  single channel     -     height, mask
  BC5   1.0 B/texel  two channels       -     NORMAL MAPS
  BC6H  1.0 B/texel  HDR RGB (float)    -     env maps
  BC7   1.0 B/texel  high-quality RGBA  4:1   everything
                                              modern

MOBILE
  ETC2  0.5-1 B/texel   the Android baseline
  ASTC  0.9-8 bpp       variable block size, best quality
                        per bit available anywhere

THE RULES

* NORMAL MAPS USE BC5, not BC7 or BC3. BC5 stores two
  channels at high precision; reconstruct z in the shader:
      n.xy = tex.Sample(s, uv).rg * 2 - 1;
      n.z  = sqrt(saturate(1 - dot(n.xy, n.xy)));
  Using a three-channel format for a normal map wastes bits
  on a channel you can derive, and BC1's colour-space
  assumptions produce visible blocking on normals.

* sRGB IS PART OF THE FORMAT. Use BC7_UNORM_SRGB for
  albedo so the hardware converts to linear for free on
  every sample. Doing the conversion in the shader is
  slower and wrong for filtering - the hardware filters in
  linear space, which is correct; shader conversion
  filters in sRGB space, which is not.

* NEVER compress data that is not colour. Masks, IDs,
  lookup tables and anything you index with must be
  uncompressed or BC4 - block compression is lossy and
  interpolates across block boundaries.
```

> **COMPRESSING A NORMAL MAP WITH BC1 OR BC7**
>
> The classic asset-pipeline bug. BC1 and BC7 are designed around perceptual colour and will happily introduce blocky artefacts in the X and Y of a normal — which show up as faceted, shimmering lighting on smooth surfaces that looks like a shader bug. BC5 exists for exactly this. If lighting looks blocky and the geometry is smooth, check the normal map's format before anything else.

Memory and streaming

```
/* THE ARITHMETIC that decides whether your game fits in VRAM. */

  4096 x 4096 RGBA8, uncompressed .... 64 MB   (+33% mips = 85)
  4096 x 4096 BC7 ................... 16 MB   (+mips = 21)
  4096 x 4096 BC1 ................... 8 MB    (+mips = 11)

  200 such textures, uncompressed .... 17 GB   impossible
  200 such textures, BC7 ............. 4.2 GB  plausible
  200 such textures, BC7 + streaming . ~1 GB   what ships

/* STREAMING: keep only the mip levels you need resident.

   A texture on a distant object needs only its 64x64 mip -
   16 KB instead of 21 MB. The standard system:
     1. every frame, work out the desired mip per texture,
        either from a feedback buffer or from distance
     2. asynchronously load missing levels
     3. evict levels nobody wants

   DX12 gives you RESERVED (tiled) RESOURCES for this: a
   texture whose pages are mapped individually, so you can
   have a 16K x 16K texture with only the visible tiles
   resident. Vulkan calls them sparse resources.

   SAMPLER FEEDBACK (DX12 Ultimate) makes the GPU tell you
   which tiles were actually sampled, which removes the
   guesswork.                                            */

/* AND THE PRACTICAL ADVICE: measure with a tool, not by
   adding up your assets. */
$ # PIX on Windows: memory view shows per-resource residency
$ # RenderDoc: resource inspector, and the texture viewer
$ #   shows the actual format and mip chain
$ nvidia-smi                      # total VRAM in use
```

How it shows up

Symptom	Cause
Texture crawls and shimmers in the distance	No mipmaps, or `MaxLOD` left at 0
Distant geometry is unexpectedly slow	Same cause — mip-less sampling thrashes the texture cache
Floors and roads look blurry at a glancing angle	Anisotropic filtering off
Visible band where the mip level changes	Bilinear instead of trilinear
Lighting is blocky on smooth surfaces	Normal map compressed with BC1/BC7 instead of BC5
Normal maps look flat after mip generation	Mips not renormalised — generate them offline
Textures darken as they recede	Mips generated in sRGB space rather than linear
Colours are washed out or too dark overall	sRGB format not used; the conversion is missing or doubled
Seams at texture edges	Wrap mode should be clamp, or the atlas has no padding
Mask or ID lookups return wrong values	A non-colour texture was block-compressed, or a linear filter is interpolating IDs
Out of VRAM	Uncompressed textures, or no streaming

Check yourself

- ✓ List the five things a texture sample does in hardware.
- ✓ Give the memory cost of a mip chain and two distinct benefits.
- ✓ Explain how mip level is selected and why that breaks in divergent flow.
- ✓ Explain why mipless sampling is slow as well as ugly.
- ✓ Explain why anisotropic filtering exists, in terms of the pixel footprint.
- ✓ Name the format for normal maps and how to reconstruct the third channel.
- ✓ Explain why sRGB should be part of the texture format rather than a shader conversion.
- ✓ Say which data must never be block-compressed and why.
- ✓ Compute the memory for a 4K RGBA8 texture with mips, and the same in BC7.
- ✓ Describe how texture streaming decides what to keep resident.

Tile-based rendering on mobile GPUs

Every phone, tablet and Apple Silicon GPU renders in a fundamentally different order from a desktop card. It is not a minor variation — it inverts which operations are cheap, and a renderer tuned for one architecture can be several times slower on the other.

Bandwidth is the whole reason

```
A desktop GPU has 500–3000 GB/s of dedicated GDDR/HBM and
a 300 W power budget.

A phone has ~50 GB/s of LPDDR, SHARED with the CPU, and
about 3 W for the whole SoC.

THE PHYSICS: moving a byte off-chip costs roughly 100x the
energy of an arithmetic operation. On a phone, DRAM traffic
IS the power budget, and power is the thermal budget, and
thermal is your sustained frame rate.

IMMEDIATE MODE (desktop) - what it costs

  for each triangle:
          rasterise
          for each fragment:
                  READ depth from DRAM
                  test, shade
                  WRITE depth to DRAM
                  READ colour, blend, WRITE colour

  Every fragment touches off-chip memory several times.
  Fine at 3 TB/s. Impossible at 50 GB/s.

TILE-BASED DEFERRED RENDERING (mobile) - the fix

  PHASE 1 - BINNING
    run ALL vertex shaders for the whole frame.
    sort the resulting primitives into screen TILES
    (typically 16x16 or 32x32 pixels).
    write the per-tile primitive lists to memory.

  PHASE 2 - for each tile, independently:
    the tile's colour+depth live in ON-CHIP TILE MEMORY -
    a few tens of KB, single-cycle access
    rasterise and shade every primitive in that tile
    ... all depth and blending traffic stays ON CHIP ...
    finally, WRITE THE FINISHED TILE to DRAM. Once.

RESULT: the colour buffer is written exactly once per
frame, and the depth buffer need never be written at all.
Bandwidth drops by an order of magnitude.
```

THE CONSEQUENCE THAT MATTERS MOST

On a tiler, **the entire frame's geometry is processed before any pixel is shaded**. Vertex output for the whole frame must be stored to memory and read back — which means vertex data and the number of draw calls cost *more* on mobile, while overdraw, blending and MSAA cost dramatically *less*. Every performance intuition from desktop needs re-examining.

What changes

	Immediate (desktop)	Tiled (mobile)
Overdraw	Expensive — DRAM traffic per layer	**Cheap** — it is all in tile memory. Some tilers also do hidden-surface removal per tile and shade each pixel once
MSAA 4×	4× render-target memory and bandwidth	**Nearly free** — samples live in tile memory and resolve on the way out
Alpha blending	Read-modify-write to DRAM	**Cheap** — on-chip
Vertex count	Cheap	**Expensive** — all vertex output is written to and read from DRAM
Draw calls	Moderate CPU cost	Higher — more binning work
Render-target switches	Cheap	**Very expensive** — flushes every tile
Reading a target you just wrote	Normal	**Forces a full flush**, unless it is the same tile via a subpass
Deferred shading (G-buffer)	The standard technique	Painful — a fat G-buffer defeats the entire point. Use subpasses or forward+
Depth pre-pass	Usually a win	Usually a **loss** — doubles the geometry cost to save overdraw that was already cheap

Load and store actions: the one thing to get right

```
/* Because a tile is loaded, worked on, and stored, you must
   tell the driver what to do at each boundary. Getting this
   wrong is the single biggest mobile performance mistake. */

  AT TILE LOAD (start of a render pass)
    CLEAR      cheapest. No read from DRAM at all - the tile
               is simply initialised on chip.
    LOAD       read the previous contents from DRAM. Costs
               full bandwidth.
    DONT_CARE  cheapest, when you will overwrite everything.

  AT TILE STORE (end of a render pass)
    STORE      write the tile to DRAM.
    DONT_CARE  discard it. FREE.

/* THE DEPTH BUFFER should almost always be:
       load  = CLEAR
       store = DONT_CARE
   You need depth during the pass and never afterwards, so
   there is no reason to spend bandwidth writing it out.
   Many engines write depth to DRAM every frame for no reason
   and lose 20-30% of their bandwidth budget to it.        */

/* Vulkan makes it explicit: */
   VkAttachmentDescription depth = {
        .loadOp         = VK_ATTACHMENT_LOAD_OP_CLEAR,
        .storeOp        = VK_ATTACHMENT_STORE_OP_DONT_CARE,
        .stencilLoadOp  = VK_ATTACHMENT_LOAD_OP_DONT_CARE,
        .stencilStoreOp = VK_ATTACHMENT_STORE_OP_DONT_CARE,
   };

/* Metal, the same: */
   pass.depthAttachment.loadAction  = MTLLoadActionClear;
   pass.depthAttachment.storeAction = MTLStoreActionDontCare;

/* GLES, via an extension that is easy to forget: */
   glInvalidateFramebuffer(GL_FRAMEBUFFER, 1,
                           (GLenum[]){GL_DEPTH_ATTACHMENT});

/* AND THE ANTI-PATTERN: a partial clear, or a draw that
   covers only part of the screen, forces a LOAD of the whole
   render target so the untouched parts survive. Clear the
   whole thing, or use DONT_CARE and cover it.             */
```

Keeping data on chip

```
/* Deferred shading writes a G-buffer, then reads it back.
   On a tiler that is a full round trip to DRAM and back -
   exactly what tiling exists to avoid.

   THE FIX: tell the API that the second pass reads the same
   TILE, not the same TEXTURE. Then the data never leaves
   chip.                                                    */

/* Vulkan SUBPASSES with input attachments: */
   /* subpass 0: write G-buffer attachments
      subpass 1: read them as INPUT ATTACHMENTS
      dependency: BY_REGION                                 */
   VkSubpassDependency dep = {
        .srcSubpass    = 0,
        .dstSubpass    = 1,
        .srcStageMask  = VK_PIPELINE_STAGE_COLOR_ATTACHMENT_OUTPUT_BIT,
        .dstStageMask  = VK_PIPELINE_STAGE_FRAGMENT_SHADER_BIT,
        .dependencyFlags = VK_DEPENDENCY_BY_REGION_BIT,  /* <-- */
   };
   /* BY_REGION is the promise that pixel (x,y) in subpass 1
      only reads pixel (x,y) from subpass 0. That is what lets
      the driver keep everything in tile memory.            */

   /* In the shader: */
   layout(input_attachment_index = 0, set = 0, binding = 0)
        uniform subpassInput gbufferAlbedo;
   vec4 albedo = subpassLoad(gbufferAlbedo);

/* Metal: programmable blending - just read the colour
   attachment directly in the fragment shader: */
   fragment float4 lighting(GBuffer gbuf [[color(0)]]) { ... }

/* GLES: GL_EXT_shader_framebuffer_fetch */
   gl_LastFragData[0]

/* This is why "just port the desktop deferred renderer" goes
   badly on mobile, and why mobile engines favour
   FORWARD+ / CLUSTERED FORWARD instead: one pass, no
   G-buffer, lights culled per tile on the CPU or in a
   compute pass.                                            */
```

THE RENDER-TARGET PING-PONG

Post-processing chains that bounce between two full-screen targets — blur horizontal, blur vertical, tonemap, bloom — cost one full flush and reload *per pass* on a tiler. Four post passes at 1080p RGBA8 is roughly 66 MB of traffic per frame, at 60 Hz nearly 4 GB/s, on a device with 50 GB/s total. Merge post passes aggressively, work at reduced resolution, and prefer compute with groupshared memory over repeated full-screen draws.

The landscape, and what "deferred" means here

GPU	Style	Note
Imagination PowerVR	TBDR	Invented it. Full hidden-surface removal per tile — opaque overdraw is essentially free
Apple	TBDR	PowerVR lineage; the same on iPhone and on Apple Silicon Macs

GPU	Style	Note
ARM Mali	TBR	Tiled, plus "forward pixel kill" rather than full HSR
Qualcomm Adreno	Hybrid	"FlexRender" — chooses tiled or immediate mode per render pass based on heuristics
NVIDIA (Maxwell+)	Tiled caching	Immediate-mode API semantics, but bins into tiles internally to save bandwidth. Invisible to you
AMD (Vega+)	DSBR	Same idea, also transparent

Note the vocabulary trap: *tile-based **deferred** rendering* is a hardware architecture — deferring *rasterisation* until the geometry is binned. *Deferred shading* is a software technique — deferring *lighting* until after a G-buffer is filled. They are unrelated, and deferred shading is the technique that fits TBDR hardware *worst*.

How it shows up

Symptom	Cause
Desktop renderer runs at a fraction of expected speed on mobile	Bandwidth — usually depth stores, render-target switches, or a G-buffer
Device gets hot and frame rate halves after a minute	Thermal throttling driven by DRAM traffic
Adding a depth pre-pass made it slower	Doubled geometry cost to save overdraw that was already free
MSAA 4× is nearly free	Correct — enable it, it is the best quality-per-cost on mobile
Frame time jumps when a post-process chain is added	One flush and reload per pass
High-poly models much more expensive than on desktop	All vertex output goes through DRAM
A partial-screen clear is slower than a full one	It forces a tile load of the whole target
Deferred renderer performs badly	G-buffer round trip; use subpasses or switch to forward+
Reading the current render target hangs or corrupts	Needs framebuffer fetch or an input attachment, not a texture read
Profiler shows huge "load/store" cost	`storeOp` left as STORE on depth

Check yourself

- ✓ Explain why mobile GPUs tile, in terms of energy per byte.
- ✓ Describe the two phases of tiled rendering and what memory each touches.
- ✓ Say what becomes cheaper on a tiler and what becomes more expensive, with three of each.
- ✓ Explain why a depth pre-pass is often a loss on mobile.
- ✓ Give the correct load and store actions for a depth buffer, and the cost of getting them wrong.
- ✓ Explain why a partial clear can be slower than a full one.
- ✓ Explain what `BY_REGION` promises and what it enables.
- ✓ Say why deferred shading fits TBDR hardware badly, and what to use instead.
- ✓ Distinguish tile-based deferred *rendering* from deferred *shading*.
- ✓ Estimate the bandwidth cost of a four-pass 1080p post chain at 60 Hz.

Why DX12, Vulkan and Metal exist

The explicit APIs are harder to use than the ones they replaced, and that is the point. They exist because the old drivers were doing enormous amounts of guessing on your behalf — badly, on one thread, at unpredictable moments. This chapter is what they took away and what they gave back.

What the old drivers were doing

```
DX11 / OpenGL: you call a function, and the driver decides
everything.

  ctx->PSSetShaderResources(0, 1, &srv);
  ctx->Draw(3, 0);

Behind that Draw the driver must:

  * check every piece of state you set and work out whether
    a new pipeline compile is needed. If so, COMPILE A
    SHADER, right now, mid-frame. -> a stutter you cannot
    predict or control.
  * track the lifetime of every resource you have ever
    bound, to know when it is safe to free or overwrite.
  * insert synchronisation between GPU operations by
    guessing your intent from the order of calls.
  * VALIDATE everything, every call, in the shipping
    driver.
  * do all of this on ONE THREAD, because the context is
    not thread-safe.

THE RESULT
  * a driver thread that is the bottleneck on a 16-core
    machine
  * frame-time spikes with no visible cause
  * per-vendor "optimisations" that recognise specific
    games and substitute different shaders - genuinely, by
    executable name
  * ~1-2 us of CPU per draw call, capping you at a few
    thousand draws per frame

THE EXPLICIT APIs' ANSWER: you already know your intent.
Say it up front, once, and the driver stops guessing.
```

Job	DX11 / GL	DX12 / Vulkan / Metal
Shader compilation	Driver, whenever it decides	**You**, by creating a PSO at load time
Resource lifetime	Driver refcounts everything	**You**, with fences
Synchronisation	Driver infers it	**You**, with barriers
Memory allocation	Driver	**You**, with heaps and placed resources
Command recording	One thread	**Any number of threads**
Validation	Always on	Debug layer only, off in release
Descriptor management	Driver, per binding call	**You**, in heaps/tables
CPU cost per draw	~1–2 µs	~0.1 µs

> **THE TRADE, STATED HONESTLY**
> You get predictable frame times, multi-threaded submission, and roughly ten times the draw calls. You pay with perhaps five times the code for a first triangle, whole new bug classes (a missed barrier is a race between GPU stages), and the obligation to do your own memory management. For a small project or a tool, DX11 or OpenGL is still the right choice. For anything shipping at scale, the explicit APIs won for good reasons.

The five concepts they all share

```
Learn these once; the three APIs differ mainly in spelling.

1. DEVICE and QUEUES
     the device is the GPU. Queues are where work goes -
     typically GRAPHICS, COMPUTE and COPY, which run
     concurrently on separate hardware engines.

2. COMMAND LISTS / BUFFERS
     you RECORD commands into a list, on any thread, and
     SUBMIT it later. Recording touches no GPU state, so
     eight threads can record eight lists at once.
     (chapter 13)

3. PIPELINE STATE OBJECTS
     every piece of state that could affect shader
     compilation - shaders, blend, depth, rasteriser,
     vertex layout, render-target formats - baked into one
     immutable object, created at load time.
     (chapter 15)

4. DESCRIPTORS and DESCRIPTOR HEAPS
     a descriptor is a small opaque struct describing a
     resource. They live in heaps; shaders index into them.
     Binding becomes "point at an offset" instead of "tell
     the driver about this texture".
     (chapter 14)

5. EXPLICIT SYNCHRONISATION
     FENCES     CPU waits for GPU
     BARRIERS   GPU waits for GPU, and transitions a
                resource between usages
     This is the part that is genuinely hard, and the part
     the debug layer will save you on.
     (chapter 16)
```

The three APIs

	DX12	Vulkan	Metal
Platforms	Windows, Xbox	Windows, Linux, Android, Switch (macOS via MoltenVK)	macOS, iOS
Verbosity to first triangle	~600 lines	~1200 lines	~150 lines
Shader language	HLSL → DXIL	GLSL/HLSL → SPIR-V	MSL
Binding model	Root signature + descriptor heaps	Descriptor set layouts + pools	Argument buffers
Memory	Heaps + placed resources, or committed	Explicit, with memory types	Mostly managed for you

	DX12	Vulkan	Metal
Render passes	Optional (`RenderPass` API added later)	Mandatory, and tiler-aware	Mandatory, tiler-aware
Ergonomics	Middle	Hardest	Easiest by a wide margin

This track uses **DX12** from here on. It is the middle of the three in complexity, it pairs with the Windows track, and its concepts map onto Vulkan and Metal almost one-to-one. Where they diverge in a way that matters, the chapters say so.

What multi-threading actually buys

```
/* THE OLD MODEL - one thread does everything. */

  main thread:  cull -> for each object: set state, Draw
                     -> the DRIVER thread then translates all
                        of that into GPU commands, serially

  On a 16-core machine you are using 2 of them, and the
  driver thread is the wall.

/* THE NEW MODEL - record in parallel, submit once. */

  thread 0: record shadow pass       -> command list A
  thread 1: record opaque, part 1    -> command list B
  thread 2: record opaque, part 2    -> command list C
  thread 3: record transparent + UI  -> command list D

  main:     queue->ExecuteCommandLists(4, {A, B, C, D});

/* THE RULES that make it safe:
     * one COMMAND ALLOCATOR per thread per frame-in-flight.
       Allocators are not thread-safe and cannot be reset
       while the GPU is still reading them.
     * command lists are recorded independently but EXECUTE
       IN THE ORDER YOU SUBMIT THEM.
     * resource state transitions must be consistent across
       list boundaries - the debug layer checks this, and it
       is where multi-threaded recording actually goes wrong.

   THE HONEST CAVEAT: parallel recording helps only if you
   are CPU-bound on draw submission. Many titles are GPU-bound
   and gain nothing. Measure which you are before building
   the machinery - and note that the draw-call ceiling rising
   from ~5,000 to ~50,000 changes what art can do, which is
   often the real benefit rather than frame time.          */
```

> **THE DEBUG LAYER IS NOT OPTIONAL**
> The explicit APIs removed validation from the shipping driver, so an error usually produces a device removal, a hang, or corrupted output with no message at all. The debug layer (DX12), validation layers (Vulkan) or Metal's API validation give you precise diagnostics for every mistake in this track. Develop with them on, always; the performance cost is irrelevant during development and they will save you days.

```
// Turn it on before creating the device - order matters.
#if defined(_DEBUG)
    ComPtr<ID3D12Debug1> dbg;
    if (SUCCEEDED(D3D12GetDebugInterface(IID_PPV_ARGS(&dbg)))) {
        dbg->EnableDebugLayer();
        dbg->SetEnableGPUBasedValidation(TRUE);   // slower,
                                                  // catches far
                                                  // more
    }
#endif

// And make errors stop the debugger where they happen:
ComPtr<ID3D12InfoQueue> iq;
if (SUCCEEDED(device.As(&iq))) {
    iq->SetBreakOnSeverity(D3D12_MESSAGE_SEVERITY_CORRUPTION, TRUE);
    iq->SetBreakOnSeverity(D3D12_MESSAGE_SEVERITY_ERROR,      TRUE);
}
```

How it shows up

Symptom	Cause
Frame spikes the first time an effect appears	Shader compiled on demand — pre-create the PSOs (chapter 15)
CPU-bound at a few thousand draws in DX11	Driver thread saturated; this is what DX12 fixes
Ported to DX12 and it got slower	Common. Usually over-synchronisation, or per-frame allocations that DX11's driver was pooling for you
Device removed, no message	Debug layer off. Turn it on
Corruption only in release builds	Validation was hiding a missing barrier
Crash resetting a command allocator	The GPU is still executing from it — needs a fence wait
Multi-threaded recording produces wrong output	Inconsistent resource states across command list boundaries
Works on NVIDIA, hangs on AMD	Almost always a missing barrier that one driver tolerated
Parallel recording gained nothing	You were GPU-bound

Check yourself

- ✓ List five things a DX11 driver does behind a single `Draw` call.
- ✓ Explain why mid-frame shader compilation causes unpredictable stutter.
- ✓ Name the five concepts shared by all three explicit APIs.
- ✓ State what moved from the driver to you, and what you get in return.
- ✓ Give the approximate CPU cost per draw call before and after.
- ✓ Explain the rule about command allocators and threads.
- ✓ Say why parallel command recording sometimes buys nothing.
- ✓ Explain why the debug layer matters more than it did in DX11.
- ✓ Give one reason to choose DX11 or OpenGL for a new project.
- ✓ Name the DX12, Vulkan and Metal terms for the binding model.

DX12: adapters, devices and the debug layer

Everything starts with picking a GPU and creating a device. It is thirty lines, and every one of them is a decision that will bite you later if you copy it from a tutorial without reading it — starting with which adapter you got and whether validation is on.

The object graph

```
IDXGIFactory                enumerates adapters, creates
     |                      swap chains
     +-- IDXGIAdapter       one GPU (or the software one)
          |
          +-- ID3D12Device   THE ROOT. Everything is created
               |             from it. Not tied to a window.
               |
               +-- ID3D12CommandQueue      where work is
               |    |                      submitted
               |    +-- IDXGISwapChain     presentation
               |
               +-- ID3D12CommandAllocator  backing memory
               |    +-- ID3D12GraphicsCommandList
               |
               +-- ID3D12DescriptorHeap    (chapter 14)
               +-- ID3D12Resource          buffers, textures
               +-- ID3D12RootSignature     (chapter 15)
               +-- ID3D12PipelineState     (chapter 15)
               +-- ID3D12Fence             (chapter 16)

NOTE what the device is NOT: it has no state. There is no
"current shader" or "current texture" on it. All state
lives in a command list, and is reset every time you reset
the list. That statelessness is what makes multi-threaded
recording possible.
```

Choosing an adapter

```
#include <d3d12.h>
#include <dxgi1_6.h>
#include <wrl/client.h>
using Microsoft::WRL::ComPtr;

#pragma comment(lib, "d3d12.lib")
#pragma comment(lib, "dxgi.lib")

static void ThrowIfFailed(HRESULT hr, const char *what)
{
    if (FAILED(hr))
        throw std::runtime_error(std::string(what) + " failed: 0x"
                                 + std::to_string((unsigned)hr));
}

ComPtr<IDXGIAdapter1> PickAdapter(IDXGIFactory6 *factory)
{
    ComPtr<IDXGIAdapter1> adapter;

    /* EnumAdapterByGpuPreference sorts for you. Without it you
       get adapter 0, which on a laptop is very often the
       INTEGRATED GPU - and then you spend an afternoon
       wondering why performance is a third of expected. */
    for (UINT i = 0;
         factory->EnumAdapterByGpuPreference(
             i, DXGI_GPU_PREFERENCE_HIGH_PERFORMANCE,
             IID_PPV_ARGS(&adapter)) != DXGI_ERROR_NOT_FOUND;
         i++)
    {
        DXGI_ADAPTER_DESC1 desc;
        adapter->GetDesc1(&desc);

        if (desc.Flags & DXGI_ADAPTER_FLAG_SOFTWARE)
            continue;              /* WARP - useful, but not
                                      what you want by default */

        /* Probe WITHOUT creating: pass nullptr for the device
           and it just tells you whether it would succeed. */
        if (SUCCEEDED(D3D12CreateDevice(adapter.Get(),
                                        D3D_FEATURE_LEVEL_12_0,
                                        _uuidof(ID3D12Device),
                                        nullptr)))
        {
            wprintf(L"using %s (%zu MB)\n", desc.Description,
                    desc.DedicatedVideoMemory / (1024 * 1024));
            return adapter;
        }
    }
    throw std::runtime_error("no D3D12-capable adapter");
}
```

> **FEATURE LEVELS ARE NOT THE WHOLE STORY**
>
> `D3D_FEATURE_LEVEL_12_0` is a coarse baseline. The things you actually care about — resource binding tier, shader model, raytracing, mesh shaders, wave intrinsics — are queried separately with `CheckFeatureSupport`. A device can report feature level 12_1 and still not support the shader model your HLSL was compiled for, which fails at PSO creation with a message that does not mention shader models.

```
/* The capabilities worth checking at startup, before you
   depend on them. */

D3D12_FEATURE_DATA_D3D12_OPTIONS opts = {};
device->CheckFeatureSupport(D3D12_FEATURE_D3D12_OPTIONS,
                            &opts, sizeof opts);
/* opts.ResourceBindingTier decides how many descriptors you
   may use per table - Tier 1 is genuinely restrictive, Tier 3
   is effectively unlimited (chapter 14). */

D3D12_FEATURE_DATA_SHADER_MODEL sm = { D3D_SHADER_MODEL_6_6 };
if (FAILED(device->CheckFeatureSupport(D3D12_FEATURE_SHADER_MODEL,
                                       &sm, sizeof sm)))

/* This takes ten minutes to add and saves hours on every
   single debugging session afterwards. Do it on day one, not
   when you first need it.                                    */
```

How it shows up

Symptom	Cause
Performance a third of expected on a laptop	Got the integrated GPU — use `EnumAdapterByGpuPreference`
Debug layer produces no output	Enabled after device creation
PSO creation fails with an unhelpful message	Shader model higher than the device supports
Corruption on another machine only	Hardcoded descriptor increment size
`DEVICE_REMOVED` with no information	DRED not enabled
`DEVICE_RESET` after a heavy frame	TDR — a single submission took over ~2 seconds
Page fault at a GPU address	A resource freed while still referenced by in-flight work
Everything is named `ID3D12Resource` in PIX	No `SetName` calls
Runs in debug, corrupts in release	GPU-based validation was masking a descriptor error
Feature works on your GPU, missing on another	Capability assumed rather than queried

Check yourself

- ✓ Draw the DX12 object graph from the factory down to a pipeline state.
- ✓ Explain why the device has no state, and what that enables.
- ✓ Say why adapter 0 is often the wrong choice and how to avoid it.
- ✓ Explain what a feature level does and does not tell you.
- ✓ Name four capabilities you must query separately.
- ✓ Say why descriptor increment sizes must be queried.

- ✓ Explain when the debug layer must be enabled and what happens otherwise.
- ✓ Say what GPU-based validation adds and what it costs.
- ✓ Explain what DRED gives you after a device removal.
- ✓ Give four causes of `DEVICE_REMOVED` and how to distinguish them.

DX12: command lists, allocators and queues

Nothing you call executes immediately. You record commands into a list, submit the list to a queue, and the GPU gets to it whenever it gets to it. The gap between "I recorded it" and "it ran" is where every DX12 lifetime bug lives.

Three objects, three jobs

```
COMMAND ALLOCATOR
  the MEMORY the commands are written into. Grows as you
  record; never shrinks. You can only RESET it - which frees
  everything at once - and only when the GPU has finished
  executing every list ever recorded from it.

COMMAND LIST
  the RECORDER. Cheap. Reset it to begin recording, Close
  it when done. A list may be reset and reused as soon as
  it is submitted - it does not own the memory.

COMMAND QUEUE
  the SUBMISSION POINT. Lists execute in submission order
  within a queue. Different queues run CONCURRENTLY.

THE LIFETIME RULE, and it is the whole chapter:

  allocator: reset only after the GPU is DONE with it
  list:      reset any time after Close + submit

So you need ONE ALLOCATOR PER FRAME IN FLIGHT, and a fence
to know when it is safe to reuse.

  frame 0 -> allocator A -> submit -> fence value 1
  frame 1 -> allocator B -> submit -> fence value 2
  frame 2 -> wait for fence >= 1, then reuse allocator A

Reset an allocator the GPU is still reading and you get
corruption or a device removal, usually several frames
later and nowhere near the cause.
```

```
/* Creating the three. */

D3D12_COMMAND_QUEUE_DESC qd = {};
qd.Type  = D3D12_COMMAND_LIST_TYPE_DIRECT;
qd.Flags = D3D12_COMMAND_QUEUE_FLAG_NONE;
ComPtr<ID3D12CommandQueue> queue;
device->CreateCommandQueue(&qd, IID_PPV_ARGS(&queue));

/* One allocator per frame in flight. */
static const UINT kFrames = 3;
ComPtr<ID3D12CommandAllocator> alloc[kFrames];
for (UINT i = 0; i < kFrames; i++)
    device->CreateCommandAllocator(
        D3D12_COMMAND_LIST_TYPE_DIRECT, IID_PPV_ARGS(&alloc[i]));

/* One list is enough if you record single-threaded. */
ComPtr<ID3D12GraphicsCommandList> cmd;
device->CreateCommandList(0, D3D12_COMMAND_LIST_TYPE_DIRECT,
                          alloc[0].Get(), nullptr,
                          IID_PPV_ARGS(&cmd));
cmd->Close();     /* lists are created OPEN. Close it so the
                     frame loop's Reset is symmetrical. */
```

The frame loop

```
UINT64 fenceValue[kFrames] = {};
UINT64 nextFence = 1;
UINT   frame = 0;

void RenderFrame()
{
    /* 1. WAIT until the GPU has finished the frame that last
          used this allocator. THIS is what makes reuse safe. */
    if (fence->GetCompletedValue() < fenceValue[frame]) {
        fence->SetEventOnCompletion(fenceValue[frame], fenceEvent);
        WaitForSingleObject(fenceEvent, INFINITE);
    }

    /* 2. Reset the allocator (frees its memory), then the list
          (begins recording). Order matters: allocator first. */
    alloc[frame]->Reset();
    cmd->Reset(alloc[frame].Get(), initialPSO.Get());

    /* 3. Record. A freshly reset list has NO STATE - no
          descriptor heaps, no root signature, no viewport, no
          render targets. You set all of it, every frame. That
          is not overhead; it is what makes lists independent
          and recordable in parallel. */
    cmd->SetGraphicsRootSignature(rootSig.Get());
    ID3D12DescriptorHeap *heaps[] = { srvHeap.Get() };
    cmd->SetDescriptorHeaps(1, heaps);
    cmd->RSSetViewports(1, &viewport);
    cmd->RSSetScissorRects(1, &scissor);

    Transition(cmd.Get(), backBuffer[frame].Get(),
               D3D12_RESOURCE_STATE_PRESENT,
               D3D12_RESOURCE_STATE_RENDER_TARGET);

    cmd->OMSetRenderTargets(1, &rtv[frame], FALSE, &dsv);
    cmd->ClearRenderTargetView(rtv[frame], clearColour, 0, nullptr);
    /* ... draws ... */

    Transition(cmd.Get(), backBuffer[frame].Get(),
               D3D12_RESOURCE_STATE_RENDER_TARGET,
               D3D12_RESOURCE_STATE_PRESENT);

    /* 4. Close, then submit. A list must be Closed before
          ExecuteCommandLists or the runtime rejects it. */
    cmd->Close();
    ID3D12CommandList *lists[] = { cmd.Get() };
    queue->ExecuteCommandLists(1, lists);

    swapChain->Present(1, 0);

    /* 5. Signal a fence AFTER the submission, so we can later
          tell when this frame's work is done. */
    fenceValue[frame] = nextFence;
    queue->Signal(fence.Get(), nextFence++);

    frame = (frame + 1) % kFrames;
}
```

> **FRAMES IN FLIGHT IS A LATENCY-VERSUS-THROUGHPUT DIAL**
> Two frames buffered keeps the GPU fed while the CPU records the next one. Three smooths hitches further but adds a frame of input latency. One means the CPU and GPU alternate, each idle half the time. Two or three is the normal range, and it must match your number of allocators and your swap-chain buffer count — mismatch them and you either stall or corrupt.

Queue types, and why they run concurrently

Type	Can do	Hardware
`DIRECT`	Everything — draw, dispatch, copy	The main graphics engine
`COMPUTE`	Dispatch and copy, no draws	A separate async compute engine on most GPUs
`COPY`	Copy only	A dedicated DMA engine — runs while the GPU renders, and is the right way to stream data
`BUNDLE`	A small pre-recorded set of draws, replayed into a direct list	Not a queue. Rarely worth it on modern drivers

```
/* ASYNC COMPUTE: overlap work that uses different units.

   A shadow pass is geometry- and depth-bound; SSAO is
   ALU-bound. Run them on separate queues and they fill each
   other's gaps - typically 5-15% of frame time on a GPU that
   supports it well.                                        */

  graphics queue:  [ shadow maps ][ gbuffer ][ lighting ]
  compute queue:         [ SSAO ][ particle sim ]
                         ^                     ^
                         |                     |
                   both running at once, on different units

/* SYNCHRONISING BETWEEN QUEUES is done with fences, on the
   GPU - no CPU involvement: */

  computeQueue->ExecuteCommandLists(1, &ssaoList);
  computeQueue->Signal(sharedFence.Get(), 42);

  /* graphics queue WAITS for that, without stalling the CPU */
  graphicsQueue->Wait(sharedFence.Get(), 42);
  graphicsQueue->ExecuteCommandLists(1, &lightingList);

/* THE COPY QUEUE is the one everybody should use and few do.
   Uploading a texture on the direct queue serialises against
   your rendering. On the copy queue it happens in parallel,
   on a DMA engine that is otherwise idle:                  */

  copyQueue->ExecuteCommandLists(1, &uploadList);
  copyQueue->Signal(uploadFence.Get(), n);
  graphicsQueue->Wait(uploadFence.Get(), n);   /* use it after */

/* THE CAVEAT: resources have state (chapter 16), and the copy
   and compute queues support only a SUBSET of states. A
   resource used on a copy queue must be in COMMON state at
   the boundary. Getting this wrong is a classic multi-queue
   bug, and the debug layer catches it.                     */
```

Recording in parallel

```
/* The rules:
     - one ALLOCATOR per thread per frame in flight
     - one LIST per thread (lists are cheap to create)
     - lists EXECUTE in submission order, whatever order they
       were recorded in                                      */

struct ThreadCtx {
    ComPtr<ID3D12CommandAllocator>    alloc[kFrames];
    ComPtr<ID3D12GraphicsCommandList> list;
};
ThreadCtx ctx[kThreads];

void RecordChunk(int t, int frame, int first, int count)
{
    auto *c = &ctx[t];
    c->alloc[frame]->Reset();
    c->list->Reset(c->alloc[frame].Get(), pso.Get());

    /* every list sets up its own state - nothing is inherited */
    c->list->SetGraphicsRootSignature(rootSig.Get());
    c->list->SetDescriptorHeaps(1, heaps);
    c->list->RSSetViewports(1, &viewport);
    c->list->RSSetScissorRects(1, &scissor);
    c->list->OMSetRenderTargets(1, &rtv[frame], FALSE, &dsv);

    for (int i = first; i < first + count; i++)
        DrawObject(c->list.Get(), i);

    c->list->Close();
}

/* Then, on the main thread: */
  parallel_for(0, kThreads, [&](int t) {
      RecordChunk(t, frame, t * per, per);
  });

  ID3D12CommandList *all[kThreads];
  for (int t = 0; t < kThreads; t++) all[t] = ctx[t].list.Get();
  queue->ExecuteCommandLists(kThreads, all);   /* ONE submit   */

/* SUBMIT IN ONE CALL where you can: each
   ExecuteCommandLists has real driver overhead, so twenty
   calls of one list is measurably worse than one call of
   twenty.

   AND NOTE the barriers: resource transitions must be
   consistent across list boundaries. If list A leaves a
   resource in RENDER_TARGET and list B expects PIXEL_SHADER
   _RESOURCE, one of them must do the transition - and the
   runtime cannot check across lists at record time, only at
   execute time.                                            */
```

THE TWO MISTAKES THAT PRODUCE DELAYED, CONFUSING CORRUPTION

Resetting an allocator the GPU is still using. Symptoms appear frames later, in unrelated draws. **Freeing or overwriting a resource that an in-flight command list still references.** Same delay, same confusion. Both are solved the same way: a fence value per frame, and nothing is reused or released until the fence says that frame completed. Build that discipline into your allocator and upload helpers on day one rather than retrofitting it.

How it shows up

Symptom	Cause
Corruption appearing a few frames after a change	Allocator reset while the GPU was still reading it
`DEVICE_REMOVED` with a page fault	A resource released while in-flight work referenced it
`ExecuteCommandLists` rejects a list	It was not `Close`d
Nothing renders after adding a second list	The new list did not set its own render targets or root signature — no state is inherited
CPU and GPU each idle half the time	Only one frame in flight
Input latency high but frame rate fine	Too many frames buffered
Async compute gives no speed-up	Over-synchronised, or the two passes use the same units
Debug layer error about resource state on the copy queue	Copy queues support only a subset of states — return to COMMON at the boundary
Parallel recording is slower than single-threaded	Too many `ExecuteCommandLists` calls, or lists too small to amortise setup
Random hangs under load	A fence waited on a value that is never signalled

Check yourself

- ✓ Say what each of allocator, list and queue owns.
- ✓ State the reset rule for allocators and for lists, and why they differ.
- ✓ Explain why you need one allocator per frame in flight.
- ✓ Walk through the five steps of the frame loop and say what each guards against.
- ✓ Explain why a freshly reset command list has no state, and why that is a feature.
- ✓ Name the queue types and what each can do.
- ✓ Explain what async compute overlaps and give a realistic gain.
- ✓ Show how two queues synchronise without involving the CPU.
- ✓ Give the rules for multi-threaded recording, including the allocator rule.
- ✓ Explain why submitting twenty lists in one call beats twenty calls.

DX12: resources, heaps and descriptors

DX11 had "create a texture". DX12 splits that into three separate decisions — where the memory lives, what the resource is, and how a shader finds it — and makes you take all three. Understanding the split is most of what makes DX12 feel large.

Memory, resource, descriptor

```
1. A HEAP is memory. It has a TYPE that decides who can
   see it and how fast.

     DEFAULT   GPU-local VRAM. Fast for the GPU, the CPU
               cannot touch it. Where everything you draw
               from lives.
     UPLOAD    CPU-writable, GPU-readable. Write-combined:
               writing is fast, READING IS CATASTROPHIC
               (uncached, ~1 byte at a time). Staging
               buffers and per-frame constants.
     READBACK  GPU-writable, CPU-readable. For getting
               results back - screenshots, queries.
     CUSTOM    you specify the pool and CPU page property.

2. A RESOURCE is a typed view of some of that memory: a
   buffer, a 2D texture, a texture array. It has a format,
   dimensions, and a STATE (chapter 16).

3. A DESCRIPTOR is a small opaque struct - 32 to 64 bytes,
   device-dependent - that tells a shader HOW to read a
   resource. It lives in a DESCRIPTOR HEAP.

THE SAME MEMORY CAN HAVE MANY DESCRIPTORS:
     one texture, viewed as
       SRV  R8G8B8A8_UNORM_SRGB   for sampling
       UAV  R8G8B8A8_UNORM        for compute writes
       RTV  R8G8B8A8_UNORM        as a render target
     Three descriptors, one resource, one allocation.
```

```
/* COMMITTED - a resource with its own implicit heap. Simple,
   and what you use until you have a reason not to. */

D3D12_HEAP_PROPERTIES hp = { D3D12_HEAP_TYPE_DEFAULT };
D3D12_RESOURCE_DESC rd = {};
rd.Dimension        = D3D12_RESOURCE_DIMENSION_TEXTURE2D;
rd.Width            = 1024;
rd.Height           = 1024;
rd.DepthOrArraySize = 1;
rd.MipLevels        = 0;              /* 0 = full chain       */
rd.Format           = DXGI_FORMAT_R8G8B8A8_UNORM;
rd.SampleDesc.Count = 1;
rd.Layout           = D3D12_TEXTURE_LAYOUT_UNKNOWN;
rd.Flags            = D3D12_RESOURCE_FLAG_NONE;

ComPtr<ID3D12Resource> tex;
device->CreateCommittedResource(
    &hp, D3D12_HEAP_FLAG_NONE, &rd,
    D3D12_RESOURCE_STATE_COPY_DEST,   /* initial state        */
    nullptr, IID_PPV_ARGS(&tex));

/* PLACED - you allocate one big heap and sub-allocate. This
   is what a real engine does: allocation is expensive
   (milliseconds, and it can fail), so you make a few large
   heaps at startup and manage offsets yourself. */

ComPtr<ID3D12Heap> heap;
D3D12_HEAP_DESC hd = {};
hd.SizeInBytes = 256ull * 1024 * 1024;
hd.Properties  = { D3D12_HEAP_TYPE_DEFAULT };
hd.Alignment   = D3D12_DEFAULT_RESOURCE_PLACEMENT_ALIGNMENT;
hd.Flags       = D3D12_HEAP_FLAG_ALLOW_ONLY_NON_RT_DS_TEXTURES;
device->CreateHeap(&hd, IID_PPV_ARGS(&heap));

device->CreatePlacedResource(heap.Get(), offset, &rd,
                             D3D12_RESOURCE_STATE_COPY_DEST,
                             nullptr, IID_PPV_ARGS(&tex));
/* Offsets must respect GetResourceAllocationInfo()'s
   alignment - 64 KB usually, 4 MB for MSAA targets. */

/* Unless you enjoy writing allocators, use D3D12MemoryAllocator
   (D3D12MA) - the same library as Vulkan's VMA, and it handles
   placed resources, pools and defragmentation properly. */
```

NEVER READ FROM AN UPLOAD HEAP

Upload memory is write-combined: writes are buffered and flushed efficiently, but reads bypass the cache entirely and go across PCIe one access at a time. A single innocent-looking `+=` on a mapped upload buffer can cost *hundreds of times* what you expect. Build your data in ordinary memory and `memcpy` it in one pass, and never use a mapped pointer as scratch space.

Getting data onto the GPU

```
/* DEFAULT heap memory is not CPU-visible, so everything goes
   via an UPLOAD staging buffer and a copy. */

void UploadBuffer(ID3D12Device *dev, ID3D12GraphicsCommandList *cmd,
                  ID3D12Resource *dst, const void *src, size_t n,
                  ComPtr<ID3D12Resource> &keepAlive)
{
    /* 1. staging buffer in UPLOAD */
    D3D12_HEAP_PROPERTIES up = { D3D12_HEAP_TYPE_UPLOAD };

/* It queries the required footprint - rows padded to 256 bytes
   - copies row by row into the staging buffer, and issues
   CopyTextureRegion. Doing this by hand is possible and
   almost never worth it. */
```

Descriptors and heaps

```
FOUR HEAP TYPES, and only two are shader-visible.

  CBV_SRV_UAV   constant buffers, textures, UAVs.
                SHADER-VISIBLE. Usually one big heap.
  SAMPLER       SHADER-VISIBLE, separate heap, max 2048.
  RTV           render target views. CPU-only.
  DSV           depth stencil views. CPU-only.

YOU MAY ONLY HAVE ONE SHADER-VISIBLE HEAP OF EACH TYPE
BOUND AT A TIME. That is the constraint that shapes every
DX12 binding design: you cannot bind a small heap per
object. You make ONE large heap and put everything in it.

SetDescriptorHeaps is also EXPENSIVE - it can flush the
GPU on some hardware. Call it once per command list, not
per draw.

THE TWO HANDLE TYPES, and confusing them is a classic bug:

  D3D12_CPU_DESCRIPTOR_HANDLE   for CREATING descriptors
                                (CreateShaderResourceView)
  D3D12_GPU_DESCRIPTOR_HANDLE   for BINDING them
                                (SetGraphicsRootDescriptorTable)

A CPU-only heap has no GPU handles at all. A shader-visible
heap has both, and you index them in parallel.

AND THE INCREMENT SIZE IS DEVICE-DEPENDENT:
  UINT n = device->GetDescriptorHandleIncrementSize(type);
  handle.ptr += index * n;
Hardcoding it works on your GPU and corrupts on another.
```

```
/* A minimal descriptor allocator - a bump pointer over one
   big heap. This is close to what real engines do for static
   descriptors. */

class DescriptorHeap {
public:
    void Init(ID3D12Device *dev, D3D12_DESCRIPTOR_HEAP_TYPE type,
              UINT count, bool shaderVisible)
    {
        D3D12_DESCRIPTOR_HEAP_DESC d = {};
        d.Type           = type;
        d.NumDescriptors = count;
        d.Flags = shaderVisible
                ? D3D12_DESCRIPTOR_HEAP_FLAG_SHADER_VISIBLE
                : D3D12_DESCRIPTOR_HEAP_FLAG_NONE;
        dev->CreateDescriptorHeap(&d, IID_PPV_ARGS(&heap_));

        size_    = dev->GetDescriptorHandleIncrementSize(type);
        cpuStart_ = heap_->GetCPUDescriptorHandleForHeapStart();
        if (shaderVisible)
            gpuStart_ = heap_->GetGPUDescriptorHandleForHeapStart();
        capacity_ = count;
    }

    UINT Allocate() {
        if (used_ >= capacity_) throw std::runtime_error("heap full");
        return used_++;
    }

    D3D12_CPU_DESCRIPTOR_HANDLE Cpu(UINT i) const
    { return { cpuStart_.ptr + SIZE_T(i) * size_ }; }

    D3D12_GPU_DESCRIPTOR_HANDLE Gpu(UINT i) const
    { return { gpuStart_.ptr + UINT64(i) * size_ }; }

    ID3D12DescriptorHeap *Get() const { return heap_.Get(); }

private:
    ComPtr<ID3D12DescriptorHeap> heap_;
    D3D12_CPU_DESCRIPTOR_HANDLE  cpuStart_{};
    D3D12_GPU_DESCRIPTOR_HANDLE  gpuStart_{};
    UINT size_ = 0, used_ = 0, capacity_ = 0;
};

/* Creating a descriptor writes into the heap slot: */
UINT slot = srvHeap.Allocate();
D3D12_SHADER_RESOURCE_VIEW_DESC srv = {};
srv.Format                  = DXGI_FORMAT_R8G8B8A8_UNORM_SRGB;
srv.ViewDimension           = D3D12_SRV_DIMENSION_TEXTURE2D;
srv.Shader4ComponentMapping = D3D12_DEFAULT_SHADER_4_COMPONENT_MAPPING;
srv.Texture2D.MipLevels     = -1;        /* all of them        */
device->CreateShaderResourceView(tex.Get(), &srv,
                                 srvHeap.Cpu(slot));

/* Binding points the shader at a slot: */
cmd->SetGraphicsRootDescriptorTable(1, srvHeap.Gpu(slot));
```

BINDLESS IS WHERE THIS IS GOING

With Resource Binding Tier 2 or 3 you can put every texture in the scene in one heap, pass an *integer index* to the shader, and index the heap directly: `ResourceDescriptorHeap[materialIndex]` in Shader Model 6.6. No per-draw descriptor tables, no rebinding, and the GPU can drive its own draws. It removes most of the binding code in this chapter, and it is what modern renderers do — worth designing toward even if you start with tables.

How it shows up

Symptom	Cause
A CPU loop over mapped memory takes milliseconds	Reading from an UPLOAD heap
Corruption or page fault after an upload	Staging buffer released before the GPU executed the copy
Texture uploads as garbage or skewed	Row pitch not padded to 256 bytes — use `UpdateSubresources`
Works on your GPU, corrupts elsewhere	Hardcoded descriptor increment size
Shader reads the wrong texture	CPU handle used where a GPU handle was needed, or the wrong slot index
Frame time collapses with many draws	`SetDescriptorHeaps` called per draw
Debug layer: heap not shader-visible	Binding a descriptor from an RTV/DSV or non-visible heap
Random blank textures	Descriptor slot overwritten by another allocation — no ownership tracking
Resource creation takes milliseconds	Committed resources per object; use placed resources from a pre-made heap
Out of memory with plenty of VRAM free	Heap fragmentation, or heap flags too restrictive for the resource type

Check yourself

- ✓ Explain the split between heap, resource and descriptor, and why DX12 separates them.
- ✓ Name the four heap types and say who can access each.
- ✓ Explain why reading from an UPLOAD heap is catastrophic.
- ✓ Describe the four steps of uploading a buffer, and the lifetime rule for the staging resource.
- ✓ Say why textures cannot be uploaded with a plain `memcpy`.
- ✓ Name the four descriptor heap types and which are shader-visible.
- ✓ State the one-heap-bound-at-a-time constraint and what it implies for your design.
- ✓ Distinguish CPU and GPU descriptor handles and give a bug from confusing them.
- ✓ Explain why descriptor increment size must be queried.
- ✓ Say what bindless changes, and which tier and shader model it needs.

DX12: root signatures and pipeline state

Two objects that between them replace all of DX11's state setting. The root signature is the function signature of your shaders; the pipeline state object is everything the driver needs to compile a shader ahead of time instead of mid-frame. Getting both right is what removes stutter.

The root signature is a function signature

```
Think of your shader as a function. The root signature
declares its parameters.

  void PSMain(cbuffer b0,            <- root parameter 0
              Texture2D t0[],        <- root parameter 1
              SamplerState s0)       <- static sampler

THREE KINDS OF ROOT PARAMETER, in cost order:

1. ROOT CONSTANTS          cost: 1 DWORD each
     values inlined directly into the command list. No
     indirection at all - the fastest possible way to get
     a handful of numbers to a shader.
     Use for: an object index, a material id, a few floats.

2. ROOT DESCRIPTORS        cost: 2 DWORDs
     a raw GPU virtual address of ONE buffer. One
     indirection. No descriptor heap involved.
     Use for: a per-object constant buffer.
     NOTE: no bounds checking, and only for buffers -
     textures cannot be root descriptors.

3. DESCRIPTOR TABLES       cost: 1 DWORD
     a pointer INTO the bound descriptor heap, plus a
     range. Two indirections.
     Use for: textures, and anything in bulk.

THE BUDGET: 64 DWORDs total. That is the whole thing.

     64 root constants, or
     32 root descriptors, or
     64 descriptor tables, or any mix.

AND SMALLER IS FASTER: the root signature is copied on
every draw. On some hardware the first 16 DWORDs live in
registers and the rest spill to memory. Aim for well under
16 DWORDs.
```

```
/* A practical root signature. */

D3D12_ROOT_PARAMETER1 params[3] = {};

/* 0: root constants - an object index. 1 DWORD. */
params[0].ParameterType = D3D12_ROOT_PARAMETER_TYPE_32BIT_CONSTANTS;

desc.Desc_1_1.pStaticSamplers   = &samp;
desc.Desc_1_1.Flags =
    D3D12_ROOT_SIGNATURE_FLAG_ALLOW_INPUT_ASSEMBLER_INPUT_LAYOUT
  | D3D12_ROOT_SIGNATURE_FLAG_DENY_HULL_SHADER_ROOT_ACCESS
  | D3D12_ROOT_SIGNATURE_FLAG_DENY_DOMAIN_SHADER_ROOT_ACCESS
  | D3D12_ROOT_SIGNATURE_FLAG_DENY_GEOMETRY_SHADER_ROOT_ACCESS;
    /* DENY flags for stages you do not use are also free
       performance. */

ComPtr<ID3DBlob> blob, err;
D3D12SerializeVersionedRootSignature(&desc, &blob, &err);
device->CreateRootSignature(0, blob->GetBufferPointer(),
```

```
                                blob->GetBufferSize(),
                                IID_PPV_ARGS(&rootSig));
```

ORDER ROOT PARAMETERS BY HOW OFTEN THEY CHANGE

Setting a root parameter invalidates everything after it on some hardware. Put the things that change least often first — per-frame, then per-material, then per-object — so a per-object update does not force the driver to re-emit the per-frame bindings. It is a five-minute reordering that costs nothing and is measurable in draw-heavy scenes.

The pipeline state object

```
/* Everything that could affect shader compilation, frozen
   into one immutable object. This is the whole point: the
   driver compiles ONCE, at load time, at a moment you chose. */

D3D12_GRAPHICS_PIPELINE_STATE_DESC pso = {};
pso.pRootSignature = rootSig.Get();
pso.VS = { vsBlob->GetBufferPointer(), vsBlob->GetBufferSize() };
pso.PS = { psBlob->GetBufferPointer(), psBlob->GetBufferSize() };

D3D12_INPUT_ELEMENT_DESC layout[] = {
  { "POSITION", 0, DXGI_FORMAT_R32G32B32_FLOAT, 0,  0,
    D3D12_INPUT_CLASSIFICATION_PER_VERTEX_DATA, 0 },

                                         a black screen - it
                                         defaults to 0, which
                                         masks out every sample */
pso.SampleDesc.Count = 1;

device->CreateGraphicsPipelineState(&pso, IID_PPV_ARGS(&pipeline));

/* WHAT IS *NOT* IN THE PSO - the state you still set per draw:
     viewport, scissor          RSSetViewports/ScissorRects
     render targets             OMSetRenderTargets
     primitive topology         IASetPrimitiveTopology
       (TYPE is in the PSO; LIST vs STRIP is not)
     vertex/index buffers       IASetVertexBuffers
     descriptor heaps           SetDescriptorHeaps
     root arguments             SetGraphicsRoot*
     stencil ref, blend factor  OMSetStencilRef, OMSetBlendFactor  */
```

PSO COUNT IS THE THING THAT SURPRISES TEAMS

A PSO is the *combination* of shaders, blend, depth, formats and layout. Ten shaders × three blend modes × two depth modes × two render-target formats is 120 PSOs, and each takes 1–50 ms to create. Real games have thousands and spend real effort on this — which is why they show a "compiling shaders" screen on first run and ship a pipeline cache. Enumerate the combinations you will actually use; do not create them lazily.

```
/* CACHING - so the second run is fast. */

/* 1. Per-PSO blob: */
ComPtr<ID3DBlob> cached;
pipeline->GetCachedBlob(&cached);
WriteFile("pso_042.bin", cached);
/* next run: */
pso.CachedPSO = { data, size };     /* driver skips the compile */

/* 2. Better - a whole-library cache: */
ComPtr<ID3D12PipelineLibrary> lib;
device->CreatePipelineLibrary(diskBlob, diskSize,
                              IID_PPV_ARGS(&lib));
lib->LoadGraphicsPipeline(L"OpaqueLit", &pso,
                          IID_PPV_ARGS(&pipeline));
if (!pipeline) {
    device->CreateGraphicsPipelineState(&pso, IID_PPV_ARGS(&pipeline));
    lib->StorePipeline(L"OpaqueLit", pipeline.Get());
}
/* At shutdown, serialise the library to disk. */

/* THE CACHE IS INVALIDATED BY: a driver update, a different
   GPU, a different OS build. Always be able to fall back to
   compiling, and never treat a cache miss as an error. */

/* 3. Create them in PARALLEL - PSO creation is thread-safe
      and CPU-bound, so it scales almost linearly: */
   parallel_for(0, psoDescs.size(), [&](size_t i) {
       device->CreateGraphicsPipelineState(&psoDescs[i],
                                           IID_PPV_ARGS(&psos[i]));
   });
/* A load screen that takes 40 s single-threaded takes 4 s on
   a modern CPU. This is worth doing on day one. */
```

Putting it together in a draw

```
cmd->SetPipelineState(pipeline.Get());
cmd->SetGraphicsRootSignature(rootSig.Get());
    /* Setting a root signature RESETS all root arguments.
       Set it first, then the arguments - the other order
       silently loses them. */

ID3D12DescriptorHeap *heaps[] = { srvHeap.Get() };
cmd->SetDescriptorHeaps(1, heaps);          /* once per list */

cmd->SetGraphicsRootConstantBufferView(1, frameCB->GetGPUVirtualAddress());
cmd->SetGraphicsRootDescriptorTable(2, srvHeap.Gpu(0));

cmd->IASetPrimitiveTopology(D3D_PRIMITIVE_TOPOLOGY_TRIANGLELIST);
cmd->IASetVertexBuffers(0, 1, &vbv);
cmd->IASetIndexBuffer(&ibv);

for (uint32_t i = 0; i < objectCount; i++) {
    cmd->SetGraphicsRoot32BitConstant(0, i, 0);   /* 1 DWORD  */
    cmd->DrawIndexedInstanced(indexCount, 1, 0, 0, 0);
}
/* The inner loop is now ONE root constant and one draw -
   which is close to the minimum possible CPU cost per
   object, and why DX12 reaches tens of thousands of draws. */
```

How it shows up

Symptom	Cause
Black screen, no errors	`SampleMask` left at 0
Root arguments appear not to take effect	Root signature set *after* them — it resets them all
PSO creation fails with a vague message	Input layout semantics do not match the vertex shader, or formats do not match the render targets
Debug layer: root signature mismatch	The shader was compiled against a different signature than the PSO uses
Root signature will not serialise	Over the 64-DWORD budget
First appearance of an effect stutters	PSO created lazily — enumerate and pre-create
Load times of tens of seconds	PSOs created serially; parallelise
Cache gives no benefit after a driver update	Expected — the cache is driver-specific
Draw calls cost more than expected	Root signature too large, or parameters ordered so per-object updates invalidate per-frame ones
Geometry renders inside-out or not at all	Cull mode versus winding order in the rasteriser state

Check yourself

- ✓ Explain the root signature as a function signature, and name its three parameter kinds with their costs.
- ✓ State the root signature budget and what happens when you exceed it.
- ✓ Say why static samplers are preferable, and what they cost.

- ✓ Explain why shader visibility and DENY flags are free performance.
- ✓ Give the rule for ordering root parameters and why it matters.
- ✓ List six pieces of state that go in a PSO and five that do not.
- ✓ Explain why `SampleMask` is a classic black-screen bug.
- ✓ Estimate a PSO count from shader and state combinations, and say why it matters.
- ✓ Describe two levels of PSO caching and what invalidates them.
- ✓ Explain why the root signature must be set before its arguments.

DX12: fences, barriers and residency

The hardest part of the explicit APIs, and the one the old drivers were silently doing for you. Fences order the CPU against the GPU; barriers order the GPU against itself. Get either wrong and you get corruption, a hang, or a device removal — usually far from the cause.

Fences: CPU-to-GPU ordering

```
/* A fence is a monotonically increasing 64-bit counter that
   the GPU writes and either side can read or wait on. That
   is the entire abstraction. */

ComPtr<ID3D12Fence> fence;
device->CreateFence(0, D3D12_FENCE_FLAG_NONE, IID_PPV_ARGS(&fence));
HANDLE event = CreateEvent(nullptr, FALSE, FALSE, nullptr);

/* GPU side: "when you reach this point in the queue, set the
   counter to n". Signal is QUEUED - it happens when the GPU
   gets there, not when you call it. */
queue->Signal(fence.Get(), n);

/* CPU side: wait until the counter reaches n. */
if (fence->GetCompletedValue() < n) {
    fence->SetEventOnCompletion(n, event);
    WaitForSingleObject(event, INFINITE);
}

/* GPU side waiting on another queue - no CPU involvement: */
otherQueue->Wait(fence.Get(), n);

/* THE CANONICAL USE - frames in flight (chapter 13): */
UINT64 frameFence[kFrames] = {};
UINT64 next = 1;

/* end of frame: */
    frameFence[i] = next;
    queue->Signal(fence.Get(), next++);

/* start of the frame that reuses slot i, kFrames later: */
    WaitForFence(frameFence[i]);
    alloc[i]->Reset();            /* now provably safe         */

/* THE THREE THINGS FENCES PROTECT

   1. command allocators   - do not reset while executing
   2. upload buffers       - do not overwrite while being read
   3. resource destruction - do not free while referenced

   Every "it corrupts a few frames later" bug is one of these
   three. If you take one habit from this chapter, take this:
   NOTHING IS REUSED OR RELEASED UNTIL A FENCE PROVES THE GPU
   IS DONE WITH IT.                                          */
```

> **DO NOT WAIT ON THE FENCE YOU JUST SIGNALLED**
> `queue->Signal(f, n); WaitForFence(n);` is a full CPU/GPU stall — you have serialised the two processors and thrown away all the pipelining the API exists to provide. It is correct, and it is what "flush" means. Use it at shutdown, on resize, and nowhere in a frame loop. If your frame time equals CPU time plus GPU time rather than the maximum of the two, this is why.

Barriers: GPU-to-GPU ordering

```
A resource is in exactly ONE STATE at a time, and the state
tells the hardware how to lay it out and cache it.

  RENDER_TARGET            being drawn into
  PIXEL_SHADER_RESOURCE    being sampled
  DEPTH_WRITE / DEPTH_READ
  UNORDERED_ACCESS         compute reads and writes
  COPY_SOURCE / COPY_DEST
  PRESENT                  handed to the display
  COMMON                   the neutral state; required at
                           queue boundaries

You cannot sample a texture you are still rendering into.
The TRANSITION between states is a barrier, and it does
three things:

  1. WAITS for prior work touching the resource to finish
  2. FLUSHES/INVALIDATES the relevant caches
  3. DECOMPRESSES or re-lays-out the memory if the two
     states use different layouts

That third one is why barriers are not free: moving a
render target to a shader resource may involve a full
depth or colour decompression pass over the surface.
```

```
/* The three barrier types. */

/* 1. TRANSITION - the common one. */
D3D12_RESOURCE_BARRIER b = {};
b.Type  = D3D12_RESOURCE_BARRIER_TYPE_TRANSITION;
b.Flags = D3D12_RESOURCE_BARRIER_FLAG_NONE;

b.Transition.StateBefore = D3D12_RESOURCE_STATE_RENDER_TARGET;
b.Transition.StateAfter  = D3D12_RESOURCE_STATE_PIXEL_SHADER_RESOURCE;
b.Transition.Subresource = D3D12_RESOURCE_BARRIER_ALL_SUBRESOURCES;
cmd->ResourceBarrier(1, &b);

/* 2. UAV - no state change, but "finish all writes before any
      reads". Needed between two dispatches where the second
      reads what the first wrote. */
D3D12_RESOURCE_BARRIER u = {};
u.Type          = D3D12_RESOURCE_BARRIER_TYPE_UAV;
u.UAV.pResource = buffer.Get();
cmd->ResourceBarrier(1, &u);

/* 3. ALIASING - when two placed resources share heap memory
      and you switch which one is live. */

/* BATCH THEM. One call with five barriers is much cheaper
   than five calls, because the driver can merge the waits. */
D3D12_RESOURCE_BARRIER batch[3] = { b0, b1, b2 };
cmd->ResourceBarrier(3, batch);

/* SPLIT BARRIERS - start the transition early, finish it
   later, so the GPU can overlap the decompression with other
   work: */
b.Flags = D3D12_RESOURCE_BARRIER_FLAG_BEGIN_ONLY;
cmd->ResourceBarrier(1, &b);
    /* ... unrelated work happens here ... */
b.Flags = D3D12_RESOURCE_BARRIER_FLAG_END_ONLY;
cmd->ResourceBarrier(1, &b);
/* Between BEGIN and END the resource may not be used at all. */
```

```
/* THE TYPICAL FRAME, as a state machine. */

  backbuffer:  PRESENT
        |  transition
        v
      RENDER_TARGET      <- draw the scene
        |  transition

  gbuffer:     RENDER_TARGET   <- geometry pass
        |
        v
      PIXEL_SHADER_RESOURCE    <- lighting pass

/* A helper, because writing the struct out every time is how
   mistakes happen: */
inline void Transition(ID3D12GraphicsCommandList *cmd,
                       ID3D12Resource *res,
                       D3D12_RESOURCE_STATES from,
                       D3D12_RESOURCE_STATES to)
{
    if (from == to) return;                /* no-op, and the
                                              debug layer
                                              complains       */
    D3D12_RESOURCE_BARRIER b = {};
    b.Type = D3D12_RESOURCE_BARRIER_TYPE_TRANSITION;
    b.Transition.pResource   = res;
    b.Transition.StateBefore = from;
    b.Transition.StateAfter  = to;
    b.Transition.Subresource = D3D12_RESOURCE_BARRIER_ALL_SUBRESOURCES;
    cmd->ResourceBarrier(1, &b);
}

/* AND TRACK THE STATE YOURSELF. The runtime does not tell you
   what state a resource is in; you must know. A small
   wrapper that stores the current state per resource and
   asserts on mismatch pays for itself immediately - the debug
   layer catches errors, but only at execute time, and only
   the ones that actually execute. */
```

ENHANCED BARRIERS ARE THE NEWER, BETTER MODEL

DX12's original barriers conflate three separate things: execution dependency, memory visibility, and layout transition. **Enhanced barriers** (Agility SDK 1.7+) split them, matching Vulkan's model and letting you express "wait for compute, but do not decompress" — which the old model could not say. New code should prefer them; the concepts in this chapter map across directly.

Too many barriers, and too few

```
/* TOO FEW: corruption, hangs, or the classic "works on
   NVIDIA, breaks on AMD" - because one driver happened to
   flush a cache the other did not.

   TOO MANY: every barrier is a potential pipeline drain. A
   barrier between every draw serialises the GPU completely
   and can cost more than the draws.                        */

/* BAD - a barrier per object. */
for (auto &o : objects) {
    Transition(cmd, o.tex, COPY_DEST, PIXEL_SHADER_RESOURCE);
    Draw(o);
}

/* GOOD - transition everything once, then draw. */
std::vector<D3D12_RESOURCE_BARRIER> barriers;
for (auto &o : objects)
    barriers.push_back(MakeTransition(o.tex, COPY_DEST,
                                      PIXEL_SHADER_RESOURCE));
cmd->ResourceBarrier((UINT)barriers.size(), barriers.data());
for (auto &o : objects) Draw(o);

/* THE GENERAL PATTERN: group your frame into PASSES, and put
   all the barriers at pass boundaries. Inside a pass, nothing
   changes state.

   A RENDER GRAPH is the industrial version of this idea: you
   declare which passes read and write which resources, and
   the graph derives the minimal barrier set, the state
   transitions and the aliasing opportunities automatically.
   Every large engine has one, for exactly this reason.    */
```

Residency

```
/* VRAM is not infinite and you are not the only application.
   Windows may EVICT your resources to system memory when
   another app needs the memory. */

DXGI_QUERY_VIDEO_MEMORY_INFO info = {};
adapter->QueryVideoMemoryInfo(0, DXGI_MEMORY_SEGMENT_GROUP_LOCAL,
                              &info);
/* info.Budget       - what the OS says you may use
   info.CurrentUsage - what you are using
   Exceeding the budget does not fail; it makes the OS start
   evicting, and your frame time falls off a cliff. */

/* Explicit control, for streaming systems: */
ID3D12Pageable *res[] = { texture.Get() };
device->Evict(1, res);                /* push to system memory */
device->MakeResident(1, res);         /* pull back - BLOCKING  */

/* The async form, so you can prefetch without stalling: */
device->EnqueueMakeResident(D3D12_RESIDENCY_FLAG_NONE, 1, res,
                            fence.Get(), fenceValue);

/* THE PRACTICAL ADVICE
     * poll the budget each frame and shed quality if you are
       over - drop mip levels, reduce the shadow atlas
     * do not fight the OS: if the budget shrinks because the
       user alt-tabbed to a browser, respect it
     * a frame time that suddenly doubles with no code change
       is very often eviction, not your rendering            */
```

How it shows up

Symptom	Cause
Corruption a few frames after a change	Allocator or upload buffer reused without a fence wait
Page fault after freeing a resource	Released while in-flight work still referenced it
Frame time equals CPU + GPU rather than max	A full flush in the frame loop
Works on NVIDIA, corrupts on AMD	Missing barrier that one driver's cache behaviour hid
Sampling a render target returns garbage	No transition from `RENDER_TARGET` to `PIXEL_SHADER_RESOURCE`
Second dispatch reads stale data	Missing UAV barrier between dispatches
Debug layer: "resource is in state X, expected Y"	Your state tracking and reality have diverged
GPU serialised, poor utilisation	Barriers per draw instead of per pass
Frame time doubles when another app opens	VRAM eviction — check the budget
Hang with a fence never reaching its value	Signalled on a different queue, or the value was never signalled at all
Debug layer complains about a same-state transition	Guard with `if (from == to) return;`

Check yourself

- ✓ Describe a fence in one sentence and say who signals and who waits.
- ✓ Name the three things fences protect and the bug from each.

- ✓ Explain why signalling and immediately waiting is a stall, and when it is legitimate.
- ✓ List six resource states and say what a transition barrier actually does.
- ✓ Explain why a transition is not free.
- ✓ Name the three barrier types and when the UAV one is needed.
- ✓ Explain what a split barrier buys.
- ✓ Give the failure mode for too few barriers and for too many.
- ✓ Explain what a render graph automates.
- ✓ Say what residency is and how a frame-time cliff can come from another application.

Project: a DX12 triangle, every line explained

The smallest complete DX12 program. Roughly 400 lines, and by the end of this chapter every one of them should be a decision you understand rather than a line you copied — which is the entire difference between using DX12 and fighting it.

The order of operations

```
STARTUP
  1.  enable the debug layer      BEFORE the device
  2.  create the DXGI factory
  3.  pick an adapter             not adapter 0
  4.  create the device
  5.  configure the info queue and DRED
  6.  create the command queue
  7.  create the swap chain       needs the QUEUE, not the
                                  device
  8.  create descriptor heaps     RTV heap for backbuffers
  9.  create RTVs for each backbuffer
  10. create command allocators   one per frame in flight
  11. create the command list
  12. create the fence and event
  13. compile shaders
  14. create the root signature
  15. create the PSO
  16. create the vertex buffer + upload it
  17. WAIT for the upload to finish

PER FRAME
  18. wait for this frame slot's fence
  19. reset allocator, then list
  20. transition backbuffer PRESENT -> RENDER_TARGET
  21. set state, clear, draw
  22. transition RENDER_TARGET -> PRESENT
  23. close, execute, present, signal

SHUTDOWN
  24. flush - wait for the GPU to be completely idle
  25. release, in any order (ComPtr does it)

Step 24 is not optional: destroying resources the GPU is
still using is a page fault or a hang, and it happens on
exit where nobody looks.
```

The shader

```
// triangle.hlsl - compile both entry points:
//   dxc -T vs_6_0 -E VSMain -Fo vs.cso triangle.hlsl
//   dxc -T ps_6_0 -E PSMain -Fo ps.cso triangle.hlsl
//
// dxc, not fxc: fxc only emits DXBC (shader model 5.1 and
// below). Anything using wave intrinsics or SM 6 features
// needs dxc.

struct VSIn  { float3 pos : POSITION; float4 col : COLOR; };
struct VSOut { float4 pos : SV_Position; float4 col : COLOR; };

VSOut VSMain(VSIn i)
{
    VSOut o;
    o.pos = float4(i.pos, 1.0);   // already in clip space -
                                  // no matrices in a first
                                  // triangle
    o.col = i.col;
    return o;
}

float4 PSMain(VSOut i) : SV_Target
{
    return i.col;                 // interpolated across the
                                  // triangle by the
                                  // rasteriser, for free
}
```

Initialisation

    CloseHandle(fenceEvent_);
}
};   /* class TriangleApp */
```

THE FOUR BLANK-SCREEN CAUSES, IN ORDER OF FREQUENCY

1. `SampleMask` left at 0. **2.** Scissor rect not set, so it is {0,0,0,0}. **3.** `RenderTargetWriteMask` left at 0. **4.** Backface culling with the winding order you did not think about. None of the four produces an error message. If you get a clear colour but no triangle, work down that list before anything else.

Where to go from here

Next step	What it teaches
Add a constant buffer with a rotation matrix	Root descriptors, per-frame upload, and the lifetime rule (chapter 15)
Move the vertex buffer to a DEFAULT heap	Staging buffers, copies and the barrier that follows (chapter 14)
Add a depth buffer	DSV heaps, and reversed-Z (chapter 8)
Add a texture	Descriptor heaps, SRVs, `UpdateSubresources` and static samplers
Draw 10,000 instances	`DrawInstanced`, and where the real CPU cost is
Handle window resize	Flush, release the backbuffers, `ResizeBuffers`, recreate RTVs — a surprising amount of care
Record from four threads	Allocator-per-thread and barrier consistency (chapter 13)
Capture it in PIX	What a frame actually looks like to a tool

How it shows up

Symptom	Cause
Clear colour appears, no triangle	One of the four causes above
Nothing at all, not even the clear	Missing barrier to `RENDER_TARGET`, or the RTV handle offset is wrong
Garbage geometry	Vertex stride or input layout offsets do not match the struct
PSO creation fails	RTV format does not match the swap chain, or semantics do not match the shader
`Present` fails validation	Backbuffer not returned to `PRESENT` state
Crash or corruption after a few seconds	Allocator reset without waiting on the fence
Crash on exit	No flush before releasing resources
Swap chain creation fails	MSAA requested on a flip-model swap chain, or the wrong swap effect
Alt-Enter does something strange	`MakeWindowAssociation` not called
Second frame renders into the first buffer	Assumed `(frame+1)%N` instead of asking `GetCurrentBackBufferIndex`

Check yourself

- ✓ List the startup steps in order and say why the debug layer must be first.
- ✓ Explain why the swap chain is created from the queue rather than the device.
- ✓ Say why `SampleMask` and the write mask must be set explicitly.
- ✓ Give the four blank-screen causes and how to distinguish them.
- ✓ Explain why the vertex buffer here is in an UPLOAD heap and why that is a shortcut.
- ✓ Say why the allocator is reset before the list, and what the fence protects.
- ✓ Explain the two places primitive topology is specified and why both are needed.
- ✓ Explain why the backbuffer index is queried rather than computed.
- ✓ Say what must happen at shutdown and what goes wrong without it.
- ✓ Get the triangle on screen, then break it four ways deliberately and recognise each symptom.

Compute shaders and GPGPU

The graphics pipeline with the graphics removed: no vertices, no rasteriser, no render target. Just a grid of threads, groupshared memory and read-write buffers. It is the same hardware as a pixel shader with the fixed-function stages switched off, and it is how most GPU work is written today.

The dispatch model

```
Dispatch(gx, gy, gz)   launches gx*gy*gz THREAD GROUPS.
[numthreads(tx,ty,tz)] says each group has tx*ty*tz threads.

  total threads = gx*gy*gz * tx*ty*tz

THE IDS available in the shader:

  SV_GroupID           which group am I in       (gx,gy,gz)
  SV_GroupThreadID     where in my group         (tx,ty,tz)
  SV_DispatchThreadID  global = GroupID*size + GroupThreadID
  SV_GroupIndex        flattened index within the group

THE HIERARCHY, and it is the same as CUDA's with different
names (chapter 1):

  thread          one lane
  wave/warp       32 (or 64) threads in lockstep
  THREAD GROUP    up to 1024 threads. Shares GROUPSHARED
                  memory and can use GroupMemoryBarrier.
                  Runs entirely on one compute unit.
  dispatch        all groups. NO synchronisation between
                  groups, and no guaranteed order.

THE RULE: cooperation within a group, none between groups.
Need a global barrier? That is a second Dispatch.

GROUP SIZE: use a multiple of the wave size. 64 is the
safe default - one wave on AMD, two on NVIDIA - and 256 is
the usual choice for 1D work. A group of 1 wastes 31 lanes
of every wave.
```

```
// A compute shader, complete.
// dxc -T cs_6_0 -E CSMain -Fo cs.cso blur.hlsl

Texture2D<float4>   Input  : register(t0);
RWTexture2D<float4> Output : register(u0);   // UAV: writable

cbuffer Params : register(b0) { uint2 Size; float Radius; };

[numthreads(8, 8, 1)]           // 64 threads - one wave on AMD
void CSMain(uint3 id : SV_DispatchThreadID)
{
    if (any(id.xy >= Size)) return;      // bounds check: the
                                         // grid is rounded up
    float4 sum = 0;
    int    n   = 0;
    for (int dy = -2; dy <= 2; dy++)
        for (int dx = -2; dx <= 2; dx++) {
            int2 p = clamp(int2(id.xy) + int2(dx, dy),
                           int2(0,0), int2(Size) - 1);
            sum += Input[p];             // [] is a LOAD, not a
            n++;                         // Sample - no filter,
        }                                // no mip, no sampler
    Output[id.xy] = sum / n;
}
```

```
/* Dispatching it from DX12. */

cmd->SetPipelineState(computePSO.Get());
cmd->SetComputeRootSignature(computeRootSig.Get());
    /* NOTE: SetCompute*, not SetGraphics*. Graphics and
       compute root arguments are SEPARATE sets of state on the
       same command list. Using the wrong setter binds nothing
       and produces no error. */

ID3D12DescriptorHeap *heaps[] = { srvUavHeap.Get() };
cmd->SetDescriptorHeaps(1, heaps);
cmd->SetComputeRootDescriptorTable(0, srvUavHeap.Gpu(0));

/* ROUND UP - the last group is partly out of bounds, which is
   why the shader needs its bounds check. */
UINT gx = (width  + 7) / 8;
UINT gy = (height + 7) / 8;
cmd->Dispatch(gx, gy, 1);

/* THEN A UAV BARRIER before anything reads the output. */
D3D12_RESOURCE_BARRIER uav = {};
uav.Type          = D3D12_RESOURCE_BARRIER_TYPE_UAV;
uav.UAV.pResource = outputTex.Get();
cmd->ResourceBarrier(1, &uav);

/* And a transition if a pixel shader will sample it: */
Transition(outputTex.Get(), D3D12_RESOURCE_STATE_UNORDERED_ACCESS,
           D3D12_RESOURCE_STATE_PIXEL_SHADER_RESOURCE);
```

COMPUTE PSOS ARE SEPARATE OBJECTS

`CreateComputePipelineState` takes a much smaller desc — a root signature and a compute shader, nothing else. There is no blend state, no rasteriser, no render-target format, because none of those stages exist. That also means a compute PSO is far cheaper to create than a graphics one, which is why compute-heavy engines have far fewer PSO problems.

Groupshared memory

```
/* The whole reason thread groups exist: a fast scratchpad
   the group shares. Same hardware as CUDA's __shared__, same
   banking rules (chapter 4).                                  */

groupshared float tile[10][10];      // 8x8 plus a 1-pixel
                                     // border

[numthreads(8, 8, 1)]
void CSMain(uint3 gid : SV_GroupID,
            uint3 tid : SV_GroupThreadID,
            uint3 did : SV_DispatchThreadID)
{
    /* COOPERATIVE LOAD: each thread fetches one texel, and a
       few also fetch the border. The 3x3 blur below then
       reads 9 texels per thread from GROUPSHARED memory
       instead of 9 from the texture cache. */
    tile[tid.y + 1][tid.x + 1] = Input[did.xy].r;
    if (tid.x == 0) tile[tid.y+1][0] = Input[did.xy - int2(1,0)].r;
    if (tid.x == 7) tile[tid.y+1][9] = Input[did.xy + int2(1,0)].r;
    /* ... and the same for y, and the corners ... */

    GroupMemoryBarrierWithGroupSync();
    /* The barrier. THREE VARIANTS, and choosing wrong is
       either a bug or wasted time:
         GroupMemoryBarrier()               groupshared only,
                                            no thread sync
         GroupMemoryBarrierWithGroupSync()  groupshared + all
                                            threads arrive
         DeviceMemoryBarrierWithGroupSync() also UAV/texture
                                            writes - slower  */

    float sum = 0;
    for (int dy = 0; dy < 3; dy++)
        for (int dx = 0; dx < 3; dx++)
            sum += tile[tid.y + dy][tid.x + dx];
    Output[did.xy] = sum / 9;
}

/* THE SAVING: without the tile, a 3x3 blur reads each texel
   NINE times. With it, once. On a bandwidth-bound filter
   that is close to a 9x reduction in traffic.

   THE LIMITS:
     * 32 KB per group typically (16 KB on older hardware)
     * more groupshared -> fewer groups resident -> lower
       occupancy (chapter 5). It is the same budget trade as
       registers.
     * ALL THREADS IN THE GROUP MUST REACH THE BARRIER. Putting
       GroupMemoryBarrierWithGroupSync inside a divergent
       branch hangs the group - and on a GPU that means a TDR
       and a device removal.                                  */
```

THE EARLY-RETURN BUG

`if (any(id.xy >= Size)) return;` is correct in the first example and *fatal* in the second: threads that returned never reach the barrier, so the rest of the group waits for ever. When a group uses barriers, every thread must run to the end — clamp the coordinates instead of returning, or guard only the final write. This produces a GPU hang, a two-second TDR and a device removal, which is a confusing way to discover a one-line mistake.

The patterns worth knowing

```
/* PARALLEL REDUCTION - sum a buffer. The canonical example,
   and the structure of half of all compute work. */

groupshared float partial[256];

[numthreads(256, 1, 1)]
void Reduce(uint3 did : SV_DispatchThreadID,
            uint  idx : SV_GroupIndex,
            uint3 gid : SV_GroupID)
{
    partial[idx] = (did.x < Count) ? Input[did.x] : 0.0;
    GroupMemoryBarrierWithGroupSync();

    /* Tree reduction: halve the active threads each step. */
    for (uint s = 128; s > 0; s >>= 1) {
        if (idx < s) partial[idx] += partial[idx + s];
        GroupMemoryBarrierWithGroupSync();
        /* the barrier is OUTSIDE the if - every thread reaches
           it, including the ones with nothing to do */
    }

    if (idx == 0) Output[gid.x] = partial[0];
    /* one partial per group. Dispatch again over those, until
       one value remains. */
}

/* BETTER: use wave intrinsics for the last steps and skip
   most of the barriers entirely (chapter 2): */
    float v = WaveActiveSum(myValue);        // whole wave, no
                                             // memory, no
                                             // barrier
    if (WaveIsFirstLane()) partial[waveId] = v;
    GroupMemoryBarrierWithGroupSync();       // ONE barrier
    if (idx < numWaves) {
        v = WaveActiveSum(partial[idx]);
        if (idx == 0) Output[gid.x] = v;
    }
/* Two barriers instead of eight, and far less groupshared
   traffic. This is the modern shape of a reduction. */

/* ATOMICS - when you need one global result and can tolerate
   contention: */
    InterlockedAdd(Counter[0], 1);
    InterlockedMax(MaxVal[0], asuint(myValue));   // float via
                                                  // bit trick
/* Every thread hitting one address serialises at L2. AGGREGATE
   FIRST - reduce within the wave, then have one lane do the
   atomic. That turns 32 atomics into 1: */
    uint total = WaveActiveCountBits(predicate);
    if (WaveIsFirstLane()) InterlockedAdd(Counter[0], total);

/* APPEND BUFFERS - a GPU-side vector, for culling and
   compaction: */
    AppendStructuredBuffer<Item> Visible : register(u1);
    if (IsVisible(item)) Visible.Append(item);
/* The counter is an atomic underneath, so the same
   aggregation advice applies for hot cases. */

/* INDIRECT DISPATCH - the GPU decides its own work size,
   with no CPU round trip: */
```

```
    cmd->ExecuteIndirect(cmdSig, 1, argBuffer, 0, nullptr, 0);
/* argBuffer was written by an earlier compute pass. This is
   how GPU-driven rendering works: cull on the GPU, write the
   draw arguments, and execute them without the CPU ever
   learning how many objects survived.                    */
```

What compute is used for

Use	Why compute rather than a pixel shader
Post-processing: blur, bloom, tonemap	Groupshared memory removes redundant texture reads; no rasteriser overhead
Particle simulation	Read-write buffers; no vertex/fragment structure to fight
Culling and LOD selection	Feeds `ExecuteIndirect`; keeps the CPU out of the loop
Light binning (clustered/forward+)	Arbitrary data structures, atomics, append buffers
Skinning, cloth, physics	Large uniform data-parallel work
Mipmap and BVH generation	Hierarchical, needs multiple dispatches with barriers
ML inference	What tensor cores are for; usually via DirectML or ONNX rather than by hand
Sorting, scan, histogram	Classic parallel primitives; use a library

> **ASYNC COMPUTE IS WHERE THE FREE PERFORMANCE IS**
>
> A shadow pass is geometry- and depth-bound; a compute post-process is ALU-bound. Run them on separate queues (chapter 13) and they fill each other's idle units — typically 5–15% of frame time for no algorithmic change. It is one of the few optimisations that costs only plumbing, and it is why compute-shader post-processing displaced pixel-shader post-processing.

How it shows up

Symptom	Cause
GPU hang, TDR, device removed	A barrier not reached by every thread — usually an early `return`
Wrong results at tile edges	Cooperative load missing the border, or a missing barrier
Reader sees stale data	No UAV barrier between the writing and reading dispatches
Bindings appear to do nothing	`SetGraphicsRoot*` used instead of `SetComputeRoot*`
Last row or column of the image is wrong	Grid not rounded up, or the bounds check is missing
Occupancy collapses after adding groupshared	Groupshared is a budget like registers
Atomics dominate the profile	Every thread hitting one address — aggregate per wave first
Group size 32 is slower than 64 on AMD	Half a wavefront idle on wave64 hardware
Async compute gives no gain	Over-synchronised, or both passes bound by the same unit
Reduction result is non-deterministic	Floating-point addition is not associative — expected, not a bug

Check yourself

- ✓ Compute the total thread count from a dispatch and a `numthreads` declaration.
- ✓ Name the four system-value IDs and what each gives you.
- ✓ Say what can synchronise within a group and what cannot between groups.

- ✓ Explain why group size should be a multiple of the wave size.
- ✓ Write a cooperative tile load and say what traffic it saves.
- ✓ Name the three barrier intrinsics and when each applies.
- ✓ Explain the early-return bug and its symptom.
- ✓ Write a tree reduction, then rewrite it with wave intrinsics and count the barriers saved.
- ✓ Explain wave aggregation for atomics and the factor it saves.
- ✓ Describe what `ExecuteIndirect` enables that the CPU path cannot.

Profiling and debugging a GPU

You cannot step through a shader with a breakpoint, and the thing you want to time runs asynchronously on another processor. GPU debugging is therefore a different discipline: capture a frame, inspect state, and measure with the right counter — in that order.

Find the bottleneck before optimising

```
FOUR THINGS CAN LIMIT A FRAME. Optimising the wrong one
changes nothing, and this is the most common wasted week in
graphics work.

1. CPU-BOUND
     GPU idle, waiting for commands.
     SIGN: GPU busy % well below 100. Frame time tracks CPU
           time.
     FIX: fewer draw calls, instancing, multi-threaded
          recording, fewer PSO switches.

2. GEOMETRY / VERTEX BOUND
     SIGN: frame time scales with triangle count; the
           vertex shader dominates.
     FIX: LODs, better culling, fewer vertices. On mobile
          this hits far sooner (chapter 10).

3. PIXEL / FILL BOUND
     SIGN: frame time scales with RESOLUTION. Halve the
           render resolution and it nearly halves.
     FIX: reduce overdraw, cheaper pixel shaders, smaller
          render targets, better early-Z.

4. BANDWIDTH BOUND
     SIGN: frame time does NOT change when you simplify the
           shader, but DOES when you shrink texture formats
           or render-target sizes.
     FIX: compression, fewer/smaller targets, tighter
          formats, better locality.

THE TWO-MINUTE TEST THAT IDENTIFIES ALL FOUR

  halve the resolution   -> much faster? PIXEL or BANDWIDTH
  replace the pixel
    shader with
    return float4(1,0,0,1)  -> much faster? PIXEL
                            -> no change?   BANDWIDTH or
                                            GEOMETRY
  draw half the objects  -> much faster? CPU or GEOMETRY
  do the same draws but
    with an empty
    command list         -> still slow? CPU-BOUND

Do this before opening a profiler. It takes minutes and it
stops you optimising the wrong thing.
```

The tools

Tool	For	Notes
PIX on Windows	DX12 frame capture and timing	The primary DX12 tool. Timing captures need hardware counters enabled
RenderDoc	Frame capture, state inspection, shader debugging	Free, cross-API, cross-platform. Best for *correctness*; deliberately not a timing tool
Nsight Graphics	NVIDIA: deep pipeline analysis	Tells you which unit is the limiter, per draw
Nsight Compute	NVIDIA: CUDA and compute kernels	Occupancy, divergence, memory efficiency, source attribution
Radeon GPU Profiler	AMD: wave occupancy timeline	Shows async compute overlap better than anything else
Arm/Mali Streamline, **Adreno GPA**, **Xcode GPU debugger**	Mobile	The only way to see tiler-specific costs
Timestamp queries	Your own in-engine timings	Always ship these — they work on user machines where no tool is installed

RENDERDOC FOR "WHY IS IT WRONG", PIX FOR "WHY IS IT SLOW"

RenderDoc lets you click a draw, see every bound resource, step through a pixel shader for a chosen pixel, and view the history of every write to that pixel. That is the fastest way to answer a correctness question. PIX and the vendor tools have the hardware counters that answer performance questions. Using the wrong one wastes an afternoon.

Timing it yourself

```
/* GPU timestamps: the GPU writes a counter into a buffer at
   points you choose. You read them back a few frames later -
   never immediately, or you stall (chapter 16). */

D3D12_QUERY_HEAP_DESC qd = {};
qd.Type  = D3D12_QUERY_HEAP_TYPE_TIMESTAMP;
qd.Count = 64;                    /* 32 pairs */
device->CreateQueryHeap(&qd, IID_PPV_ARGS(&queryHeap));

/* Results land in a READBACK buffer. */
CreateBuffer(D3D12_HEAP_TYPE_READBACK, 64 * sizeof(UINT64),
             &readback);

/* The frequency is per-QUEUE and can change with clocks - ask
   each frame, do not cache it once. */
UINT64 freq = 0;
queue->GetTimestampFrequency(&freq);

/* --- recording --- */
cmd->EndQuery(queryHeap.Get(), D3D12_QUERY_TYPE_TIMESTAMP, 0);
    /* EndQuery, even for the "begin" - a timestamp is a point,
       not a range. Confusing, and it catches everyone once. */
    DrawShadowPass(cmd);
cmd->EndQuery(queryHeap.Get(), D3D12_QUERY_TYPE_TIMESTAMP, 1);

cmd->ResolveQueryData(queryHeap.Get(),
                      D3D12_QUERY_TYPE_TIMESTAMP,
                      0, 2, readback.Get(), 0);

/* --- reading, N frames later --- */
UINT64 *ts = nullptr;
D3D12_RANGE r = { 0, 2 * sizeof(UINT64) };
readback->Map(0, &r, (void **)&ts);
double ms = double(ts[1] - ts[0]) / double(freq) * 1000.0;
readback->Unmap(0, nullptr);

/* CAVEATS THAT MAKE NAIVE TIMINGS LIE

   1. The GPU pipelines aggressively. Two adjacent "passes"
      may overlap, so their measured times sum to more than
      the frame. Timestamps measure WHEN, not HOW LONG.

   2. Clocks vary. A GPU idling at 300 MHz and boosting to
      2.5 GHz gives you an 8x spread on the same work. Lock
      the clocks when benchmarking:
        nvidia-smi -lgc 1500,1500
        or use the tool's "stable power state" option.

   3. The first frame after a PSO change includes the
      compile. Discard the first several frames, always.

   4. Vsync makes everything look like 16.67 ms. Turn it off
      to measure.                                          */
```

Debugging a shader

```
/* You cannot printf from a shader. Four techniques, roughly
   in order of how often they are the right one. */

/* 1. OUTPUT THE VALUE AS COLOUR. Crude, immediate, and it
      answers most questions. */
        return float4(frac(worldPos.xyz * 0.1), 1);   /* is my
                                                         position
                                                         sane? */
        return float4(normal * 0.5 + 0.5, 1);         /* normals */
        return float4(uv, 0, 1);                      /* UVs     */
        return float4(depth.xxx / 100.0, 1);          /* depth   */
/* Values outside [0,1] clip to white or black, so scale
   deliberately - "everything is white" usually means your
   value is 47, not 0.47. */

/* 2. RENDERDOC PIXEL DEBUGGING. Capture, click the pixel,
      "Debug this pixel", and step through the shader with all
      intermediate values shown. This is the closest thing to
      a real debugger and it is remarkably good. */

/* 3. WRITE TO A UAV and read it back. The GPU's printf. */
        RWStructuredBuffer<float4> Debug : register(u7);
        if (all(id.xy == uint2(512, 384)))    /* one pixel only */
                Debug[0] = float4(computedValue, 0, 0, 1);
/* Guard it to ONE invocation, or thousands of threads race
   for slot 0 and you learn nothing. */

/* 4. WARP/WAVE INSPECTION in Nsight or PIX: pause a dispatch
      and inspect live registers per lane. Heavy, but the only
      way to see divergence directly. */

/* AND THE STRUCTURAL ONE: bisect the shader. Replace the
   second half with a constant, see if the artefact persists,
   and halve again. Four iterations localises almost any
   shader bug, and it needs no tools at all.               */
```

> **TIMING CAPTURES NEED PERMISSION**
>
> PIX and the vendor profilers read hardware performance counters, which are disabled by default because they can leak information between processes. On Windows you need *Developer Mode* plus, for NVIDIA, the "allow access to GPU performance counters" setting in the control panel. The symptom is a capture that opens with every timing showing zero, which looks like a tool bug and is a permissions problem.

Make captures readable

```
/* An unmarked capture is 4,000 anonymous draws. Ten minutes
   of markers turns it into a readable frame. */

#include <pix3.h>

PIXBeginEvent(cmd, PIX_COLOR(255,0,0), "Shadow Pass");
    for (auto &light : lights) {
        PIXBeginEvent(cmd, PIX_COLOR(255,128,0),
                      "Light %d", light.id);
        DrawShadowMap(cmd, light);
        PIXEndEvent(cmd);
    }
PIXEndEvent(cmd);

/* An RAII wrapper so an early return cannot unbalance them: */
struct GpuScope {
    ID3D12GraphicsCommandList *c;
    GpuScope(ID3D12GraphicsCommandList *cl, const char *n,
             UINT col = PIX_COLOR_DEFAULT) : c(cl)
    { PIXBeginEvent(c, col, n); }
    ~GpuScope() { PIXEndEvent(c); }
};
#define GPU_SCOPE(cmd, name) GpuScope _s##__LINE__(cmd, name)

/* Plus SetName on every resource and PSO (chapter 12).
   Together these two habits are the difference between a
   capture you can read and one you cannot. */

/* Vulkan: vkCmdBeginDebugUtilsLabelEXT
   Metal:  pushDebugGroup / popDebugGroup
   All three tools understand all three.                    */
```

Reading the counters that matter

```
# NVIDIA, a compute kernel:
$ ncu --set full -o report ./app

  Speed Of Light
    Compute (SM) Throughput          18.2%
    Memory Throughput                91.4%     <-- the limiter
  Occupancy
    Achieved Occupancy               24.1%
    Theoretical Occupancy            50.0%     <-- and a gap
  Memory Workload Analysis
    L1 Hit Rate                      12.3%
    Global Load Efficiency           23.0%     <-- uncoalesced

# Read it top-down: memory-bound, poor coalescing, and only
# half the theoretical occupancy achieved. Fix the access
# pattern (chapter 4) before touching anything else.

# The gap between achieved and theoretical occupancy is
# usually load imbalance or the tail effect (chapter 5).

# AMD:
$ rgp ./app          # then open in Radeon GPU Profiler
# The wavefront timeline shows async compute overlap directly.

# Mobile:
$ Streamline / Adreno GPA - look for tile load/store cost
# above all else (chapter 10).
```

How it shows up

Symptom	Cause
Optimised the shader, no change	Not pixel-bound — run the four-way test first
Capture shows all timings as zero	Performance counters not permitted; enable Developer Mode
Pass timings sum to more than the frame	Passes overlap; timestamps measure when, not how long
Timings vary 3× run to run	Clock boost — lock the clocks
First frame is 50× slower	PSO compilation; discard warm-up frames
Everything measures 16.67 ms	Vsync
Debug UAV output is garbage	Every thread writing the same slot — guard to one invocation
Debug colour output is entirely white	Value outside [0,1]; scale it
Capture is 4,000 unnamed draws	No debug markers or resource names
Achieved occupancy far below theoretical	Load imbalance or the tail effect
Frame time doubles when another app opens	VRAM eviction (chapter 16)

Check yourself

- ✓ Name the four possible bottlenecks and the sign of each.
- ✓ Give the four-step test that identifies the bottleneck without a profiler.
- ✓ Say which tool to reach for on a correctness question and which on a performance one.

- ✓ Explain why timestamps measure when rather than how long.
- ✓ Give three reasons a naive GPU timing lies.
- ✓ Name four ways to debug a shader and when each applies.
- ✓ Explain why a debug UAV write must be guarded to one invocation.
- ✓ Say why a capture might show all timings as zero.
- ✓ Read a Speed-of-Light report and say what to fix first.
- ✓ Explain what a gap between achieved and theoretical occupancy usually means.

What a GPU driver actually does

Between your `Draw` call and the silicon sits several hundred thousand lines of someone else's code, split across a user-mode library and a kernel driver. Knowing what each half does closes the loop between this track and the Linux and Windows driver tracks — and explains most of the odd behaviour you have met along the way.

The two halves

```
    YOUR APPLICATION
         |  d3d12.dll / libvulkan.so
         v
    +-------------------------------------------------------+
    |  USER-MODE DRIVER  (UMD)                              |
    |    runs IN YOUR PROCESS, at your privilege            |
    |                                                       |
    |    * compiles DXIL/SPIR-V -> the GPU's real ISA       |
    |    * translates API calls into hardware COMMAND       |
    |      PACKETS, written into a buffer                   |
    |    * manages descriptors and their hardware layout    |
    |    * per-application workarounds and shader           |
    |      replacements, keyed on the executable name       |
    |                                                       |
    |    A CRASH HERE CRASHES YOUR APP, and nothing else.   |
    |    This is why most of the driver lives here.         |
    +-------------------------------------------------------+
         |  ioctl / DeviceIoControl  - the ONLY kernel entry
         v
    +-------------------------------------------------------+
    |  KERNEL-MODE DRIVER  (KMD)                            |
    |    ring 0. Shared by every process on the machine.    |
    |                                                       |
    |    * SUBMITS command buffers to the hardware rings    |
    |    * SCHEDULES between processes - your game and the  |
    |      compositor and the browser all want the GPU      |
    |    * manages GPU VIRTUAL MEMORY and page tables       |
    |    * handles interrupts and fence completion          |
    |    * power and clock management                       |
    |    * RESETS the GPU when something hangs (TDR)        |
    |                                                       |
    |    A CRASH HERE IS A BUGCHECK / KERNEL PANIC.         |
    +-------------------------------------------------------+
         |  MMIO, doorbells, DMA
         v
    THE GPU

    THE SPLIT IS DELIBERATE: everything that can be done at
    application privilege is, so that the enormous, fast-moving,
    game-specific part of the driver cannot take down the
    machine. Only the parts that genuinely need ring 0 -
    submission, memory mapping, interrupts, arbitration between
    processes - live in the kernel.
```

> **THIS IS EXACTLY THE SPLIT YOU LEARNED IN THE DRIVER TRACKS**
> A GPU driver is the largest example of the same architecture: a user-mode component doing the complex, untrusted work, and a small kernel component owning the hardware, the address space and the arbitration. Compare Windows' WDM/KMDF/UMDF split and the Linux DRM/KMS design — the reasoning is identical, and GPU drivers are simply where it is pushed hardest.

How a draw actually reaches the GPU

```
/* Follow one Draw all the way down. */

  1. YOUR CODE
        cmd->DrawInstanced(3, 1, 0, 0);

  2. UMD, in your process
        appends a hardware command packet to the command
        allocator's memory. On AMD that is a PM4 packet; on
        NVIDIA a method write. Perhaps 20-100 bytes.
        NO SYSCALL. This is why DX12 draw calls are ~0.1 us.

  3. ExecuteCommandLists
        UMD builds a submission descriptor and calls into the
        KMD. ONE ioctl for the whole list - not one per draw.

  4. KMD
        * validates the buffer belongs to you
        * ensures every referenced resource is RESIDENT and
          mapped in this process's GPU page tables
        * places the submission in a hardware RING BUFFER
        * writes a DOORBELL register - an MMIO write that
          tells the GPU "there is work"

  5. GPU COMMAND PROCESSOR
        fetches from the ring, decodes packets, and feeds the
        front end. The GPU is now executing.

  6. COMPLETION
        the GPU writes a fence value to memory and raises an
        INTERRUPT. The KMD's ISR runs, signals the OS
        synchronisation object, and your WaitForSingleObject
        returns.

  NOTE how few kernel transitions there are: one per SUBMIT,
  not one per draw. That is the single biggest structural
  reason DX12 and Vulkan are faster than DX11 and OpenGL -
  the batching is explicit and under your control.        */
```

GPU virtual memory

```
Modern GPUs have an MMU and per-process page tables, for
the same reasons a CPU does.

  GPU virtual address
       |  GPU page tables, per process
       v
  physical: VRAM, or system RAM over PCIe, or migrated
            between them by the driver

WHAT THIS BUYS
  * isolation: one process cannot read another's textures.
    Before per-process GPU page tables this was genuinely
    not true, and it was a real vulnerability class.
  * OVERSUBSCRIPTION: allocate more than VRAM and let the
    driver page. Slow, but it works instead of failing.
  * a stable address for a resource across residency
    changes - GetGPUVirtualAddress() stays valid even if
    the pages move.

WHAT IT COSTS
  * a GPU page fault is enormously expensive - the whole
    wave stalls, and on older hardware the whole GPU
  * this is what a DRED page-fault report is telling you
    (chapter 12): a shader dereferenced a GPU VA that is
    not mapped, almost always a freed resource or a
    descriptor pointing at nothing

IOMMU / SMMU applies here too: on a system with an IOMMU
the GPU's DMA is itself translated, which is what makes
GPU passthrough to a VM safe (virtualisation chapter 16).
```

Scheduling, preemption and TDR

```
/* THE GPU IS SHARED. Your game, the compositor, the browser
   playing video and Windows' own UI all submit work. The KMD
   arbitrates.                                              */

  PREEMPTION GRANULARITY - how quickly a running job can be
  interrupted:

    DRAW-LEVEL     between draw calls. Old hardware.
    PRIMITIVE      between triangles.
    PIXEL / WAVE   mid-draw. Modern hardware.
    INSTRUCTION    fully preemptible. Newest.

  Coarse preemption is why a single enormous draw or dispatch
  can make the whole desktop stutter: nothing else can run
  until it finishes.

/* TDR - TIMEOUT DETECTION AND RECOVERY

   If a submission does not complete within ~2 seconds,
   Windows assumes the GPU is hung:
     1. the KMD is asked to reset the GPU
     2. every application's device is marked REMOVED
     3. your app gets DXGI_ERROR_DEVICE_REMOVED with
        DXGI_ERROR_DEVICE_RESET (chapter 12)

   CAUSES, in order of likelihood:
     * an infinite loop in a shader
     * a compute dispatch that is genuinely too large - split
       it, or it will TDR on slower GPUs even though it works
       on yours
     * a barrier a group never reaches (chapter 18)
     * an actual driver or hardware fault

   THE REGISTRY KEY people reach for:
     HKLM\System\CurrentControlSet\Control\GraphicsDrivers
        TdrDelay = 60
   Raise it FOR DEBUGGING ONLY. Shipping software that needs
   it has a bug, and users will not have set it.

   Linux equivalents: amdgpu.lockup_timeout, and the
   GPU reset paths in i915/amdgpu. Same idea, same causes. */
```

> **APPLICATION PROFILES ARE REAL, AND THEY EXPLAIN A LOT**
>
> Drivers ship per-executable profiles that change defaults, force settings, and in some cases *substitute entire shaders* with hand-optimised replacements. This is why renaming your executable can change performance, why a driver update can alter behaviour with no change on your side, and why benchmarking against a shipped game tells you about the profile as much as the hardware. When something behaves differently on one vendor for no reason you can find, this is a real candidate.

The open-source stacks

Layer	Linux	Windows
Kernel driver	`drivers/gpu/drm/` — amdgpu, i915/xe, nouveau, panfrost, msm	WDDM miniport (vendor, closed)

Layer	Linux	Windows
Kernel framework	DRM/KMS — mode setting, GEM/TTM memory, `dma-fence`, scheduler	DXGkrnl
User-mode driver	Mesa: RADV, ANV, NVK, turnip, panvk	Vendor UMD (closed)
Shader compiler	NIR + ACO or LLVM	Vendor back end
Interface	libdrm ioctls	D3DKMT ioctls

Mesa is the best code to read if you want to see this for real: `src/amd/vulkan` (RADV) is a complete, readable Vulkan driver, and `drivers/gpu/drm/amdgpu` is a complete kernel driver for the same hardware. Between them they contain every idea in this chapter, in code you can build and instrument — which is a rare thing for hardware this complex.

```
# Look at what the driver is doing on a Linux box.

$ lsmod | grep -E 'amdgpu|i915|nouveau'
$ dmesg | grep -i drm
[drm] amdgpu kernel modesetting enabled.
[drm] Initialized amdgpu 3.57.0 for 0000:03:00.0 on minor 0

# Every GPU client, and what it is using:
$ sudo cat /sys/kernel/debug/dri/0/clients
$ sudo cat /sys/kernel/debug/dri/0/amdgpu_gem_info
$ sudo cat /sys/kernel/debug/dri/0/amdgpu_vm_info    # page tables

# The ring buffers - the actual submission queues:
$ sudo cat /sys/kernel/debug/dri/0/amdgpu_ring_gfx | head

# A GPU hang, after the fact:
$ sudo cat /sys/kernel/debug/dri/0/amdgpu_gpu_recover
$ dmesg | grep -i 'ring gfx timeout\|GPU reset'

# Trace submissions as they happen:
$ sudo perf trace -e 'amdgpu:*' -a
$ sudo cat /sys/kernel/debug/tracing/events/amdgpu/available_filters

# And the disassembly of what your shader really became:
$ RADV_DEBUG=shaders ./app 2>shaders.txt
$ head -50 shaders.txt        # actual GCN/RDNA assembly
```

Where this track sits

You have gone from "a GPU hides latency instead of reducing it" to reading the assembly a driver generated for your shader. The natural continuations are Linux kernel and drivers if you want to work on the KMD side, compilers if the shader back end is the interesting part, concurrency because a GPU is the most parallel machine you will program, and AI and large language models for the workload that now drives most GPU design decisions.

How it shows up

Symptom	Cause
`DEVICE_REMOVED` after a heavy dispatch	TDR — split the work; it will fail on slower GPUs too
Whole desktop stutters during your frame	Coarse preemption and a very long draw or dispatch
DRED reports a page fault	A shader dereferenced an unmapped GPU VA — usually a freed resource or a stale descriptor

Symptom	Cause
Performance changes after renaming the executable	Driver application profile
Behaviour changes after a driver update, no code change	UMD shader compiler or profile change
Works on one vendor, hangs on another	Almost always a missing barrier one driver tolerated
Allocation succeeds but everything is slow	Oversubscribed VRAM; the driver is paging
A GPU crash takes down the whole machine	A KMD bug — rare, and reportable
Raising `TdrDelay` "fixed" it	It did not; you have a shader or dispatch that is too long

Check yourself

- ✓ Draw the UMD/KMD split and say what each half does.
- ✓ Explain why most of a GPU driver lives in user mode.
- ✓ Trace one `Draw` from your call to the GPU executing it, naming each layer.
- ✓ Say how many kernel transitions a thousand draws cost, and why that matters.
- ✓ Give three things GPU virtual memory buys and one it costs.
- ✓ Explain what a DRED page-fault report is telling you.
- ✓ Define preemption granularity and say what coarse granularity causes.
- ✓ Explain TDR, its usual causes, and why raising `TdrDelay` is not a fix.
- ✓ Say what an application profile is and three symptoms of one.
- ✓ Name the Linux equivalents of the UMD and the KMD, and where to read them.

TRACK

Video & image systems

How a picture becomes bytes and back again: colour and pixel formats, the transform-and-predict machinery inside every codec, the fixed-function blocks that run it, and the V4L2 and DRM drivers that feed them.

21 chapters

How an image is represented

An image is a sampled measurement of light, stored as numbers. Every later chapter — colour, compression, drivers — is an argument about which numbers, how many bits each, and in what order in memory. Getting this layer wrong produces green faces, diagonal stripes and off-by-one-row corruption.

A picture is a sampling of a continuous signal

```
The world is continuous. A sensor measures it at a grid of
points, and quantises each measurement to an integer.

  SPATIAL SAMPLING     how many points   -> resolution
  TEMPORAL SAMPLING    how often         -> frame rate
  AMPLITUDE QUANTISING how finely        -> bit depth

EACH HAS ITS OWN ALIASING ARTEFACT, and naming them is
half of image work:

  spatial undersampling  -> MOIRE, jagged edges, texture
                            shimmer. Fix: filter BEFORE
                            sampling (an optical low-pass
                            filter, or mipmaps - GPU
                            chapter 9).

  temporal undersampling -> the WAGON-WHEEL effect, judder,
                            strobing. Fix: motion blur, or
                            a higher frame rate.

  amplitude quantising   -> BANDING in gradients. Fix:
                            more bits, or DITHER - adding
                            noise below the quantisation
                            step converts a visible contour
                            into invisible grain.

Nyquist applies to all three: to represent detail at
frequency f you must sample at more than 2f. Everything a
codec does is a controlled violation of this, chosen so the
error lands where the eye will not look.
```

Bit depth	Levels	Where used
1	2	Fax, e-ink, masks
8	256	The web, SDR video, most sensors' output after processing
10	1024	HDR video (HEVC Main10, AV1), broadcast. The current default for anything serious
12	4096	Cinema, high-end capture
16 integer	65536	Raw sensor data, intermediate processing
16 float (half)	~1000 with huge range	HDR compositing, GPU render targets
32 float	—	Scientific, film scanning, linear-light working space

WHY 8 BITS IS NOT ENOUGH FOR A GRADIENT

A smooth sky spanning 100 pixels between two adjacent 8-bit levels produces a visible step — the eye is extremely good at spotting an edge in an otherwise flat area, far better than at judging absolute brightness. This is *banding*, and it is the single most common visible defect in 8-bit video. Ten bits mostly fixes it; dithering fixes it at 8 bits by trading a contour for noise, which the eye forgives.

Planar, semi-planar and packed

```
The same 4 pixels, three ways of arranging them in memory.

PACKED / INTERLEAVED  - components of one pixel adjacent

  RGBA8:  R0 G0 B0 A0  R1 G1 B1 A1  R2 G2 B2 A2  ...

  + one pointer, one stride
  + perfect for a GPU texture unit reading whole pixels
  - reading only one component wastes bandwidth (GPU
    chapter 4: this is AoS)

PLANAR - each component in its own contiguous plane

  Y  plane:  Y0 Y1 Y2 Y3 Y4 ...
  Cb plane:  U0 U1 ...
  Cr plane:  V0 V1 ...

  + each plane can have a DIFFERENT RESOLUTION - which is
    the whole point, because chroma is subsampled
    (chapter 3)
  + a filter that only needs luma reads one plane
  - three pointers, three strides, three allocations

SEMI-PLANAR - luma separate, chroma interleaved

  Y  plane:  Y0 Y1 Y2 Y3 ...
  UV plane:  U0 V0 U1 V1 ...

  + TWO planes, and the chroma pair is fetched in one
    access - which is what hardware codecs and display
    controllers actually want
  -> this is NV12, and it is the most common video pixel
     format in the world.

THE RULE OF THUMB
  GPUs and image files like PACKED.
  Codecs and display hardware like SEMI-PLANAR.
  Image processing code likes PLANAR.
Conversions between them are a real cost in every pipeline.
```

Stride is not width

```
/* THE SINGLE MOST COMMON BUG IN IMAGE CODE. */

  WIDTH   how many pixels are meaningful in a row
  STRIDE  how many BYTES from the start of one row to the
          start of the next        (also called PITCH)

  stride >= width * bytes_per_pixel,  and often strictly >

  WHY THERE IS PADDING
    * hardware wants each row aligned to 16, 32, 64, 128 or
      256 bytes so a DMA burst or a SIMD load never straddles
    * a 1920-wide NV12 buffer very often has a 1984 or 2048
      byte stride
    * a sub-image (a crop, a tile) has the PARENT's stride

/* WRONG - assumes packed rows. Works on 1920x1080 by luck,
   corrupts on 1922x1080 with a skew that looks like the
   image was sheared. */
for (int i = 0; i < w * h; i++)
        dst[i] = src[i];

/* RIGHT - one row at a time. */
for (int y = 0; y < h; y++)
        memcpy(dst + y * dst_stride,
               src + y * src_stride,
               w * bytes_per_pixel);   /* copy WIDTH, step
                                          STRIDE               */

/* AND FOR CHROMA in a subsampled format, the chroma plane has
   its OWN stride and its own height: */
for (int y = 0; y < h / 2; y++)
        memcpy(dst_uv + y * dst_uv_stride,
               src_uv + y * src_uv_stride,
               w);                     /* NV12: w bytes = w/2
                                          U + w/2 V pairs      */

/* THE DIAGONAL-SKEW SYMPTOM: if an image looks sheared, with
   each row shifted a little further than the last, you have
   used width where stride was needed. The shift per row is
   exactly (stride - width * bpp).                            */
```

NEGATIVE STRIDE IS LEGAL AND MEANS BOTTOM-UP

Windows DIBs, some capture APIs and BMP files store rows bottom-to-top, expressed as a pointer to the *last* row and a negative stride. Code that computes `row * stride` handles this automatically; code that computes `abs(stride)` or assumes the buffer starts at the lowest address produces a vertically flipped image or a buffer underrun. If your image is upside down, check the sign before adding a flip.

Sizing a buffer

```
/* Get this wrong and you get a heap overflow that shows up as
   corruption in whatever was allocated next. */

size_t plane_size(int stride, int height)   { return (size_t)stride * height; }

/* RGBA8, 1920x1080, 256-byte aligned rows */
        stride = align_up(1920 * 4, 256);        /* 7936        */
        size   = 7936 * 1080;                     /* 8,570,880  */

/* NV12, 1920x1080 */
        y_stride  = align_up(1920, 128);          /* 1920       */
        y_size    = 1920 * 1080;                  /* 2,073,600  */
        uv_stride = y_stride;                     /* same!      */
        uv_size   = uv_stride * (1080 / 2);       /* 1,036,800  */
        total     = y_size + uv_size;             /* 3,110,400  */
                                                  /* = w*h*1.5  */

/* P010 (10-bit NV12), 1920x1080 - each sample is 16 bits with
   the value in the TOP 10, bottom 6 zero. */
        y_stride  = 1920 * 2;                     /* 3840       */
        total     = 3840 * 1080 * 3 / 2;          /* 6,220,800  */

/* THE TRAPS

   1. ODD DIMENSIONS. A 4:2:0 format needs even width and
      height, because chroma is half in each direction.
      1921x1080 either rounds up (and the extra column is
      garbage) or is rejected. Most hardware requires
      multiples of 2, and many require 16.

   2. THE LAST ROW. Some hardware reads a full aligned row
      even for the final line, so the buffer must be a
      multiple of the alignment, not just stride*height.
      Allocators for video usually round the whole thing up.

   3. ALIGNMENT OF THE BASE POINTER, not just the stride.
      A DMA engine may require the buffer itself to be 4 KB
      aligned (Linux chapter 24).                          */
```

What comes off a sensor

```
A camera sensor does NOT produce RGB. Each photosite
measures one colour, through a BAYER filter:

     R G R G R G          50% green, because the eye is
     G B G B G B          most sensitive to green
     R G R G R G
     G B G B G B

DEMOSAICING interpolates the two missing components at
every site. It is the first and most quality-critical step
of an image pipeline, and it is why a "12 megapixel" camera
does not have 12 million real RGB measurements.

THE FULL ISP PIPELINE (SoC chapter on the home page):

  Bayer raw
    -> black level, defective pixel correction
    -> lens shading correction
    -> white balance
    -> DEMOSAIC                    -> now RGB
    -> colour correction matrix    -> a known colour space
    -> gamma / tone curve          -> now non-linear
    -> noise reduction, sharpening
    -> RGB to YCbCr                -> chapter 3
    -> chroma subsampling
    -> to the encoder

EVERY STAGE IS LOSSY OR OPINIONATED. "Raw" formats
(DNG, CR2) store the Bayer data so the decisions can be
made later; JPEG and video store the output, with the
decisions baked in.
```

How it shows up

Symptom	Cause
Image sheared diagonally	Used width where stride was needed
Image upside down	Negative stride, or a bottom-up format
Visible steps in a sky or gradient	Banding — 8-bit quantisation; use 10-bit or dither
Moiré on fine patterns	Spatial aliasing — filter before downsampling
Heap corruption after decoding	Buffer sized as `w*h*bpp` instead of `stride*h`, or chroma plane forgotten
Right-hand column is garbage	Reading padding as image data — crop to width
Works at 1920×1080, fails at odd sizes	4:2:0 needs even dimensions; alignment assumptions broke
Colours look plausible but wrong	Component order — RGBA versus BGRA (chapter 4)
Bottom of the frame is corrupt	Last-row alignment; the buffer needed rounding up
DMA fails or produces nothing	Base pointer not aligned to the engine's requirement

Check yourself

- ✓ Name the three sampling axes and the aliasing artefact each produces.
- ✓ Explain banding and give two fixes.

- ✓ Say why dithering makes a gradient look better despite adding noise.
- ✓ Distinguish packed, planar and semi-planar, and say which hardware prefers each.
- ✓ Define stride and give the symptom of confusing it with width.
- ✓ Explain what a negative stride means and what breaks if you take its absolute value.
- ✓ Compute the total buffer size for 1920×1080 NV12 and for P010.
- ✓ Say why 4:2:0 requires even dimensions.
- ✓ Explain what a Bayer filter is and why demosaicing is necessary.
- ✓ List the ISP stages between a sensor and an encoder, and say which are irreversible.

Colour, gamma and colour spaces

The number 128 in a pixel does not mean "half as bright as 255". Almost every colour bug in software comes from that one fact, and from code that treats stored values as if they were light.

The single most important idea

```
PIXEL VALUES ARE NOT LINEAR IN LIGHT.

sRGB, roughly:      light = (value / 255) ^ 2.2

  value    relative light
    0        0.000
   64        0.052        <- a QUARTER of the value gives
  128        0.216           5% of the light
  192        0.528        <- HALF the value gives 22%
  255        1.000

WHY IT IS DONE

  Human vision is roughly logarithmic: we distinguish
  dark tones far more finely than bright ones. Storing
  LINEAR light in 8 bits wastes most codes on highlights
  nobody can tell apart, and leaves visible banding in the
  shadows.

  A gamma curve spends the codes where the eye looks. It
  is perceptual compression, and it predates computers -
  CRT phosphors happened to have a response near 2.2, so
  the convention was free.

THE CONSEQUENCE

  Any arithmetic that models LIGHT - averaging, blending,
  resizing, blurring, alpha compositing, lighting - must
  be done in LINEAR space. Doing it on stored values is
  mathematically wrong, and the error is visible.
```

```
/* THE CLASSIC DEMONSTRATION: average black and white.

   In sRGB values:      (0 + 255) / 2  = 128
   128 in sRGB is 21.6% of the light.

   In linear light:     (0.0 + 1.0) / 2 = 0.5
   0.5 linear encodes back to sRGB 188.

   So the "correct" mid-grey is 188, not 128. Averaging in
   the wrong space makes everything TOO DARK, and it is why
   badly-resized images look muddier than the original.   */

/* THE CORRECT SANDWICH */

float srgb_to_linear(float c)      /* decode */
{
        return (c <= 0.04045f) ? c / 12.92f
                               : powf((c + 0.055f) / 1.055f, 2.4f);
        /* the linear segment near zero avoids an infinite
           slope at 0 - it is why sRGB is "gamma 2.2-ish"
           rather than exactly 2.2                          */
}

float linear_to_srgb(float c)      /* encode */
{
        return (c <= 0.0031308f) ? c * 12.92f
                                 : 1.055f * powf(c, 1.0f / 2.4f) - 0.055f;
}

/* resize, blur, blend, light -> ALL between those two calls. */

/* AND THE FREE VERSION: let the hardware do it.
     GPU:  use a _SRGB texture format and an _SRGB render
           target. The sampler decodes on read and the ROP
           encodes on write, for nothing, and it filters in
           linear space which is also correct (GPU chapter 9).
     Display: a framebuffer declared sRGB gets the same
           treatment in the display controller.

   Doing the conversion in a shader is slower AND filters in
   the wrong space. Use the format.                       */
```

ALPHA BLENDING IN SRGB IS WRONG, AND EVERYONE DOES IT

Compositing 50% of a bright colour over a dark one with plain sRGB arithmetic gives a result that is too dark, with a characteristic dark fringe around anti-aliased edges — most visible on white text over a dark background. Browsers, UI toolkits and many game engines do this, partly for speed and partly because "fixing" it changes the appearance of every existing asset. Know that it is wrong, and know why your text looks thin.

What a colour space actually specifies

```
THREE INDEPENDENT THINGS, and conflating them causes most
colour-management confusion:

1. PRIMARIES - which physical red, green and blue.
     Given as CIE xy coordinates. Two displays both
     "showing RGB(255,0,0)" emit different reds if their
     primaries differ. This defines the GAMUT: the set of
     colours representable at all.

2. TRANSFER FUNCTION - how code values map to light.
     sRGB, BT.1886, PQ, HLG, linear, Log-C...
     This is "gamma", above.

3. WHITE POINT - what RGB(255,255,255) means.
     D65 (6500 K) almost everywhere; D50 in print.

A COLOUR SPACE = primaries + transfer + white point.
Change any one and the same numbers mean a different
colour.

THE ONES YOU WILL MEET

  sRGB / BT.709    same primaries. The web and HD video.
                   Slightly different transfer functions,
                   which is a real and annoying subtlety.
  BT.601           SD video. DIFFERENT primaries, and a
                   different YCbCr matrix (chapter 3).
  DCI-P3           wider gamut. Apple displays, cinema.
  BT.2020          very wide. UHD and HDR.
  ACEScg, Rec.2100 working spaces for grading and HDR.

THE CONVERSION between two RGB spaces is a 3x3 matrix,
applied IN LINEAR LIGHT:

  decode transfer -> matrix (RGB_a -> XYZ -> RGB_b)
    -> gamut map if out of range -> encode transfer

Skipping the decode is the same error as before, one level
up.
```

Untagged data is the real problem

```
/* Pixel values alone are meaningless. They need METADATA
   saying which colour space they are in. When that metadata
   is missing, software GUESSES - and different software
   guesses differently.                                    */

  WHERE THE TAG LIVES
    images   ICC profile, or EXIF ColorSpace, or a PNG cHRM
             + gAMA chunk
    video    the "VUI" in the bitstream: colour_primaries,
             transfer_characteristics, matrix_coefficients,
             video_full_range_flag
    surfaces DXGI_COLOR_SPACE_*, VkColorSpaceKHR,
             drm_color_encoding / drm_color_range properties

/* THE FOUR VIDEO TAGS, and they are separate on purpose: */

  colour_primaries          1 = BT.709, 5 = BT.601 PAL,
                            6 = BT.601 NTSC, 9 = BT.2020
  transfer_characteristics  1 = BT.709, 16 = PQ, 18 = HLG
  matrix_coefficients       1 = BT.709, 6 = BT.601,
                            9 = BT.2020 non-constant
  video_full_range_flag     0 = LIMITED (16-235), 1 = FULL
                            (0-255)

/* THAT LAST ONE causes more visible bugs than the other
   three combined - see below. */

# Read what a file actually claims:
$ ffprobe -v error -select_streams v:0 \
    -show_entries stream=color_primaries,color_transfer,color_space,color_range \
    -of default=nw=1 input.mp4
color_range=tv
color_space=bt709
color_transfer=bt709
color_primaries=bt709

# "unknown" for any of them means the next tool will guess.
# The usual guess is: BT.601 below 720 lines, BT.709 at or
# above. Which is why an SD clip scaled to HD sometimes
# shifts colour.
```

LIMITED RANGE VERSUS FULL RANGE

Broadcast video stores luma in **16–235**, not 0–255, leaving headroom and footroom for filter overshoot. If a decoder outputs limited-range data and something downstream treats it as full range, blacks become dark grey and whites become light grey — a *washed out* image. Do the opposite and blacks clip to zero and highlights blow out — *crushed*. This is the single most common video colour bug, it is entirely a metadata problem, and both directions look like a broken display rather than a tagging error.

A correct pipeline, in order

```
SOURCE (tagged: BT.709, limited range, 8-bit)
     |
     |  1. expand range 16-235 -> 0-1
     |  2. YCbCr -> RGB with the BT.709 matrix (chapter 3)
     v
NON-LINEAR RGB, BT.709 primaries
     |
     |  3. decode the transfer function
     v
LINEAR RGB, BT.709 primaries
     |
     |  4. ALL image maths happens HERE:
     |     resize, blur, blend, composite, colour grade
     |
     |  5. matrix to the DISPLAY's primaries
     v
LINEAR RGB, display primaries
     |
     |  6. encode the display's transfer function
     |  7. dither to the output bit depth
     v
DISPLAY

SKIPPING STEP 3 is the commonest error and makes everything
too dark.
SKIPPING STEP 5 is the second, and makes wide-gamut content
oversaturated on an sRGB screen - or sRGB content look flat
on a P3 one.
SKIPPING STEP 7 puts banding back after you paid for
precision.
```

How it shows up

Symptom	Cause
Blacks are grey, whites are dull	Limited-range data treated as full range
Shadows crushed, highlights clipped	Full-range data treated as limited
Downscaled image looks darker than the original	Resizing in gamma space instead of linear
Dark halo around white text on a dark background	Alpha compositing in gamma space
Colours oversaturated on a wide-gamut display	sRGB content shown without a gamut conversion
Colour shifts when an SD clip is upscaled	BT.601 versus BT.709 matrix guessed from height
Screenshot does not match the app	One of them applied a colour transform the other did not
Banding after colour correction	Processed in 8 bits, or no dither on output
Two players show the same file differently	Untagged stream; each guessed
Blending looks right on GPU, wrong on CPU	The GPU used an sRGB format and decoded automatically

Check yourself

- ✓ Explain why pixel values are not linear in light, and why that encoding was chosen.
- ✓ Compute the correct mid-grey between black and white in sRGB, and say why 128 is wrong.
- ✓ Name four operations that must be done in linear light.

- ✓ Say why using an sRGB texture format beats converting in a shader.
- ✓ Name the three things a colour space specifies and give an example that differs in each.
- ✓ List the four video colour tags and what each controls.
- ✓ Explain limited versus full range and the symptom of each mismatch direction.
- ✓ Give the seven steps of a correct colour pipeline in order.
- ✓ Say what happens when steps 3, 5 and 7 are skipped.
- ✓ Read a file's colour tags with `ffprobe` and say what "unknown" implies.

YCbCr and chroma subsampling

The first and largest compression step in every video pipeline happens before the codec runs: separate brightness from colour, then throw away three quarters of the colour. It halves the data for almost no visible loss — and it is why red text on video looks smeared.

Why separate luma from chroma

```
The eye has ~6 million cones and ~120 million rods, and the
cones are concentrated in the fovea. Spatial acuity for
BRIGHTNESS is several times higher than for COLOUR.

So: transform RGB into one brightness channel and two
colour-difference channels, and then store the colour ones
at lower resolution.

  Y   luma          brightness. Keep at full resolution.
  Cb  blue-difference   B - Y, scaled
  Cr  red-difference    R - Y, scaled

In 4:2:0 this saves 50% of the data before any codec has
done anything, and in a blind test almost nobody sees it on
natural imagery.

IT ALSO DECORRELATES. R, G and B in a photograph are highly
correlated - a bright pixel is bright in all three. Y, Cb
and Cr are much less so, and a transform codec compresses
uncorrelated channels far better (chapter 6).

NOTE THE NAMES, because people use them interchangeably and
they are not the same:
  Y'CbCr   digital, gamma-encoded. What video uses.
           The prime means "non-linear".
  YUV      strictly the analogue PAL/SECAM version.
           Universally misused to mean Y'CbCr. Every API
           you will meet says "YUV" and means Y'CbCr.
  YCoCg    a cheaper, reversible variant used in some
           codecs and GPU texture formats.
  Luma vs LUMINANCE: luma (Y') is computed from
           gamma-encoded RGB; luminance (Y) is a linear
           light quantity. They are not the same thing, and
           conflating them is why some "greyscale"
           conversions look wrong.
```

The matrix, and why there are several

```
/* BT.709 (HD), full range, gamma-encoded R'G'B' in [0,1]. */

    Y' =  0.2126 R' + 0.7152 G' + 0.0722 B'
    Cb = (B' - Y') / 1.8556
    Cr = (R' - Y') / 1.5748

/* Note the coefficients sum to 1 and green dominates - the
   eye is most sensitive there. */

/* BT.601 (SD) uses DIFFERENT coefficients: */
    Y' =  0.299  R' + 0.587  G' + 0.114  B'

/* BT.2020 (UHD): */
    Y' =  0.2627 R' + 0.6780 G' + 0.0593 B'

/* USING THE WRONG ONE produces a colour shift that is subtle
   on most content and obvious on saturated reds and greens -
   faces go slightly wrong, skies shift. It is the classic
   "why does my SD clip look off after upscaling" bug
   (chapter 2).                                            */

/* THE INTEGER FORM, which is what code actually runs.
   8-bit, LIMITED range: Y in [16,235], Cb/Cr in [16,240]
   with 128 as neutral.                                    */

static inline void rgb_to_ycbcr_bt709(uint8_t r, uint8_t g, uint8_t b,
                                      uint8_t *y, uint8_t *cb, uint8_t *cr)
{
        /* fixed point, 16-bit fractions, limited range */
        int Y  = ( 4735 * r + 15934 * g +  1608 * b + 32768) >> 16;
        int Cb = (-2607 * r -  8773 * g + 11380 * b + 32768) >> 16;
        int Cr = (11380 * r - 10336 * g -  1044 * b + 32768) >> 16;

        *y  = (uint8_t)clamp(Y  + 16,  16, 235);
        *cb = (uint8_t)clamp(Cb + 128, 16, 240);
        *cr = (uint8_t)clamp(Cr + 128, 16, 240);
}

/* THE FOUR THINGS THAT MUST AGREE between encoder and
   decoder, or the colour is wrong:
     1. the matrix     (601 / 709 / 2020)
     2. the range      (limited / full)
     3. the transfer   (chapter 2)
     4. the primaries  (chapter 2)
   All four are carried in the bitstream's VUI, and all four
   are routinely missing.                                  */
```

The subsampling notation

```
J : a : b   over a conceptual 4x2 block of pixels

  J = width of the region                    (always 4)
  a = number of chroma samples in the TOP row
  b = number of chroma CHANGES in the BOTTOM row
      (b = 0 means "same as the top row", i.e. vertical
       subsampling too)

4:4:4     no subsampling. Chroma at full resolution.
    Y Y Y Y        C C C C
    Y Y Y Y        C C C C
    -> 24 bits/pixel at 8-bit. Screen capture, graphics,
       professional capture, chroma keying.

4:2:2     horizontal only. Half the chroma columns.
    Y Y Y Y        C   C
    Y Y Y Y        C   C
    -> 16 bits/pixel. Broadcast, editing formats, most
       capture cards. Survives colour correction well.

4:2:0     horizontal AND vertical. A quarter the chroma.
    Y Y Y Y        C   C
    Y Y Y Y        (shared with the row above)
    -> 12 bits/pixel. H.264/HEVC/AV1 baseline, every
       streaming service, every phone camera. THE default.

4:1:1     quarter horizontal, full vertical. DV, NTSC
          legacy. Rare now.

THE SAVING
  4:4:4 -> 4:2:2   33% less data
  4:4:4 -> 4:2:0   50% less data
before the codec has compressed anything at all.
```

> **CHROMA SITING IS A REAL THING AND IT IS WHY FORMATS DISAGREE**
>
> When you keep one chroma sample for four luma samples, *where* does it sit? MPEG-2 and H.264 place it left-aligned, vertically centred between the two rows. JPEG and MPEG-1 place it in the centre of the 2×2 block. Getting it wrong shifts colour half a pixel relative to luma — invisible on photographs, clearly visible as coloured fringes on sharp graphics and text. It is signalled by `chroma_sample_loc_type`, and most converters ignore it.

What subsampling actually costs

```
4:2:0 IS NEARLY FREE ON NATURAL IMAGES and expensive on
everything else.

FINE ON              BAD ON
  photographs          text and UI, especially coloured
  faces, skin          thin saturated lines
  natural scenes       screen recordings
  film                 chroma keying / green screen
                       anything to be colour graded
                       red and blue detail specifically

THE RED TEXT PROBLEM, concretely:
  red is almost entirely in Cr. Subsample Cr by 2 in each
  direction and a one-pixel red line becomes a two-pixel
  smear with dark edges. This is why:
    * a screen recording of a terminal looks soft
    * subtitles burned in before encoding look worse than
      subtitles rendered by the player
    * you record screencasts at 4:4:4 if you can, and
      upscale the resolution if you cannot

THE GENERATION-LOSS PROBLEM:
  decode 4:2:0 -> edit -> re-encode 4:2:0 subsamples
  again, on data that was already interpolated. Colour
  detail degrades every pass. Editing formats use 4:2:2 or
  4:4:4 for exactly this reason, and you only go to 4:2:0
  on the final delivery encode.

CHROMA KEYING on 4:2:0 gives ragged edges, because the key
is computed from chroma that only exists at half
resolution. Broadcast shoots 4:2:2 minimum, often 4:4:4.
```

Converting, correctly

```
# The command lines that actually matter, and the flags people
# leave out.

# Encode 4:4:4 - for screen content, if your decoder supports it
$ ffmpeg -i in.mov -c:v libx264 -profile:v high444 \
         -pix_fmt yuv444p -crf 18 out.mp4
# NOTE: many hardware decoders and most browsers do NOT
# support 4:4:4 H.264. Check your target before shipping it.

# The safe compromise for screen content: 4:2:0 at double
# resolution, downscaled on playback. Ugly, and it works.

# Convert 4:2:0 -> 4:2:2 for editing, with a good chroma
# upsampler rather than nearest-neighbour:
$ ffmpeg -i in.mp4 -vf "scale=in_color_matrix=bt709:\
out_color_matrix=bt709,format=yuv422p10le" -c:v prores_ks out.mov

# TAG IT. An untagged file will be guessed at (chapter 2):
$ ffmpeg -i in.y4m -c:v libx264 \
    -color_primaries bt709 -color_trc bt709 \
    -colorspace bt709 -color_range tv \
    -pix_fmt yuv420p out.mp4

# Inspect what you produced:
$ ffprobe -show_streams -select_streams v:0 out.mp4 | \
    grep -E 'pix_fmt|color_'
pix_fmt=yuv420p
color_range=tv
color_space=bt709
color_transfer=bt709
color_primaries=bt709

# THE CHROMA UPSAMPLER MATTERS. ffmpeg's default swscale
# chroma interpolation is fast and mediocre; -sws_flags
# +full_chroma_int+accurate_rnd is measurably better for
# anything you will look at closely.
```

> **DO NOT COLOUR-CORRECT 4:2:0 FOOTAGE AGGRESSIVELY**
>
> Chroma only exists at quarter resolution, so any operation that amplifies colour — saturation boosts, secondary colour keys, heavy grading — amplifies the interpolation artefacts too, producing blocky colour patches that were invisible in the original. If the material will be graded, capture 4:2:2 or better. This is not a preference; it is the reason professional formats exist.

How it shows up

Symptom	Cause
Faces slightly wrong, skies shifted	BT.601 matrix used on HD content, or vice versa
Red or blue text smeared with dark edges	4:2:0 subsampling of saturated colour
Coloured fringes offset half a pixel	Chroma siting mismatch between encoder and decoder
Screen recordings look soft	4:2:0 on screen content — use 4:4:4 or higher resolution
Green-screen key has ragged edges	Keying from subsampled chroma

Symptom	Cause
Colour degrades a little every edit	Repeated 4:2:0 round trips; edit in 4:2:2
Blocky colour patches after a saturation boost	Amplified chroma interpolation artefacts
File plays but colours are wrong in one player only	Untagged stream; players guess differently
4:4:4 file will not play on a phone or in a browser	Hardware decoders usually support 4:2:0 only
Greyscale conversion looks too dark or too light	Luma versus luminance confusion — the wrong coefficients, or done in the wrong space

Check yourself

- ✓ Explain why luma and chroma are separated, giving both the perceptual and the compression reason.
- ✓ Distinguish Y'CbCr from YUV, and luma from luminance.
- ✓ Give the BT.709 luma coefficients and say why green dominates.
- ✓ Name the four properties that must agree between encoder and decoder for correct colour.
- ✓ Decode the `J:a:b` notation and give the bits per pixel for 4:4:4, 4:2:2 and 4:2:0.
- ✓ Explain chroma siting and the artefact from getting it wrong.
- ✓ Say why red text suffers most from 4:2:0.
- ✓ Explain why editing formats use 4:2:2 or better.
- ✓ Explain why chroma keying needs 4:2:2 minimum.
- ✓ Write an `ffmpeg` command that encodes 4:2:0 with correct colour tags.

Pixel formats, strides and tiling

A FourCC is a promise about byte order, plane count, subsampling and bit packing. Different subsystems make that promise using different names for the same layout, and one of them is almost certainly lying about endianness. This chapter is the decoder ring.

The formats you will actually meet

FourCC	Layout	bpp	Where
NV12	Y plane, then interleaved **UV**, 4:2:0	12	The universal video format. Hardware codecs, display controllers, cameras
NV21	Same but **VU** order	12	Android camera preview. The swap is why previews come out purple
I420 / YU12	Three planes: Y, U, V, 4:2:0	12	Software codecs, libavcodec's native layout, WebRTC
YV12	Three planes: Y, **V, U**	12	Same as I420 with the chroma planes swapped. A classic source of purple output
P010	NV12 with 16-bit samples, value in the **top 10 bits**	24	10-bit HDR. Note the 6 zero bits at the bottom
YUY2 / YUYV	Packed 4:2:2, order Y U Y V	16	USB webcams, capture cards
UYVY	Packed 4:2:2, order U Y V Y	16	Broadcast SDI, macOS
RGBA / BGRA	Packed 8-bit	32	GPUs, UI. The order differs by API and by endianness
RGB565	Packed 16-bit, 5-6-5	16	Embedded displays, low-memory framebuffers
AYUV / Y410	Packed 4:4:4	32	Screen content, professional capture

NV12 IS THE FORMAT TO KNOW

If you learn one layout, learn this one. Every hardware encoder, every hardware decoder, every display controller and almost every camera ISP speaks NV12. A pipeline that stays in NV12 end to end never converts; one that drops into RGB in the middle pays a full-frame conversion twice, and on a 4K60 stream that is gigabytes per second of pointless memory traffic.

```
NV12, 8x4 pixels. Two planes.

Y PLANE, y_stride bytes per row, 4 rows
  +-------------------------------+--------+
  | Y00 Y01 Y02 Y03 Y04 Y05 Y06 Y07| padding|
  | Y10 Y11 ...                   | padding|
  | Y20 ...                       | padding|
  | Y30 ...                       | padding|
  +-------------------------------+--------+

UV PLANE, uv_stride bytes per row, 2 rows (half height)
  +-------------------------------+--------+
  | U00 V00 U01 V01 U02 V02 U03 V03| padding|   covers Y
  | U10 V10 U11 V11 U12 V12 U13 V13| padding|   rows 0-1
  +-------------------------------+--------+   and 2-3

ONE (U,V) PAIR SERVES A 2x2 BLOCK OF LUMA.

Addressing:
  Y at (x,y)     = base   + y * y_stride + x
  U at (x,y)     = uvbase + (y/2) * uv_stride + (x/2)*2
  V at (x,y)     = uvbase + (y/2) * uv_stride + (x/2)*2 + 1

The uv plane usually shares the Y stride, and usually
follows the Y plane in one allocation - but NEITHER IS
GUARANTEED. Always use the offsets and strides the
allocator gave you.
```

```
/* Reading a pixel from NV12, correctly. */

struct nv12 {
        uint8_t *y,  *uv;
        int      y_stride, uv_stride;
        int      width, height;
};

static void nv12_get(const struct nv12 *f, int x, int y,
                     uint8_t *Y, uint8_t *U, uint8_t *V)
{
        *Y = f->y[(size_t)y * f->y_stride + x];

        const uint8_t *uv = f->uv + (size_t)(y / 2) * f->uv_stride
                                  + (x / 2) * 2;
        *U = uv[0];
        *V = uv[1];      /* NV21 swaps these two lines */
}

/* CONVERTING NV12 -> RGB, BT.709 limited range. The integer
   form, because this runs per pixel. */
static void nv12_to_rgb(uint8_t Y, uint8_t U, uint8_t V,
                        uint8_t *r, uint8_t *g, uint8_t *b)
{
        int y = (Y - 16)  * 1192;      /* 255/219 in Q10 */
        int u =  U - 128;
        int v =  V - 128;

        int R = (y + 1836 * v)               >> 10;
        int G = (y -  547 * v -  218 * u)    >> 10;
        int B = (y + 2166 * u)               >> 10;

        *r = clamp_u8(R);  *g = clamp_u8(G);  *b = clamp_u8(B);
        /* CLAMPING IS NOT OPTIONAL: limited-range input can
           legally exceed 0-255 after conversion (that is what
           the headroom is FOR), and without a clamp you wrap
           around and get bright speckles in dark areas. */
}

/* AND IN PRACTICE: do not write this loop. Use libyuv, or
   swscale, or a shader, or the hardware colour-space
   converter in your display controller. All three are
   several times faster and already correct. */
```

10-bit packing, and the trap in it

```
/* P010: 16 bits per sample, value in the TOP 10 bits. */

     bit  15 14 13 12 11 10 09 08 07 06 05 04 03 02 01 00
          [------------ 10-bit value -------------] 0  0  0  0  0  0
                                                    ^^^^^^^^^^^^^^^^
                                                    must be zero

/* SO: to read the actual value you SHIFT DOWN, and to write
   one you SHIFT UP.                                          */
        uint16_t sample = plane[i];
        uint16_t value  = sample >> 6;        /* 0..1023      */

        plane[i] = value << 6;                /* writing back */

/* FORGETTING THE SHIFT gives you an image that is 64x too
   bright and clipped to white, or 64x too dark - depending on
   which direction you missed.

   THE OTHER 10-BIT PACKINGS, and they are all different:

     P010      16-bit container, value in top 10.   MSB-aligned
     P016      16-bit container, all 16 used
     yuv420p10le  16-bit container, value in BOTTOM 10.
                  LSB-aligned - the OPPOSITE of P010, and this
                  is ffmpeg's native 10-bit layout
     V210      packed 4:2:2, THREE 10-bit samples per 32-bit
               word with 2 bits wasted. Broadcast SDI.
     10-bit MIPI RAW  four pixels in five bytes, the low bits
               of all four gathered in the fifth. Camera
               sensors.

   Converting between P010 and yuv420p10le is a shift by 6 in
   one direction. Getting the direction wrong is one of the
   most common 10-bit bugs, and it looks like a broken
   exposure rather than a bit-packing error.                  */
```

> **THE ENDIANNESS LIE IN RGBA NAMES**
>
> DirectX's `DXGI_FORMAT_B8G8R8A8_UNORM` lists components in *memory order*. OpenGL's `GL_RGBA` with `GL_UNSIGNED_INT_8_8_8_8` lists them in *most-significant-bit-first order of a 32-bit integer*, which on a little-endian machine is the reverse. So `GL_BGRA` + `GL_UNSIGNED_BYTE` matches DXGI's `B8G8R8A8`, but `GL_RGBA` + `GL_UNSIGNED_INT_8_8_8_8_REV` also does. If red and blue are swapped, this is why, and the fix is one enum rather than a byte-shuffling loop.

Tiled and compressed layouts

```
LINEAR layout: row after row. Simple, and bad for 2D
access - a vertical neighbour is `stride` bytes away, in a
different DRAM page.

TILED layout: the image is cut into small rectangles and
each tile is stored contiguously.

  LINEAR                   TILED (4x4 tiles)
  0  1  2  3  4  5         [0  1  4  5] [2  3  6  7]
  6  7  8  9 10 11         [8  9 12 13] [10 11 14 15]

WHY: a 2D access pattern - a filter kernel, a motion
compensation block, a texture sample - touches a small
square. In a tiled layout that square is one or two DRAM
pages instead of sixteen. The bandwidth saving is large,
and every GPU and video block uses it.

THE PROBLEM: tiling is VENDOR AND HARDWARE SPECIFIC and
usually undocumented. A tiled buffer produced by the
decoder cannot be read by the CPU without either
detiling or knowing the exact swizzle.

PLUS FRAMEBUFFER COMPRESSION (AFBC on Arm, DCC on AMD,
UBWC on Qualcomm, Delta Color Compression on NVIDIA):
lossless block compression applied on the fly to save
bandwidth, with a separate metadata plane. Also opaque.

HOW LINUX EXPRESSES THIS: DRM FORMAT MODIFIERS. A buffer is
described by (fourcc, modifier), where the modifier names
the exact tiling and compression:

  DRM_FORMAT_MOD_LINEAR
  DRM_FORMAT_MOD_ARM_AFBC(...)
  DRM_FORMAT_MOD_QCOM_COMPRESSED
  I915_FORMAT_MOD_Y_TILED

NEGOTIATING A COMMON MODIFIER between the camera, the
decoder, the GPU and the display is what makes zero-copy
possible (chapter 18). Get it wrong and something in the
chain silently inserts a full-frame detiling copy - or
produces a garbled image that looks like scrambled
rectangles.
```

Inspecting a buffer

```
# What format is this device actually offering?
$ v4l2-ctl -d /dev/video0 --list-formats-ext
        [0]: 'YUYV' (YUYV 4:2:2)
                Size: Discrete 1920x1080
                        Interval: Discrete 0.033s (30.000 fps)
        [1]: 'MJPG' (Motion-JPEG, compressed)
        [2]: 'NV12' (Y/UV 4:2:0)

# Dump raw frames and look at them:
$ v4l2-ctl -d /dev/video0 --set-fmt-video=width=1920,height=1080,pixelformat=NV12 \
           --stream-mmap --stream-count=1 --stream-to=frame.nv12

$ ffplay -f rawvideo -pixel_format nv12 -video_size 1920x1080 frame.nv12
# If it looks right, your format assumption is correct. If the
# bottom third is noise, your stride or plane offsets are wrong.

# Convert and inspect:
$ ffmpeg -f rawvideo -pix_fmt nv12 -s 1920x1080 -i frame.nv12 frame.png

# Every format ffmpeg knows, with its bit depth and plane count:
$ ffmpeg -pix_fmts | head -20

# Check what a DRM buffer really is:
$ sudo cat /sys/kernel/debug/dri/0/framebuffer
framebuffer[42]:
        allocated by = compositor
        format=XR24 little-endian (0x34325258)
        modifier=0x100000000000002        <-- NOT linear
        size=1920x1080
        pitch[0]=7680
```

How it shows up

Symptom	Cause
Image is purple or orange, luma looks fine	U and V swapped — NV12 versus NV21, or I420 versus YV12
Red and blue swapped	RGBA versus BGRA, or an endianness-naming mismatch
Bottom third of the frame is noise	Chroma plane offset or stride wrong
Image sheared diagonally	Width used as stride (chapter 1)
10-bit content is blown out or nearly black	Missing the shift by 6 between P010 and LSB-aligned
Bright speckles in dark areas	No clamp after limited-range conversion
Image looks like scrambled rectangles	A tiled buffer read as linear
Pipeline works but uses far more bandwidth than expected	A hidden detiling or format-conversion copy from a modifier mismatch
Colours wrong only on one platform	Different default matrix or range for the same FourCC
Zero-copy path silently stops working after an update	The negotiated modifier changed; check the DRM framebuffer debug node

Check yourself

✓ Describe NV12's plane layout and write the addressing for Y, U and V at (x, y).

- ✓ Say what distinguishes NV12 from NV21 and I420 from YV12, and the symptom of confusing them.
- ✓ Explain why staying in NV12 through a pipeline matters.
- ✓ Explain P010's bit packing and how it differs from `yuv420p10le`.
- ✓ Say why a clamp is required after limited-range YCbCr to RGB.
- ✓ Explain the RGBA/BGRA endianness naming trap.
- ✓ Explain why tiling exists and what it costs you.
- ✓ Say what a DRM format modifier describes and why negotiating one matters.
- ✓ Dump a raw frame from a V4L2 device and view it with the correct format.
- ✓ Diagnose "the bottom third of my frame is noise".

HDR and wide colour gamut

HDR changes three things at once — the transfer function, the gamut and the bit depth — and most "HDR looks wrong" bugs come from changing one without the others. It also introduces the first transfer function in history that specifies *absolute* brightness, which breaks a lot of assumptions.

What HDR actually changes

```
SDR                          HDR

peak ~100 nits (cd/m2)       peak 1000–10000 nits
BT.709 gamut                 BT.2020 container, P3 in
                             practice
gamma ~2.2, RELATIVE         PQ (absolute) or HLG (relative)
8-bit                        10-bit minimum, 12 for grading

"Nits" = candela per square metre. Useful anchors:

  0.005    the darkest a good OLED can show
  1        a lit interior at night
  100      SDR reference white – a paper page, a monitor
  203      HDR "diffuse white" reference (ITU-R BT.2408)
  1000     a typical consumer HDR TV's peak
  4000     a mastering monitor
  10000    the PQ maximum
  1600000  the sun

THE MISCONCEPTION worth killing early: HDR is not "brighter
everything". It is a WIDER RANGE. Diffuse white – a shirt,
a wall, a page of text – should still sit near 100–200
nits. What HDR adds is HEADROOM for specular highlights,
the sun, a lightbulb, a reflection – things that were
previously clipped to the same white as the shirt.

If an HDR image looks uniformly blinding, someone has
mapped SDR white to HDR peak. That is the most common
authoring error.
```

PQ and HLG

	PQ (ST 2084)	HLG (ARIB STD-B67)
Encodes	**Absolute** nits — 0.0001 to 10,000	**Relative** scene light, like SDR gamma
Code value 940 (10-bit) means	Exactly 10,000 nits	"Peak of whatever this display does"
SDR-compatible?	No — looks very dark on an SDR screen	**Yes**, roughly. Its lower half is close to a gamma curve
Needs display metadata?	Yes — the display must tone-map from mastering peak to its own	No — it adapts by design
Used by	HDR10, HDR10+, Dolby Vision, streaming, UHD Blu-ray	Broadcast, BBC/NHK, live sport, iPhone video
Designed for	Mastered content shown in a dark room	Live production and mixed SDR/HDR distribution

```
/* PQ, the ST 2084 EOTF. Note it returns ABSOLUTE nits. */

#define M1 (2610.0 / 16384.0)          /* 0.1593017578125 */
#define M2 (2523.0 / 4096.0 * 128.0)   /* 78.84375        */
#define C1 (3424.0 / 4096.0)           /* 0.8359375       */
#define C2 (2413.0 / 4096.0 * 32.0)    /* 18.8515625      */
#define C3 (2392.0 / 4096.0 * 32.0)    /* 18.6875         */

double pq_to_nits(double e)            /* e in [0,1]      */
{
        double p  = pow(e, 1.0 / M2);
        double num = fmax(p - C1, 0.0);
        double den = C2 - C3 * p;
        return 10000.0 * pow(num / den, 1.0 / M1);
}

double nits_to_pq(double nits)
{
        double y = fmin(fmax(nits / 10000.0, 0.0), 1.0);
        double p = pow(y, M1);
        return pow((C1 + C2 * p) / (1.0 + C3 * p), M2);
}

/* THE CONSEQUENCE OF "ABSOLUTE": a PQ value is a promise
   about photons. It does not adapt. Show 10,000-nit content
   on a 600-nit display and the display MUST tone-map, and the
   quality of that tone map is now a property of the TV, not
   of your content. Hence the metadata below.             */

/* HLG, by contrast, is relative and has a system gamma that
   depends on the display's peak - it degrades gracefully and
   needs no metadata, which is why broadcasters chose it. */
```

WHY HDR NEEDS 10 BITS, NOT AS A NICETY

PQ spreads its code values over a range 100× wider than SDR. At 8 bits the steps between adjacent codes become visible as banding in gradients — a sky, a wall lit by a lamp — much sooner than in SDR. Ten bits is the practical minimum and it is why HEVC Main10 and AV1 Main (which is 10-bit capable) became the HDR codecs. An "8-bit HDR" file is a red flag.

The metadata

```
/* PQ content must tell the display what it was mastered on,
   so the display knows how to tone-map. Two levels: */

/* 1. MASTERING DISPLAY COLOUR VOLUME (SMPTE ST 2086)
      static, per title. */
     display_primaries  R, G, B in CIE xy
     white_point        xy
     max_display_mastering_luminance   e.g. 1000 nits
     min_display_mastering_luminance   e.g. 0.005 nits

/* 2. CONTENT LIGHT LEVEL (CTA-861.3)
      also static, and often more useful in practice. */
     MaxCLL   Maximum Content Light Level - the brightest
              single pixel in the whole title
     MaxFALL  Maximum Frame-Average Light Level - the
              brightest frame, averaged. This is what
              protects the panel from being asked to run at
              peak across the whole screen.

/* 3. DYNAMIC METADATA - per scene or per frame.
     HDR10+       SMPTE ST 2094-40, open, royalty-free-ish
     Dolby Vision ST 2094-10, proprietary, licensed, and
                  carries a full colour-volume mapping plus
                  optionally a second enhancement layer

   HDR10 = PQ + BT.2020 + 10-bit + static metadata. It is the
   baseline that everything supports, and the one to target
   unless you have a reason not to.                        */

# Setting it with ffmpeg - the syntax is unpleasant and
# exact. The values are in units of 1/50000 for chromaticity
# and 1/10000 nits for luminance.
$ ffmpeg -i in.mov -c:v libx265 -pix_fmt yuv420p10le \
  -x265-params "hdr-opt=1:repeat-headers=1:\
colorprim=bt2020:transfer=smpte2084:colormatrix=bt2020nc:\
master-display=G(13250,34500)B(7500,3000)R(34000,16000)\
WP(15635,16450)L(10000000,1):max-cll=1000,400" \
  out.mp4

# Verify - and this is worth doing every time, because a
# silently-dropped side-data block is the usual failure:
$ ffprobe -show_frames -read_intervals "%+#1" \
    -show_entries frame=side_data_list out.mp4
[SIDE_DATA]
side_data_type=Mastering display metadata
red_x=34000/50000 ...
max_luminance=10000000/10000
[/SIDE_DATA]
[SIDE_DATA]
side_data_type=Content light level metadata
max_content=1000
max_average=400
[/SIDE_DATA]
```

> **METADATA IS THE PART THAT GETS LOST**
> Remux a file, run it through a filter, transcode it with default settings, or pass it through a player that does not understand side data, and the mastering metadata quietly disappears. The video still decodes, the colour tags may survive, and the display now tone-maps with no idea what it is looking at — producing a washed-out or crushed picture that looks like a decoder bug. When HDR "looks wrong", check the metadata survived *before* suspecting anything else.

Tone mapping and gamut mapping

```
TONE MAPPING: 1000 nits of content, 400 nits of display.

CLIP                everything above 400 becomes 400.
                    Highlights lose all detail; a sunset
                    becomes a white disc. Cheap, and bad.

REINHARD            L' = L / (1 + L). Smooth, and it
                    desaturates and flattens the whole
                    image, including the parts that fitted
                    perfectly well.

ROLL-OFF / BT.2390  linear below a knee, a smooth curve
                    above it. Preserves everything that
                    fits and compresses only the excess.
                    THIS IS THE RIGHT DEFAULT.

ACES / HABLE        filmic S-curves from film emulation.
                    Popular in games; more of a look than
                    a mapping.

DYNAMIC             HDR10+/Dolby Vision drive the curve
                    per scene, so a dark scene and a bright
                    one are mapped differently.

GAMUT MAPPING is the same problem in colour: BT.2020
content on a P3 display has saturated colours that simply
do not exist there.

  CLIP        oversaturated colours all become the same
              boundary colour -> flat patches, lost detail
  COMPRESS    squeeze the whole gamut inward -> everything
              slightly duller, but relationships preserved
  PERCEPTUAL  preserve hue and lightness, sacrifice
              saturation. Usually what you want.

AND THE HARD DIRECTION: HDR -> SDR. You are throwing away
most of the range. A naive conversion looks grey and flat;
a good one applies a roll-off AND a saturation boost,
because desaturation is what makes tone-mapped images look
washed out.
```

```
# Tone map HDR to SDR with something reasonable, in linear
# light (chapter 2 - doing it in PQ space is wrong):
$ ffmpeg -i hdr.mp4 -vf "\
zscale=t=linear:npl=100,\
format=gbrpf32le,\
zscale=p=bt709,\
tonemap=tonemap=bt2390:desat=0,\
zscale=t=bt709:m=bt709:r=tv,\
format=yuv420p" \
  -c:v libx264 -crf 20 sdr.mp4

# The chain, read left to right:
#   zscale t=linear   decode PQ to linear light
#   npl=100           "nominal peak luminance" - the anchor
#   format=gbrpf32le  work in float; 8-bit here would band
#   zscale p=bt709    gamut map BT.2020 -> BT.709
#   tonemap=bt2390    the roll-off curve
#   desat=0           do NOT desaturate; bt2390 handles it
#   zscale t=bt709    encode the SDR transfer function
#   format=yuv420p    back to 8-bit 4:2:0

# Getting the ORDER wrong - tone mapping before linearising,
# or gamut mapping after encoding - produces plausible-looking
# output that is measurably wrong, which is worse than an
# obvious failure.
```

How it shows up

Symptom	Cause
HDR content looks washed out and grey	PQ decoded as if it were gamma, or metadata lost so the display tone-mapped blindly
Everything uniformly blinding	SDR white mapped to HDR peak instead of ~203 nits
Highlights are flat white discs	Clipping instead of a roll-off tone map
Banding in HDR skies	8-bit, or an 8-bit intermediate in the chain
HDR file plays but looks like SDR	Transfer tagged as bt709 instead of smpte2084
Metadata present in the master, gone after transcode	Side data dropped — pass `hdr-opt` / `repeat-headers` and verify
Colours oversaturated and blotchy	BT.2020 clipped to the display gamut rather than mapped
Tone-mapped SDR looks lifeless	No saturation compensation after the roll-off
HLG content too dark on an SDR screen	HLG is only *roughly* compatible; it still wants its system gamma applied
Two HDR TVs show the same file very differently	Expected — with static metadata, tone mapping is the display's choice

Check yourself

- ✓ Name the three things HDR changes relative to SDR.
- ✓ Explain why HDR is not "brighter everything", and where diffuse white should sit.
- ✓ Distinguish PQ from HLG in terms of absolute versus relative, and say who uses each.
- ✓ Explain why HDR needs 10 bits.
- ✓ Say what MaxCLL and MaxFALL each describe and why MaxFALL protects the panel.
- ✓ Name the components of HDR10 and say why it is the baseline.

- ✓ Explain why static metadata means two TVs legitimately differ.
- ✓ Compare clipping, Reinhard and BT.2390 roll-off as tone maps.
- ✓ Explain why tone mapping must happen in linear light.
- ✓ Say why naive HDR-to-SDR conversion looks washed out and what fixes it.

Why compression works

Raw 4K60 video is 12 gigabits per second. A streaming service delivers the same picture in 15 megabits — a ratio of 800:1. That is not clever packing; it is the systematic removal of four different kinds of redundancy, three of which you never notice.

The problem, in numbers

```
/* Uncompressed video is not slightly too big. It is
   impossible.                                          */

  bitrate = width * height * bpp * fps

  1920x1080  4:2:0 8-bit  30 fps
        1920 * 1080 * 1.5 * 8 * 30      =  747 Mbit/s
  3840x2160  4:2:0 10-bit 60 fps
        3840 * 2160 * 1.5 * 10 * 60     =  7.5 Gbit/s
  3840x2160  4:4:4 12-bit 60 fps
        3840 * 2160 * 3   * 12 * 60     = 17.9 Gbit/s

  ONE HOUR of the middle one: 3.4 TERABYTES.
  Delivered at 15 Mbit/s: 6.75 GB. A ratio of about 500:1.

  FOR COMPARISON
    a good LOSSLESS image compressor    ~2:1
    lossless video (FFV1, lossless x264) ~2-3:1

  So lossless gets you 2x and we need 500x. Everything
  interesting in this chapter is about the other 250x, and all
  of it is DISCARDING INFORMATION.
```

The four redundancies

```
1. SPATIAL - neighbouring pixels are similar
     A photograph is mostly smooth. Knowing a pixel tells
     you a lot about the one beside it.
     EXPLOITED BY: intra prediction (predict from
     neighbours) and the transform (concentrate energy into
     a few coefficients).                    Chapters 7, 11

2. TEMPORAL - consecutive frames are nearly identical
     At 30 fps, 33 ms apart, most of the frame did not
     change, and what did change mostly MOVED.
     EXPLOITED BY: motion compensation - describe this
     block as "that block over there, shifted".
     THE BIGGEST WIN BY FAR.                    Chapter 9

3. STATISTICAL - symbols are not equally likely
     After prediction, most residuals are near zero. Give
     the common values short codes.
     EXPLOITED BY: entropy coding.               Chapter 8
     This is the only one that is LOSSLESS.

4. PERCEPTUAL - the eye does not see everything
     Less acuity for colour than brightness. Less for high
     spatial frequencies. Less next to a strong edge, and
     for a moment after a scene cut.
     EXPLOITED BY: chroma subsampling (chapter 3) and
     QUANTISATION (chapter 7).
     THIS IS WHERE THE LOSS HAPPENS, deliberately.

THE STRUCTURE OF EVERY CODEC SINCE 1990

  PREDICT   -> guess the block from what the decoder
               already has (neighbours, or an earlier
               frame)
  TRANSFORM -> convert the prediction ERROR to frequency,
               concentrating its energy
  QUANTISE  -> divide and round. THE LOSSY STEP.
  ENTROPY   -> code the result losslessly

and the decoder runs it backwards. H.261 in 1988 and AV1 in
2018 differ in how well each stage is done, not in the
structure.
```

QUANTISATION IS THE ONLY LOSSY STEP

Prediction, transform and entropy coding are all reversible in principle. It is quantisation — dividing coefficients by a step size and rounding — that throws information away, and it is the *only* place that happens. That is why one number, the quantisation parameter, controls quality and bitrate throughout every codec, and why "QP" is the number you actually tune.

The theoretical floor

```
/* Shannon: you cannot losslessly code a source below its
   ENTROPY.

     H = - sum over symbols of  p(s) * log2 p(s)   bits/symbol

   A source where every one of 256 values is equally likely
   has H = 8 bits. Nothing can compress it. Random data does
   not compress - not because compressors are weak, but
   because there is nothing there.

   A source where 0 occurs 90% of the time:
     H = -(0.9*log2(0.9) + 0.1*log2(0.1/255)*255...) ~ 0.9 bits

   So the whole game is: TRANSFORM THE DATA UNTIL ITS ENTROPY
   IS LOW, then code near that floor.

   Prediction does exactly that. Raw pixel values are roughly
   uniform over their range. Prediction RESIDUALS - the error
   after guessing - cluster hard around zero:

     raw pixel values      residuals after prediction
     .....::::::::::::.           :
     ...::::::::::::::...        :::
     .:::::::::::::::::.        ..:::..
     0            255         -50  0  +50

   Same information, far lower entropy. The entropy coder then
   gets close to that floor (chapter 8).                  */
```

Rate-distortion: the actual decision

```
An encoder is not "compressing". It is repeatedly choosing
between options that trade BITS against ERROR.

  Should this block be intra or inter coded?
  Which of 35 intra directions?
  Split into four sub-blocks, or not?
  Which reference frame? Which motion vector?
  What quantisation step?

Each choice costs some RATE (bits) and causes some
DISTORTION (error). You cannot minimise both.

THE LAGRANGIAN, and this one equation is the heart of every
modern encoder:

     J = D + lambda * R

  D  distortion - usually SSD (sum of squared differences)
                or SATD (transformed absolute differences)
  R  rate - the actual bits this choice costs
  lambda  the exchange rate between them, derived from QP

The encoder tries the options, computes J for each, and
picks the smallest. That is RATE-DISTORTION OPTIMISATION,
and it is why encoding is 10-100x slower than decoding.

     distortion
        |*
        | *
        |  *.
        |    *..              the RD CURVE
        |       *....
        |           *.......
        |                  *.........
        +------------------------------ rate

A BETTER CODEC is one whose curve sits lower and left: the
same quality for fewer bits. "AV1 is 30% better than H.264"
means its curve is 30% left at equal quality - measured
with BD-rate, which integrates the gap between two curves.

AND THE PRESET DIAL: "veryslow" searches more options and
lands closer to the true optimum. "ultrafast" tries a
handful. Same codec, same decoder, 2-3x difference in
bitrate for the same quality - which is why encoder
QUALITY is mostly a search problem, not a format one.
```

Measuring what you lost

Metric	What it measures	Trust it?
PSNR	Log of mean squared error	Poorly. Correlates weakly with what people see, but it is cheap, stable and every paper quotes it
SSIM	Structural similarity — luminance, contrast, structure	Better. Still misses temporal artefacts
MS-SSIM	SSIM at several scales	Better again; a reasonable default
VMAF	Netflix's machine-learned fusion of several metrics, trained on human scores	The best automated proxy in common use. Tuned for streaming content on a TV

Metric	What it measures	Trust it?
BD-rate	Average bitrate difference between two codecs at equal quality	The standard way to compare codecs. Depends entirely on which quality metric feeds it
Human eyes	The actual target	The only ground truth, and the reason every metric above is a compromise

```
# Compute them, on a real pair of files.
$ ffmpeg -i encoded.mp4 -i original.y4m \
    -lavfi "[0:v][1:v]libvmaf=feature='name=psnr|name=float_ssim'" \
    -f null -
VMAF score: 93.412
PSNR y:42.31 u:45.02 v:44.88
SSIM: 0.9871

# ROUGH VMAF ANCHORS, for streaming content:
#   95+   visually indistinguishable from the source
#   90    excellent; the usual target for a top rendition
#   80    good; noticeable on an A/B but fine standalone
#   60    watchable, clearly compressed
#   <50   obviously bad

# THE CAVEATS THAT MATTER
#   * VMAF was trained on 1080p TV viewing. Its numbers mean
#     less for a phone, for screen content, or for 4K.
#   * every metric here compares FRAME TO FRAME. None of them
#     sees flicker, pumping, or a scene that breaks up for
#     three frames after a cut - which is what viewers
#     actually complain about.
#   * optimising a metric directly ("VMAF hacking") produces
#     encoders that score well and look worse. Sharpening
#     filters do this reliably.
#   * ALWAYS LOOK AT THE VIDEO. A metric tells you where to
#     look, not whether it is acceptable.
```

> **COMPRESSION ARTEFACTS ARE NOT RANDOM NOISE**
> Each has a signature that names its cause. **Blocking** — visible square edges — is coarse quantisation plus a block transform. **Ringing / mosquito noise** — shimmer around sharp edges — is quantising away high-frequency coefficients (Gibbs). **Banding** in gradients is quantisation plus insufficient bit depth. **Smearing** is motion compensation failing to find a match. **Pumping** — quality visibly oscillating — is rate control. Recognising the artefact tells you which knob to turn.

How it shows up

Symptom	Cause
Visible square blocks	QP too high; deblocking filter disabled or too weak
Shimmering around text and edges	Ringing — high-frequency coefficients quantised away
Gradients show contours	Banding; needs higher bit depth or dither
Quality visibly pulses	Rate control reacting to scene complexity (chapter 13)
Detail smears during fast motion	Motion search failing, or too few bits for a hard scene
File is huge despite a low bitrate setting	Rate control mode misunderstood — CRF ignores bitrate
Encoding takes hours	A slow preset; the search space grew, not the codec

Symptom	Cause
Metrics look fine, viewers complain	A temporal artefact no frame-wise metric sees
Random or already-compressed data will not compress	Its entropy is already at the floor
Re-encoding degrades every pass	Generation loss — each pass quantises already-quantised data

Check yourself

- ✓ Compute the raw bitrate of 4K60 4:2:0 10-bit and the ratio to a 15 Mbit/s stream.
- ✓ Say roughly what lossless compression achieves on video, and why that is not enough.
- ✓ Name the four redundancies and the codec stage that exploits each.
- ✓ Say which single stage is lossy and why that makes QP the master control.
- ✓ State Shannon's entropy bound and explain why random data does not compress.
- ✓ Explain why prediction lowers entropy without losing information.
- ✓ Write the rate-distortion Lagrangian and say what each term is.
- ✓ Explain what an encoder preset changes, and why it affects bitrate but not the decoder.
- ✓ Compare PSNR, SSIM and VMAF, and give two things none of them measure.
- ✓ Name five compression artefacts and the cause of each.

Transform and quantisation: JPEG end to end

JPEG is thirty years old and still the clearest illustration of how every codec works. Follow one 8×8 block from pixels to bits and back, and you have understood the machinery inside H.264, HEVC and AV1 — they differ in the details, not the shape.

The whole encoder

```
RGB image
  |  1. colour transform  -> Y'CbCr           (chapter 3)
  |  2. chroma subsample  -> 4:2:0 or 4:2:2
  v
planes, split into 8x8 BLOCKS
  |  3. level shift: subtract 128 -> range [-128,127]
  |  4. FORWARD DCT       -> 64 frequency coefficients
  |  5. QUANTISE          -> divide by a table, round
  |                          THE LOSSY STEP
  |  6. ZIGZAG scan       -> 1D, low frequencies first
  |  7. DC differential, AC run-length
  |  8. HUFFMAN code                          (chapter 8)
  v
bitstream

The decoder runs it backwards, and only step 5 cannot be
undone.

NOTE THE ORDER: transform BEFORE quantise. Quantising
pixels directly just posterises the image. Quantising
FREQUENCIES lets you keep the ones the eye cares about and
discard the ones it does not - that is the entire
trick.
```

The DCT, concretely

```
/* The 2D DCT-II. 64 pixels in, 64 coefficients out - no
   compression yet, just a change of basis.               */

  F(u,v) = 1/4 C(u) C(v) *
           sum_{x=0..7} sum_{y=0..7}
               f(x,y) * cos((2x+1) u pi / 16)
                      * cos((2y+1) v pi / 16)

  C(0) = 1/sqrt(2),  C(k) = 1 otherwise

/* WHAT THE 64 OUTPUTS MEAN

     F(0,0)  the DC coefficient: the block's average
             brightness. Typically 10-100x larger than
             anything else.
     F(1,0)  a slow horizontal ramp
     F(0,1)  a slow vertical ramp
     F(7,7)  the finest checkerboard the block can hold

   THE PROPERTY THAT MATTERS - ENERGY COMPACTION. On natural
   images, almost all the energy lands in the top-left few
   coefficients. A typical smooth block:

     -415  -30   -61    27     56   -20    -2     0
      4    -22   -61    10     13    -7    -9     5
     -47    7     77   -25    -29    10     5    -6
     -49   12     34   -15    -10     6     2     2
      12   -7    -13    -4     -2     2    -3     3
      -8    3      2    -6     -2     1     4     2
      -1    0      0    -2     -1    -3     4    -1
       0    0     -1    -4     -1     0     1     2

   Fifty of those 64 numbers are single digits. After
   quantisation nearly all of them become ZERO - and a long
   run of zeros costs almost nothing to code.             */

/* NOBODY COMPUTES THE FORMULA. The separable fast DCT does
   8 rows then 8 columns, and the AAN algorithm needs just
   5 multiplies and 29 adds per 8-point transform. Modern
   codecs go further and use INTEGER transforms - see the
   note below.                                            */
```

WHY MODERN CODECS ABANDONED THE TRUE DCT

The real DCT uses cosines, so an encoder and a decoder on different hardware can round differently — and in a video codec that error *accumulates* across every predicted frame, causing drift between encoder and decoder. H.264 onwards therefore use **integer approximations** of the DCT: exactly specified, bit-exact on every implementation, and computable with adds and shifts alone. JPEG predates that insight, which is why two JPEG decoders can legitimately produce slightly different pixels.

Quantisation: where the loss happens

```
/* Divide each coefficient by a per-position step and round. */

     Fq(u,v) = round( F(u,v) / Q(u,v) )

/* The standard JPEG luminance table at quality 50. Note the
   values GROW toward the bottom right - high frequencies get
   coarser steps, because the eye notices them less.       */

     16  11  10  16  24  40  51  61
     12  12  14  19  26  58  60  55
     14  13  16  24  40  57  69  56
     14  17  22  29  51  87  80  62
     18  22  37  56  68 109 103  77
     24  35  55  64  81 104 113  92
     49  64  78  87 103 121 120 101
     72  92  95  98 112 100 103  99

/* Applying it to the block above: */

     -26  -3  -6   2   2  -1   0   0
       0  -2  -4   1   1   0   0   0
      -3   1   5  -1  -1   0   0   0
      -3   1   2  -1   0   0   0   0
       1   0   0   0   0   0   0   0
       0   0   0   0   0   0   0   0
       0   0   0   0   0   0   0   0
       0   0   0   0   0   0   0   0

   FORTY-FOUR ZEROS out of 64, and they are all in the bottom
   right - which is exactly what the zigzag scan is designed
   to exploit.

   THE QUALITY DIAL scales this table:
     quality 90 -> divide the table by ~5   -> finer steps
     quality 50 -> the table as printed
     quality 10 -> multiply by ~5           -> almost
                   everything becomes zero

   CHROMA gets its own, coarser table - another application of
   the same perceptual argument as subsampling.

   AND THE REASON ARTEFACTS LOOK THE WAY THEY DO:
     quantise the DC too coarsely  -> BLOCKING (each block's
                                      average steps visibly)
     quantise the AC too coarsely  -> RINGING around edges,
                                      because a sharp edge
                                      needs its high
                                      frequencies             */
```

Zigzag and run-length

```
The zeros are clustered bottom-right, so scan in the order
that visits low frequencies first:

   0  1  5  6 14 15 27 28
   2  4  7 13 16 26 29 42
   3  8 12 17 25 30 41 43
   9 11 18 24 31 40 44 53
  10 19 23 32 39 45 52 54
  20 22 33 38 46 51 55 60
  21 34 37 47 50 56 59 61
  35 36 48 49 57 58 62 63

Our block becomes:

  -26, -3, 0, -3, -2, -6, 2, -4, 1, -3, 1, 1, 5, 1, 2,
  -1, 1, -1, 2, 0, 0, 0, 0, 0, -1, -1, 0, 0, ... 0

-> a short burst of values, then a long tail of zeros.

THEN:
  DC is coded DIFFERENTIALLY against the previous block's
     DC - adjacent blocks have similar averages, so the
     difference is small.
  AC is coded as (RUN, SIZE) pairs: "5 zeros, then a value
     needing 3 bits". A single EOB symbol ends the block
     once only zeros remain - which is why 44 trailing
     zeros cost about four bits, not 44 values.

Those symbols then go to the Huffman coder (chapter 8).

MODERN CODECS DO THE SAME THING with better tools: adaptive
scan orders that learn where the coefficients actually are,
context-modelled arithmetic coding instead of Huffman, and
several transform sizes rather than only 8x8.
```

Where JPEG stops and video codecs begin

JPEG	What modern codecs added
Fixed 8×8 blocks	4×4 to 64×64, chosen per region — small blocks for detail, large for smooth areas (chapter 11)
No prediction between blocks except the DC	Full **intra prediction** from neighbouring pixels, in 35+ directions
No prediction between images	**Motion compensation** — the biggest win of all (chapter 9)
True DCT, drift-prone	Integer transforms, bit-exact; plus DST and identity transforms for particular content
Huffman coding	Context-adaptive arithmetic coding, ~10–15% better (chapter 8)
Visible block edges	**In-loop deblocking**, so the filtered frame is what gets referenced (chapter 12)
One quality for the whole image	Per-block QP, driven by rate-distortion optimisation and perceptual masking

```
# Look inside a real JPEG.
$ djpeg -verbose -verbose photo.jpg > /dev/null
Quantization table 0:
    3   2   2   3   4   6   8  10
    2   2   2   3   4   9  10   9
    ...
Huffman table 0x00: ...
Start Of Frame 0xc0: width=1920, height=1080, components=3
    Component 1: 2hx2v q=0        <-- luma, 2x2 sampling
    Component 2: 1hx1v q=1        <-- chroma, subsampled 4:2:0
    Component 3: 1hx1v q=1

# The quantisation tables ARE the quality setting - there is no
# "quality 82" stored in the file, only the tables it produced.
# This is how tools guess a JPEG's original quality, and why
# the guess is approximate.

$ identify -format "%Q\n" photo.jpg      # ImageMagick's guess
82

# Re-encoding LOSSLESSLY, to strip metadata or rotate:
$ jpegtran -copy none -optimize -progressive -outfile out.jpg in.jpg
# jpegtran works on the coefficients directly - no decode, no
# re-quantisation, no generation loss. Anything that decodes
# to pixels and re-encodes loses quality every time.
```

GENERATION LOSS IS NOT SYMMETRICAL

Re-encoding a JPEG at the *same* quality still degrades it: the second encoder's 8×8 grid may not align with the first's, and it quantises coefficients that were already quantised. Re-encoding at a *higher* quality is worse than pointless — it makes the file bigger while preserving the original's artefacts faithfully. If you must edit, work from the original, or use coefficient-domain tools like `jpegtran` that never decode to pixels.

How it shows up

Symptom	Cause
Visible 8×8 squares	DC quantised too coarsely; quality too low
Shimmer or halo around text and edges	Ringing — AC coefficients quantised away
Colour bleeding across sharp edges	Chroma subsampling plus a coarser chroma table
File degrades a little every save	Generation loss from decode–re-encode
Higher quality setting produced a bigger, uglier file	Re-encoding an already-lossy source
Two decoders produce slightly different pixels	JPEG's floating-point DCT is not bit-exact
Photographs compress well, screenshots do not	Sharp edges need high frequencies; the DCT spreads them across many coefficients
Rotating a JPEG made it blurrier	A pixel-domain tool re-encoded it; use `jpegtran`
Progressive JPEG loads oddly but is smaller	Working as intended — same coefficients, different scan order

Check yourself

✓ List the eight JPEG encoding steps in order and name the only lossy one.

- ✓ Explain why the transform comes before quantisation.
- ✓ Say what the DC coefficient represents and why it dominates.
- ✓ Define energy compaction and say why it makes natural images compressible.
- ✓ Explain why the quantisation table's values grow toward the bottom right.
- ✓ Say which artefact comes from coarse DC quantisation and which from coarse AC.
- ✓ Explain what the zigzag scan achieves and how EOB exploits it.
- ✓ Explain why modern codecs use integer transforms rather than a true DCT.
- ✓ Name five things video codecs added that JPEG lacks.
- ✓ Explain why re-encoding at a higher quality is worse than pointless.

Entropy coding: Huffman, arithmetic and CABAC

The last stage of every codec, and the only lossless one. It takes the quantised symbols and writes them in as few bits as their statistics allow — and the gap between "as few as Huffman allows" and "as few as information theory allows" is worth about 15% of your bitrate.

Huffman: one integer number of bits per symbol

```
Build a binary tree, most frequent symbols nearest the
root. Symbol probabilities:

  A 0.45   B 0.25   C 0.15   D 0.10   E 0.05

                (1.0)
               /     \
            A(.45)  (.55)
                   /     \
                B(.25)   (.30)
                         /     \
                      C(.15)   (.15)
                               /     \
                            D(.10)  E(.05)

  A = 0        1 bit
  B = 10       2 bits
  C = 110      3 bits
  D = 1110     4 bits
  E = 1111     4 bits

Average = .45(1) + .25(2) + .15(3) + .10(4) + .05(4) = 2.00
Entropy = 2.04... wait, entropy here is 1.98 bits.

So Huffman costs 2.00 where the floor is 1.98. Close - on
THIS distribution.

THE FUNDAMENTAL LIMIT: a Huffman code must use a WHOLE
NUMBER of bits per symbol. When one symbol is very likely,
that rounding is brutal:

  P(zero) = 0.95  ->  ideal cost = -log2(0.95) = 0.074 bits
                      Huffman must spend      = 1 bit
                      THIRTEEN TIMES too many.

And "mostly zeros" is exactly what a quantised transform
block looks like (chapter 7). This is why JPEG's entropy
coder leaves real compression on the table, and why every
codec after it moved to arithmetic coding.

THE WORKAROUND JPEG USES: code (RUN, SIZE) PAIRS rather
than individual coefficients, so one symbol covers many
zeros. It helps, and it is still not enough.
```

Arithmetic coding: fractional bits

```
/* The whole message becomes ONE number in [0,1). Each symbol
   narrows the interval in proportion to its probability. */

  Alphabet: A=0.6  B=0.3  C=0.1
  Encode "ABA":

  start                 [0.0000, 1.0000)   width 1.0
  'A' -> first 60%      [0.0000, 0.6000)   width 0.6
  'B' -> next 30% of it [0.3600, 0.5400)   width 0.18
  'A' -> first 60%      [0.3600, 0.4680)   width 0.108

  Transmit ANY number in the final interval - say 0.4.
  Bits needed = -log2(0.108) = 3.21 bits.

  Huffman on this alphabet: A=1 bit, B=2, C=2 -> "ABA" = 4 bits.

/* THE KEY PROPERTY: a symbol of probability p costs
   -log2(p) bits, and that number need not be an integer.
   A symbol with p = 0.95 genuinely costs 0.074 bits, because
   it barely narrows the interval at all.

   THE PRACTICAL PROBLEMS, and their solutions:

   1. Infinite precision is impossible.
      -> RENORMALISATION: as the interval narrows, the leading
         bits stop changing. Emit them and rescale. The
         encoder keeps a fixed-width register.

   2. The E3 / straddle condition: the interval sits across
      0.5 so no leading bit is settled.
      -> count the pending bits and emit them once the
         ambiguity resolves.

   3. Division is expensive in hardware.
      -> MULTIPLICATION-FREE variants using lookup tables.
         This is exactly what CABAC's M-coder does.

   4. It was patented until the mid-2000s.
      -> which is why JPEG has an arithmetic mode that
         nobody implemented, and why H.264 shipped CAVLC as
         well as CABAC.                                    */
```

> **CODING IS ONLY HALF OF IT; MODELLING IS THE OTHER HALF**
>
> An arithmetic coder achieves `-log2(p)` bits — but only if your *p* is right. A coder with a perfect model and a mediocre engine beats a perfect engine with a bad model, every time. That is why modern codecs spend enormous effort on **context modelling**: not "how do I write this bit cheaply", but "given everything the decoder already knows, how likely is this bit to be 1?"

CABAC: context-adaptive binary arithmetic coding

```
H.264's entropy coder, and the shape of every one since.
THREE STAGES:

1. BINARISATION
     Every syntax element becomes a string of bits.
     A motion vector difference of 5 becomes, say,
     "1 1 1 1 1 0" in a unary-ish code. Now the coder only
     ever handles BINARY decisions, which makes the
     arithmetic tractable in hardware.

2. CONTEXT MODELLING
     Each bin is coded with a probability chosen from a
     CONTEXT selected by neighbouring data:

       coding "is this block's coefficient non-zero?"
         context depends on how many neighbours were
         non-zero
       coding a motion vector
         context depends on the neighbours' motion vectors
       coding a skip flag
         context depends on whether the blocks above and
         left were skipped

     H.264 has ~460 contexts. Each holds a 6-bit
     probability state and an MPS (most probable symbol)
     flag.

3. BINARY ARITHMETIC CODING
     The M-coder: multiplication-free, table-driven,
     4 x 64 entries. Two paths:
       REGULAR    uses and updates a context
       BYPASS     assumes p = 0.5, no context, much faster
                  - used for sign bits and the tails of
                  long values, which really are random

ADAPTATION: after coding each bin, the context's state
moves toward what actually happened. The model tracks the
content as it changes, with no side information - the
decoder performs the identical update.

THE RESULT: 10-15% smaller than CAVLC at the same quality,
for free at the decoder. AV1's multi-symbol coder and
VVC's CABAC are refinements of the same idea.
```

```
/* The decoder side, simplified, to show the shape. */

typedef struct { uint8_t state; uint8_t mps; } ctx_t;

static int decode_bin(cabac_t *c, ctx_t *ctx)
{
        /* Look up the sub-interval width for this state. */
        int qIdx  = (c->range >> 6) & 3;
        int rLPS  = rangeTabLPS[ctx->state][qIdx];
        c->range -= rLPS;

        int bin;
        if (c->offset >= c->range) {          /* LPS path      */
                c->offset -= c->range;
                c->range   = rLPS;
                bin        = 1 - ctx->mps;
                if (ctx->state == 0)
                        ctx->mps ^= 1;        /* flip MPS      */
                ctx->state = transIdxLPS[ctx->state];
        } else {                              /* MPS path      */
                bin        = ctx->mps;
                ctx->state = transIdxMPS[ctx->state];
        }

        renormalise(c);          /* shift in bits until range
                                    is back in range          */
        return bin;
}

/* NOTE WHAT THIS COSTS: the next decision depends on the
   updated state, which depends on this decision. CABAC is
   INHERENTLY SERIAL - one bin at a time, with a loop-carried
   dependency.

   That single property is why:
     * CABAC decode is the hardest part of a video decoder to
       accelerate, and often the bottleneck at high bitrates
     * hardware decoders have a dedicated CABAC engine, and
       its throughput sets the maximum bitrate the chip
       supports
     * H.264 levels specify a maximum bin rate, not just a
       bitrate
     * SLICES and TILES exist partly so several CABAC engines
       can run in parallel - each slice resets the contexts
       and can be decoded independently. WPP (wavefront
       parallel processing) in HEVC is the refined version.  */
```

What came after

Coder	Used by	Idea
Huffman	JPEG, MPEG-2, MP3	Static tree, integer bits
CAVLC	H.264 baseline	Several VLC tables, switched by context. Cheaper than CABAC, ~10% worse
CABAC	H.264 main+, HEVC, VVC	Binary, adaptive, context-modelled
Boolean coder	VP8, VP9	Similar to CABAC, patent-free by design

Coder	Used by	Idea
Multi-symbol coder	AV1	Codes a symbol from an alphabet of up to 16 directly, instead of binarising. Fewer serial steps for the same compression — an explicit answer to CABAC's throughput problem
ANS / rANS	JPEG XL, Zstandard, LZFSE	Asymmetric numeral systems: arithmetic-coding efficiency with table-driven speed close to Huffman. The most important recent development

```
# See the effect for yourself.
$ ffmpeg -i in.y4m -c:v libx264 -crf 23 -coder 0 cavlc.mp4   # CAVLC
$ ffmpeg -i in.y4m -c:v libx264 -crf 23 -coder 1 cabac.mp4   # CABAC
$ ls -l cavlc.mp4 cabac.mp4
-rw-r--r-- 12481923 cavlc.mp4
-rw-r--r-- 10847216 cabac.mp4        # ~13% smaller, same CRF

# CABAC is on by default in every profile above Baseline. The
# only reasons to disable it:
#   * a decoder that genuinely only supports Baseline
#   * extremely low-power decode
#   * you need the higher bin throughput CAVLC allows

# Where the decode time actually goes:
$ perf record -g ffmpeg -i cabac.mp4 -f null -
$ perf report --sort symbol | head
  31.2%  ff_h264_decode_mb_cabac
  18.4%  h264_idct_add8_8_avx
  12.1%  ff_h264_filter_mb            # deblocking
# At high bitrates the CABAC line grows and everything else
# stays flat - it scales with BITS, not with pixels.
```

> **ENTROPY CODING IS WHERE BITSTREAM CORRUPTION BECOMES CATASTROPHIC**
>
> Because arithmetic coding has no byte alignment and the context state is carried forward, a single flipped bit desynchronises the decoder for the rest of the slice — you do not get one wrong pixel, you get garbage until the next resynchronisation point. That is why streams have start codes, slices and IDR frames, and why a dropped packet on a long GOP produces seconds of smearing rather than one bad frame (chapter 10).

How it shows up

Symptom	Cause
File ~13% larger than expected at the same CRF	CAVLC instead of CABAC
Decode is CPU-bound at high bitrate, fine at low	CABAC — it scales with bits, not pixels
Hardware decoder rejects a valid stream	Bin rate over the level limit, even though the bitrate is within it
Garbage from a corruption point to the end of the frame	Arithmetic decoder desynchronised; no resync until the next slice
Multi-threaded decode gains little	One slice per frame — nothing to parallelise across
Encoder is slow in the entropy stage	RDO is calling the entropy coder to measure real bit costs, repeatedly
Lossless mode still compresses well	Entropy coding alone; no quantisation involved
Already-compressed data does not shrink	Its entropy is already near the floor (chapter 6)

Check yourself

✓ Build a Huffman code for a given distribution and compute its average length.

- ✓ Explain Huffman's fundamental limit and quantify it for a symbol with p = 0.95.
- ✓ Encode a three-symbol message with arithmetic coding and compute the bits used.
- ✓ Name three practical problems arithmetic coding must solve and how each is solved.
- ✓ Explain why modelling matters more than the coder itself.
- ✓ Describe CABAC's three stages and what binarisation buys.
- ✓ Explain what a context is and give two examples of how one is selected.
- ✓ Explain why CABAC is inherently serial and name three consequences.
- ✓ Say what slices and tiles do for entropy decoding.
- ✓ Explain why a single bit error destroys the rest of a slice.

Temporal redundancy and motion compensation

The single largest saving in video compression. Consecutive frames are nearly identical, and what did change mostly *moved* — so instead of coding a block, code a vector pointing at where it used to be. This one idea is the difference between JPEG-per-frame and real video.

The idea

```
FRAME N-1                    FRAME N

+----------------+           +----------------+
|                |           |                |
|    [ball]      |           |       [ball]   |
|                |           |                |
|  static bg     |           |  static bg     |
+----------------+           +----------------+

CODING FRAME N INDEPENDENTLY  (as JPEG would)
  every block from scratch. ~50 KB.

CODING IT AS A DIFFERENCE FROM N-1
  background blocks: identical -> "SKIP". Zero bits beyond
                     the flag.
  ball blocks:       "copy from (x-12, y+3) in frame N-1,
                     plus this small residual"
  -> ~2 KB. TWENTY-FIVE TIMES SMALLER.

THE THREE PIECES

  1. MOTION VECTOR   where to copy from
  2. REFERENCE INDEX which earlier frame
  3. RESIDUAL        the error after copying, transformed
                     and quantised exactly as in chapter 7

A typical P-frame is 5-20% the size of an I-frame of the
same content. On static content it can be 1%.

AND THE FAILURE MODES FALL OUT OF THIS DIRECTLY:
  a scene cut          -> nothing matches -> huge frame
  a fade or flash      -> everything changed slightly ->
                          every block has a residual
  new content entering -> occlusion; no source to copy
  noise / grain        -> genuinely random, cannot be
                          predicted, and it destroys
                          compression efficiency
```

BLOCK MATCHING IS NOT MOTION ESTIMATION

The encoder is not trying to understand the scene. It searches for the block that *minimises cost*, which is usually but not always the physically correct match. On a repeating texture — a brick wall, a picket fence — it will happily pick a neighbouring identical block. That is fine: the decoder reproduces exactly what the encoder chose, so the picture is correct even when the "motion" is physically nonsense. Motion vectors are a compression tool, not a measurement, and using them for computer vision gives poor results for exactly this reason.

Searching

```
/* THE COST FUNCTION. SAD is cheap and standard; SATD
   (Hadamard-transformed) correlates better with what the
   transform will actually cost, and is what good encoders use
   for the final decision.                                    */

static int sad_16x16(const uint8_t *cur, int cs,
                     const uint8_t *ref, int rs)
{
        int sum = 0;
        for (int y = 0; y < 16; y++)
                for (int x = 0; x < 16; x++)
                        sum += abs(cur[y*cs + x] - ref[y*rs + x]);
        return sum;
}

/* FULL SEARCH over +/-64 pixels: 129 x 129 = 16,641 positions,
   each 256 subtractions = 4.3 MILLION operations PER BLOCK.
   At 8160 blocks per 1080p frame and 30 fps that is 10^12
   operations per second. Nobody does this.               */

/* WHAT ENCODERS ACTUALLY DO */

  1. PREDICT THE STARTING POINT. Motion is spatially and
     temporally coherent, so the neighbours' vectors and the
     co-located block's vector are excellent guesses. Start
     there, and you are usually within a pixel or two.

  2. DIAMOND / HEXAGON SEARCH. Test a small pattern around the
     current best, move to the winner, repeat until the centre
     wins. Typically 20-50 positions instead of 16,641.

  3. HIERARCHICAL / PYRAMID SEARCH. Search a 1/8-scale image
     first to find large motion cheaply, then refine at each
     level up. This is how you find fast motion without a
     huge search window.

  4. EARLY TERMINATION. If the cost is already below a
     threshold, stop.

/* AND THE PREDICTED VECTOR IS ALSO WHAT GETS CODED: the
   bitstream carries the DIFFERENCE between the actual vector
   and the predicted one. Coherent motion therefore costs
   almost nothing - a pan where every block moves identically
   codes as a field of zeros.                             */
```

Sub-pixel accuracy

```
Real motion is not a whole number of pixels. Restricting
vectors to integers leaves a residual that the transform
then has to code - expensively.

H.264 onward: QUARTER-PIXEL precision for luma.
AV1 and VVC: EIGHTH-pixel in some modes.

HOW: interpolate the reference frame.

  half-pixel   a 6-tap filter (1,-5,20,20,-5,1)/32 in
               H.264 - not bilinear, because bilinear
               blurs and blurring the reference degrades
               every future frame that predicts from it
  quarter-pixel  average of the two nearest half/full
               positions

THE PAYOFF: typically 20-30% bitrate reduction over
integer-pixel motion. It is one of the largest single wins
in H.264 over MPEG-2.

THE COST: the interpolation filter runs on EVERY predicted
block, in the DECODER. It is one of the most expensive
parts of decoding, and the reason motion compensation is
always a hand-written SIMD routine.

AND A SUBTLETY: the filter must be BIT-EXACT and specified
by the standard. If the encoder and decoder interpolate
even slightly differently, the error feeds into the next
frame's reference and DRIFTS - accumulating until the
picture visibly diverges. This is why every codec after
MPEG-2 specifies integer arithmetic exactly.
```

Beyond one vector per block

```
/* Simple block translation cannot express zoom, rotation, or
   two objects in one block. Codecs added tools for each. */

/* VARIABLE BLOCK SIZE (H.264 onwards)
     16x16 down to 4x4, chosen per region. Large blocks for
     flat backgrounds - one vector covers a lot. Small blocks
     at object boundaries, where two things move differently.
     HEVC goes to 64x64, AV1 to 128x128 (chapter 11).      */

/* BI-PREDICTION
     Average two predictions, from a past AND a future frame:
        pred = (ref0[mv0] + ref1[mv1] + 1) / 2
     Better on occlusion (something hidden in the past may be
     visible in the future) and it AVERAGES AWAY NOISE, which
     often beats either reference alone. Requires B-frames
     (chapter 10).                                          */

/* WEIGHTED PREDICTION
     pred = w * ref[mv] + o
     Handles fades and lighting changes, where every pixel
     changed by a multiplicative or additive amount. Without
     it, a one-second fade costs as much as a scene cut.  */

/* GLOBAL / WARPED MOTION (AV1, and VVC's affine mode)
     One affine or perspective model for the whole frame, or
     per block:
        x' = a*x + b*y + c
        y' = d*x + e*y + f
     Expresses pan, zoom and rotation in six parameters
     instead of thousands of vectors. A slow zoom becomes
     nearly free.                                           */

/* OVERLAPPED BLOCK MC (OBMC)
     Blend predictions from neighbouring blocks' vectors near
     the block edges, so the block boundary is not a
     discontinuity. Reduces blocking at source rather than
     filtering it afterwards.                               */

/* AND WHAT IS STILL HARD
     non-rigid motion  - water, fire, cloth, foliage
     occlusion         - genuinely new pixels must be intra
                         coded
     film grain        - random by construction. AV1's answer
                         is to REMOVE it before encoding and
                         SYNTHESISE it in the decoder from a
                         parametric model - which is far
                         cheaper than coding noise.        */
```

> **GRAIN AND NOISE ARE THE ENEMY OF EVERY CODEC**
>
> Motion compensation predicts, and noise is by definition unpredictable — so every noisy block gets a large residual and consumes bits. A grainy source can cost several times the bitrate of a clean one at the same perceptual quality. This is why encoders ship denoisers, why streaming services denoise before encoding, and why AV1's film grain synthesis exists: strip the grain, code the clean signal cheaply, and add statistically-matched grain back at playback.

Looking at the vectors

```
# Visualise motion vectors over the video:
$ ffplay -flags2 +export_mvs -vf codecview=mv=pf+bf+bb input.mp4
#   pf = P-frames forward, bf = B forward, bb = B backward

# Or render them to a file:
$ ffmpeg -flags2 +export_mvs -i input.mp4 \
    -vf codecview=mv=pf+bf+bb -c:v libx264 -crf 18 mvs.mp4

# WHAT TO LOOK FOR
#   long vectors in a static area  -> the search found a false
#                                     match; usually harmless,
#                                     occasionally a sign of
#                                     noise
#   a field of identical vectors   -> a pan. Should be cheap.
#   chaotic vectors everywhere     -> the encoder is failing to
#                                     predict; expect a big
#                                     frame
#   no vectors at all              -> an I-frame

# Per-frame sizes, which is where prediction success shows:
$ ffprobe -select_streams v -show_entries \
    frame=pict_type,pkt_size -of csv input.mp4 | head -20
frame,I,142883
frame,P,8214
frame,B,3102
frame,B,2894
frame,P,9017

# The I-frame is 15x the P-frames. That ratio IS temporal
# redundancy, measured. If your P-frames are nearly as big as
# your I-frames, prediction is failing - check for noise, a
# scene cut, or a source that was already heavily compressed.
```

How it shows up

Symptom	Cause
P-frames nearly as large as I-frames	Prediction failing — noise, grain, or a constantly-changing scene
Bitrate spikes at every scene cut	Expected; nothing to predict from. Rate control must absorb it (chapter 13)
Fades cost as much as cuts	Weighted prediction disabled
Detail smears during fast motion	Motion search window too small, or the preset too fast
Blocks appear to slide independently	Block size too large for the motion; sub-block partitioning would help
Grainy source needs 3× the bitrate	Noise is unpredictable — denoise, or use grain synthesis
Encoder is very slow	Motion search dominates; a faster preset shrinks the search
Picture drifts wrong over a long GOP	Encoder and decoder interpolating differently — a conformance bug
Motion vectors give poor optical flow	Expected — they minimise bits, not physical error
Slow zoom is expensive on H.264, cheap on AV1	Warped/global motion expresses it in six parameters

Check yourself

✓ Explain why a P-frame is typically 5–20% the size of an I-frame.

- ✓ Name the three pieces of information an inter-coded block carries.
- ✓ Explain why block matching is not the same as measuring motion.
- ✓ Estimate the cost of a full search and name three techniques that avoid it.
- ✓ Explain why motion vectors are coded as differences from a prediction.
- ✓ Say what quarter-pixel motion buys and what it costs the decoder.
- ✓ Explain drift and why interpolation filters must be bit-exact.
- ✓ Give three tools beyond simple block translation and what each handles.
- ✓ Explain why film grain is expensive and how AV1 addresses it.
- ✓ Read a per-frame size listing and say whether prediction is working.

Frame types, GOPs and reference management

Once frames predict from other frames, order matters — and the order they are stored in is not the order they are shown. Every seeking bug, every "the first two seconds are broken" streaming complaint, and the whole design of adaptive streaming comes out of this chapter.

The frame types

```
I-FRAME   Intra. Coded from itself alone, like a JPEG.
          Large - 5 to 20x a P-frame. Decodable with no
          other frame.

P-FRAME   Predicted. References EARLIER frames.
          Small. Useless without its references.

B-FRAME   Bi-predicted. References earlier AND later
          frames, and can average the two.
          Smallest - often half a P-frame.

AND THE ONE THAT MATTERS OPERATIONALLY:

IDR       Instantaneous Decoder Refresh. An I-frame that
          also RESETS the reference list - nothing after
          it may reference anything before it.

A PLAIN I-FRAME IS NOT A SEEK POINT. Later frames may
still reference frames from before it, so starting there
gives you garbage. Only an IDR (or an HEVC CRA/BLA, or an
AV1 keyframe) is a guaranteed entry point.

This distinction is the source of a great many bugs. When
someone says "I set keyint=250 but seeking is still
broken", they emitted I-frames and not IDRs.

  $ ffmpeg ... -x264-params "keyint=48:min-keyint=48:\
    scenecut=0:open-gop=0"
                                     ^^^^^^^^^^^ closed GOP
                                     forces IDR
```

Display order versus decode order

```
A B-frame needs a FUTURE frame, so that future frame must
be DECODED FIRST. The bitstream is reordered.

DISPLAY ORDER (what the viewer sees)
  I0   B1   B2   P3   B4   B5   P6
   |    ^    ^   ^     ^    ^    ^
   |    |    |   |     |    |    |
   +----+----+---+     +----+----+
     B1,B2 need I0 AND P3

DECODE ORDER (what is in the file)
  I0   P3   B1   B2   P6   B4   B5

P3 arrives before the B-frames that need it.

THE CONSEQUENCES

1. TWO TIMESTAMPS PER FRAME
     PTS  Presentation Time Stamp - when to show it
     DTS  Decode Time Stamp       - when to decode it
   For B-frames, PTS != DTS, and DTS can even be negative
   at the start of a stream. Container muxers must carry
   both (chapter 15).

2. LATENCY. The decoder cannot output frame B1 until it
   has decoded P3. With 3 B-frames that is 4 frames of
   structural delay - 133 ms at 30 fps. THIS IS WHY
   VIDEOCONFERENCING DISABLES B-FRAMES ENTIRELY.

3. A REORDER BUFFER is required, sized by
   max_num_reorder_frames in the stream. Getting it wrong
   gives you frames displayed out of order - a stutter
   that looks like dropped frames but is not.

4. Seeking must land on an IDR and decode forward to the
   target, discarding output until the PTS matches.
```

WHY B-FRAMES ARE SO CHEAP

Two reasons, and the second is the underrated one. First, occlusion: something hidden in the past frame may be visible in the future one, so bi-prediction finds a match where forward prediction cannot. Second, *averaging two references halves the noise* — the prediction is closer to the truth than either reference alone, so the residual is smaller. That is why a B-frame is often half the size of a P-frame even on content with simple motion.

GOP structure

```
/* A Group Of Pictures runs from one keyframe to the next. */

  IBBPBBPBBPBBI...           classic MPEG-2, GOP of 12
  IBBBPBBBPBBBP...           H.264, 3 B-frames
  I P P P P P P P...         low latency, no B-frames

/* CLOSED vs OPEN GOP

     CLOSED  no frame references across the boundary. Every
             GOP is independently decodable. Slightly less
             efficient; MANDATORY for adaptive streaming,
             because you must be able to splice segments.

     OPEN    B-frames at the start of a GOP may reference the
             previous GOP's last P-frame. A little more
             efficient, and it breaks clean splicing.

   Streaming: ALWAYS closed, with the GOP length equal to the
   segment length.

/* GOP LENGTH is a three-way trade:

     SHORT (1-2 s)     fast seeking, quick channel change,
                       fast recovery from packet loss, and
                       cheap ABR switching.
                       COSTS BITS - I-frames are expensive.

     LONG (5-10 s)     better compression, 10-20% smaller at
                       the same quality.
                       Slow seek, slow start, and a lost
                       packet corrupts until the next
                       keyframe.

   TYPICAL CHOICES
     streaming VOD        2 s, matching the segment
     live streaming       1-2 s (latency)
     broadcast            0.5-1 s (channel change)
     videoconference      infinite, with periodic refresh
                          instead (see below)
     archival             10 s+, or all-intra for editing

/* SCENE-CUT DETECTION: a good encoder inserts a keyframe at a
   cut anyway, because prediction across a cut is useless.
   Forcing a fixed interval AND allowing scene cuts gives you
   both - but for segmented streaming you must disable scene
   cuts so segment boundaries stay aligned:
     -x264-params "keyint=48:min-keyint=48:scenecut=0"       */
```

Reference management

```
H.264 onward keep a DECODED PICTURE BUFFER of several
frames, and each block chooses which one to predict from.

  DPB, up to 16 frames:
    [ I0 ] [ P3 ] [ P6 ] [ P9 ] ...

  block A -> reference index 0 (the most recent)
  block B -> reference index 2 (three frames back)

WHY MULTIPLE REFERENCES HELP
  * periodic motion - a walking figure, a rotating fan -
    matches a frame several back better than the last one
  * occlusion - something briefly hidden reappears
  * noise - an older, cleaner frame may match better
  * a flash or a dropped frame is skipped over

Typical gain: 5-10% for 4 references over 1. Diminishing
returns beyond that, and the DPB costs MEMORY -
16 references at 4K 10-bit is about 400 MB, which is why
levels cap it.

HIERARCHICAL B-FRAMES / PYRAMID - the modern structure:

  display:  I0  b1  B2  b3  P4
  decode:   I0  P4  B2  b1  b3

  temporal layer 0:  I0 ........... P4     never discarded
  temporal layer 1:        B2             references L0
  temporal layer 2:    b1     b3          references L0,L1
                       ^^     ^^
                 lowercase b = NOT used as a reference

THIS GIVES YOU TEMPORAL SCALABILITY FOR FREE: drop layer 2
and you have a valid 15 fps stream. Drop layer 1 too and
you have 7.5 fps. Used by:
  * videoconferencing, to shed frame rate under congestion
    (SVC), without re-encoding
  * streaming, for trick modes
  * and it compresses BETTER than a flat IBBP structure,
    because the layer-0 frames are coded at higher quality
    and everything else predicts from them.

LONG-TERM REFERENCES: pin a frame in the DPB indefinitely -
a clean background, or the last known-good frame. WebRTC
uses these to recover from loss without a full keyframe.
```

Low latency, and intra refresh

```
/* Videoconferencing cannot afford B-frames (reordering
   latency) or periodic I-frames (a bitrate spike that blows
   the buffer and causes a stall).

   INTRA REFRESH solves the second: instead of one huge
   I-frame, refresh a COLUMN of blocks each frame. After N
   frames the whole picture has been refreshed.             */

     frame 0:  [I][ ][ ][ ][ ]     I = intra column
     frame 1:  [ ][I][ ][ ][ ]
     frame 2:  [ ][ ][I][ ][ ]
     frame 3:  [ ][ ][ ][I][ ]
     frame 4:  [ ][ ][ ][ ][I]     fully refreshed

   Plus a constraint: blocks may not predict from the
   not-yet-refreshed region, or the refresh is undone.

   RESULT: every frame is roughly the same size - no spikes,
   no buffer stalls - and a decoder joining at any point has
   a correct picture after N frames.

$ ffmpeg ... -c:v libx264 -tune zerolatency \
    -x264-params "intra-refresh=1:bframes=0:sliced-threads=1"

/* -tune zerolatency sets, among other things:
     bframes=0            no reorder delay
     sync-lookahead=0     no lookahead buffering
     sliced-threads=1     threads work within a frame, not
                          across frames - frame-level
                          threading adds N frames of latency
     rc-lookahead=0

   THE COST: roughly 10-20% worse compression. That is the
   price of the latency, and it is not negotiable.        */
```

FRAME-THREADING IS A HIDDEN SOURCE OF LATENCY

By default `x264` and `x265` use frame-level threading: thread N works on frame N while thread N+1 works on frame N+1. With 8 threads that is up to 8 frames of encoder delay — a third of a second at 25 fps — before a single byte emerges. Any real-time use needs `sliced-threads` or an explicit thread limit. This surprises people who have already disabled B-frames and cannot work out where the latency is coming from.

Inspecting structure

```
# Frame types and sizes in decode order:
$ ffprobe -select_streams v -show_entries \
    frame=pict_type,key_frame,pkt_pts_time,pkt_dts_time,pkt_size \
    -of csv=p=0 input.mp4 | head
1,I,0.000000,-0.083333,142883      # note DTS < PTS: B-frames
0,P,0.133333,-0.050000,8214        # present
0,B,0.033333,-0.016667,3102
0,B,0.066667,0.016667,2894

# Just the keyframe positions - what you can seek to:
$ ffprobe -select_streams v -skip_frame nokey \
    -show_entries frame=pkt_pts_time -of csv=p=0 input.mp4
0.000000
2.000000
4.000000          # a clean 2-second GOP

# Are they real IDRs? Look at the NAL types:
$ ffmpeg -i input.mp4 -c copy -bsf:v trace_headers -f null - 2>&1 \
    | grep -E 'nal_unit_type' | sort | uniq -c
   1500 nal_unit_type = 1     # non-IDR slice
     50 nal_unit_type = 5     # IDR slice          <-- these
     51 nal_unit_type = 7     # SPS
     51 nal_unit_type = 8     # PPS

# NOTE the SPS/PPS repeated before every IDR - that is
# repeat-headers, and without it a player that tunes in
# mid-stream has no parameter sets and cannot start.

# GOP structure at a glance:
$ ffprobe -select_streams v -show_entries frame=pict_type \
    -of csv=p=0 input.mp4 | head -30 | tr '\n' ' '
I B B P B B P B B P B B P I B B P ...
```

How it shows up

Symptom	Cause
Seeking lands on a broken frame	I-frames but not IDRs — use a closed GOP
First seconds of a stream are garbage	SPS/PPS not repeated before each keyframe
Frames displayed out of order	Reorder buffer too small, or PTS/DTS mishandled
Video and audio drift apart	PTS used where DTS was needed, or vice versa (chapter 15)
133 ms of unexplained latency	B-frames — disable them for real-time
Latency persists after disabling B-frames	Frame-level threading; use `sliced-threads`
Bitrate spikes every GOP, buffer stalls	Periodic I-frames; use intra refresh
ABR switching produces a glitch	GOP boundaries not aligned across renditions, or an open GOP
Packet loss corrupts several seconds	Long GOP — nothing recovers until the next keyframe
4K decode runs out of memory	DPB size — 16 references at 4K is hundreds of megabytes

Check yourself

✓ Distinguish I, P and B frames by what they reference and their typical relative sizes.

- ✓ Explain why an I-frame is not necessarily a seek point, and what is.
- ✓ Write a display order and its corresponding decode order for an IBBP structure.
- ✓ Explain why PTS and DTS differ and where DTS can be negative.
- ✓ Give two reasons B-frames compress so well.
- ✓ Explain closed versus open GOP and why streaming requires closed.
- ✓ State the three-way trade in GOP length with a typical value for two use cases.
- ✓ Explain hierarchical B-frames and the temporal scalability they provide free.
- ✓ Describe intra refresh and the problem it solves.
- ✓ Name two sources of encoder latency beyond B-frames.

Intra prediction, inter prediction and partitioning

Everything a codec codes is a *prediction error*. The tools that generate the prediction — directional extrapolation from neighbours, motion vectors into other frames, and the block splitting that chooses where each applies — are where most of the gain from H.264 to AV1 actually came from.

Intra prediction: guessing from neighbours

```
JPEG codes each 8x8 block independently. That wastes the
fact that the pixels immediately above and to the left are
ALREADY DECODED and are excellent predictors.

  A B C D E F G H     <- reconstructed row above
I . . . .
J . . . .             the 4x4 block to predict
K . . . .
L . . . .
^
reconstructed column left

H.264's 4x4 luma modes, all built from those 13 pixels:

  0 VERTICAL      copy A B C D straight down
  1 HORIZONTAL    copy I J K L across
  2 DC            fill with the average of all of them
  3 DIAGONAL DOWN-LEFT
  4 DIAGONAL DOWN-RIGHT
  5 VERTICAL-RIGHT
  6 HORIZONTAL-DOWN
  7 VERTICAL-LEFT
  8 HORIZONTAL-UP

Nine modes for 4x4, four for 16x16.
HEVC:  35 modes - DC, PLANAR, and 33 angles.
AV1:   56 directional modes plus PAETH, SMOOTH, and
       intra block copy.

PLANAR / SMOOTH deserves a mention: it interpolates a
gradient across the block rather than copying a direction.
Skies and soft shading are extremely common and a
directional copy handles them badly, so planar is one of
the most-selected modes in real content.

THE ENCODER TRIES THEM ALL and picks by rate-distortion
(chapter 6): the mode index costs a few bits, and the
residual costs what it costs.

WHY IT MATTERS: on a clean edge, the right directional mode
makes the residual almost zero. This is the single biggest
reason an H.264 I-frame is roughly HALF the size of an
equivalent-quality JPEG.
```

> **PREDICTION USES *RECONSTRUCTED* NEIGHBOURS, NOT ORIGINAL ONES**
> The encoder must predict from the same pixels the decoder will have — which are the quantised, reconstructed ones, not the source. So every encoder contains a complete decoder inside it, reconstructing each block before coding the next. Get that wrong and encoder and decoder diverge, which is **drift**: an error that compounds through every subsequent prediction until the picture visibly falls apart.

Partitioning: choosing the block size

```
One size cannot fit both a flat wall and a face.

  LARGE blocks   fewer vectors, fewer mode decisions,
                 less overhead. Good on flat or uniformly
                 moving regions.
  SMALL blocks   follow detail and object boundaries.
                 Good at edges. Costs overhead per block.

H.264   macroblock 16x16, split to 16x8, 8x16, 8x8, and
        8x8 further to 8x4, 4x8, 4x4.

HEVC    QUADTREE. A 64x64 Coding Tree Unit recursively
        split into four, down to 8x8:

          +---------------+       +-------+-------+
          |               |       |       |   |   |
          |               |  ->   |       +---+---+
          |               |       |       |   |   |
          +---------------+       +---+---+-------+
                                  | | |   |       |
                                  +-+-+   |       |
                                  | | |   |       |
                                  +---+---+-------+

        Flat sky -> one 64x64 block, a handful of bits.
        Detailed foliage -> many 8x8 blocks.
        This alone is worth a large part of HEVC's gain
        over H.264, and it is why HEVC helps most at high
        resolutions - a 4K frame has far more area that is
        locally flat.

AV1     quadtree PLUS 1:2, 2:1 and 1:4, 4:1 rectangular
        splits, 128x128 down to 4x4. Ten partition types
        per node.

VVC     quadtree + binary + ternary splits, in any
        combination - the most flexible, and the most
        expensive to search.

THE COST IS ENCODER TIME. Each additional partition type
multiplies the search space, and the encoder must
rate-distortion test them all. This is why HEVC encoding is
roughly 5-10x slower than H.264 and AV1 slower again, for
the same picture.
```

Inter prediction, in detail

```
/* The modes an encoder chooses between for each block. */

  SKIP / MERGE
      Take the motion vector from a neighbour, code NO
      residual and NO vector - just a flag.
      On static content this is most of the frame, and it is
      why a still shot costs almost nothing.
      HEVC's MERGE builds a candidate list from spatial and
      temporal neighbours; you code only the INDEX.

  INTER with MVD
      A merge candidate as the predictor, plus a coded motion
      vector DIFFERENCE. Coherent motion -> tiny differences.

  BI-PREDICTION
      Two references, averaged (chapter 9).

  INTRA, inside a P or B frame
      Sometimes prediction from a neighbour beats prediction
      from another frame - new content entering the shot,
      an occlusion boundary, a scene with a lot of noise.
      A "P-frame" is full of intra blocks at a scene cut.

/* THE CANDIDATE LIST IS THE INTERESTING PART. Coding a full
   motion vector costs 10-20 bits. Coding "use candidate 1"
   costs 1-2. So codecs spend real design effort on making the
   candidate list contain the right answer:

     spatial neighbours    left, above, above-right,
                           below-left, above-left
     temporal              the co-located block in a
                           previously coded frame
     history-based (AV1/VVC)  a rolling table of recently
                           used vectors anywhere in the frame
     pairwise average      the mean of two other candidates

   When the list is good, most blocks cost a few bits total.
   That is where modern codecs beat older ones far more than
   in the transform.                                       */
```

The tools that came later

Tool	What it handles	First in
Intra block copy	Predict from elsewhere in the *same* frame — repeated UI elements, text, game HUDs	HEVC SCC, AV1
Palette mode	Blocks with few distinct colours — screen content, graphics	HEVC SCC, AV1
Affine motion	Zoom and rotation, via a 4- or 6-parameter model per block	AV1, VVC
Compound / wedge prediction	Two predictions blended along a diagonal edge — an object boundary inside one block	AV1
OBMC	Blending neighbours' predictions at block edges, reducing blocking at source	AV1
CfL — chroma from luma	Predict chroma from the reconstructed luma of the same block	AV1

Tool	What it handles	First in
Multiple transform sizes and types	DCT, DST and identity transforms chosen per block — identity is right for sharp screen content	HEVC, AV1

```
# Watch the encoder's decisions. x264 will tell you what it
# chose, which is the fastest way to understand a bitrate.

$ x264 --crf 23 --psnr --verbose input.y4m -o out.264 2>&1 | tail -20
x264 [info]: frame I:50    Avg QP:20.11  size: 42883
x264 [info]: frame P:1200  Avg QP:23.44  size:  8214
x264 [info]: frame B:2250  Avg QP:25.87  size:  3102
x264 [info]: consecutive B-frames: 12.5%  8.2% 30.1% 49.2%
x264 [info]: mb I  I16..4: 22.1% 61.3% 16.6%
x264 [info]: mb P  I16..4:  2.1%  4.8%  0.9%  P16..4: 45.2% 18.1% 6.2%  skip:22.7%
x264 [info]: mb B  I16..4:  0.3%  0.6%  0.1%  B16..8: 12.1%  3.2%  direct: 8.9%  skip:74.8%
                                                                          ^^^^^^^^^^

# 74.8% of B-frame macroblocks are SKIPPED - copied with no
# residual and no vector. THAT is where the compression is.
# If that number is low, the content is noisy or the motion
# search is failing (chapter 9).

# Intra modes chosen in an I-frame:
$ x264 --crf 23 --verbose ... 2>&1 | grep 'i16 v,h,dc'
x264 [info]: i16 v,h,dc,p: 31% 24% 27% 18%
x264 [info]: i8 v,h,dc,ddl,ddr,vr,hd,vl,hu: 22% 19% 13% 6% 6% 8% 7% 10% 9%
# A healthy spread. If almost everything is DC, the content is
# flat; if it is all one direction, you may be looking at
# something synthetic.
```

> **MORE TOOLS MEANS SLOWER, NOT AUTOMATICALLY BETTER**
>
> AV1 has roughly ten times H.264's decision space. An encoder that searches it badly — a fast preset, or an immature implementation — can produce *worse* output than a well-tuned H.264 encoder at the same speed. The format sets the ceiling; the encoder's search decides how close you get. This is why "AV1 is 30% better" is only true at slow presets, and why `x264 --preset veryslow` beats `SVT-AV1 --preset 12` at equal encoding time.

How it shows up

Symptom	Cause
Skip percentage very low on static content	Noise or grain defeating prediction (chapter 9)
I-frames much larger than expected	Intra prediction failing — noisy or highly detailed source
HEVC barely beats H.264 on your content	Low resolution — the quadtree gains most where large flat areas exist
AV1 output worse than H.264 at the same encode time	Preset too fast for the search space
Screen content compresses badly	Needs intra block copy, palette mode or an identity transform
Picture degrades progressively through a GOP	Drift — encoder predicting from source rather than reconstructed pixels
Visible seams along object edges	Block partitioning too coarse; OBMC or wedge prediction would help
Slow zoom is expensive	No affine or warped motion model
Encoding time explodes on a newer codec	Partition and mode search space, not the transform

Check yourself

- ✓ Explain what intra prediction predicts from, and why planar mode matters.
- ✓ Say why an H.264 I-frame is smaller than an equivalent JPEG.
- ✓ Explain why the encoder must predict from reconstructed pixels, and what drift is.
- ✓ Describe the HEVC quadtree and say why it helps most at high resolution.
- ✓ Name four inter modes and say which dominates on static content.
- ✓ Explain why the merge candidate list is worth so much design effort.
- ✓ Say why intra blocks appear inside P-frames.
- ✓ Name four tools added after H.264 and what each handles.
- ✓ Read an x264 statistics dump and say what the skip percentage tells you.
- ✓ Explain why a newer codec can produce worse output at the same encoding time.

In-loop filters and post-processing

Block-based coding produces block-shaped artefacts. Filtering them away is worth 5–10% of bitrate — but only if the filter runs *inside* the coding loop, so that the cleaned frame is what future frames predict from. That word "in-loop" is the whole idea.

In-loop versus post-processing

```
POST-PROCESSING - filter on the way to the screen

  decode -> reconstruct -> [reference buffer]
                       \-> FILTER -> display

  The reference is UNFILTERED. Every future frame predicts
  from blocky data, so the artefacts propagate and the
  filter has to remove them again, every frame.
  It is also OPTIONAL, so two decoders show different
  pictures. MPEG-2 worked this way.

IN-LOOP - filter before storing as a reference

  decode -> reconstruct -> FILTER -> [reference buffer]
                                  \-> display

  The reference is CLEAN. Prediction from it is better, so
  residuals are smaller, so you spend fewer bits - 5-10%
  at the same quality.
  And it is NORMATIVE: every decoder must apply exactly
  the same filter, or drift (chapter 11).

THIS IS WHY IN-LOOP FILTERING IS NOT COSMETIC. It changes
what the encoder can predict from, which changes the
bitrate. Turning deblocking off does not just look worse -
it costs bits.
```

The deblocking filter

```
/* Blocking happens because each block is quantised
   independently, so two neighbours' DC levels can differ by a
   step even though the original was smooth. The filter
   smooths ACROSS block edges - and only where the
   discontinuity looks like an artefact rather than real
   content.                                                  */

  FOR EACH EDGE, decide a BOUNDARY STRENGTH (bS):

    bS = 4   one side is intra-coded AND the edge is a
             macroblock boundary        -> strongest filter
    bS = 3   one side is intra-coded
    bS = 2   either side has non-zero transform coefficients
    bS = 1   different reference frames, or motion vectors
             differing by >= 1 pixel
    bS = 0   nothing differs                -> DO NOT FILTER

  THEN a content test, and this is the clever part:

    filter only if
        |p0 - q0| < alpha  AND
        |p1 - p0| < beta   AND
        |q1 - q0| < beta

    where p are pixels left of the edge and q right of it,
    and alpha/beta scale with QP.

  THE LOGIC: a SMALL step across the edge with FLAT sides is
  almost certainly an artefact - smooth it. A LARGE step is
  almost certainly a real edge in the picture - leave it
  alone. That single heuristic is why deblocking does not
  turn everything to mush.

  AND alpha/beta SCALE WITH QP: at low QP the quantisation
  error is small, so only tiny steps get filtered. At high QP
  the filter works much harder. The filter strength follows
  the artefact severity automatically.

/* TUNING, in x264: */
    --deblock -1:-1     sharper, more blocking. Good for
                        high-bitrate, detailed content.
    --deblock 0:0       the default.
    --deblock 1:1       softer, less blocking. Good for
                        low-bitrate or animation.
/* The two numbers are alpha and beta offsets. Film grain and
   detailed live action usually want negative; flat animation
   and low bitrates want positive.                           */
```

> **DEBLOCKING IS A LARGE FRACTION OF DECODE TIME**
>
> It touches every pixel, several times, with data-dependent branches — typically 15–30% of a software decoder's runtime, comparable to motion compensation. It is always hand-written SIMD, and it is one of the first things a hardware decoder implements as a fixed-function block. When profiling a decoder, `ff_h264_filter_mb` or its equivalent near the top of the profile is normal, not a bug.

The filters that came after

Filter	Fixes	In
Deblocking	Block-edge discontinuities	H.264, HEVC, AV1, VVC
SAO — sample adaptive offset	Ringing and banding. Adds a small per-category offset to samples, with the offsets sent in the bitstream	HEVC
CDEF — constrained directional enhancement	Ringing, while *preserving* edges — it detects the dominant direction in each block and filters along it	AV1
Loop restoration	Wiener and self-guided filters that restore detail lost to quantisation, with parameters chosen per unit by the encoder	AV1
ALF — adaptive loop filter	A Wiener filter whose coefficients are computed per frame by the encoder to minimise error against the source	VVC
LMCS — luma mapping with chroma scaling	Redistributes code values to suit the content, particularly HDR	VVC
Film grain synthesis	Not a filter — grain is *removed* before encoding and *re-generated* from parameters at playback	AV1, H.264 SEI, VVC

```
/* SAO, because it shows the general shape of the newer
   filters: the ENCODER measures the error and SENDS a
   correction.                                          */

  BAND OFFSET
    Split the sample range into 32 bands. For four chosen
    bands, send an offset. Applied to every sample in those
    bands.
    -> fixes BANDING in gradients, because it can nudge one
       band's level without touching the others.

  EDGE OFFSET
    Classify each sample against two neighbours in one of four
    directions (0deg, 90deg, 135deg, 45deg):

       category 0:  local minimum      -> add offset[0]
       category 1:  edge, falling      -> add offset[1]
       category 2:  edge, rising       -> add offset[2]
       category 3:  local maximum      -> add offset[3]

    -> fixes RINGING, by pulling overshoots back toward their
       neighbours.

  The offsets are chosen by the ENCODER to minimise error
  against the ORIGINAL frame - so unlike deblocking, which is
  a fixed heuristic, SAO is a measured correction. That is
  why it works on artefacts deblocking cannot see.

/* CDEF in AV1 goes further: it estimates the DOMINANT
   DIRECTION of each 8x8 block, then applies a nonlinear
   filter ALONG that direction (which preserves the edge) and
   a weaker one across it (which removes the ringing). The
   direction search is why it costs more than SAO and why it
   looks better on detailed content.                    */
```

Post-processing, outside the loop

```
# Filters the player or the display applies. NOT normative -
# they change the picture, not the bitstream, and every
# device does something different.

  DEINTERLACING     for legacy interlaced sources. yadif,
                    bwdif, or a motion-compensated filter.
                    Getting it wrong gives combing on motion.
  DEBANDING         adds dither or gradient reconstruction.
                    gradfun, deband.
  UPSCALING         Lanczos, or a learned model (DLSS,
                    FSR, NVIDIA VSR, Apple's neural scaler).
  SHARPENING        popular, and it amplifies compression
                    artefacts as enthusiastically as detail.
  FRAME INTERPOLATION  "motion smoothing" on TVs. Produces the
                    soap-opera effect, and 60-120 ms of
                    latency - which is why every TV has a
                    "game mode" that turns it off.
  TONE MAPPING      HDR to SDR (chapter 5).

# In practice:
$ ffplay -vf "bwdif=mode=send_field,gradfun=1.2:8" input.mkv

# THE ORDER MATTERS, and the general rule is:
#   deinterlace -> denoise/deband -> scale -> sharpen
# Scaling interlaced content before deinterlacing destroys the
# field structure and cannot be undone. Sharpening before
# scaling amplifies what the scaler then smears.

# AND THE HONEST WARNING: post-processing cannot recover
# information. A deband filter is guessing what the gradient
# should have been; an upscaler is inventing detail. Both can
# look better and neither is more correct. If you control the
# encode, fix it there - more bits, higher bit depth, better
# rate control - because that is the only place the
# information still exists.
```

> **DO NOT SHARPEN BEFORE MEASURING QUALITY**
>
> Sharpening reliably raises perceived detail and reliably *lowers* PSNR and SSIM while often raising VMAF — which is why "VMAF hacking" with a sharpening filter is a known way to produce encoders that score well and look worse (chapter 6). If you are comparing encoders, disable every post-process on both sides, or you are measuring the filter.

How it shows up

Symptom	Cause
Visible block edges at moderate bitrate	Deblocking disabled or offsets too negative
Picture looks soft and smeared	Deblocking too strong — try negative offsets
Bitrate rose after disabling deblocking	Expected — references are dirtier, so residuals grow
Two decoders show different pictures	A post-process filter, not an in-loop one — in-loop is normative
Ringing around text that deblocking does not fix	Needs SAO or CDEF; deblocking only sees block edges
Banding in gradients despite enough bits	SAO band offset disabled, or 8-bit throughout

Symptom	Cause
Decoder profile dominated by the filter	Normal — deblocking is 15–30% of decode
Combing artefacts on motion	Interlaced source not deinterlaced, or the wrong field order
Grain looks wrong or absent on AV1	Film grain synthesis not applied by the decoder
TV adds noticeable input lag	Frame interpolation; use game mode

Check yourself

- ✓ Explain the difference between in-loop and post-processing filtering, and why it affects bitrate.
- ✓ Say why in-loop filters must be normative.
- ✓ Describe how boundary strength is decided and what `bS = 0` means.
- ✓ Explain the content test that stops deblocking smoothing real edges.
- ✓ Say why the filter thresholds scale with QP.
- ✓ Explain what SAO band offset and edge offset each fix.
- ✓ Say what makes SAO different in kind from deblocking.
- ✓ Explain what CDEF adds over SAO.
- ✓ Explain AV1 film grain synthesis and why it saves bits.
- ✓ Give the correct order for a post-processing chain and one ordering mistake.

Rate control and buffer models

Deciding the quantisation parameter for every frame, under a constraint you cannot violate. It is the part of encoding that most affects what viewers actually see, and the part most often configured by copying a command line without understanding which mode it selected.

The modes, and which one you want

Mode	You specify	Use for
CQP	A fixed QP	Testing and research only. Bitrate varies wildly with content
CRF	A quality target	**The default for anything stored.** Constant perceptual quality, variable bitrate, one pass
ABR (1-pass)	An average bitrate	Rarely the right answer — it must guess the future, and it guesses badly
2-pass VBR	A target bitrate or file size	When the size is a hard requirement. Pass 1 measures complexity, pass 2 spends accordingly
CBR	A constant bitrate	Broadcast, and links with a fixed capacity. Wastes bits on easy content by padding
Capped CRF	CRF *plus* a maximum bitrate	**The right answer for streaming.** Quality-driven, but never exceeds what the client can pull

```
# CRF - the one to reach for.
$ ffmpeg -i in.mov -c:v libx264 -crf 23 -preset slow out.mp4

#   x264 CRF 18   visually lossless-ish
#         23      the default; good
#         28      noticeably compressed
#   x265 and AV1 use a similar scale but the numbers are NOT
#   comparable - x265 CRF 28 is roughly x264 CRF 23.
#   +6 CRF is about half the bitrate. -6 is about double.

# CAPPED CRF - quality-driven with a ceiling. This is what
# streaming services actually use:
$ ffmpeg -i in.mov -c:v libx264 -crf 23 \
    -maxrate 6M -bufsize 12M -preset slow out.mp4
#   crf      the quality you want
#   maxrate  the ceiling you must not exceed
#   bufsize  how much short-term variation is allowed
# Easy scenes come out well under 6M; hard scenes are capped.

# 2-PASS, when the SIZE is the requirement:
$ ffmpeg -i in.mov -c:v libx264 -b:v 5M -pass 1 -an -f null /dev/null
$ ffmpeg -i in.mov -c:v libx264 -b:v 5M -pass 2 out.mp4
# Pass 1 writes a stats file recording each frame's
# complexity. Pass 2 distributes the bit budget across the
# whole file, giving hard scenes more and easy ones less.

# CBR - genuinely constant, with padding:
$ ffmpeg -i in.mov -c:v libx264 -b:v 5M -minrate 5M -maxrate 5M \
    -bufsize 5M -x264-params "nal-hrd=cbr" out.ts

# THE MISTAKE PEOPLE MAKE: setting -b:v AND -crf together.
# CRF wins and the bitrate is ignored, so the file comes out
# a completely different size than intended and nobody can
# see why.
```

> **CRF IS NOT "CONSTANT QUALITY", IT IS CONSTANT *EFFORT***
>
> CRF adjusts QP per frame using a complexity estimate, deliberately spending fewer bits on frames where the eye will not notice — fast motion, dark scenes, high-detail texture. That is *adaptive quantisation*, and it is why CRF looks better than fixed QP at the same average bitrate. It also means the measured PSNR varies frame to frame by design, which surprises people benchmarking it.

The buffer model

```
A decoder receives bits at some rate and consumes a whole
frame instantly at each display time. If the buffer runs
dry, playback stalls. The HRD (Hypothetical Reference
Decoder) is the model that guarantees it will not.

  buffer
  fullness
     |     /\      /\
     |    /  \    /  \        fills at the bitrate,
full |---/----\--/----\-----  drains by one frame's bits
     |  /      \/      \      at each frame time
     | /                \
empty|/------------------\--  <-- UNDERFLOW = a stall
     +----------------------- time

THE THREE PARAMETERS

  bitrate    the fill rate
  bufsize    the buffer capacity, in bits
  initial    how full before playback starts - this is
             your startup delay

THE RULE: bufsize / bitrate = the seconds of variation
allowed.

  bufsize = bitrate      1 second of slack. Tight; forces
                         near-constant frame sizes; costs
                         quality on hard scenes.
  bufsize = 2 x bitrate  the usual streaming choice.
  bufsize = 5 x bitrate  loose. Better quality, but the
                         client needs a bigger buffer and
                         a longer startup delay.

WHY IT MATTERS
  * a live stream that overflows the client buffer causes
    REBUFFERING - the visible failure viewers actually
    complain about
  * hardware decoders implement the HRD literally, and a
    non-conformant stream can be REJECTED outright even
    though software players accept it
  * broadcast multiplexers allocate a fixed slot; exceeding
    it corrupts the whole multiplex, not just your channel

AND THE FRAME-SIZE CONSEQUENCE: an I-frame is 10-20x a
P-frame (chapter 10). With a tight buffer the encoder must
either shrink the I-frame - hurting the whole GOP that
predicts from it - or spread the cost over the following
frames. Both look worse than a bigger buffer.
```

Adaptive quantisation and lookahead

```
/* WITHIN a frame, not all blocks deserve the same QP. */

  PSYCHOVISUAL MASKING: the eye cannot see quantisation error
  in a busy, high-contrast region, but sees it immediately in
  a smooth one. So:

     flat areas    -> LOWER QP (finer quantisation)
                      because banding and blocking would show
     detailed areas -> HIGHER QP
                      because the detail masks the error

  This is backwards from what "spend bits where the detail is"
  suggests, and it is measurably better.

    --aq-mode 1    variance-based AQ
    --aq-mode 2    auto-variance
    --aq-mode 3    auto-variance with a dark-scene bias -
                   x264's default, because dark areas show
                   banding badly
    --aq-strength  how aggressive, default 1.0

/* LOOKAHEAD: the encoder buffers N frames before deciding. */

    --rc-lookahead 40      x264's default

  WITH LOOKAHEAD THE ENCODER CAN:
    * see a scene cut coming and not waste bits on the frames
      about to be discarded
    * identify frames that many others will predict from and
      spend MORE on them - MB-tree / macroblock tree, which
      propagates a "how much does this block matter to the
      future" weight backwards
    * distribute the bit budget over an upcoming hard scene
      instead of reacting to it late

  MB-TREE IS WORTH 5-15% ON ITS OWN and is why x264 at
  --preset slow beats a naive encoder at the same bitrate.

  THE COST: latency. 40 frames of lookahead is 1.6 seconds at
  25 fps. Real-time encoding sets --rc-lookahead 0 and
  accepts the loss (chapter 10).                            */
```

QUALITY PUMPING AND HOW TO RECOGNISE IT

If quality visibly oscillates — sharp, then soft, then sharp again on a two-second cycle — rate control is overreacting. Usual causes: `bufsize` too small for the content, ABR mode trying to hit an average without lookahead, or a GOP whose I-frame consumes so much of the budget that the following frames are starved. The fix is almost always a larger `bufsize` or switching to capped CRF; it is very rarely a higher bitrate.

Rate control for adaptive streaming

```
# A streaming ladder is several renditions of the same source,
# and the client switches between them. Constraints:

  1. GOP-ALIGNED. Every rendition must have a keyframe at the
     same timestamps, or switching produces a glitch.
       -x264-params "keyint=48:min-keyint=48:scenecut=0"
     with 48 = 2 seconds at 24 fps. Scene cuts MUST be
     disabled or the alignment breaks (chapter 10).

  2. CAPPED CRF per rung, not fixed bitrate. An easy scene at
     1080p may only need 2 Mbit/s; forcing 6 wastes bandwidth
     and gains nothing.

  3. THE LADDER ITSELF should be per-title. Netflix's
     per-title encoding measures each title's complexity and
     builds a custom ladder - an animated series needs far
     less bitrate at 1080p than a grainy film, and a fixed
     ladder over-serves one and under-serves the other.

# A reasonable fixed ladder, for reference:
#   1920x1080  crf 21  maxrate  6000k  bufsize 12000k
#   1280x720   crf 21  maxrate  3000k  bufsize  6000k
#    854x480   crf 22  maxrate  1500k  bufsize  3000k
#    640x360   crf 23  maxrate   800k  bufsize  1600k
#    426x240   crf 24  maxrate   400k  bufsize   800k

# Segment and package:
$ ffmpeg -i in.mp4 \
  -c:v libx264 -crf 21 -maxrate 6000k -bufsize 12000k \
  -x264-params "keyint=48:min-keyint=48:scenecut=0" \
  -f hls -hls_time 2 -hls_playlist_type vod \
  -hls_segment_filename "1080p_%03d.ts" 1080p.m3u8

# VERIFY THE ALIGNMENT - this is the check people skip:
$ for f in 1080p 720p 480p; do
    echo -n "$f: "
    ffprobe -select_streams v -skip_frame nokey \
      -show_entries frame=pkt_pts_time -of csv=p=0 $f.m3u8 \
      | head -5 | tr '\n' ' '
    echo
  done
1080p: 0 2 4 6 8
720p:  0 2 4 6 8
480p:  0 2 4 6 8        # aligned. If these differ, switching
                        # will glitch.
```

How it shows up

Symptom	Cause
File size nothing like the bitrate you set	`-crf` and `-b:v` both given; CRF won
Quality visibly pulses	`bufsize` too small, or ABR without lookahead
Playback rebuffers on a good connection	Peak bitrate exceeds what the buffer model allows — cap it
Hardware decoder rejects a valid-looking stream	HRD non-conformance
ABR switching glitches	GOPs not aligned across renditions, or scene cuts left on

Symptom	Cause
Dark scenes band badly	Adaptive quantisation off, or `aq-mode` without the dark bias
First frames after a cut look terrible	No lookahead, so the encoder reacted late
Real-time encoding has 1.6 s of latency	`rc-lookahead` — set it to 0
Two-pass produced a smaller file than requested	The content was easier than the target; that is correct behaviour
Animation over-served, film under-served by one ladder	Fixed ladder rather than per-title

Check yourself

- ✓ Name the six rate-control modes and say which to use for stored video, for streaming and for a fixed file size.
- ✓ Explain what CRF actually holds constant.
- ✓ Say what happens if you specify both a bitrate and a CRF.
- ✓ Draw the HRD buffer model and say what underflow means to a viewer.
- ✓ Explain what `bufsize / bitrate` represents and give a typical value.
- ✓ Explain why a tight buffer hurts quality across a whole GOP.
- ✓ Explain adaptive quantisation and why flat areas get *lower* QP.
- ✓ Say what lookahead enables, and name the technique worth 5–15%.
- ✓ Give three constraints on rate control for an adaptive streaming ladder.
- ✓ Verify GOP alignment across renditions and say what a mismatch causes.

The codec landscape: H.264 to AV1 and beyond

Choosing a codec is rarely a technical decision. Compression efficiency is the easy part; what actually decides it is hardware decode support, patent licensing, and how much CPU you can afford to spend on encoding. This chapter is the map.

The codecs that matter

Codec	Year	Bitrate vs H.264	HW decode	Licensing
MPEG-2	1995	+150%	Everywhere	Expired
H.264 / AVC	2003	baseline	**Universal**	MPEG LA pool; most patents expiring
VP9	2013	−35%	Wide (2015+)	Royalty-free (Google)
H.265 / HEVC	2013	−40%	Wide (2015+)	**Three pools plus unpooled holders.** The reason it failed on the web
AV1	2018	−50%	Growing (2020+)	Royalty-free (AOMedia)
H.266 / VVC	2020	−65%	Rare	Pools forming; same uncertainty as HEVC
H.267 / ECM	~2028	−80% (target)	None	Unknown

THOSE PERCENTAGES ARE MARKETING UNTIL YOU NAME THE CONDITIONS

"AV1 is 50% better than H.264" means: at a slow preset, on 4K content, measured by a specific metric, at a specific quality point. At fast presets the gap shrinks dramatically; at 480p it is far smaller; and `x264 --preset veryslow` beats `SVT-AV1 --preset 10` at equal *encoding time*. Always ask which encoder, which preset, which resolution, which metric — the format sets a ceiling, the encoder decides how close you get (chapter 11).

Why HEVC lost the web

```
HEVC is technically excellent and commercially poisoned.

H.264's licensing:  ONE pool (MPEG LA), a published rate
                    card, a cap on annual fees, and free
                    for internet video that is free to
                    end users. Everyone knew the cost.

HEVC's licensing:   MPEG LA -> then HEVC Advance appeared
                    -> then Velos Media -> plus companies
                    holding patents outside every pool.
                    Different terms, some demanding
                    CONTENT royalties (a fee per stream,
                    not per device), and no way to know
                    your total exposure.

THE RESULT
  * no browser shipped HEVC for years; Safari eventually
    did because Apple pays anyway
  * Google, Mozilla, Amazon, Netflix, Cisco, Intel, ARM
    and others formed AOMedia and built AV1 specifically
    to escape this
  * HEVC still won in one place - BROADCAST AND PHYSICAL
    MEDIA - where device makers already pay pool fees and
    hardware support was mandated

THE LESSON, and it repeats with VVC: a codec's success is
decided by whether an implementer can determine the cost
in advance. VVC is technically ahead of AV1 and is
repeating HEVC's licensing structure.

AV1's counter-position: AOMedia members grant a royalty-free
licence, and the patent defence is collective. It is not a
guarantee of zero risk - Sisvel formed an AV1 pool in 2019 -
but the practical outcome so far is that AV1 ships.
```

Choosing, in practice

```
/* THE DECISION TREE THAT ACTUALLY APPLIES */

  Must it play EVERYWHERE, including 2012 hardware?
      -> H.264 High profile, 4:2:0 8-bit. No exceptions.
         Still ~80% of internet video for this reason alone.

  Web video, modern browsers, you control the encode?
      -> AV1 for the top rungs, H.264 fallback for the rest.
         This is what YouTube and Netflix do.

  Broadcast, set-top, Blu-ray, or a TV app?
      -> HEVC. Hardware decode is mandated and the licensing
         is already paid by the device maker.

  Apple ecosystem?
      -> HEVC. Hardware encode AND decode on every device
         since 2017, and HDR support is well integrated.

  Real-time conferencing?
      -> H.264 (universal, low latency, cheap hardware
         encode) or AV1 if both ends support it. VP8 still
         appears in WebRTC fallbacks.

  Editing / mastering / archival?
      -> ProRes, DNxHR, or FFV1. Intra-only, 4:2:2 or 4:4:4,
         10-bit+. NOT a delivery codec - you want every frame
         independently decodable and no generation loss
         (chapter 3).

  Screen recording, text-heavy?
      -> H.264 4:4:4 if your decoder supports it, or AV1 with
         palette and intra-block-copy. 4:2:0 destroys text.

/* AND THE ONE THAT CATCHES PEOPLE OUT

   HARDWARE ENCODE IS NOT HARDWARE DECODE. A phone from 2019
   decodes AV1 in software only, but has HEVC decode in
   silicon. A GPU may encode H.264 and HEVC but only decode
   AV1. Check both directions before committing.          */
```

Profiles, levels and tiers

```
/* A codec is a menu. A PROFILE says which tools you may use;
   a LEVEL says how big and fast. A decoder claims support for
   a profile AND a level, and both must be satisfied.       */

  H.264 PROFILES
    Baseline    no B-frames, no CABAC. Videoconferencing.
    Main        + B-frames, CABAC, interlacing.
    High        + 8x8 transform, custom quant matrices.
                THE ONE YOU WANT. Universally supported and
                ~10% better than Main.
    High10, High 4:2:2, High 4:4:4  more bit depth and chroma.
                Poor hardware support - check before using.

  LEVELS cap: resolution, frame rate, bitrate, DPB size, and
  the number of motion vectors per second.

    Level 3.1   720p30       14 Mbit/s
    Level 4.0   1080p30      20 Mbit/s
    Level 4.2   1080p60      50 Mbit/s
    Level 5.1   4K30        240 Mbit/s
    Level 6.2   8K120       800 Mbit/s

  HEVC adds TIERS: Main tier for consumer, High tier for
  professional, with much higher bitrate caps at the same
  level.

/* WHY THIS MATTERS PRACTICALLY: a hardware decoder implements
   a level literally. Exceed the DPB size or the bin rate and
   it REFUSES the stream or produces corruption - even though
   ffmpeg plays it fine on your desktop. A stream that is
   "1080p at 20 Mbit/s" but declares level 4.0 while actually
   using 6 reference frames will fail on devices that took the
   declaration at face value.                               */

# Check what a file declares:
$ ffprobe -v error -select_streams v:0 \
    -show_entries stream=codec_name,profile,level,width,height \
    -of default=nw=1 input.mp4
codec_name=h264
profile=High
level=40

# Constrain the encoder to a target device:
$ ffmpeg -i in.mov -c:v libx264 -profile:v high -level:v 4.0 \
    -maxrate 20M -bufsize 25M out.mp4
# x264 will then refuse settings that would violate the level,
# rather than silently producing an unplayable file.
```

> **THE 80/20 OF CODEC SELECTION**
>
> If you are unsure: **H.264 High profile, level 4.0, 4:2:0 8-bit, CRF 21, closed 2-second GOP** plays on essentially every device made since 2010 and is good enough for almost everything. Add an AV1 rendition when you have measured that the bandwidth saving is worth the encoding cost. Reaching for a newer codec before you have measured is how projects acquire compatibility bugs they cannot reproduce.

The encoders

Encoder	Codec	Character
x264	H.264	Mature, fast, superbly tuned. Still the quality/speed benchmark everything else is measured against
x265	HEVC	Good quality, slow. Presets are not comparable to x264's
SVT-AV1	AV1	The practical AV1 encoder — scalable threading, sane speed/quality curve. Presets 0 (slowest) to 13
libaom	AV1	The reference. Best quality at glacial speed; used for research and for the very top rungs
rav1e	AV1	Rust, focused on correctness and speed
NVENC / QuickSync / AMF / V4L2 M2M	Various	Hardware. 10–50× faster, noticeably worse per bit — fine for live, wasteful for VOD (chapter 16)

```
# A fair comparison, which is harder than it looks.
# Same source, same target quality metric, measure BOTH size
# and time.

$ time ffmpeg -i src.y4m -c:v libx264  -preset veryslow -crf 23 h264.mp4
$ time ffmpeg -i src.y4m -c:v libx265  -preset slow     -crf 28 hevc.mp4
$ time ffmpeg -i src.y4m -c:v libsvtav1 -preset 4 -crf 35        av1.mp4

# THE CRF SCALES ARE DIFFERENT. Roughly equivalent quality:
#   x264 crf 23  ~  x265 crf 28  ~  SVT-AV1 crf 35
# Comparing "crf 23" across all three is the most common
# benchmarking error and makes AV1 look terrible.

$ for f in h264 hevc av1; do
    printf "%-6s %8s bytes  VMAF " $f $(stat -c%s $f.mp4)
    ffmpeg -v error -i $f.mp4 -i src.y4m \
      -lavfi libvmaf -f null - 2>&1 | grep -o 'score:.*'
  done

# AND REPORT THE ENCODING TIME. A 40% bitrate saving that
# costs 20x the CPU is a business decision, not a technical
# win - it may be right for a title streamed a million times
# and clearly wrong for a security camera.
```

How it shows up

Symptom	Cause
AV1 looks worse than H.264 in your test	Comparing the same CRF number, or too fast a preset
File plays on desktop, fails on a TV or phone	Level or profile exceeded — check the DPB and reference count
HEVC will not play in a browser	Licensing, not capability. Safari only, and not always
Hardware decodes the codec but will not encode it	They are separate blocks; check both directions
4:4:4 or 10-bit H.264 will not play	High 4:4:4 / High10 profiles have poor hardware support
Battery drains fast playing AV1 on an older phone	Software decode
Encoding a live stream cannot keep up	Software encoder too slow — use hardware, or a faster preset
Editing a delivery-codec file is painfully slow	Long GOP; transcode to an intra-only editing codec first

Symptom	Cause
Legal review blocks a codec late in a project	Licensing was never checked — do it before you build

Check yourself

- ✓ Give the approximate bitrate saving of VP9, HEVC and AV1 over H.264, and the conditions that qualify those numbers.
- ✓ Explain why HEVC failed on the web despite being technically strong.
- ✓ Say what AOMedia was formed to do and what its licensing position is.
- ✓ Choose a codec for: universal web playback, a TV app, videoconferencing and editing.
- ✓ Explain the difference between hardware encode and hardware decode support.
- ✓ Distinguish a profile from a level, and say what a level caps.
- ✓ Explain why a stream can play in ffmpeg and fail on a hardware decoder.
- ✓ Give the safe default configuration for maximum compatibility.
- ✓ Say why comparing encoders at the same CRF number is wrong.
- ✓ Explain why encoding time belongs in any codec comparison.

Containers, timestamps and A/V sync

A codec produces a stream of compressed frames with no notion of time, language or what audio goes with them. The container supplies all of that — and the reason lip sync drifts, seeking misses, and files play in one player but not another is almost always here rather than in the codec.

What a container does

```
A CONTAINER (or "format", or "wrapper") provides:

  MULTIPLEXING     interleave video, audio, subtitles so a
                   player can read them in one pass without
                   seeking
  TIMING           a timestamp for every packet
  INDEXING         "the keyframe nearest 3:42 is at byte
                   offset N" - what makes seeking possible
  METADATA         title, language, chapters, cover art
  CODEC SETUP      the "extradata" a decoder needs before
                   the first frame: SPS/PPS for H.264,
                   sequence header for AV1

THE CODEC AND CONTAINER ARE INDEPENDENT. "MP4" says nothing
about the video codec inside it. A .mp4 can hold H.264,
HEVC, AV1 or MPEG-4 Part 2; an .mkv can hold anything at
all. "It is an MP4" is not a statement about
compatibility.

AND THE CONFUSION THAT FOLLOWS: a device that "supports
MP4" means it supports SOME codecs in MP4. Nearly every
playback failure reported as "this MP4 does not work" is a
codec, profile or level problem (chapter 14), not a
container problem.
```

Container	Strengths	Use for
MP4 / ISOBMFF	Universal support, good indexing, fragmentable	The default for anything delivered. Also the base of DASH and CMAF
MKV / WebM	Any codec, any number of tracks, extensible, robust to truncation	Archival, anything unusual. WebM is the restricted subset browsers accept
MPEG-TS	188-byte packets, resynchronises after loss, no index needed	Broadcast, HLS segments, anything over a lossy link
fMP4 / CMAF	Fragmented MP4 — a moov header then independent segments	Streaming. One format serving both HLS and DASH
MOV	MP4's ancestor; richer professional metadata	Editing, ProRes
Annex B / raw ES	No container at all — just NAL units with start codes	Debugging, and feeding a hardware decoder directly

Timestamps and timebases

```
/* A timestamp is an INTEGER in a container-defined TIMEBASE.
   It is not seconds.                                          */

    time_in_seconds = timestamp * timebase

  MP4        timebase = 1 / timescale, chosen per track.
             90000 is traditional; 1000 (milliseconds) common.
  MPEG-TS    always 1/90000. PCR at 27 MHz.
  MKV        1/1000000000 by default (nanoseconds).

/* WHY NOT JUST USE SECONDS: 30000/1001 fps (NTSC's 29.97)
   cannot be represented exactly in any decimal. With a
   timescale of 30000 each frame is exactly 1001 ticks, and
   there is no accumulating rounding error. Floating point
   here loses sync over a long file, slowly, in a way that is
   very hard to debug.                                         */

/* TWO TIMESTAMPS PER PACKET (chapter 10): */

    PTS   when to PRESENT it
    DTS   when to DECODE it

  With B-frames, PTS != DTS and DTS may start negative:

    packet:   I     P     B     B     P     B     B
    DTS:     -2    -1     0     1     2     3     4
    PTS:      0     3     1     2     6     4     5

  DTS is always monotonically increasing. PTS is not.
  A muxer that writes PTS where DTS belongs produces a file
  that plays wrong or not at all.

/* EDIT LISTS - MP4's way of saying "start playback at PTS
   0.0666 even though the first sample has PTS 0". Used to
   trim, to compensate for encoder delay, and for that
   negative-DTS offset.

   MANY TOOLS IGNORE THEM, which is why a file can be in sync
   in one player and 66 ms out in another. If audio and video
   are offset by exactly one or two frames, suspect an edit
   list.                                                       */

# Look at the real numbers:
$ ffprobe -select_streams v -show_entries \
    packet=pts,dts,pts_time,dts_time,duration -of csv input.mp4 | head -5
packet,0,-1024,0.000000,-0.021333,512
packet,3072,0,0.064000,0.000000,512
packet,1024,512,0.021333,0.010667,512

$ ffprobe -show_entries stream=time_base,start_time,duration \
    -select_streams v input.mp4
time_base=1/48000
start_time=0.000000
```

> **EVERY SYNC BUG IS A TIMESTAMP BUG**
>
> Audio and video are decoded by independent decoders at independent rates. The *only* thing keeping them together is their timestamps and a common clock. If lip sync drifts, nothing is wrong with either codec — a timestamp is being generated, converted, or ignored incorrectly somewhere in the chain.

How playback actually stays in sync

```
THREE POSSIBLE MASTER CLOCKS:

1. AUDIO MASTER   (what almost everyone uses)
     The audio device consumes samples at a fixed, known
     rate, so its playback position IS a clock. Video is
     presented to match.
     If video falls behind: DROP frames.
     If video runs ahead:   REPEAT or wait.
     WHY: humans notice an audio glitch instantly and a
     dropped video frame barely at all. Audio must never
     stutter, so audio wins.

2. EXTERNAL CLOCK
     The system clock, or a PCR from a broadcast stream.
     Used when both audio and video must follow a third
     party - live broadcast, or synchronised playback
     across devices.

3. VIDEO MASTER
     Rare. Used when frame-accurate video matters more than
     audio continuity - editing, frame-stepping.

THE DRIFT PROBLEM, and it is physical:
  the sound card's crystal runs at 47,999.6 Hz while
  claiming 48,000. That is 8 ppm - about 30 ms per hour.
  Over a two-hour film, a minute of accumulated error if
  nothing corrects it.

  THE FIX: RESAMPLE the audio slightly - 48000 in,
  47999.6 out - so it tracks the master clock. This is
  what every serious player does, and it is inaudible.
  The naive alternative (drop or duplicate a sample block)
  is audible as a click.

ACCEPTABLE ERROR, from ITU-R BT.1359:
  audio LEADING video:   -40 ms is detectable
  audio LAGGING video:   +60 ms is detectable
  Asymmetric because in the real world sound always
  arrives after light, so we tolerate lag better.
  Aim for +/-20 ms.
```

Fragmented MP4 and streaming

```
/* A normal MP4 has one 'moov' box holding the index for the
   entire file. Two consequences:

   1. If moov is at the END (which is where a muxer naturally
      writes it, since it needs the whole file first), a
      player must download the whole file before it can start.
      -> +faststart moves it to the front. THIS IS THE MOST
         COMMON MP4 MISTAKE.                                  */

$ ffmpeg -i in.mov -c copy -movflags +faststart out.mp4

/*  2. It cannot be produced live, because you do not know
       the index until you are finished.
       -> FRAGMENTED MP4: a small moov with no sample table,
          then a sequence of (moof + mdat) fragments, each
          self-describing.                                   */

    [ftyp][moov]  [moof][mdat] [moof][mdat] [moof][mdat] ...
                  \___________/
                   one fragment - independently decodable if
                   it starts with a keyframe

$ ffmpeg -i in.mp4 -c copy \
    -movflags "frag_keyframe+empty_moov+default_base_moof" \
    out_frag.mp4

/* CMAF is fMP4 with a specific set of constraints, so that
   ONE set of segments serves both HLS and DASH. Before CMAF
   you encoded twice - MPEG-TS for HLS, fMP4 for DASH - and
   stored both. Now you store one.

   THE REQUIREMENTS for segmented streaming, all of which
   must hold (chapters 10 and 13):
     * closed GOP, keyframe at every segment boundary
     * segment duration an exact multiple of the GOP
     * identical timestamps across every rendition
     * scene-cut keyframes DISABLED, or alignment breaks   */

# Verify segments really do start with a keyframe:
$ for s in seg_*.m4s; do
    printf "%s " $s
    ffprobe -v error -select_streams v -read_intervals "%+#1" \
      -show_entries frame=key_frame -of csv=p=0 "$s"
  done
seg_001.m4s 1
seg_002.m4s 1
seg_003.m4s 1        # all 1 = correct. Any 0 = a broken
                     # switch point.
```

> **VARIABLE FRAME RATE BREAKS ASSUMPTIONS EVERYWHERE**
>
> Screen recordings, phone cameras and browser capture routinely produce VFR: frames arrive when something changed, so durations vary. Tools that assume constant frame rate — many editors, naive muxers, anything computing `frame_number / fps` — will produce drifting sync. Convert to CFR at ingest with `-vsync cfr -r 30`, or carry the real timestamps end to end. Choosing halfway produces a file that is subtly wrong and very hard to diagnose.

Diagnosing sync

```
# 1. Are the streams offset at the start?
$ ffprobe -show_entries stream=index,codec_type,start_time \
    -of csv input.mp4
stream,0,video,0.000000
stream,1,audio,0.021333        # audio starts 21 ms later

# A small offset is normal - encoder delay. A large one, or
# one that GROWS, is the bug.

# 2. Does the gap grow over time? This distinguishes a fixed
#    offset from drift.
$ ffprobe -select_streams v -show_entries packet=pts_time \
    -of csv=p=0 input.mp4 | tail -1
7200.033333
$ ffprobe -select_streams a -show_entries packet=pts_time \
    -of csv=p=0 input.mp4 | tail -1
7203.115000          # 3 SECONDS out after 2 hours -> drift,
                     # not an offset. Suspect a clock or a
                     # wrong timebase.

# 3. Fix a fixed offset:
$ ffmpeg -i in.mp4 -itsoffset 0.15 -i in.mp4 \
    -map 0:v -map 1:a -c copy fixed.mp4

# 4. Check for VFR:
$ ffprobe -select_streams v -show_entries frame=pkt_duration_time \
    -of csv=p=0 in.mp4 | sort | uniq -c | sort -rn | head
   4021 0.033333
    118 0.041667        # mixed durations = VFR
     37 0.025000

# 5. The empirical test that beats all of the above: encode a
#    clapperboard. A visible flash and a simultaneous click,
#    then step through frame by frame and count.
$ ffmpeg -f lavfi -i "testsrc=size=640x480:rate=30" \
         -f lavfi -i "sine=frequency=1000:duration=10" \
         -t 10 synctest.mp4
```

How it shows up

Symptom	Cause
Video must fully download before playing	`moov` at the end — use `+faststart`
Sync drifts steadily over a long file	Clock drift with no resampling, or a wrong timebase
Fixed offset, constant throughout	Encoder delay or a missing edit list
In sync in one player, out in another	Edit list honoured by one and ignored by the other
Sync fine at first, drifts in an editor	VFR source treated as CFR
File will not play, "moov atom not found"	Truncated upload of a non-faststart MP4
Seeking lands in the wrong place	Missing or wrong index; MPEG-TS has none, so players estimate
ABR switch produces a glitch	Segments not starting on a keyframe, or timestamps not aligned
Audio clicks periodically	Sample dropping instead of resampling to correct drift
Remuxing broke playback	Extradata (SPS/PPS) not carried across

Check yourself

- ✓ Name five things a container provides that a codec does not.
- ✓ Explain why "it is an MP4" says nothing about compatibility.
- ✓ Explain what a timebase is and why 30000/1001 motivates integer timestamps.
- ✓ Distinguish PTS from DTS and say which is monotonic.
- ✓ Explain what an edit list does and the sync symptom of ignoring one.
- ✓ Name the three master-clock choices and say why audio usually wins.
- ✓ Explain clock drift and the correct way to compensate.
- ✓ Give the acceptable A/V sync window and why it is asymmetric.
- ✓ Explain `+faststart` and what fragmented MP4 adds beyond it.
- ✓ Distinguish a fixed offset from drift using timestamps.

Hardware encoders and decoders

A dedicated block that decodes 4K60 at a fraction of a watt, where software would need several CPU cores. It is not a fast CPU — it is a fixed-function pipeline with fixed capabilities, and knowing what it can and cannot do decides whether your product works on battery.

Why the silicon exists

```
DECODING 4K60 HEVC

  software, 8 CPU cores      ~25 W, and the phone is now
                             unusable for anything else
  hardware VPU               ~0.5 W

A 50x power difference. That is the entire argument, and it
is why every SoC has one (see the SoC section on the home
page). Battery life on video playback is almost entirely a
question of whether the hardware path was used.

WHAT THE BLOCK ACTUALLY CONTAINS

  +-------------------------------------------------+
  |  entropy decoder (CABAC)  - the serial bottleneck  |
  |    -> its throughput sets the max bitrate the      |
  |       chip supports (chapter 8)                    |
  |  inverse transform + dequantise                    |
  |  motion compensation - the interpolation filters   |
  |  intra prediction                                  |
  |  in-loop filters: deblock, SAO, CDEF               |
  |  reference frame DMA + a reference cache           |
  +-------------------------------------------------+
                |
          DRAM: the DPB (chapter 10)

IT IS A PIPELINE, not a processor. Every stage is
hard-wired for specific codecs, specific profiles and
specific block sizes. There is no microcode to change - a
chip that decodes H.264 and HEVC will never decode AV1,
ever, at any clock speed.

WHICH IS WHY the codec landscape (chapter 14) moves so
slowly: adopting a new codec means waiting for a hardware
generation, then for the installed base to turn over.
Roughly five to eight years.
```

HARDWARE ENCODE IS WORSE PER BIT THAN SOFTWARE, ALWAYS

A fixed-function encoder has a fixed, shallow search: limited motion search range, few partition candidates, no multi-pass lookahead, simplified rate-distortion decisions. Expect **20–50% more bitrate** than `x264 --preset slow` at the same quality. That is the price of 50× the speed and 1/50th the power. Use hardware for live and for anything power-constrained; use software for VOD you encode once and stream a million times.

The constraints that bite

```
/* A hardware codec has HARD limits, and it fails ungracefully
   when you exceed them - usually a silent fall back to
   software (slow), or an error code with no explanation. */

  CODEC AND PROFILE
      "H.264 decode" means specific profiles. High 4:4:4 or
      High10 is often absent even where High is present
      (chapter 14).

  LEVEL
      Max resolution, frame rate, bitrate, DPB size and BIN
      RATE. A stream can be within the bitrate and still
      exceed the bin rate.

  PIXEL FORMAT
      Almost always NV12 in, NV12 out (chapter 4). Feeding it
      RGB means a conversion pass you did not budget for.

  ALIGNMENT
      Width and height usually to 16 or 32; stride to 128 or
      256; the buffer base to 4 KB. A 1920x1080 surface is
      often physically 1920x1088 - the extra 8 rows are real
      and must not be displayed.

  MEMORY
      Physically contiguous, or IOMMU-mapped. Often a specific
      heap - CMA, or a carve-out. malloc'd memory will not do.

  TILING
      The output may be in a vendor tiled or compressed layout
      (chapter 4). Reading it with the CPU without detiling
      gives you scrambled rectangles.

  CONCURRENCY
      Usually ONE session, or a small fixed number. Two apps
      both wanting hardware decode is a real failure mode on
      phones.

  LATENCY
      The pipeline is deep. Frames go in and come out several
      later - you must feed it continuously and collect
      asynchronously, never call "decode this frame" and wait.

/* THE 1088 PROBLEM, concretely: H.264 codes in 16x16
   macroblocks, so 1080 rounds up to 1088. The bitstream
   carries CROPPING information saying "display 1080 of these
   1088 rows". Ignore it and you get 8 rows of garbage at the
   bottom - one of the most common hardware-decode bugs, and
   it looks like a driver fault.                          */
```

The APIs

API	Platform	Notes
V4L2 M2M	Linux, embedded	The kernel-native interface. Stateful and stateless variants (chapter 17)
VA-API	Linux, Intel and AMD	The desktop standard. Exposes both decode and encode
NVDEC / NVENC	NVIDIA, all platforms	Via the Video Codec SDK, or ffmpeg's `_nvenc` / `_cuvid`

API	Platform	Notes
MediaCodec	Android	The only sanctioned path. Wraps whatever the vendor provides
VideoToolbox	Apple	Clean API, excellent hardware
DXVA2 / D3D11VA / D3D12 Video	Windows	Decode via the graphics stack; integrates with the swap chain
Media Foundation	Windows	Higher-level; wraps DXVA and vendor encoders
VDPAU	Linux, legacy	Decode only, largely superseded by VA-API

```
# What does this machine actually have?

$ vainfo                                  # VA-API
libva info: VA-API version 1.20.0
vainfo: Driver version: Intel iHD driver
      VAProfileH264High               : VAEntrypointVLD
      VAProfileH264High               : VAEntrypointEncSlice
      VAProfileHEVCMain               : VAEntrypointVLD
      VAProfileHEVCMain10             : VAEntrypointVLD
      VAProfileAV1Profile0            : VAEntrypointVLD
#     VLD = decode.  EncSlice = encode.
#     Note AV1 appears for VLD only - decode but not encode.

$ v4l2-ctl --list-devices                 # V4L2
$ ls /dev/video* /dev/media*

$ nvidia-smi --query-gpu=name --format=csv  # NVIDIA
$ ffmpeg -hide_banner -encoders | grep -E 'nvenc|vaapi|qsv|v4l2m2m'
 V....D h264_nvenc    NVIDIA NVENC H.264 encoder
 V....D h264_vaapi    H.264/AVC (VAAPI)
 V....D h264_v4l2m2m  V4L2 mem2mem H.264 encoder

$ ffmpeg -hide_banner -hwaccels
Hardware acceleration methods:
vdpau  cuda  vaapi  qsv  drm  vulkan

# THE TEST THAT MATTERS - did it actually use hardware?
$ ffmpeg -hwaccel vaapi -hwaccel_device /dev/dri/renderD128 \
    -hwaccel_output_format vaapi -i in.mp4 -f null - 2>&1 | tail -3
# then watch the GPU's video engine:
$ sudo intel_gpu_top          # look for the "Video" row
$ nvidia-smi dmon -s u        # the "dec" and "enc" columns
# If those stay at 0%, you are on the software path and
# something silently fell back.
```

Zero-copy, and why it is the whole game

```
THE NAIVE PIPELINE - four copies of every frame:

  decoder -> DRAM -> CPU reads -> converts NV12 to RGB
          -> DRAM -> GPU uploads as a texture
          -> DRAM -> composites -> display

  At 4K60 NV12 that is 12 MB per frame, 750 MB/s per copy.
  Four copies plus a colour conversion is several GB/s of
  memory traffic, and on a phone that is the entire
  bandwidth budget (mobile GPU chapter 10).

THE ZERO-COPY PIPELINE - one buffer, passed by handle:

  decoder writes NV12 into a DMABUF
     |  export as an fd
     v
  GPU imports the SAME memory as an EGLImage / VkImage
     |
     v
  display controller scans out the SAME memory directly,
  converting NV12 to RGB in its own hardware plane
  (chapter 18)

  ZERO copies. The pixels are written once, by the decoder,
  and read once, by the display.

WHAT MAKES IT WORK, and all four must hold:
  1. DMABUF - a kernel object representing a buffer,
     passed between drivers as a file descriptor
  2. an agreed PIXEL FORMAT (NV12) and MODIFIER (the exact
     tiling - chapter 4)
  3. an IOMMU or contiguous memory so every device can
     address it
  4. explicit or implicit FENCING so the GPU does not read
     a frame the decoder is still writing

WHEN ONE OF THOSE FAILS the stack silently inserts a copy,
or a format conversion, or both. Your pipeline still works
and uses three times the power. This is the single most
common performance problem in embedded video, and it is
invisible unless you measure memory bandwidth.
```

> **"IT WORKS" AND "IT IS ON THE FAST PATH" ARE DIFFERENT QUESTIONS**
>
> Every media framework falls back gracefully. Ask for hardware decode into a GPU texture and, if any link in the chain cannot be negotiated, you will get a working pipeline with a hidden `memcpy` and a software colour conversion. Frame rate may even be fine on a desktop. The way to know is to measure: GPU video engine utilisation, memory bandwidth, and power — not whether the picture appears.

How it shows up

Symptom	Cause
8 rows of garbage at the bottom of the picture	Cropping information ignored — 1080 versus 1088
Hardware decode "works" but CPU is at 100%	Silent fallback to software; check the video engine counter
Battery drains during playback	Software decode, or a copy-heavy pipeline

Symptom	Cause
Image is scrambled rectangles	Tiled output read as linear
Decoder rejects a stream ffmpeg plays fine	Profile, level, DPB size or bin rate exceeded
Second app cannot get a decoder	Limited concurrent sessions
Decode stalls waiting for output	Pipeline depth — feed continuously, collect asynchronously
Buffer allocation fails	Needs contiguous or heap-specific memory, not `malloc`
Hardware encode is 40% bigger than x264	Expected — shallow search
Tearing or a frame torn between two images	Missing fence between decoder and consumer

Check yourself

- ✓ Give the rough power ratio between hardware and software 4K decode.
- ✓ Explain why a hardware block cannot gain support for a new codec.
- ✓ Say how much worse hardware encode is per bit, and when that is the right trade.
- ✓ Name six hard constraints a hardware codec imposes.
- ✓ Explain the 1080/1088 cropping problem and its symptom.
- ✓ Name the hardware codec API on Linux embedded, Android, Apple and Windows.
- ✓ Show how to verify that hardware acceleration is actually being used.
- ✓ Explain what DMABUF is and the four conditions zero-copy requires.
- ✓ Estimate the memory traffic of a four-copy 4K60 pipeline.
- ✓ Explain why a working pipeline is not necessarily a fast one.

V4L2: capture and memory-to-memory

Video4Linux2 is how Linux talks to cameras, capture cards, and — through the memory-to-memory extension — hardware codecs and scalers. It is an ioctl-based API with a buffer-queue model, and once you have internalised that model, every V4L2 device works the same way.

The buffer queue model

```
V4L2 is built on TWO QUEUES per stream. You never allocate
and free per frame; you hand buffers to the driver and get
them back.

  userspace                       driver
     |                              |
     |  VIDIOC_QBUF  ------------>  | INPUT QUEUE
     |  "here is an empty buffer"   |   driver fills it
     |                              |     from the sensor
     |                              v
     |                           [ hardware DMA ]
     |                              |
     |  VIDIOC_DQBUF <------------  | DONE QUEUE
     |  "here is a full one"        |
     v
  process it, then QBUF it again

THE LIFECYCLE, and every V4L2 program is these seven steps:

  1. open("/dev/video0")
  2. VIDIOC_QUERYCAP     what can this device do?
  3. VIDIOC_S_FMT        set resolution and pixel format
  4. VIDIOC_REQBUFS      ask the driver to allocate N
                         buffers (or accept yours)
  5. VIDIOC_QUERYBUF + mmap    map them into your address
                         space
  6. VIDIOC_QBUF x N     hand them all over
     VIDIOC_STREAMON     go
  7. loop: poll() -> VIDIOC_DQBUF -> use -> VIDIOC_QBUF

THE THREE MEMORY MODELS

  V4L2_MEMORY_MMAP     the DRIVER allocates; you mmap.
                       The default, and what most devices
                       support.
  V4L2_MEMORY_USERPTR  YOU allocate; you pass a pointer.
                       Needs an IOMMU or contiguous memory,
                       and many drivers refuse it.
  V4L2_MEMORY_DMABUF   you pass an fd for a buffer another
                       driver allocated.
                       THIS IS THE ZERO-COPY ONE
                       (chapter 16), and it is what you
                       want for anything real.
```

```
/* A minimal capture loop. This is the whole API. */

#include <linux/videodev2.h>
#include <sys/ioctl.h>
#include <sys/mman.h>
#include <fcntl.h>
#include <poll.h>
#include <string.h>
#include <errno.h>

/* EVERY ioctl must be retried on EINTR. A signal — including
   the one your profiler sends — will otherwise look like a
   device failure. */
static int xioctl(int fd, unsigned long req, void *arg)
{
        int r;
        do { r = ioctl(fd, req, arg); }
        while (r == -1 && errno == EINTR);
        return r;
}

#define NBUF 4
struct buffer { void *start; size_t length; };
static struct buffer bufs[NBUF];

int capture_init(const char *dev, int w, int h, uint32_t fourcc)
{
        int fd = open(dev, O_RDWR | O_NONBLOCK);
        if (fd < 0) return -1;

        /* 2. What is this? */
        struct v4l2_capability cap = {0};
        if (xioctl(fd, VIDIOC_QUERYCAP, &cap) < 0) return -1;
        if (!(cap.capabilities & V4L2_CAP_VIDEO_CAPTURE)) return -1;
        if (!(cap.capabilities & V4L2_CAP_STREAMING))     return -1;

        /* 3. Set the format. THE DRIVER MAY CHANGE IT — always
              read back what you actually got. Asking for
              1920x1080 NV12 and getting 1280x720 YUYV without
              noticing is the classic V4L2 mistake. */
        struct v4l2_format fmt = {0};
        fmt.type = V4L2_BUF_TYPE_VIDEO_CAPTURE;
        fmt.fmt.pix.width       = w;
        fmt.fmt.pix.height      = h;

        if (xioctl(fd, VIDIOC_DQBUF, &b) < 0) return -1;

        /* b.timestamp is the CAPTURE time, from the driver.
           Use it - do not stamp frames when your code happens
           to run, or you build jitter into every downstream
           timestamp (chapter 15). */
        use(bufs[b.index].start, b.bytesused, b.timestamp);

        /* GIVE IT BACK IMMEDIATELY. Holding buffers starves
           the driver: with 4 buffers, holding 4 means the
           hardware has nowhere to write and DROPS FRAMES. */
        return xioctl(fd, VIDIOC_QBUF, &b);
}
```

BUFFER COUNT IS A LATENCY-VERSUS-DROPS DIAL

Too few and the driver has nowhere to write while you are processing, so frames are dropped. Too many and you add latency — each queued frame is one frame period of delay before yours is displayed. Four to six is the usual range for capture; a real-time pipeline uses the minimum that never drops. Check `v4l2_buffer.sequence` for gaps: a jump means frames were lost, and the driver will not tell you any other way.

Memory-to-memory: codecs and scalers

```
The same queue model, but with TWO streams on ONE device:

  OUTPUT queue   what you send TO the device
                 (confusingly named - "output" is from the
                  APPLICATION's point of view)
                 V4L2_BUF_TYPE_VIDEO_OUTPUT_MPLANE

  CAPTURE queue  what you get back
                 V4L2_BUF_TYPE_VIDEO_CAPTURE_MPLANE

FOR A DECODER
  OUTPUT  = compressed bitstream in
  CAPTURE = decoded NV12 frames out

FOR AN ENCODER
  OUTPUT  = raw NV12 frames in
  CAPTURE = compressed bitstream out

Same device, same ioctls, both queues streaming
simultaneously. You poll for both.

TWO KINDS OF M2M CODEC, and the difference is fundamental:

  STATEFUL   the driver parses the bitstream itself, finds
             the headers, manages the DPB, handles
             resolution changes. You feed it bytes and get
             frames. Most vendor drivers.

  STATELESS  the driver does ONE frame at a time and you
             supply ALL the parsed state - SPS, PPS, slice
             parameters, the reference list - through
             V4L2 request-API controls. The hardware is
             dumber and the kernel driver is far smaller;
             userspace (ffmpeg, GStreamer, Chromium) does
             the parsing.
             Used by Rockchip, Allwinner, RPi and the newer
             mainline drivers. It is where the kernel is
             heading, because it keeps codec-specific
             complexity out of the kernel.
```

```
/* The decoder sequence, stateful. The asymmetry in step 4 is
   the part people get wrong. */

  1. open the m2m device, VIDIOC_QUERYCAP
       -> V4L2_CAP_VIDEO_M2M_MPLANE

  2. S_FMT on OUTPUT: the compressed format
       fmt.type = V4L2_BUF_TYPE_VIDEO_OUTPUT_MPLANE
       fmt.fmt.pix_mp.pixelformat = V4L2_PIX_FMT_H264
       fmt.fmt.pix_mp.plane_fmt[0].sizeimage = 1024*1024
       /* you must size the bitstream buffer yourself */

  3. REQBUFS + QBUF on OUTPUT, STREAMON, and feed the first
     chunk of bitstream - INCLUDING SPS/PPS.

  4. WAIT FOR THE SOURCE CHANGE EVENT.
       VIDIOC_SUBSCRIBE_EVENT V4L2_EVENT_SOURCE_CHANGE
       The driver parses the headers and only THEN knows the
       real resolution. You cannot set the CAPTURE format
       before this - you do not know it yet.

       On the event:
         G_FMT on CAPTURE     -> the real resolution
         G_SELECTION          -> the CROP rectangle
                                 (the 1080-vs-1088 problem,
                                  chapter 16)
         REQBUFS on CAPTURE   -> now you can allocate
         STREAMON on CAPTURE

  5. Now both queues stream. Poll for both:
       POLLOUT -> an OUTPUT buffer is free, feed more bitstream
       POLLIN  -> a CAPTURE buffer holds a decoded frame

  6. Resolution can change MID-STREAM. You get another
     SOURCE_CHANGE event, and must:
       STREAMOFF capture, REQBUFS(0), reallocate, STREAMON.
     Handling this is what separates a demo from a product.

  7. Draining at end of stream:
       VIDIOC_DECODER_CMD with V4L2_DEC_CMD_STOP
       keep dequeuing CAPTURE until you get a buffer with
       V4L2_BUF_FLAG_LAST set.
     Skip this and you lose the last few frames - the pipeline
     is deep (chapter 16).
```

THE MULTIPLANAR API IS NOT OPTIONAL

Formats with separate planes — NV12, I420 — need `V4L2_BUF_TYPE_*_MPLANE` and the `v4l2_pix_format_mplane` structures, where each plane has its own length, stride and DMABUF fd. Most codec drivers accept *only* the multiplanar variants. Code written against the single-planar API works for a YUYV webcam and fails immediately on a hardware codec, with an error that just says `EINVAL`.

The tools

```
# Everything about a device:
$ v4l2-ctl -d /dev/video0 --all
Driver Info:
        Driver name      : uvcvideo
        Card type        : Integrated Camera
        Capabilities     : 0x84a00001
                Video Capture
                Streaming
Format Video Capture:
        Width/Height     : 1920/1080
        Pixel Format     : 'YUYV'
        Bytes per Line   : 3840
        Size Image       : 4147200

# What formats, sizes and rates does it support?
$ v4l2-ctl -d /dev/video0 --list-formats-ext

# Capture frames straight to a file:
$ v4l2-ctl -d /dev/video0 \
    --set-fmt-video=width=1920,height=1080,pixelformat=NV12 \
    --stream-mmap --stream-count=100 --stream-to=out.nv12

# Controls - exposure, gain, focus:
$ v4l2-ctl -d /dev/video0 --list-ctrls
$ v4l2-ctl -d /dev/video0 --set-ctrl=exposure_auto=1
$ v4l2-ctl -d /dev/video0 --set-ctrl=exposure_absolute=300

# THE MEDIA CONTROLLER. On an embedded SoC the camera is not
# one device but a GRAPH: sensor -> CSI receiver -> ISP ->
# several /dev/video nodes. You must configure the LINKS and
# the format at EVERY pad, or streaming fails with EPIPE.
$ media-ctl -d /dev/media0 -p          # print the graph
$ media-ctl -d /dev/media0 \
    -V "'ov5640 1-003c':0 [fmt:UYVY8_2X8/1920x1080]"
$ media-ctl -d /dev/media0 -l "'csi':1 -> 'isp':0 [1]"

# EPIPE from STREAMON on an embedded platform almost always
# means a pad format mismatch somewhere in that graph - the
# formats must agree link by link.

# ffmpeg through V4L2:
$ ffmpeg -f v4l2 -input_format nv12 -video_size 1920x1080 \
    -i /dev/video0 -c:v h264_v4l2m2m -b:v 4M out.mp4

# Kernel-side tracing when nothing works:
$ echo 0x1f | sudo tee /sys/class/video4linux/video0/dev_debug
$ dmesg -w
```

How it shows up

Symptom	Cause
Frames come out at the wrong size or format	Did not read back what `S_FMT` actually set
Image sheared diagonally	`bytesperline` ignored (chapter 1)
Frames dropped under load	Buffers held too long — requeue immediately; check `sequence` for gaps
Latency of several frames	Too many buffers queued

Symptom	Cause
`EINVAL` from every codec ioctl	Single-planar API against a multiplanar device
`EPIPE` from `STREAMON` on embedded	Media-controller pad formats do not match link by link
Decoder produces nothing	Waiting for frames before handling `SOURCE_CHANGE`
Last few frames missing	No drain — send `DEC_CMD_STOP` and wait for `BUF_FLAG_LAST`
8 rows of garbage at the bottom	`G_SELECTION` crop rectangle ignored
Random `EINTR` failures	ioctls not retried
Stream breaks when resolution changes mid-file	Second `SOURCE_CHANGE` not handled

Check yourself

- ✓ Describe the V4L2 queue model and the seven steps of a capture program.
- ✓ Name the three memory models and say which enables zero-copy.
- ✓ Explain why every ioctl must be retried on `EINTR`.
- ✓ Say why you must read back the format after `S_FMT`.
- ✓ Explain the buffer-count trade and how to detect dropped frames.
- ✓ Explain what OUTPUT and CAPTURE mean on an m2m device, for both a decoder and an encoder.
- ✓ Distinguish stateful from stateless codec drivers and say which direction the kernel is taking.
- ✓ Explain why the CAPTURE format cannot be set before `SOURCE_CHANGE`.
- ✓ Describe the drain sequence and what is lost without it.
- ✓ Say what the media controller configures and what `EPIPE` usually means.

DRM/KMS, planes and zero-copy display

The last stage of the pipeline, and the one that decides whether video playback costs half a watt or five. The display controller can scan out NV12 directly, scale it, convert its colour and composite it — if you ask correctly. If you do not, the GPU does all of that instead, at ten times the power.

The KMS object model

```
Kernel Mode Setting exposes the display hardware as five
object types. Every display configuration is a set of
properties on these.

FRAMEBUFFER    a buffer plus its format and modifier
     |         (chapter 4). Wraps a DMABUF or GEM object.
     v
PLANE          a hardware scanout engine. Reads a
     |         framebuffer, optionally scales it, converts
     |         its colour, and positions it.
     |           PRIMARY  the main one, one per CRTC
     |           OVERLAY  extra planes for compositing
     |           CURSOR   small, always on top
     v
CRTC           the scanout engine proper. Owns the mode
     |         (resolution, refresh, timings), blends the
     |         planes, and generates the pixel clock.
     v
ENCODER        converts the pixel stream to a signal -
     |         HDMI, DisplayPort, MIPI DSI, LVDS.
     v
CONNECTOR      the physical port and the attached display.
               Carries EDID: what the monitor supports.

THE CHAIN: framebuffer -> plane -> CRTC -> encoder ->
connector -> the screen.

PLANES ARE THE POINT OF THIS CHAPTER. A hardware plane can
do, for free and in the display controller:
  * YUV to RGB conversion
  * scaling
  * positioning and cropping
  * alpha blending with the other planes
  * (sometimes) rotation and colour management

That is exactly the work a GPU composite would otherwise
do, and the display controller does it while reading the
pixels it has to read anyway - so it costs no extra memory
bandwidth at all.
```

THE VIDEO PLANE IS WHY PHONES CAN PLAY 4K FOR HOURS

Put decoded NV12 on an overlay plane and the pipeline is: decoder writes the frame once, display controller reads it once. The GPU is never involved and can stay powered down. Composite the same frame with the GPU instead and you add a texture read, a colour conversion, a render pass and a write — several hundred megabytes per second at 4K60, and the GPU cannot idle. On mobile that is the difference between a warm phone and a hot one.

Atomic modesetting

```
/* The old API set one thing at a time - mode, then plane,
   then cursor - and each could fail halfway, leaving the
   display in a broken intermediate state. The ATOMIC API
   submits every change as ONE transaction that either applies
   completely or not at all.                                  */

#include <xf86drm.h>
#include <xf86drmMode.h>

int fd = open("/dev/dri/card0", O_RDWR | O_CLOEXEC);

/* You must ask for the modern capabilities explicitly. */
drmSetClientCap(fd, DRM_CLIENT_CAP_UNIVERSAL_PLANES, 1);
drmSetClientCap(fd, DRM_CLIENT_CAP_ATOMIC, 1);

/* Build a request from property changes. */
drmModeAtomicReq *req = drmModeAtomicAlloc();

drmModeAtomicAddProperty(req, plane_id, prop_fb_id,   fb_id);
drmModeAtomicAddProperty(req, plane_id, prop_crtc_id, crtc_id);
/* SRC coordinates are 16.16 FIXED POINT - the source
   rectangle within the framebuffer. */
drmModeAtomicAddProperty(req, plane_id, prop_src_x, 0);
drmModeAtomicAddProperty(req, plane_id, prop_src_y, 0);
drmModeAtomicAddProperty(req, plane_id, prop_src_w, 1920 << 16);
drmModeAtomicAddProperty(req, plane_id, prop_src_h, 1080 << 16);
/* CRTC coordinates are plain integers - where it lands on
   screen. Different units for source and destination, in the
   same call, is a reliable source of bugs. */
drmModeAtomicAddProperty(req, plane_id, prop_crtc_x, 0);
drmModeAtomicAddProperty(req, plane_id, prop_crtc_y, 0);
drmModeAtomicAddProperty(req, plane_id, prop_crtc_w, 3840);
drmModeAtomicAddProperty(req, plane_id, prop_crtc_h, 2160);
/* src != crtc size means the plane SCALES - for free. */

/* TEST_ONLY asks "would this work?" without changing
   anything. This is the single most useful feature of the
   atomic API: probe your configuration, fall back if the
   hardware cannot do it, and never leave the display broken. */
int ret = drmModeAtomicCommit(fd, req,
                              DRM_MODE_ATOMIC_TEST_ONLY, NULL);
if (ret == 0)
        drmModeAtomicCommit(fd, req,
                            DRM_MODE_ATOMIC_NONBLOCK |
                            DRM_MODE_PAGE_FLIP_EVENT, user_data);
else
        fallback_to_gpu_composite();

drmModeAtomicFree(req);

/* PAGE_FLIP_EVENT means the commit happens at the next
   VBLANK and you get an event on the fd when it has. That is
   how you avoid tearing and how you pace your rendering -
   read the event, then draw the next frame. */
```

Getting video onto a plane

```
THE FULL ZERO-COPY PATH (chapter 16):

  V4L2 decoder
    VIDIOC_EXPBUF  ->  dmabuf fd
          |
          v
  drmPrimeFDToHandle(fd, dmabuf_fd, &gem_handle)
          |
          v
  drmModeAddFB2WithModifiers(
          fd, w, h, DRM_FORMAT_NV12,
          handles,      /* the same handle for both planes */
          pitches,      /* per-plane stride                */
          offsets,      /* per-plane offset into the buffer*/
          modifiers,    /* THE TILING - must match!        */
          &fb_id, DRM_MODE_FB_MODIFIERS)
          |
          v
  atomic commit: put fb_id on an overlay plane
          |
          v
  the display controller scans it out, converting NV12 to
  RGB in hardware.

THE FOUR THINGS THAT MUST LINE UP, and any one of them
failing sends you back to a GPU composite:

  1. FORMAT   the plane must advertise NV12 (or P010 for
              10-bit). Query IN_FORMATS on the plane.
  2. MODIFIER the exact tiling the decoder produced must be
              one the plane accepts (chapter 4).
  3. SCALING  the plane's min/max scale factors. Many
              overlay planes cannot scale at all, and some
              cannot scale down below 1:2.
  4. BANDWIDTH the display controller has a fixed budget.
              Two 4K planes may simply exceed it, and the
              commit fails at TEST_ONLY.

AND COLOUR: a YUV plane needs its properties set, or you
get the washed-out or crushed picture of chapter 2:
  COLOR_ENCODING  ITU-R BT.601 / BT.709 / BT.2020
  COLOR_RANGE     YCbCr limited range / YCbCr full range
Defaults are usually BT.601 limited, which is wrong for
almost all modern content.
```

```
# What planes does this hardware have, and what can they do?
$ sudo modetest -M i915 -p
Planes:
id      crtc    fb      CRTC x,y   x,y    gamma size    possible crtcs
31      0       0       0,0        0,0    0               0x00000001
  formats: XR24 AR24 NV12 P010 YUYV
  props:
        6 IN_FORMATS:
                flags: immutable blob
                value blob = 42
                        NV12: LINEAR, I915_FORMAT_MOD_Y_TILED,
                              I915_FORMAT_MOD_4_TILED
        20 type: OVERLAY               <-- an overlay plane
        68 COLOR_ENCODING: ITU-R BT.709
        69 COLOR_RANGE: YCbCr limited range

# The whole display topology:
$ sudo modetest -M i915 -c        # connectors and modes
$ sudo modetest -M i915 -e        # encoders
$ sudo modetest -M i915 -a -s 32@31:1920x1080   # test a mode

# Is the compositor actually using a plane, or falling back?
$ sudo cat /sys/kernel/debug/dri/0/i915_display_info
$ sudo cat /sys/kernel/debug/dri/0/state
plane[31]: plane 1B
        crtc-pos: 3840x2160+0+0
        src-pos: 1920.000000x1080.000000+0.000000+0.000000
        format=NV12 modifier=0x100000000000002
        color-encoding=ITU-R BT.709
#  ^ NV12 on a plane, scaled 1920 -> 3840. This is the fast
#    path working.

# On Wayland, ask the compositor:
$ WAYLAND_DEBUG=1 mpv --gpu-context=wayland video.mp4 2>&1 \
    | grep -i 'dmabuf\|plane'
$ sudo cat /sys/kernel/debug/dri/0/state | grep -c 'format=NV12'
# 0 means every frame is being composited by the GPU.
```

PLANE ASSIGNMENT IS A NEGOTIATION YOU CAN LOSE SILENTLY

A compositor tries to put your video on a hardware plane and falls back to GPU composition when it cannot — because another window overlaps it, because the scaling factor is out of range, because a rounded corner needs alpha, or because bandwidth is exhausted. Nothing tells you. The picture is identical; the power draw triples. On Linux the way to know is `/sys/kernel/debug/dri/0/state`; on Android it is `dumpsys SurfaceFlinger` and the `DEVICE` versus `CLIENT` composition column.

Tearing, vblank and presentation

```
/* TEARING: the scanout reads the framebuffer while you are
   writing it, so the top of the screen shows the old frame
   and the bottom the new one.

   THE FIX: DOUBLE BUFFERING plus a flip at VBLANK - the
   interval between the last line of one frame and the first
   of the next, when nothing is being read.                */

  drmModePageFlip(fd, crtc, new_fb, DRM_MODE_PAGE_FLIP_EVENT,
                  user_data);
  /* returns immediately; the flip happens at the next vblank */

  struct pollfd p = { .fd = drm_fd, .events = POLLIN };
  poll(&p, 1, -1);
  drmHandleEvent(drm_fd, &evctx);    /* your page_flip_handler
                                        runs; now the old
                                        buffer is free to
                                        reuse               */

/* THE RULE: do not touch a buffer until you have been told
   the flip completed. It is exactly the fence discipline of
   GPU chapter 16, in a different API.

/* VARIABLE REFRESH RATE - the display waits for you instead
   of the other way round. FreeSync/G-Sync/HDMI VRR, exposed
   as the CRTC's VRR_ENABLED property. Removes judder when
   the content rate does not divide the refresh rate.

/* AND THE CADENCE PROBLEM, which VRR was invented for:
     24 fps film on a 60 Hz display needs 3:2 PULLDOWN -
     frame A for 3 refreshes, frame B for 2, alternating.
     The uneven timing is visible as JUDDER on slow pans.
     A 120 Hz display divides evenly by both 24 and 30, which
     is why 120 Hz panels matter more for film than for games.

/* MULTIPLE PLANES, ONE COMMIT: the atomic API lets you flip
   the UI plane and the video plane in the same transaction,
   so they change together. Flipping them separately means one
   frame where the subtitle belongs to the previous video
   frame - a subtle artefact that is very hard to attribute.*/
```

How it shows up

Symptom	Cause
Video playback drains the battery	GPU compositing instead of a hardware plane
Washed-out or crushed video	`COLOR_ENCODING` / `COLOR_RANGE` plane properties not set (chapter 2)
Atomic commit fails with `EINVAL`	Format, modifier, scaling range or bandwidth — use `TEST_ONLY` to find out which
Fast path works alone, stops when a UI element overlaps	The compositor fell back; nothing reports it
Horizontal tear across the picture	Writing the scanout buffer without waiting for vblank
Video and subtitles are one frame out of step	Planes flipped in separate commits
Judder on slow pans	3:2 pulldown — 24 fps on a 60 Hz display

Symptom	Cause
Scrambled rectangles on screen	Modifier mismatch between decoder and plane
Second display cannot be enabled at full resolution	Display controller bandwidth exhausted
Works on one SoC, falls back on another	Different plane capabilities — query `IN_FORMATS`, never assume

Check yourself

- ✓ Name the five KMS object types and the chain from buffer to screen.
- ✓ List five things a hardware plane does for free, and say why they cost no extra bandwidth.
- ✓ Explain why atomic modesetting replaced the legacy API.
- ✓ Say what `TEST_ONLY` is for and why it is the most useful part of the API.
- ✓ Explain the units of the source and destination rectangles and the bug from confusing them.
- ✓ Trace a decoded frame from V4L2 to a plane, naming each call.
- ✓ Give the four conditions that must hold for the zero-copy path.
- ✓ Say which colour properties a YUV plane needs and what the defaults usually are.
- ✓ Explain the vblank flip discipline and what must not be touched until the event arrives.
- ✓ Determine from a running Linux system whether video is on a plane or being composited.

Media frameworks and acceleration APIs

Between your application and the hardware sits a stack of abstractions whose job is to hide the differences between vendors — and whose main failure mode is to hide the fact that it silently stopped using the hardware at all.

The stack

```
YOUR APPLICATION

     |
   HARDWARE

EACH LAYER CAN FALL BACK. That is the design goal - a
pipeline that always works - and the operational problem,
because "always works" and "works efficiently" are
different properties and only one of them is reported.
```

Framework	Where	Character
ffmpeg / libav*	Everywhere	The universal toolkit. A library and a CLI; every other framework uses it or reimplements it
GStreamer	Linux, embedded	A graph of elements negotiating caps. Powerful, and the negotiation is where the difficulty lives
MediaCodec / ExoPlayer	Android	The only sanctioned path. ExoPlayer handles the container and adaptive streaming above it
AVFoundation / VideoToolbox	Apple	Clean, well documented, hardware paths that work by default
Media Foundation	Windows	Transform-based; wraps DXVA and vendor encoders
libcamera	Linux	Replaces ad-hoc V4L2 camera code — handles the media graph, 3A and per-sensor tuning
Chromium / WebCodecs	Browsers	WebCodecs exposes raw encode and decode to JavaScript, hardware-backed where available

GStreamer, and the negotiation problem

```
# A pipeline is a graph of elements. The pieces negotiate
# CAPS - format, resolution, framerate, and crucially the
# memory type.

$ gst-launch-1.0 filesrc location=in.mp4 ! qtdemux ! h264parse \
    ! avdec_h264 ! videoconvert ! autovideosink
#   ^ software decode, and a videoconvert that will quietly
#     do an NV12 -> RGB pass on the CPU

# The hardware version, with everything staying in GPU memory:
$ gst-launch-1.0 filesrc location=in.mp4 ! qtdemux ! h264parse \
    ! vaapih264dec ! "video/x-raw(memory:VASurface)" \
    ! vaapipostproc ! vaapisink
#              ^^^^^^^^^^^^^^^^^^^ the caps filter that FORCES
#              the frames to stay in VA surfaces. Without it
#              GStreamer may insert a download to system
#              memory and you lose the whole benefit.

# V4L2 on embedded:
$ gst-launch-1.0 v4l2src device=/dev/video0 \
    ! "video/x-raw,format=NV12,width=1920,height=1080" \
    ! v4l2h264enc ! h264parse ! matroskamux ! filesink location=out.mkv

# THE DIAGNOSTIC THAT MATTERS - see what was actually
# negotiated, element by element:
$ GST_DEBUG=GST_CAPS:5 gst-launch-1.0 ... 2>&1 | grep -i 'caps:'

# Or dump the graph and look at it:
$ GST_DEBUG_DUMP_DOT_DIR=/tmp gst-launch-1.0 ...
$ dot -Tpng /tmp/*PLAYING*.dot -o pipeline.png
# Every element and the caps on every link. If you see
# videoconvert or a "system memory" caps where you expected
# a hardware memory type, you found your problem.

# "not-negotiated" is GStreamer's most common error and it
# always means: no common format between two adjacent
# elements. Read the caps on both sides and look for the
# missing overlap - usually a pixel format or a modifier
# (chapter 4).
```

> **HARDWARE MEMORY TYPES ARE THE WHOLE POINT**
> Every acceleration API has a notion of "a frame that lives in hardware memory" — `memory:VASurface`, `memory:DMABuf`, `memory:GLMemory`, `AVHWFramesContext`. Keeping frames in that domain from decoder to display is what zero-copy *is* (chapter 16). The moment a frame is downloaded to system memory the benefit is gone, and every framework will do that download automatically and silently to make an otherwise-impossible link work.

ffmpeg's hardware model

```
/* Two contexts, and understanding the split is most of it. */

  AVHWDeviceContext   the device: a VA display, a CUDA
                      context, a DRM fd
  AVHWFramesContext   a POOL of frames living on that device,
                      with a fixed format and size

/* Decoding into hardware frames: */

  AVBufferRef *hw_device = NULL;
  av_hwdevice_ctx_create(&hw_device, AV_HWDEVICE_TYPE_VAAPI,
                         "/dev/dri/renderD128", NULL, 0);

  codec_ctx->hw_device_ctx = av_buffer_ref(hw_device);
  codec_ctx->get_format    = get_hw_format;   /* see below */

/* THE CALLBACK IS MANDATORY. libavcodec asks which pixel
   format you want from a list; if you do not pick the
   hardware one, it silently gives you software frames and
   everything still works, slowly. */

static enum AVPixelFormat get_hw_format(AVCodecContext *ctx,
                                        const enum AVPixelFormat *fmts)
{
        for (const enum AVPixelFormat *p = fmts;
             *p != AV_PIX_FMT_NONE; p++)
                if (*p == AV_PIX_FMT_VAAPI)
                        return *p;
        fprintf(stderr, "no hardware format offered\n");
        return AV_PIX_FMT_NONE;      /* fail LOUDLY rather
                                        than fall back */
}

/* After decode, frame->format is AV_PIX_FMT_VAAPI and
   frame->data[3] is the VASurfaceID. The pixels are NOT in
   frame->data[0] - reading them requires an explicit
   transfer, which is exactly the copy you are trying to
   avoid: */

  av_hwframe_transfer_data(sw_frame, hw_frame, 0);   /* SLOW  */

/* Or export as DMABUF and hand it to DRM/KMS or the GPU
   (chapter 18): */
  av_hwframe_map(drm_frame, hw_frame, AV_HWFRAME_MAP_DIRECT);

/* THE CLI equivalents: */
$ ffmpeg -hwaccel vaapi -hwaccel_device /dev/dri/renderD128 \
    -hwaccel_output_format vaapi \
    -i in.mp4 -c:v h264_vaapi -b:v 5M out.mp4
#          ^^^^^^^^^^^^^^^^^^^^^^^^^ WITHOUT this the frames
#          are downloaded to system memory after decode and
#          uploaded again before encode - two full copies per
#          frame, and it still "works".
```

Android and the browser

```
// MediaCodec - Android's only sanctioned codec API.
// The same queue model as V4L2 underneath (chapter 17).

MediaCodec codec = MediaCodec.createDecoderByType("video/avc");
MediaFormat fmt = MediaFormat.createVideoFormat("video/avc", 1920, 1080);
fmt.setByteBuffer("csd-0", spsBuffer);      // SPS
fmt.setByteBuffer("csd-1", ppsBuffer);      // PPS

// THE ZERO-COPY DECISION IS THIS ONE LINE:
codec.configure(fmt, surface, null, 0);
//                   ^^^^^^^
//   a Surface  -> frames go straight to the compositor,
//                 never touch the CPU. Fast path.
//   null       -> frames come back as ByteBuffers you must
//                 read, convert and upload. Slow path.
// Passing null "to inspect the frames" is how a video app
// becomes a battery problem.

codec.start();
for (;;) {
    int in = codec.dequeueInputBuffer(10000);
    if (in >= 0) { /* fill and queueInputBuffer */ }

    MediaCodec.BufferInfo info = new MediaCodec.BufferInfo();
    int out = codec.dequeueOutputBuffer(info, 10000);
    if (out >= 0)
        codec.releaseOutputBuffer(out, true);  // true = render
                                               // it to the
                                               // Surface
}

// Check what the fast path is doing:
//   adb shell dumpsys SurfaceFlinger
//   look at the composition column: DEVICE = a hardware
//   plane, CLIENT = GPU composited (chapter 18)
```

```
// WebCodecs - raw codec access in the browser, hardware-backed
// where the platform allows.

const decoder = new VideoDecoder({
  output: (frame) => {
    // A VideoFrame. It may live in GPU memory - draw it
    // straight to a canvas or a WebGL texture and it never
    // touches JS memory.
    ctx.drawImage(frame, 0, 0);
    frame.close();          // MANDATORY. VideoFrames hold
                            // hardware buffers and the pool is
                            // small; forgetting close() stalls
                            // the decoder within a few frames.
  },
  error: (e) => console.error(e),
});

// Ask before you commit - support varies by browser and
// platform, and hardwareAcceleration is a HINT:
const support = await VideoDecoder.isConfigSupported({
  codec: 'avc1.640028',            // High profile, level 4.0
  hardwareAcceleration: 'prefer-hardware',
});

decoder.configure({ codec: 'avc1.640028', codedWidth: 1920,
                    codedHeight: 1080 });
decoder.decode(new EncodedVideoChunk({
  type: 'key', timestamp: 0, data: chunkBytes }));
```

EVERY FRAMEWORK WILL LIE TO YOU BY SUCCEEDING

Ask for hardware decode into a texture. If the modifier does not match, or the format is unsupported, or the surface is the wrong type, the framework inserts a download, a colour conversion and an upload, and returns success. Frame rate on a desktop may be unaffected. The only reliable check is to measure the video engine's utilisation and the memory bandwidth — `intel_gpu_top`, `nvidia-smi dmon`, `dumpsys SurfaceFlinger`, or `/sys/kernel/debug/dri/0/state` — not whether the picture appears.

How it shows up

Symptom	Cause
CPU at 100% despite requesting hardware decode	`get_format` callback missing, or the fallback was taken
Two full-frame copies per frame in the profile	`-hwaccel_output_format` not set
GStreamer: "not-negotiated"	No common caps between adjacent elements — dump the graph
GStreamer works but is slow	A `videoconvert` or a download inserted during negotiation
Android app drains battery playing video	`configure()` called with `null` instead of a Surface
MediaCodec stalls after a few frames	Output buffers not released
WebCodecs decoder stalls	`frame.close()` not called
Works on one machine, falls back on another	Different driver, format or modifier support
Frames arrive but pixels are empty	Hardware frame read as if it were software — `data[0]` is not the picture
Encoder output is much larger than expected	Hardware encoder, shallow search (chapter 16)

Check yourself

- ✓ Name the four layers between an application and video hardware.
- ✓ Explain why every layer falling back gracefully is an operational problem.
- ✓ Say what a hardware memory type is and name three examples.
- ✓ Explain GStreamer caps negotiation and what "not-negotiated" means.
- ✓ Distinguish `AVHWDeviceContext` from `AVHWFramesContext`.
- ✓ Explain why ffmpeg's `get_format` callback is mandatory and what happens without it.
- ✓ Say what `-hwaccel_output_format` prevents.
- ✓ Identify the one line in a MediaCodec setup that decides the fast path.
- ✓ Explain why `VideoFrame.close()` is mandatory in WebCodecs.
- ✓ Give three ways to verify hardware acceleration is genuinely in use.

Debugging a video pipeline

A video bug has a visible signature, and the signature names the layer. Learning to read "green frame", "diagonal skew", "washed out", "judder" as diagnoses rather than symptoms turns a day of guessing into ten minutes of bisection.

Read the artefact, find the layer

What you see	Layer	Look at
Diagonal skew, each row shifted further	Buffer	Stride confused with width (ch 1)
Purple / orange picture, luma correct	Buffer	U and V swapped — NV12 vs NV21 (ch 4)
Scrambled rectangles	Buffer	Tiled buffer read as linear; modifier mismatch
Washed out or **crushed**	Colour	Limited/full range mismatch (ch 2)
Slight colour shift, faces off	Colour	BT.601 vs BT.709 matrix
Bottom rows garbage	Codec	Crop ignored — 1080 vs 1088 (ch 16)
Green frame then correct	Codec	Displaying before the first keyframe, or an uninitialised DPB
Smearing that clears at a keyframe	Transport	Packet loss; references corrupted (ch 10)
Blocking that pulses	Encoder	Rate control (ch 13)
Judder on pans	Display	Cadence — 24 fps on 60 Hz (ch 18)
Tearing, a horizontal seam	Display	No vblank synchronisation
Lip sync drift	Container	Timestamps (ch 15)
Combing on motion	Source	Interlaced, not deinterlaced

BISECT THE PIPELINE, DO NOT STARE AT THE OUTPUT

A pipeline is capture → encode → mux → transmit → demux → decode → convert → display. The fastest way to localise a bug is to *dump the intermediate*: write the raw frames after capture, the elementary stream after encode, the decoded frames before display. Whichever dump is the first to look wrong contains the bug. Ten minutes of dumping beats a day of reasoning about which stage is guilty.

Dumping at every stage

```
# 1. AFTER CAPTURE - raw frames from the device
$ v4l2-ctl -d /dev/video0 \
    --set-fmt-video=width=1920,height=1080,pixelformat=NV12 \
    --stream-mmap --stream-count=30 --stream-to=cap.nv12
$ ffplay -f rawvideo -pixel_format nv12 -video_size 1920x1080 cap.nv12
# Wrong here -> sensor, ISP, or your format assumption.

# 2. AFTER ENCODE - the elementary stream, no container
$ ffmpeg -i input.mp4 -c:v copy -bsf:v h264_mp4toannexb -f h264 es.264
$ ffplay es.264
# Plays -> the codec data is fine and the problem is the
# container or the transport.

# 3. AFTER DECODE - what the decoder actually produced
$ ffmpeg -i input.mp4 -pix_fmt nv12 -f rawvideo dec.nv12
$ ffplay -f rawvideo -pixel_format nv12 -video_size 1920x1080 dec.nv12
# Correct here but wrong on screen -> conversion or display.

# 4. COMPARE two stages numerically rather than by eye
$ ffmpeg -i original.y4m -i decoded.y4m \
    -lavfi "[0:v][1:v]psnr=stats_file=psnr.log" -f null -
$ awk '$0 ~ /psnr_avg/ {print}' psnr.log | sort -t: -k6 -n | head
# The worst frames first. A single terrible frame among good
# ones is a dropped reference; a gradual decline is drift
# (chapter 11).

# 5. VISUAL DIFF, which finds what metrics miss
$ ffmpeg -i a.mp4 -i b.mp4 \
    -lavfi "[0:v][1:v]blend=all_mode=difference,eq=contrast=8" \
    -c:v libx264 -crf 18 diff.mp4
# Black = identical. Anything visible is a real difference,
# amplified 8x.
```

Inspecting the bitstream itself

```
# When the pixels are wrong and you suspect the stream.

# Every NAL unit, its type and size:
$ ffmpeg -i in.mp4 -c copy -bsf:v trace_headers -f null - 2>&1 | head -60
[trace_headers] Sequence Parameter Set
[trace_headers] 0           forbidden_zero_bit          0
[trace_headers] 1           nal_ref_idc                11 = 3
[trace_headers] 3           nal_unit_type            00111 = 7
[trace_headers] 8           profile_idc           01100100 = 100
[trace_headers] 16          level_idc             00101000 = 40
[trace_headers] ...         pic_width_in_mbs_minus1   = 119
[trace_headers] ...         pic_height_in_map_units_minus1 = 67
#                                                      ^^ 68
#   68 * 16 = 1088, and frame_cropping tells you it is really
#   1080. This is where you check the crop (chapter 16).

# Frame types, sizes and timestamps in one view:
$ ffprobe -select_streams v -show_entries \
    frame=pict_type,key_frame,pkt_size,pkt_pts_time \
    -of csv=p=0 in.mp4 | head -20

# Bitrate over time - finds spikes and starved regions:
$ ffprobe -select_streams v -show_entries frame=pkt_size \
    -of csv=p=0 in.mp4 | awk '{s+=$1; n++}
      n%30==0 {printf "%d %.0f kbit/s\n", n/30, s*8/1000; s=0}'

# Is the file structurally valid at all?
$ ffmpeg -v error -i in.mp4 -f null -
# Silence = clean. Any output here is a real decode error.

# Deeper conformance:
$ ffmpeg -v verbose -err_detect explode -i in.mp4 -f null -
# Turns warnings that are normally tolerated into failures.

# For MP4 box structure:
$ MP4Box -info in.mp4
$ mp4dump in.mp4 | head -40
# Missing moov, wrong track duration, an edit list you did not
# expect (chapter 15) - all visible here.
```

> **"IT PLAYS IN VLC" PROVES ALMOST NOTHING**
> VLC and ffmpeg are extraordinarily tolerant — they resynchronise after corruption, guess missing metadata, ignore level violations and work around broken muxers. A hardware decoder does none of that. If a file plays in VLC and fails on a device, the file is very likely wrong and VLC is compensating. Test with `-err_detect explode`, and on the actual target.

Performance, not correctness

```
# THE FIRST QUESTION: is the hardware path in use at all
# (chapters 16, 19)?

$ sudo intel_gpu_top             # "Video" and "VideoEnhance" rows
$ nvidia-smi dmon -s u           # "dec" and "enc" columns
$ adb shell dumpsys SurfaceFlinger | grep -A5 'Composition'
$ sudo cat /sys/kernel/debug/dri/0/state | grep -c 'format=NV12'
# Zero in any of these = you are on the software path.

# THE SECOND: where is the time going?
$ perf top -p $(pidof myplayer)
# Expect to see, in a healthy software decoder:
#   ff_h264_decode_mb_cabac      entropy   (chapter 8)
#   h264_idct_add8_8_avx         transform
#   ff_h264_filter_mb            deblock   (chapter 12)
#   ff_hscale / yuv2rgb          CONVERSION - if this is high,
#                                you have an unnecessary
#                                format conversion

# THE THIRD: memory bandwidth, which is what actually limits
# embedded pipelines (chapter 16).
$ sudo perf stat -e uncore_imc/data_reads/,uncore_imc/data_writes/ \
    -a sleep 5
# Compare against the theoretical (frame size x fps x copies).
# Much higher than expected = hidden copies.

# LATENCY, end to end, measured rather than estimated:
$ ffmpeg -f lavfi -i "testsrc=size=640x480:rate=60" \
    -vf "drawtext=text='%{pts\\:hms}':fontsize=48:x=10:y=10" \
    -f v4l2 /dev/video1
# Point a camera at the screen showing the timestamp, and
# compare. Crude, and it measures the WHOLE chain including
# the display, which is the number that actually matters.

# GStreamer's built-in latency tracer:
$ GST_DEBUG="GST_TRACER:7" GST_TRACERS="latency" \
    gst-launch-1.0 ... 2>&1 | grep latency
```

The method

1. **Name the artefact.** Use the table above. Half of all video bugs are identified by their appearance alone.
2. **Bisect by dumping.** Raw after capture, elementary stream after encode, raw after decode. The first bad dump contains the bug.
3. **Check the metadata before the pixels.** Format, stride, colour tags, crop, timestamps. These are cheap to inspect and are the cause far more often than the codec.
4. **Reproduce with ffmpeg alone.** If `ffmpeg -i in -f null -` is clean, the file is fine and your pipeline is not.
5. **Test on the target.** Desktop tolerance hides level violations, missing headers and alignment problems that a hardware decoder will not accept.

6 **Separate correctness from performance.** They have different tools and different answers, and confusing them wastes the most time.

How it shows up

Symptom	Cause
Plays on desktop, fails on device	Level, profile, alignment or missing SPS/PPS — desktop tolerance
First frames green or grey	Rendering before the first keyframe
Corruption clears at each keyframe	Packet loss corrupting references
Frame rate fine, power high	Software path or hidden copies — measure, do not watch
PSNR fine, viewers complain	A temporal artefact no frame-wise metric sees (ch 6)
Bug disappears under a debugger	Timing-dependent — a buffer race or a missing fence
Works with 4 buffers, drops with 2	Starving the driver (ch 17)
Encoder output valid but unplayable on a TV	Non-conformant HRD or an exceeded level
Latency far above the sum of the stages	Queueing between stages, or encoder lookahead
Reproducible only at a specific resolution	Alignment — try a multiple of 16 in both dimensions

Check yourself

- ✓ Given diagonal skew, purple output and a washed-out picture, name the layer for each.
- ✓ Explain the bisect-by-dumping method and the three points to dump at.
- ✓ Extract an elementary stream from an MP4 and say what it proves if it plays.
- ✓ Use `trace_headers` to find the coded height and the crop.
- ✓ Say why "it plays in VLC" is weak evidence.
- ✓ Give three ways to verify the hardware path is in use.
- ✓ Read a decoder profile and identify an unnecessary format conversion.
- ✓ Describe a way to measure true end-to-end latency.
- ✓ Explain why a frame-wise metric can look fine while viewers complain.
- ✓ List the six steps of the method in order.

Project: a capture-to-encode pipeline

A complete program: capture NV12 from a V4L2 camera, encode it with a hardware codec, and mux it to a file — with the frames never once copied by the CPU. Everything in this track appears here at once, and the zero-copy path is the part that makes it worth building rather than downloading.

What we are building

```
/dev/video0            /dev/video11          out.mp4
CAMERA                 HARDWARE ENCODER
V4L2 capture           V4L2 M2M
     |                      |
     |  VIDIOC_EXPBUF       |
     |  -> dmabuf fd        |
     +--------------------->|  OUTPUT queue
                            |  V4L2_MEMORY_DMABUF
                            |
                            |  the encoder reads the
                            |  CAMERA'S buffer directly.
                            |  ZERO COPIES.
                            |
                            |  CAPTURE queue
                            |  -> H.264 bitstream
                           v
                      userspace: mux to MP4

THE PROPERTY WE ARE ENFORCING
  the CPU never touches a pixel. It moves file descriptors
  and a few hundred bytes of bitstream per frame.

THE MEASUREMENT THAT PROVES IT
  at 1080p30 NV12, one copy is 93 MB/s. A naive pipeline
  does three or four (chapter 16). We will measure memory
  bandwidth and CPU and show both are near zero.

TARGET: a Raspberry Pi 4/5, a Rockchip or i.MX board, or
any x86 machine with a UVC camera and VA-API. The V4L2 code
is identical; only the device node changes.
```

The shared header

```
/* pipeline.h */

#ifndef PIPELINE_H
#define PIPELINE_H

#include <linux/videodev2.h>
#include <stdint.h>
#include <stdbool.h>

#define MAX_BUFS 8

}
```

`VIDIOC_EXPBUF` IS THE WHOLE PROJECT

It turns a driver-allocated buffer into a file descriptor that any other driver can import. Without it you must `mmap` the camera buffer, `memcpy` into an encoder buffer, and pay 93 MB/s at 1080p30 — plus a second copy if the encoder cannot take your memory either. A driver that does not implement `EXPBUF` cannot participate in a zero-copy pipeline at all, and that is worth discovering at design time rather than after the code is written.

The encoder side

```
/* encoder.c - a V4L2 M2M encoder whose OUTPUT queue imports
   the camera's dmabufs. */

int encoder_open(struct stream *out, struct stream *cap_out,
                 const struct stream *cam, int bitrate)
{
        int fd = open("/dev/video11", O_RDWR | O_NONBLOCK | O_CLOEXEC);
        if (fd < 0) { perror("encoder"); return -1; }
        out->fd = cap_out->fd = fd;   /* one device, two queues */

        /* --- OUTPUT queue: raw frames IN.
               "OUTPUT" is from the APPLICATION's point of view
               (chapter 17). --- */
        out->type   = V4L2_BUF_TYPE_VIDEO_OUTPUT_MPLANE;
        out->memory = V4L2_MEMORY_DMABUF;      /* <-- import   */

        struct v4l2_format f = {0};
        f.type = out->type;
        f.fmt.pix_mp.width        = cam->width;

        }
}

/* THE BUFFER DISCIPLINE, which is the part that goes wrong:

   A camera buffer is IN USE from the moment the encoder
   accepts it until the encoder returns the OUTPUT buffer.
   Requeue it to the camera before that and the encoder reads
   a frame the sensor is overwriting - producing tearing that
   looks like a decoder bug.

   And if you never requeue, the camera runs out of buffers
   and starts dropping frames silently. Watch
   v4l2_buffer.sequence for gaps (chapter 17).            */
```

THE ELEMENTARY STREAM IS NOT A FILE ANYONE CAN PLAY

`out.h264` is raw Annex B — no container, no timestamps, no duration. It plays in ffmpeg because ffmpeg guesses a frame rate, and it will not play in most players or seek at all. Mux it. The `-r` below is a claim about frame rate, not a measurement; for variable-rate capture you must carry the real timestamps through and mux from those (chapter 15).

Building and running

```
$ gcc -O2 -Wall -o pipeline main.c capture.c encoder.c
$ ./pipeline /dev/video0 /dev/video11 out.h264

# Find the encoder node - it is not always video11:
$ for d in /dev/video*; do
    echo -n "$d: "
    v4l2-ctl -d $d --info | grep -i 'card type' | cut -d: -f2
  done
/dev/video0:  Integrated Camera
/dev/video11: bcm2835-codec-encode      <-- this one

$ v4l2-ctl -d /dev/video11 --list-formats-ext --all | head -30
# Confirm it accepts NV12 in and H264 out, and check the
# DMABUF capability:
$ v4l2-ctl -d /dev/video11 --info | grep -i 'streaming\|m2m'

# Mux the elementary stream:
$ ffmpeg -r 30 -i out.h264 -c:v copy -movflags +faststart out.mp4

# VERIFY IT IS ACTUALLY CORRECT (chapter 20):
$ ffmpeg -v error -i out.mp4 -f null -            # silence = clean
$ ffprobe -select_streams v -show_entries \
    frame=pict_type,pkt_size -of csv=p=0 out.mp4 | head
I,84213
P,3241
P,2988
# I-frame 25x a P-frame. Prediction is working (chapter 9).

# PROVE THE ZERO COPY - this is the point of the exercise.
$ pidstat -p $(pidof pipeline) 1 5
# CPU should be 1-3%. If it is 40%, something is copying.

$ sudo perf stat -e uncore_imc/data_reads/,uncore_imc/data_writes/ \
    -a -- sleep 10
# At 1080p30 NV12 the FLOOR is:
#   camera writes    93 MB/s
#   encoder reads    93 MB/s
#   encoder writes   ~0.5 MB/s (the bitstream)
# ~190 MB/s total. If you measure 400+, there is a hidden
# copy (chapter 16).

$ sudo perf top -p $(pidof pipeline)
# You should see poll and ioctl. If memcpy or a yuv2rgb
# routine appears, the fast path is not being taken.
```

Extensions worth doing

Exercise	What it teaches
Mux to fragmented MP4 in-process rather than writing Annex B	Timestamps, timebases and `+faststart` (ch 15)
Add a preview: import the same dmabuf into a DRM plane	The full zero-copy display path (ch 18)
Carry the camera's real timestamps into the container	Why VFR breaks naive muxers
Handle a resolution change mid-stream	`SOURCE_CHANGE`, and the reallocation dance (ch 17)

Exercise	What it teaches
Implement the drain on Ctrl-C	`ENC_CMD_STOP` and `BUF_FLAG_LAST` — without it you lose the last frames
Force a keyframe on demand	`V4L2_CID_MPEG_VIDEO_FORCE_KEY_FRAME`, and why a streaming server needs it
Compare hardware output with `x264 --preset slow` at equal VMAF	The 20–50% penalty, measured on your own hardware (ch 16)
Deliberately requeue the camera buffer too early	Reproduce the tearing, so you recognise it later
Set the buffer count to 2 and watch `sequence`	Frame drops, and why buffer count is a latency dial

How it shows up

Symptom	Cause
`EXPBUF` returns `ENOTTY`	Driver has no dmabuf export — zero-copy is impossible; you must copy
`QBUF` on the encoder returns `EINVAL`	Single-planar structs against a multiplanar device, or a stride mismatch
Tearing, half of two different frames	Camera buffer requeued before the encoder finished with it
Frames dropped, `sequence` has gaps	Too few buffers, or buffers held too long
Output file is truncated garbage	`sizeimage` too small for a keyframe
Player will not open `out.h264`	Elementary stream — mux it
Stream will not play from the middle	`REPEAT_SEQ_HEADER` not set
CPU at 40% instead of 2%	A copy somewhere — check `perf top` for `memcpy`
Camera gives YUYV, not NV12	The mode does not exist; a conversion is unavoidable — choose it deliberately
Last second of video missing	No drain at exit
Works at 1920×1080, fails at 1280×720	Stride assumption; read `bytesperline` back

Check yourself

- ✓ Draw the pipeline and say where a copy would occur without `EXPBUF`.
- ✓ Explain what `VIDIOC_EXPBUF` produces and why it enables zero-copy.
- ✓ Say why the encoder's OUTPUT queue uses `V4L2_MEMORY_DMABUF` while its CAPTURE queue uses `MMAP`.
- ✓ Explain why the camera buffer must not be requeued until the encoder returns its OUTPUT buffer.
- ✓ Say how to detect dropped frames, and what causes them.
- ✓ Explain why `sizeimage` must be sized for a keyframe.
- ✓ Say why `REPEAT_SEQ_HEADER` matters for a stream someone joins late.
- ✓ Compute the memory bandwidth floor for 1080p30 NV12 and say what a higher figure means.
- ✓ Give two ways to prove the CPU is not touching pixels.
- ✓ Explain why the raw `.h264` is not a playable file.

TRACK

AI & large language models

The mathematics first, then machine learning, then transformers and LLMs — ending with running a model on embedded hardware.

28 chapters

What this track assumes and where it goes

Twenty-eight chapters from "what is a vector" to a working transformer you write yourself. No prior machine learning, and no mathematics beyond school algebra — everything else is built here.

Why an embedded engineer should read this

```
THREE HONEST REASONS:

1. THE WORK IS ARRIVING IN YOUR DOMAIN.
   Keyword spotting on a Cortex-M4. Anomaly detection on
   a motor controller. Vision on a $5 SoC. NPUs in
   application processors you already ship. Someone has
   to write the driver for the accelerator, decide
   whether the model fits in SRAM, and explain why the
   quantised version is 3% less accurate.

2. THE INTUITIONS TRANSFER BOTH WAYS.
   A transformer's forward pass is a fixed sequence of
   matrix multiplications over a known-size working set.
   That is a MEMORY BANDWIDTH problem and a CACHE
   BLOCKING problem - things you already reason about.
   Conversely, understanding numerical precision, fixed
   point and saturation is exactly what quantisation
   needs, and embedded engineers already have it.

3. AND THE PLAIN ONE: these systems are now part of the
   tooling you use every day. Knowing what they are -
   really, mechanically - is the difference between using
   them well and guessing.

WHAT THIS TRACK IS NOT:
  · not a research course. No proofs of convergence, no
    measure theory.
  · not a framework tutorial. You will see PyTorch, but
    the point is what it computes, not its API.
  · not a survey. One path, taken properly, ending at a
    working transformer.
```

What is assumed

```
/* YOU NEED:
     · comfort with C (the C track), or any language with
       loops, arrays and functions
     · school algebra: symbols, functions, exponents
     · the willingness to write out a small example by hand
       when the notation stops making sense

/* YOU DO NOT NEED:
     · university mathematics. Linear algebra, calculus and
       probability are each built from zero here, in the
       amount this subject actually uses - which is much
       less than a full course.
     · Python experience. The code is readable if you know
       C; the small amount of syntax you need is introduced
       where it appears.
     · a GPU. Everything in this track runs on a laptop CPU.
       The final project runs on a Raspberry Pi.

/* THE TOOLS, if you want to run the code:
     python3, numpy, and eventually torch (CPU build)

     $ python3 -m venv venv
     $ source venv/bin/activate     # Windows:
                                    # venv\Scripts\activate
     $ pip install numpy matplotlib
     $ pip install torch --index-url \
           https://download.pytorch.org/whl/cpu

   THE NUMPY-ONLY CHAPTERS COME FIRST DELIBERATELY. Writing
   a matrix multiply as three nested loops before ever
   calling a library is the difference between knowing what
   a framework does and trusting that it does something.  */
```

The shape of the track

```
PART 1 — THE MATHEMATICS (chapters 02–11)
  Exactly what is needed, and no more.

  02 vectors            what a vector IS and what
                        operations mean
  03 matrices           as transformations, not tables
  04 matmul             THE core operation — and where
                        all the compute goes
  05 eigen/SVD          why some directions matter more
  06 derivatives        rate of change; gradients
  07 chain rule         -> BACKPROPAGATION. The chapter
                        everything trains on.
  08 probability        distributions, expectation
  09 Bayes              likelihood, estimation
  10 information theory entropy -> CROSS-ENTROPY, which
                        is the loss function you will
                        use for every model here
  11 optimisation       gradient descent, momentum, Adam

PART 2 — MACHINE LEARNING (12–15)
  12 what ML is         and when it is the wrong tool
  13 regression         the simplest models, done fully
  14 neural networks    the MLP; why non-linearity
                        matters
  15 training           loss, initialisation,
                        regularisation, what goes wrong

PART 3 — LANGUAGE MODELS (16–25)
  16 tokenisation       text -> integers. Where many
                        weird model behaviours originate.
  17 embeddings         integers -> vectors with meaning
  18 sequence models    RNNs and LSTMs, and why they were
                        replaced
  19 attention          THE key idea
  20 the transformer    the full architecture
  21 multi-head + positional encoding
  22 norm, residuals, FFN
  23 pretraining        and scaling laws
  24 fine-tuning        instruction tuning, RLHF, DPO
  25 inference          sampling, the KV cache, context
                        length

PART 4 — MAKING IT RUN (26–28)
  26 quantisation       int8, int4, and what precision
                        costs
  27 edge deployment    NPUs, TFLite Micro, ONNX, memory
                        budgets — THE EMBEDDED CHAPTER
  28 PROJECT            a character-level transformer,
                        written and trained from scratch,
                        in numpy and then in PyTorch

THE DEPENDENCY THAT MATTERS: chapters 04, 07 and 10 are
load-bearing. Matrix multiplication, the chain rule and
cross-entropy appear in every chapter after them. If a
later chapter stops making sense, the gap is almost
always in one of those three.
```

Notation

```
/* Introduced once, used throughout. Refer back here.     */

   SCALARS        lowercase italic:  x, y, alpha
   VECTORS        lowercase bold:    x, w      (column
                                               vectors by
                                               default)
   MATRICES       uppercase bold:    W, X, A
   TENSORS        the general case: an n-dimensional array.
                  A scalar is rank 0, a vector rank 1, a
                  matrix rank 2. "Tensor" in this field just
                  means "n-dimensional array" - the physics
                  meaning is not implied.

   x_i            the i-th element of vector x
   W_ij           row i, column j of W
   x^T            transpose
   ||x||          the norm (length) of x
   x · y          dot product
   A @ B          matrix multiplication (numpy/PyTorch
                  notation, used in code)
   A * B          ELEMENTWISE product (in code) - NOT matrix
                  multiplication. A frequent source of silent
                  bugs.

   SHAPES ARE WRITTEN LIKE THIS:  (batch, seq_len, d_model)
   and you should read every line of model code by tracking
   shapes. MOST BUGS IN THIS FIELD ARE SHAPE BUGS. The
   habit to build now: after every operation, ask "what
   shape is this, and why?"

   f(x)           a function
   df/dx          derivative
   ∇f             gradient - the vector of all partial
                  derivatives
   E[X]           expectation
   P(x)           probability

/* AND THE ONE CONVENTION THAT CONFUSES EVERYONE:

   In mathematics, a linear layer is usually written
        y = W x + b        with x a COLUMN vector
   In code, data comes in ROWS, so it is written
        Y = X @ W.T + b    or often just  X @ W + b
   with W stored already transposed.

   THESE ARE THE SAME OPERATION. When a paper and an
   implementation seem to disagree about which index is
   which, this is usually why.                          */
```

HOW TO READ THIS TRACK

Do the arithmetic by hand at least once per chapter. A 2×2 matrix multiply, one step of gradient descent, one softmax over three numbers. The notation is compressed and it hides the fact that everything here is arithmetic you could do on paper — until you have done it on paper, the compression reads as magic. Every chapter ends with a "check yourself" list written to be answerable without looking.

An honest framing of the subject

```
/* WHAT THESE SYSTEMS ARE:
     Function approximators with an enormous number of
     parameters, fitted to data by gradient descent. A large
     language model is a function from a sequence of tokens
     to a probability distribution over the next token,
     with a few hundred billion adjustable numbers, fitted
     to a large fraction of the written internet.

     THAT DESCRIPTION IS COMPLETE AND MECHANICAL. Everything
     in chapters 16–25 is an elaboration of it.

/* WHAT IS GENUINELY SURPRISING:
     That scaling this simple recipe — more parameters, more
     data, more compute — produces capabilities nobody
     explicitly designed: translation, arithmetic, code,
     in-context learning from examples in the prompt.
     Chapter 23 covers the scaling laws that describe this
     empirically. NOBODY HAS A COMPLETE THEORY OF WHY IT
     WORKS AS WELL AS IT DOES. That is the honest state of
     the field, and any source that tells you otherwise is
     selling something.

/* WHAT IS OFTEN OVERSTATED:
     · these are not databases; they do not retrieve facts
       reliably
     · they have no persistent memory between calls beyond
       what is in the context window (chapter 25)
     · confident output and correct output are not
       correlated as strongly as the fluency suggests
     · "reasoning" is a description of behaviour, not a
       claim about mechanism

/* WHAT THIS MEANS FOR AN ENGINEER:
     Treat model output as UNTRUSTED INPUT. Validate it,
     constrain it, and design the system so a wrong answer
     is recoverable. That is the same discipline you apply
     to a sensor reading or a network packet, and it is the
     right one here.                                    */
```

Check yourself

- ✓ State three reasons this material is relevant to embedded work.
- ✓ List what the track assumes and what it deliberately does not.
- ✓ Name the four parts and the three load-bearing chapters.
- ✓ Explain the difference between `A @ B` and `A * B`.
- ✓ Explain why `y = Wx + b` and `Y = X @ W + b` are the same operation.
- ✓ Give a complete, mechanical, one-sentence definition of a large language model.
- ✓ Say what is genuinely surprising about scaling, and what is commonly overstated.

Linear algebra: vectors and vector spaces

A vector is an array of numbers, and also a point in space, and also a direction with a length. Holding all three pictures at once is most of what "having intuition for linear algebra" means.

Three views of the same object

```
x = [3, 4]

AS AN ARRAY          two numbers in order. This is what
                     the computer stores:
                         float x[2] = {3.0f, 4.0f};

AS A POINT           the location (3, 4) in the plane

AS AN ARROW          from the origin to (3, 4), with a
                     DIRECTION and a LENGTH of 5

      y
      |
    4 +--------* (3,4)
      |       /|
      |      / |
      |     /  |    length = sqrt(3^2 + 4^2) = 5
      |    /   |
      |   /    |
      |  /     |
      | /      |
      +--------+------ x
      0        3

IN MACHINE LEARNING, THE THIRD VIEW IS THE USEFUL ONE:
a vector represents something, its DIRECTION carries the
meaning, and its LENGTH is often incidental. Two word
embeddings pointing the same way mean similar things,
whether one has length 3 and the other 30 (chapter 17).

AND THE DIMENSION IS NOT TWO. A word embedding lives in
768 or 4096 dimensions. YOU CANNOT PICTURE THAT, and you
do not need to: every operation below is defined
element by element and works identically at any
dimension. The 2-D picture is for intuition; the
arithmetic is what runs.
```

The operations

```
import numpy as np

a = np.array([3.0, 4.0])
b = np.array([1.0, 2.0])

# --- ADDITION: elementwise. Geometrically, tip to tail. ---
a + b            # [4., 6.]

# --- SCALAR MULTIPLICATION: scales the length,
#     keeps the direction (or reverses it if negative) ---
2 * a            # [6., 8.]
-1 * a           # [-3., -4.]

# --- IN C, so the loop is visible: ---
#   void vec_add(float *out, const float *x,
#                const float *y, int n) {
#       for (int i = 0; i < n; i++)
#           out[i] = x[i] + y[i];
#   }
#   That is the whole operation, at any dimension.

# --- NORM: the length ---
np.linalg.norm(a)                # 5.0
np.sqrt(np.sum(a**2))            # the same thing

#   L2 norm (Euclidean):  sqrt(sum(x_i^2))     <- the default
#   L1 norm (Manhattan):  sum(|x_i|)
#   L-inf norm:           max(|x_i|)
#   These appear again as REGULARISERS in chapter 15: L2
#   shrinks all weights, L1 drives some to exactly zero.

# --- NORMALISATION: length 1, direction preserved ---
a_hat = a / np.linalg.norm(a)      # [0.6, 0.8]
np.linalg.norm(a_hat)              # 1.0

#   A UNIT VECTOR IS PURE DIRECTION. This is why embeddings
#   are often normalised before comparison - you want to ask
#   "same direction?" without "same magnitude?" muddying it.

# --- DOT PRODUCT: the operation everything is built on ---
np.dot(a, b)                       # 3*1 + 4*2 = 11
a @ b                              # the same

#   int dot(const float *x, const float *y, int n) {
#       float s = 0;
#       for (int i = 0; i < n; i++) s += x[i] * y[i];
#       return s;
#   }

#   MULTIPLY-ACCUMULATE. One line. It is the single most
#   executed operation in all of machine learning, which is
#   why every DSP and NPU has a MAC unit and why chapter 04
#   is about doing many of these at once.
```

What the dot product means

```
   THE GEOMETRIC IDENTITY, and it is worth memorising:

        a · b = ||a|| ||b|| cos(theta)

   where theta is the angle between them.

   SO THE SIGN AND SIZE OF A DOT PRODUCT TELL YOU ABOUT
   ALIGNMENT:

     a · b  LARGE POSITIVE   ->  pointing the same way
     a · b  ZERO             ->  PERPENDICULAR (orthogonal)
     a · b  LARGE NEGATIVE   ->  pointing opposite ways

        b               b            b
        ^               ^             \
        |               |              \
        +---> a         +---> a    a <--+
     theta = 45         theta = 90   theta = 135
     dot > 0            dot = 0      dot < 0

   COSINE SIMILARITY removes the magnitudes:

        cos(theta) = (a · b) / (||a|| ||b||)

        +1  identical direction
         0  unrelated
        -1  opposite

   THIS IS THE STANDARD MEASURE OF SEMANTIC SIMILARITY
   BETWEEN EMBEDDINGS. When a vector database "finds similar
   documents", it is computing this, or its unnormalised
   cousin, against every stored vector.

   AND IT IS ALSO WHAT ATTENTION COMPUTES (chapter 19): a
   query vector is dotted with every key vector, and the
   result says how much each position matters. The whole
   mechanism is "dot product as a relevance score".
```

```
def cosine_similarity(a, b):
    return np.dot(a, b) / (np.linalg.norm(a) *
                           np.linalg.norm(b))

king  = np.array([0.9, 0.7, 0.1])
queen = np.array([0.8, 0.8, 0.1])
truck = np.array([0.1, 0.2, 0.9])

cosine_similarity(king, queen)   # 0.99  - very similar
cosine_similarity(king, truck)   # 0.36  - not similar

# IF THE VECTORS ARE ALREADY NORMALISED, cosine similarity
# IS JUST THE DOT PRODUCT - which is why production
# retrieval systems normalise once at insert time and then
# do nothing but MACs at query time. A useful optimisation
# to recognise when reading such code.
```

Vector spaces, bases and spans

```
/* A VECTOR SPACE is a set of vectors closed under addition
   and scalar multiplication. For our purposes: R^n, the set
   of all n-element real vectors. Nothing exotic.

/* LINEAR COMBINATION - the central idea: */

        c1*v1 + c2*v2 + ... + ck*vk

   Everything in linear algebra is a statement about which
   vectors can be written as linear combinations of which
   others.

/* SPAN: all the vectors you can reach. */
    span{[1,0]}           = the x-axis (a LINE)
    span{[1,0], [0,1]}    = the whole plane
    span{[1,0], [2,0]}    = still just the x-axis - the
                            second vector adds NOTHING

/* LINEAR INDEPENDENCE: no vector in the set is a
   combination of the others. [1,0] and [2,0] are DEPENDENT.
   [1,0] and [0,1] are INDEPENDENT.

/* BASIS: an independent set that spans the space. A basis
   for R^n always has exactly n vectors.
   THE STANDARD BASIS for R^3:
        e1 = [1,0,0], e2 = [0,1,0], e3 = [0,0,1]
   and [3, 4, 5] = 3*e1 + 4*e2 + 5*e3. The COORDINATES ARE
   THE COEFFICIENTS - that is all a coordinate is.

/* DIMENSION: the number of vectors in a basis.

/* WHY THIS MATTERS FOR MACHINE LEARNING - and it does,
   directly:

   AN EMBEDDING SPACE IS A VECTOR SPACE, and the interesting
   claim is that MEANING IS ENCODED IN DIRECTIONS. The famous
   example:

        vec("king") - vec("man") + vec("woman")
             lands near vec("queen")

   Read that as: there is a DIRECTION in the space that
   corresponds roughly to "gender", and another to "royalty",
   and they combine linearly. THE LINEAR ALGEBRA IS DOING
   SEMANTIC WORK.

   (The real behaviour is messier than the popular version
   suggests - the analogy only works with certain
   normalisations and often the nearest neighbour is one of
   the input words. But the underlying claim, that
   directions carry meaning, holds up and is central to
   chapter 17.)

   THE MODERN VERSION OF THIS IDEA IS THE SUPERPOSITION
   HYPOTHESIS: a model with d dimensions represents far more
   than d features, by placing them in ALMOST-orthogonal
   directions. In high dimensions there are exponentially
   many nearly-perpendicular directions, so this is
```

```
   possible - and it is one reason big models do
   disproportionately better than small ones.           */
```

HIGH DIMENSIONS ARE STRANGE

In 768 dimensions, two random unit vectors are almost always nearly orthogonal — the expected cosine similarity is about zero with a standard deviation near $1/\sqrt{768} \approx 0.036$. So *any* measured similarity above ~0.1 is meaningful, and near-orthogonality is the default rather than a coincidence. Most of the volume of a high-dimensional ball is near its surface, and most of a Gaussian's mass is in a thin shell. Do not trust 2-D intuition about distances in these spaces; trust the arithmetic.

Vectors in practice

```
import numpy as np

# SHAPES. Track them obsessively (chapter 01).
v = np.array([1.0, 2.0, 3.0])
v.shape           # (3,)      a 1-D array - NOT a column
                  #           or a row, just 1-D

col = v.reshape(3, 1)     # (3, 1)  a column
row = v.reshape(1, 3)     # (1, 3)  a row

# NUMPY BROADCASTING - the rule that makes batched code
# short, and the source of many silent bugs:
#   compare shapes from the RIGHT; dimensions must be equal
#   or one of them must be 1; size-1 dimensions are
#   stretched.

batch = np.random.randn(32, 768)     # 32 vectors of dim 768
bias  = np.random.randn(768)         # (768,)
out   = batch + bias                 # (32, 768) - bias
                                     # added to every row

# THE CLASSIC BUG:
a = np.random.randn(32, 1)
b = np.random.randn(1, 32)
c = a + b                            # (32, 32) !!
# You wanted elementwise addition of 32 numbers and got a
# 32x32 outer sum. It runs, it produces numbers, and the
# model trains badly. ASSERT YOUR SHAPES:
assert c.shape == (32, 1), c.shape

# BATCHED OPERATIONS - one vector per row, always:
X = np.random.randn(32, 768)         # a BATCH of 32

norms = np.linalg.norm(X, axis=1, keepdims=True)  # (32, 1)
X_normalised = X / norms                          # (32, 768)

# all pairwise dot products between two batches:
A = np.random.randn(32, 768)
B = np.random.randn(64, 768)
sims = A @ B.T                        # (32, 64)
# THIS IS ATTENTION'S CORE COMPUTATION IN ONE LINE
# (chapter 19), and it is why chapter 04 exists.

# --- AND THE PRECISION NOTE, for the embedded reader ---
# float32 gives ~7 decimal digits; float16 gives ~3.
# Summing 4096 products in float16 accumulates real error,
# so hardware MAC units accumulate in HIGHER PRECISION than
# they multiply in - int8 x int8 -> int32, fp16 x fp16 ->
# fp32. When you meet quantisation in chapter 26, this is
# the reason the accumulator is always wider.
```

How it shows up

Symptom	Cause
A result is (32, 32) where (32, 1) was expected	Broadcasting a column against a row
Cosine similarity above 1.0	Floating-point error, or the norms were computed on the wrong axis

Symptom	Cause
All similarities near zero	Normal in high dimensions — compare against 1/√d, not against 0.5
Division by zero in normalisation	A zero vector — add a small epsilon
Similarity dominated by one long vector	Dot product used where cosine similarity was meant
`ValueError: shapes not aligned`	Missing transpose — `A @ B` instead of `A @ B.T`
Silently wrong results with no error	Broadcasting hid a shape mistake — assert shapes
Accuracy collapses in float16	Accumulation error over long dot products — widen the accumulator

Check yourself

- ✓ Give the three views of a vector and say which one matters most for embeddings.
- ✓ Compute the norm of [3, 4] and normalise it, by hand.
- ✓ Write the dot product as a C loop.
- ✓ State the geometric identity for the dot product and interpret all three sign cases.
- ✓ Define cosine similarity and say why retrieval systems normalise at insert time.
- ✓ Define span, linear independence, basis and dimension.
- ✓ Explain what "meaning is encoded in directions" claims, and one caveat.
- ✓ Explain why two random vectors in 768 dimensions are nearly orthogonal.
- ✓ State the broadcasting rule and give the classic bug it causes.
- ✓ Say why MAC hardware accumulates in higher precision than it multiplies.

Linear algebra: matrices as transformations

A matrix is a grid of numbers. It is more usefully a *function* that takes vectors to vectors. Once you see a matrix as a transformation, every neural network layer becomes readable.

A matrix is a function

```
THE DEFINITION THAT MAKES EVERYTHING CLICK:

  THE COLUMNS OF A MATRIX ARE WHERE THE BASIS VECTORS GO.

Take W = [ 2  0 ]     as columns:  [2]  and  [0]
         [ 0  3 ]                  [0]       [3]

e1 = [1,0] is sent to [2,0]   (the first column)
e2 = [0,1] is sent to [0,3]   (the second column)

And because the transformation is LINEAR, everything else
follows:
    W [3,4] = 3*(where e1 goes) + 4*(where e2 goes)
            = 3*[2,0] + 4*[0,3]
            = [6, 12]

THAT IS THE WHOLE OF MATRIX-VECTOR MULTIPLICATION. You
never have to remember the index formula: just read the
columns as destinations.

SOME TRANSFORMATIONS IN 2-D:

  SCALE          [2 0]      stretch x by 2, y by 3
                 [0 3]

  ROTATION       [cos -sin]  rotate by theta
                 [sin  cos]

  SHEAR          [1 1]      slide x by the amount of y
                 [0 1]

  PROJECTION     [1 0]      flatten onto the x-axis;
                 [0 0]      INFORMATION IS LOST

  IDENTITY       [1 0]      change nothing
                 [0 1]

WHAT "LINEAR" MEANS, precisely:
    W(a + b) = Wa + Wb
    W(c * a) = c * (Wa)
Grid lines stay straight, parallel and evenly spaced, and
the origin does not move.

THAT LAST CLAUSE IS WHY NEURAL NETWORKS NEED A BIAS TERM
AND NON-LINEARITIES. A linear map alone cannot move the
origin, cannot bend anything, and a stack of them
collapses into a single matrix (chapter 14).
```

Shapes, and what they tell you

```
import numpy as np

W = np.array([[1., 2., 3.],
              [4., 5., 6.]])
W.shape        # (2, 3)  -> 2 ROWS, 3 COLUMNS

# A (m, n) MATRIX MAPS R^n -> R^m.
#   n = the INPUT dimension  (columns)
#   m = the OUTPUT dimension (rows)
# Read it right to left: it eats an n-vector, emits an
# m-vector.

x = np.array([1., 1., 1.])     # (3,)
W @ x                          # (2,)  -> [6., 15.]

# TRANSPOSE: flip rows and columns
W.T.shape                      # (3, 2)

# --- THE INDEX FORMULA, for completeness ---
#   (W x)_i = sum_j W_ij * x_j
#   Row i of W, dotted with x. So a matrix-vector product is
#   m DOT PRODUCTS (chapter 02).

# --- IN CODE, so it is concrete: ---
# void matvec(float *y, const float *W, const float *x,
#             int m, int n) {
#     for (int i = 0; i < m; i++) {
#         float s = 0.0f;
#         for (int j = 0; j < n; j++)
#             s += W[i*n + j] * x[j];     /* ROW-MAJOR */
#         y[i] = s;
#     }
# }
# NOTE THE ROW-MAJOR INDEXING W[i*n + j]. C, numpy and
# PyTorch are row-major; Fortran and BLAS conventions are
# column-major. Getting this wrong transposes your model
# silently.

# --- A NEURAL NETWORK LAYER IS EXACTLY THIS ---
#      y = W x + b
#   W: (out_features, in_features)
#   x: (in_features,)
#   b: (out_features,)
#   y: (out_features,)
#
# nn.Linear(768, 3072) holds a (3072, 768) weight matrix.
# It maps a 768-dimensional vector to a 3072-dimensional
# one. THAT IS ALL A LINEAR LAYER IS.

# --- BATCHED, which is how it actually runs ---
X = np.random.randn(32, 768)      # 32 inputs, ROWS
W = np.random.randn(3072, 768)
b = np.random.randn(3072)

Y = X @ W.T + b                   # (32, 3072)
# One matrix multiply does all 32 at once. This is why
# batching matters for throughput - see chapter 04.
```

Special matrices worth recognising

```
/* --- IDENTITY --- */
    I = np.eye(3)
    I @ x == x       for every x

/* --- DIAGONAL: independent scaling per dimension --- */
    D = np.diag([2., 3., 4.])
    D @ x            # [2*x0, 3*x1, 4*x2]
    /* CHEAP: O(n) instead of O(n^2). Whenever a
       transformation is diagonal, the implementation should
       be an elementwise multiply, not a matmul. LayerNorm's
       scale parameter is exactly this (chapter 22). */

/* --- SYMMETRIC: A == A.T --- */
    Covariance matrices, Gram matrices, attention scores
    before masking when queries and keys are the same. They
    have real eigenvalues and orthogonal eigenvectors
    (chapter 05).

/* --- ORTHOGONAL: Q.T @ Q == I --- */
    ROTATIONS AND REFLECTIONS. They PRESERVE LENGTHS AND
    ANGLES:
        ||Q x|| == ||x||
    And the inverse is free: Q^-1 == Q.T.

    WHY THIS MATTERS FOR TRAINING: an orthogonal
    transformation neither amplifies nor shrinks. Orthogonal
    weight initialisation is used in deep networks precisely
    to stop signals exploding or vanishing as they pass
    through many layers (chapter 15).

/* --- TRIANGULAR --- */
    np.tril(np.ones((4,4)))
        [[1 0 0 0]
         [1 1 0 0]
         [1 1 1 0]
         [1 1 1 1]]
    THIS EXACT MATRIX IS THE CAUSAL MASK IN A TRANSFORMER
    (chapter 20): position i may attend to positions 0..i and
    nothing later. When you see tril() in model code, that is
    what it is doing.

/* --- SPARSE --- */
    Mostly zeros. Stored as (index, value) pairs. Pruned
    networks and mixture-of-experts routing produce these,
    and exploiting sparsity is a major topic in inference
    hardware - but only STRUCTURED sparsity (e.g. 2:4)
    reliably translates into speed, because unstructured
    sparsity destroys memory locality.                    */
```

Inverse, rank and singularity

```
/* --- INVERSE: the transformation that undoes it --- */
    A @ A_inv == I

    A_inv = np.linalg.inv(A)

/* NOT EVERY MATRIX HAS ONE. If the transformation LOST
   INFORMATION, it cannot be undone:

        P = [1 0]     flattens the plane onto a line.
            [0 0]     Every point on a vertical line maps to
                      the same output. Which one would the
                      inverse return?

   Such a matrix is SINGULAR, and its DETERMINANT IS ZERO.

/* --- DETERMINANT: the volume scale factor --- */
    np.linalg.det(np.diag([2., 3.]))     # 6.0
    /* the unit square becomes a 2x3 rectangle */

    det == 0   ->  the transformation COLLAPSES space
                   -> singular, no inverse
    det < 0    ->  orientation is FLIPPED (a reflection)

/* --- RANK: the dimension of the output space --- */
    np.linalg.matrix_rank(A)

    A (3, 3) matrix with rank 3 is FULL RANK - invertible.
    Rank 2 means it squashes 3-D into a plane. Rank 1 means
    everything lands on a line.

/* --- WHY THIS SECTION MATTERS, and it does concretely ---

   1. LOW-RANK ADAPTATION (LoRA), the standard way to
      fine-tune a large model (chapter 24), works by adding
      a LOW-RANK UPDATE:

          W_new = W + B @ A       with A: (r, d), B: (d, r)
                                  and r much smaller than d

      Instead of training d*d numbers, you train 2*d*r. For
      d = 4096 and r = 8 that is 16.7 million parameters
      versus 65,536 - a 250x reduction. THE ENTIRE TECHNIQUE
      IS A STATEMENT ABOUT RANK.

   2. YOU ALMOST NEVER COMPUTE AN INVERSE NUMERICALLY.
      To solve Ax = b, use np.linalg.solve(A, b), not
      inv(A) @ b. It is faster and far more numerically
      stable. Explicit inversion is a red flag in numerical
      code.

   3. NEAR-SINGULAR MATRICES are the practical problem. A
      determinant of 1e-15 is not zero, but the inverse will
      be numerically garbage. The CONDITION NUMBER
      (np.linalg.cond) measures this: how much a small input
      error is amplified. A condition number of 1e10 means
      you have lost ten digits of precision.

   4. AND IN DEEP LEARNING, INVERSES BARELY APPEAR AT ALL.
      Training uses gradient descent (chapter 11), not
      solving linear systems. The concepts matter for
```

```
      UNDERSTANDING - especially rank - more than for the
      code you will write.                                */
```

> **COMPOSITION IS MULTIPLICATION**
> Applying transformation `A` and then `B` is the same as applying the single matrix `B @ A`. Note the order: the rightmost matrix acts first, because it is written next to the vector in `B @ (A @ x)`. This is exactly why stacked linear layers with no non-linearity between them collapse into one layer — `W3 @ W2 @ W1` is just some other matrix, and the depth bought you nothing. The whole reason activation functions exist is to break this collapse (chapter 14).

How it shows up

Symptom	Cause
`shapes (32,768) and (3072,768) not aligned`	Missing `.T` — inner dimensions must match
Model trains but outputs are nonsense	Weight matrix transposed — row-major vs column-major
`LinAlgError: singular matrix`	Rank-deficient — the transformation lost information
Results differ wildly between runs	Ill-conditioned matrix — check `np.linalg.cond`
A deep stack performs no better than one layer	No non-linearity — the layers collapsed
Activations explode through the layers	Weight scale — orthogonal initialisation helps
Diagonal operation is unexpectedly slow	Materialised as a full matmul instead of an elementwise multiply
The model attends to future tokens	Causal mask (`tril`) missing or inverted
Pruning gives no speedup	Unstructured sparsity — hardware needs structured patterns

Check yourself

- ✓ State what the columns of a matrix represent, and use it to compute `W [3,4]` by hand.
- ✓ Say what a `(m, n)` matrix does to dimensions, and which is input and which output.
- ✓ Write matrix-vector multiplication as a C loop with row-major indexing.
- ✓ Give the weight shape of `nn.Linear(768, 3072)` and explain it.
- ✓ Explain what makes a matrix orthogonal and why that helps deep networks.
- ✓ Say what `tril` is doing in transformer code.
- ✓ Explain the connection between determinant, rank and invertibility.
- ✓ Explain LoRA as a statement about rank, with the parameter count.
- ✓ Say why `solve` is preferred over `inv`.
- ✓ Explain why stacked linear layers collapse and what prevents it.

Matrix multiplication: the core operation

Well over 90% of the arithmetic in training or running a neural network is matrix multiplication. This chapter is the one an embedded engineer will find most familiar — it is a memory hierarchy problem wearing a mathematics costume.

The definition

```
A is (m, k)     B is (k, n)     C = A @ B is (m, n)

     C_ij = sum over p of  A_ip * B_pj

IN WORDS: element (i, j) of the result is ROW i OF A
dotted with COLUMN j OF B.

THE INNER DIMENSIONS MUST MATCH. That is the only rule,
and it is the rule your shape errors are about:

     (m, k) @ (k, n) -> (m, n)
          ^^^^^^^ these must be equal
     ^^^          ^^^ these survive

A WORKED 2x3 @ 3x2:

  A = [1 2 3]        B = [ 7  8]
      [4 5 6]            [ 9 10]
                         [11 12]

  C_00 = 1*7 + 2*9  + 3*11 = 7 + 18 + 33 = 58
  C_01 = 1*8 + 2*10 + 3*12 = 8 + 20 + 36 = 64
  C_10 = 4*7 + 5*9  + 6*11 = 28 + 45 + 66 = 139
  C_11 = 4*8 + 5*10 + 6*12 = 32 + 50 + 72 = 154

  C = [ 58  64]
      [139 154]

DO THIS ONCE BY HAND. It is the last time you will need
the index formula, and it makes every shape error
afterwards obvious.

PROPERTIES:
  ASSOCIATIVE     (AB)C = A(BC)   <- and the grouping
                                     changes the COST
                                     enormously
  DISTRIBUTIVE    A(B+C) = AB + AC
  NOT COMMUTATIVE AB != BA        <- usually not even the
                                     same shape
  TRANSPOSE       (AB)^T = B^T A^T   <- note the reversal;
                                        this shows up
                                        constantly in
                                        backpropagation
                                        (chapter 07)
```

What it costs

```
/* (m, k) @ (k, n) requires  m * n * k  multiply-accumulates.

   FOR A TRANSFORMER LAYER with d_model = 4096 and a batch
   of 1024 tokens:
     the QKV projection:  1024 x 4096 x 12288
                          = 51.5 GFLOP-pairs, i.e. ~103
                            GFLOPs counting multiply and add

   AND A FULL FORWARD PASS of a 70-billion-parameter model
   on one token is roughly 2 * 70e9 = 140 GFLOPs. THE RULE
   OF THUMB WORTH MEMORISING:

     inference FLOPs  ~=  2 * (number of parameters) * tokens
     training FLOPs   ~=  6 * (number of parameters) * tokens

   The factor of 6 is: 2 for the forward pass, 4 for the
   backward pass (which computes two gradients per weight).
   This single formula is how every training-cost estimate
   in every paper is produced, and it is used again in
   chapter 23.

/* --- THE NAIVE IMPLEMENTATION --- */
    for (i = 0; i < m; i++)
      for (j = 0; j < n; j++) {
        float s = 0;
        for (p = 0; p < k; p++)
            s += A[i*k + p] * B[p*n + j];   /* <-- B IS
                                                   STRIDED */
        C[i*n + j] = s;
      }

/* THIS IS CORRECT AND SLOW, and the reason is entirely
   familiar to an embedded engineer:

   A[i*k + p]   walks CONTIGUOUSLY. Good: one cache miss
                per line, then hits.
   B[p*n + j]   jumps n floats every iteration. EVERY ACCESS
                IS A CACHE MISS on a large matrix.

   With n = 4096 and 64-byte lines, each B access pulls in a
   line and uses 4 bytes of it. YOU ARE RUNNING AT 1/16 OF
   MEMORY BANDWIDTH before you even count latency.

/* --- FIX 1: LOOP REORDERING (ikj) --- */
    for (i = 0; i < m; i++)
      for (p = 0; p < k; p++) {
        float a = A[i*k + p];
        for (j = 0; j < n; j++)
            C[i*n + j] += a * B[p*n + j];  /* BOTH
                                              CONTIGUOUS */
      }
    /* 2-5x faster for a one-line change, purely from access
       pattern. Vectorises cleanly too. */

/* --- FIX 2: BLOCKING / TILING --- */
    Work on TILES that fit in cache. Load a tile of A and a
    tile of B, compute all the products they contribute to,
    then move on.

    for (ii = 0; ii < m; ii += BS)
```

```
      for (pp = 0; pp < k; pp += BS)
        for (jj = 0; jj < n; jj += BS)
          /* multiply the BS x BS blocks */

    Choose BS so three BS x BS tiles fit in L1 or L2. This
    turns an O(m*n*k) memory-traffic problem into
    O(m*n*k / BS), and it is THE reason a tuned BLAS is 10-50x
    faster than the naive loop.

/* --- FIX 3: SIMD --- */
    NEON on ARM, AVX on x86. Eight or sixteen MACs per
    instruction.

    #include <arm_neon.h>
    float32x4_t acc = vdupq_n_f32(0.0f);
    for (p = 0; p < k; p += 4) {
        float32x4_t va = vld1q_f32(&A[i*k + p]);
        float32x4_t vb = vld1q_f32(&B[p*n + j]);
        acc = vfmaq_f32(acc, va, vb);   /* fused
                                           multiply-add */
    }

/* --- FIX 4: DEDICATED HARDWARE --- */
    GPU tensor cores, ARM SME, NPU MAC arrays, systolic
    arrays. All of them are "do a small matrix multiply as
    one instruction". A systolic array flows data through a
    grid of MAC units so each value loaded from memory is
    REUSED by many multipliers - the same tiling idea,
    implemented in silicon.

/* --- AND THE POINT --- */
    NEVER WRITE YOUR OWN MATMUL FOR PRODUCTION. Use BLAS,
    cuBLAS, oneDNN, CMSIS-NN, or whatever your NPU vendor
    ships. Write one once to understand it, then never
    again.

    But DO understand the cost model, because it explains
    every performance decision in the rest of this track.  */
```

Compute bound and memory bound

```
ARITHMETIC INTENSITY = FLOPs performed / bytes moved

FOR A SQUARE (n,n) @ (n,n) MATMUL:
  FLOPs  = 2 n^3
  bytes  = 3 n^2 * 4      (two inputs, one output, fp32)
  intensity = 2n / 12  ~= n / 6

SO INTENSITY GROWS WITH n. Big matmuls are COMPUTE BOUND;
the hardware can keep its multipliers busy.

FOR A MATRIX-VECTOR PRODUCT (n,n) @ (n,1):
  FLOPs  = 2 n^2
  bytes  = n^2 * 4        (the matrix dominates)
  intensity ~= 0.5

CONSTANT, AND TINY. Matrix-vector is MEMORY BOUND: you
read each weight once, use it twice, and throw it away.

THE ROOFLINE:

  performance
     ^
     |          ____________ peak compute
     |         /
     |        /   COMPUTE BOUND
     |       /
     |      /
     |     /  MEMORY BOUND
     |    /   (slope = memory bandwidth)
     |   /
     +--/------------------------> arithmetic intensity
        ^
        the ridge point

WHY THIS EXPLAINS LLM INFERENCE:

  PREFILL (processing the prompt) does matrix-MATRIX
    products over all prompt tokens at once. COMPUTE
    BOUND. Fast per token.

  DECODE (generating one token at a time) does
    matrix-VECTOR products - batch of one. MEMORY BOUND.
    Every weight in the model must be read from memory to
    produce ONE token.

FOR A 70B MODEL IN fp16 THAT IS 140 GB READ PER TOKEN. At
2 TB/s of HBM bandwidth, that is ~70 ms per token, ~14
tokens/second - AND THE ARITHMETIC UNITS ARE MOSTLY IDLE.

THIS SINGLE FACT DRIVES:
  · QUANTISATION (chapter 26) - int4 weights means 1/4 the
    bytes, so ~4x the tokens per second. The speedup comes
    from BANDWIDTH, not from faster arithmetic.
  · BATCHING - serve 32 requests together and the weight
    read is amortised across 32 tokens
  · SPECULATIVE DECODING - a small model proposes several
    tokens, the big model verifies them in ONE
    memory-bound pass
  · KV CACHING (chapter 25) - and why the KV cache itself
    becomes the bandwidth bottleneck at long contexts
```

```
   IF YOU REMEMBER ONE THING FROM THIS TRACK'S SYSTEMS SIDE:
   GENERATING TEXT IS A MEMORY BANDWIDTH PROBLEM.
```

Where matmuls appear

```
import numpy as np

# --- 1. A LINEAR LAYER (chapter 03) ---
X = np.random.randn(32, 768)        # batch, d_in
W = np.random.randn(768, 3072)      # d_in, d_out
Y = X @ W                           # (32, 3072)

# --- 2. ATTENTION SCORES (chapter 19) ---
Q = np.random.randn(32, 128, 64)    # batch, seq, d_head
K = np.random.randn(32, 128, 64)
scores = Q @ K.transpose(0, 2, 1)   # (32, 128, 128)
# BATCHED MATMUL: numpy and torch treat all leading
# dimensions as batch and multiply the last two. This is how
# multi-head attention runs every head in one call
# (chapter 21).

# --- 3. THE OUTPUT PROJECTION TO VOCABULARY ---
h = np.random.randn(32, 4096)          # hidden states
W_out = np.random.randn(4096, 50000)   # vocab
logits = h @ W_out                     # (32, 50000)
# 6.5 GFLOPs for a batch of 32. The vocabulary projection is
# often the single largest matmul in a small model, which is
# why weight tying (sharing it with the embedding table) is
# common (chapter 17).

# --- ASSOCIATIVITY IS A REAL OPTIMISATION ---
A = np.random.randn(1000, 5)
B = np.random.randn(5, 1000)
C = np.random.randn(1000, 20)

# (A @ B) @ C : 1000*1000*5 + 1000*20*1000 = 25,000,000
# A @ (B @ C) : 5*20*1000   + 1000*20*5    =    200,000
#                                            125x FEWER
# Same answer. THIS IS EXACTLY WHY LOW-RANK METHODS ARE
# CHEAP (chapter 03's LoRA), and why linear-attention
# variants reorder Q(K^T V) as (QK^T)V or not depending on
# the sequence length.

# --- CHECKING YOUR SHAPES, always ---
def linear(x, W, b):
    assert x.shape[-1] == W.shape[0], \
        f"{x.shape} @ {W.shape}"
    out = x @ W + b
    assert out.shape[-1] == W.shape[1]
    return out
```

THE DEBUGGING HABIT

When model code does not work, print shapes before printing values. Nine times in ten the bug is a transpose, a missing batch dimension, or a broadcast that silently produced the wrong rank. Shapes are cheap to check and they localise the error immediately; values tell you almost nothing until the shapes are right.

How it shows up

Symptom	Cause
`shapes (a,b) and (c,d) not aligned`	`b != c` — a missing transpose
Result has an extra dimension	Broadcasting over an unintended batch axis
Naive matmul is 30× slower than numpy	Cache-hostile access pattern — reorder and tile
GPU utilisation near zero during generation	Memory-bound decode — expected; batch or quantise
Quantising to int4 gives 4× speedup but not 4× FLOPs	The gain is bandwidth, not arithmetic
Throughput collapses at batch size 1	Matrix-vector, not matrix-matrix
An operation is far slower than the FLOP count suggests	Low arithmetic intensity — check the roofline
Chained matmuls are unexpectedly slow	Wrong association order — regroup
Results differ slightly between CPU and GPU	Different summation order in floating point — expected

Check yourself

- ✓ Multiply a 2×3 by a 3×2 by hand.
- ✓ State the shape rule and predict the output shape of any pair.
- ✓ State the FLOP rules for inference and training, and explain the factor of 6.
- ✓ Explain why `B[p*n + j]` is cache-hostile and what reordering fixes.
- ✓ Explain blocking and how to choose the tile size.
- ✓ Define arithmetic intensity and compute it for matmul and matrix-vector.
- ✓ Explain why prefill is compute bound and decode is memory bound.
- ✓ Compute tokens/second for a 70B fp16 model at 2 TB/s and explain the number.
- ✓ Explain why int4 quantisation speeds up generation.
- ✓ Give the associativity example and say why LoRA is cheap.

Eigenvectors, SVD and dimensionality

Some directions survive a transformation unchanged, and some carry most of the information in a dataset. Finding them is how you compress, denoise, and understand what a matrix is really doing.

Eigenvectors: the directions that survive

```
MOST vectors change direction when a matrix acts on them.
A FEW ONLY GET SCALED:

     A v = lambda * v

v is an EIGENVECTOR, lambda is its EIGENVALUE.

A = [3 1]      try v = [1, 1]:
    [1 3]            A v = [3+1, 1+3] = [4, 4] = 4 * [1,1]
                     EIGENVECTOR, eigenvalue 4

               try v = [1, -1]:
                     A v = [3-1, 1-3] = [2, -2]
                         = 2 * [1,-1]
                     EIGENVECTOR, eigenvalue 2

               try v = [1, 0]:
                     A v = [3, 1]  - a DIFFERENT direction.
                     Not an eigenvector.

GEOMETRICALLY, for this A: the plane is stretched by 4
along the [1,1] diagonal and by 2 along [1,-1]. THOSE TWO
NUMBERS AND DIRECTIONS DESCRIBE THE ENTIRE
TRANSFORMATION.

WHAT THE EIGENVALUES TELL YOU:
  |lambda| > 1   that direction is AMPLIFIED
  |lambda| = 1   preserved
  |lambda| < 1   SHRUNK toward zero
  lambda < 0     flipped
  complex        rotation is involved

AND THE REASON THIS MATTERS FOR NEURAL NETWORKS:

APPLYING A MATRIX REPEATEDLY - which is exactly what a
deep network, or a recurrent network unrolled over time,
does - AMPLIFIES ALONG THE LARGEST EIGENVALUE AND KILLS
EVERYTHING ELSE:

     A^n v  ->  dominated by lambda_max^n

  lambda_max > 1  ->  EXPLODING GRADIENTS
  lambda_max < 1  ->  VANISHING GRADIENTS

That is not a metaphor; it is the literal mechanism
behind why deep RNNs could not be trained (chapter 18)
and why weight initialisation is chosen to keep the
spectrum near 1 (chapter 15).

EIGENDECOMPOSITION, when it exists:

     A = V diag(lambda) V^-1

"change to the eigenbasis, scale each axis, change back."
For SYMMETRIC matrices, V is ORTHOGONAL and this is
always possible with real eigenvalues - which is why
covariance matrices are so pleasant to work with.
```

Singular value decomposition

```
/* EIGENVECTORS ONLY EXIST NICELY FOR SQUARE MATRICES. THE
   SVD WORKS FOR ANY MATRIX AT ALL, AND IT IS THE MORE
   USEFUL TOOL.                                          */

        A  =  U  S  V^T

     A: (m, n)   any matrix
     U: (m, m)   ORTHOGONAL - output directions
     S: (m, n)   DIAGONAL, non-negative, sorted DESCENDING
                 - the SINGULAR VALUES
     V: (n, n)   ORTHOGONAL - input directions

/* THE GEOMETRIC READING, and it is complete:

     EVERY LINEAR TRANSFORMATION IS
         a ROTATION (V^T),
         then a SCALING along axes (S),
         then another ROTATION (U).

   That is all any matrix ever does. The singular values say
   how much stretching happens in each of n perpendicular
   directions.                                           */

import numpy as np

A = np.array([[3., 1.], [1., 3.], [0., 2.]])   # (3, 2)
U, s, Vt = np.linalg.svd(A, full_matrices=False)

U.shape     # (3, 2)
s           # [4.24, 1.87]   <- SORTED, DESCENDING, always
Vt.shape    # (2, 2)

# reconstruct
A_check = U @ np.diag(s) @ Vt
np.allclose(A, A_check)      # True

/* WHAT THE SINGULAR VALUES MEAN:

   · s[0] is the largest stretch factor = the SPECTRAL NORM
   · the number of NON-ZERO singular values is the RANK
     (chapter 03)
   · s[0] / s[-1] is the CONDITION NUMBER - how badly the
     matrix amplifies errors
   · a singular value of 1e-16 is numerically zero, which is
     the reliable way to compute rank

/* --- LOW-RANK APPROXIMATION: THE ECKART-YOUNG THEOREM --- */

    Keep only the k largest singular values:

        A_k = U[:, :k] @ diag(s[:k]) @ Vt[:k, :]

    THIS IS PROVABLY THE BEST RANK-k APPROXIMATION TO A, in
    the least-squares sense. Not a heuristic - optimal.

    STORAGE: k(m + n + 1) numbers instead of m*n.
    For a (4096, 4096) matrix with k = 64:
        16.8 million -> 524 thousand.  32x smaller.

/* AND THIS IS DIRECTLY WHY LoRA WORKS (chapters 03, 24).
```

```
   The empirical observation is that the WEIGHT UPDATE
   during fine-tuning has low intrinsic rank - the
   adaptation lives in a small subspace - so representing it
   as B @ A with small r loses almost nothing.

   IT IS ALSO the basis of several model-compression methods,
   of PCA below, and of classical latent semantic analysis -
   which was doing "embeddings via SVD" decades before
   neural embeddings (chapter 17).                        */
```

PCA: finding the directions that matter

```
/* THE QUESTION: given data in 768 dimensions, which few
   directions capture most of the variation?             */

import numpy as np

X = np.random.randn(1000, 50)      # 1000 samples, 50 dims

# 1. CENTRE THE DATA. Not optional - PCA finds directions of
#    variance ABOUT THE MEAN, and skipping this makes the
#    first component point at the mean instead.
X_centred = X - X.mean(axis=0)

# 2. SVD OF THE CENTRED DATA
#    (More stable than eigendecomposing the covariance
#     matrix, which squares the condition number.)
U, s, Vt = np.linalg.svd(X_centred, full_matrices=False)

# 3. THE PRINCIPAL COMPONENTS ARE THE ROWS OF Vt
components = Vt[:10]               # top 10 directions

# 4. PROJECT ONTO THEM
X_reduced = X_centred @ components.T    # (1000, 10)

# 5. HOW MUCH DID WE KEEP?
variance = s**2 / (len(X) - 1)
explained = variance / variance.sum()
print(explained[:10].sum())        # e.g. 0.85 -> 85%

/* THE INTERPRETATION:
     PC1  the direction of greatest variance in the data
     PC2  the greatest remaining variance, PERPENDICULAR to
          PC1
     ... and so on. Each is orthogonal to all previous ones.

/* WHERE YOU MEET IT:
     · VISUALISATION: project 768-dimensional embeddings to
       2-D to plot them. (t-SNE and UMAP are more popular
       for this and preserve local structure better - but
       they DISTORT global distances, so never read
       cluster-to-cluster distances off a t-SNE plot.)
     · WHITENING: decorrelate and unit-scale features before
       training
     · NOISE REDUCTION: keep the top components, discard the
       tail
     · UNDERSTANDING WHAT A MODEL LEARNED: PCA of a layer's
       activations often reveals interpretable directions

/* AND THE HONEST LIMITATION: PCA IS LINEAR. It finds
   directions, not curves. Data on a spiral or a sphere has
   structure PCA cannot represent, which is precisely the
   gap that non-linear models - autoencoders, and neural
   networks generally (chapter 14) - fill.

/* --- THE POWER METHOD, because it explains a lot --- */
    def power_iteration(A, iters=100):
        v = np.random.randn(A.shape[1])
        for _ in range(iters):
            v = A @ v
            v = v / np.linalg.norm(v)   # RENORMALISE, or it
                                        # overflows
```

```
    return v, v @ A @ v             # eigenvector,
                                    # eigenvalue

Repeatedly multiply and renormalise; converge to the
dominant eigenvector. NOTHING BUT MATRIX-VECTOR PRODUCTS.

THIS IS THE SAME AMPLIFICATION that causes exploding
gradients - here used deliberately. It is also,
essentially, PageRank. And the renormalisation step is
exactly what normalisation layers do inside a network
(chapter 22): stop repeated multiplication from
diverging.                                              */
```

WHERE THIS ACTUALLY APPEARS IN MODERN MODELS

```
LoRA fine-tuning        a low-rank update; ch. 24
Model compression       SVD of weight matrices
Attention analysis      SVD of the QK matrix reveals
                        what a head compares
Embedding visualisation PCA / t-SNE / UMAP; ch. 17
Gradient clipping       bounding the spectral norm
Spectral normalisation  dividing weights by s[0] to
                        stabilise training
Whitening               decorrelating inputs; ch. 15
```

You will rarely call `np.linalg.svd` in a training loop. You will constantly meet the *ideas* — rank, spectrum, dominant direction — in explanations of why something trains or does not.

The numerical reality

```
/* --- DO NOT EIGENDECOMPOSE A COVARIANCE MATRIX --- */
    /* WRONG - squares the condition number */
    C = X.T @ X / n
    vals, vecs = np.linalg.eigh(C)

    /* RIGHT - SVD of the data directly */
    U, s, Vt = np.linalg.svd(X_centred)
    /* The singular values of X are the square roots of the
       eigenvalues of X^T X, so you get the same answer with
       half the numerical damage. */

/* --- SIGNS ARE ARBITRARY --- */
    If v is an eigenvector, so is -v. Different libraries,
    versions and platforms return different signs. NEVER
    WRITE A TEST THAT DEPENDS ON THE SIGN of a component;
    compare absolute values or fix a convention yourself.

/* --- ORDER IS ONLY GUARANTEED FOR SVD --- */
    np.linalg.svd returns singular values DESCENDING.
    np.linalg.eig returns eigenvalues in NO PARTICULAR
    ORDER. np.linalg.eigh (symmetric) returns them
    ASCENDING. Read the docs; assuming the wrong one silently
    selects the least important components.

/* --- COST --- */
    Full SVD of an (m, n) matrix is O(m n min(m,n)).
    For a (4096, 4096) weight matrix that is billions of
    operations - seconds, not microseconds.

    IF YOU ONLY NEED THE TOP k:
        from scipy.sparse.linalg import svds
        U, s, Vt = svds(A, k=10)          # ITERATIVE
    or randomised SVD, which is what scikit-learn's
    TruncatedSVD uses by default. Both are dramatically
    cheaper and are what production code uses.

/* --- AND A WARNING ABOUT INTERPRETATION --- */
    A large singular value means a direction with large
    VARIANCE. That is not the same as a direction that is
    IMPORTANT FOR YOUR TASK. A feature can vary enormously
    and be irrelevant; a subtle direction can be decisive.
    PCA is unsupervised - it does not know what you are
    predicting. When labels are available, methods that use
    them (LDA, or simply training a model) will find better
    directions.                                          */
```

How it shows up

Symptom	Cause
PC1 points at the data mean	Data not centred before PCA
Components flip sign between runs	Eigenvector signs are arbitrary — expected
Selected the least important components	Assumed descending order from `eigh`, which is ascending
Gradients explode through depth	Largest eigenvalue above 1, amplified by repeated multiplication
Gradients vanish through depth	Largest eigenvalue below 1

Symptom	Cause
Numerically garbage principal components	Eigendecomposed the covariance matrix — use SVD of the data
SVD takes minutes	Full decomposition where truncated or randomised SVD suffices
Reduced features perform worse than raw	PCA is unsupervised — high variance is not relevance
t-SNE clusters look far apart but are not	t-SNE does not preserve global distances
`power_iteration` overflows	Missing renormalisation each step

Check yourself

- ✓ Define an eigenvector and verify one by hand for a 2×2 matrix.
- ✓ Explain how eigenvalues cause exploding and vanishing gradients.
- ✓ State the SVD and give the rotate–scale–rotate reading.
- ✓ Say what singular values tell you about rank, norm and conditioning.
- ✓ State the Eckart–Young result and compute the storage saving for a rank-64 approximation of a 4096×4096 matrix.
- ✓ Connect low-rank approximation to LoRA.
- ✓ Write the five steps of PCA and explain why centring is mandatory.
- ✓ Say what PCA cannot represent and what fills that gap.
- ✓ Describe the power method and its two connections elsewhere in the track.
- ✓ Give three numerical pitfalls: covariance eigendecomposition, signs, ordering.

Calculus: derivatives and gradients

A derivative answers one question: if I nudge this input, how much does the output move? Training a neural network is nothing but asking that question about a few billion inputs at once and stepping downhill.

The derivative

```
THE DEFINITION:

     f'(x) = lim       f(x + h) - f(x)
             h->0      ---------------
                              h

IN WORDS: the rate of change. The slope of the tangent
line. "If x increases by a tiny amount, f increases by
f'(x) times that amount."

     f(x) = x^2

      |          .
      |         /
      |       ./  slope at x=3 is 6
      |     ../
      |   ..
      | ..
   ---+------------
      0    3

  f'(3) = 6  means: nudge x from 3 to 3.001 and f goes
  from 9 to about 9.006.

THE ONLY DERIVATIVES YOU NEED HERE:

  f(x) = c            f' = 0
  f(x) = x            f' = 1
  f(x) = x^n          f' = n x^(n-1)
  f(x) = e^x          f' = e^x          <- itself!
  f(x) = ln(x)        f' = 1/x
  f(x) = sin(x)       f' = cos(x)

  sum:      (f + g)' = f' + g'
  scalar:   (c f)'   = c f'
  product:  (f g)'   = f' g + f g'
  quotient: (f/g)'   = (f' g - f g') / g^2
  CHAIN:    f(g(x))' = f'(g(x)) * g'(x)   <- CHAPTER 07.
                                              THE ONE THAT
                                              MATTERS.

THE SIGN IS THE POINT:

  f'(x) > 0   f is INCREASING here -> to decrease f, go
              LEFT
  f'(x) < 0   f is DECREASING here -> to decrease f, go
              RIGHT
  f'(x) = 0   flat: a minimum, a maximum, or a saddle

SO: TO MINIMISE f, MOVE IN THE DIRECTION OPPOSITE TO THE
DERIVATIVE. That single sentence is gradient descent
(chapter 11), and everything else is bookkeeping.
```

Partial derivatives and the gradient

```
/* Real functions have many inputs. A neural network's loss
   is a function of every weight in the model - billions of
   them.

   A PARTIAL DERIVATIVE holds all other inputs fixed:

        f(x, y) = x^2 + 3xy + y^2

        df/dx = 2x + 3y        (treat y as a constant)
        df/dy = 3x + 2y        (treat x as a constant)

   THE GRADIENT collects them all into a vector:

        grad f = [df/dx, df/dy]

   At the point (1, 2):
        grad f = [2*1 + 3*2, 3*1 + 2*2] = [8, 7]

/* THE TWO FACTS ABOUT THE GRADIENT THAT MATTER:

   1. IT POINTS IN THE DIRECTION OF STEEPEST INCREASE.
      So -grad f points steepest DOWNHILL. That is the
      update rule.

   2. ITS MAGNITUDE IS THE STEEPNESS. A large gradient means
      a small step changes the loss a lot; near a minimum
      the gradient goes to zero and progress stalls
      naturally.

/* THE UPDATE RULE, in full: */

        w  <-  w - learning_rate * grad_w L

   Every training run of every model in this track is that
   line, repeated.

/* --- IN CODE --- */
import numpy as np

def f(v):
    x, y = v
    return x**2 + 3*x*y + y**2

def grad_f(v):
    x, y = v
    return np.array([2*x + 3*y, 3*x + 2*y])

# ONE STEP OF GRADIENT DESCENT
v = np.array([1.0, 2.0])
lr = 0.1
for step in range(5):
    g = grad_f(v)
    v = v - lr * g
    print(step, v, f(v))

# Watch f decrease. That is the entire mechanism of
# training, at two parameters instead of seventy billion.

/* --- HIGHER DERIVATIVES, briefly --- */
    The HESSIAN is the matrix of second partial derivatives.
```

```
    It describes CURVATURE:
      · all eigenvalues positive -> a bowl, a true minimum
      · mixed signs               -> a SADDLE POINT
      · near-zero eigenvalues     -> a flat plateau

    SECOND-ORDER METHODS (Newton's method) use it and
    converge in far fewer steps. NOBODY USES THEM FOR LARGE
    NEURAL NETWORKS: the Hessian for n parameters has n^2
    entries. For a 7-billion-parameter model that is 4.9e19
    numbers. Not storable, not computable, not close.

    SO ALL DEEP LEARNING IS FIRST-ORDER. Adam and friends
    (chapter 11) approximate curvature information cheaply
    from the history of gradients, which is the closest
    anyone gets.                                          */
```

The functions that actually appear

```
/* You need the derivatives of these five. They are the
   whole vocabulary of a neural network's forward pass.  */

/* --- ReLU: the default activation --- */
    relu(x)  = max(0, x)
    relu'(x) = 1 if x > 0 else 0

    ONE COMPARISON AND A SELECT. No exponentials, no
    division. That cheapness is a large part of why deep
    learning became practical - and it matters even more on
    an MCU (chapter 27).

    THE PROBLEM: for x <= 0 the gradient is EXACTLY ZERO. A
    unit that always outputs zero never updates. This is a
    DEAD ReLU, and it is a real failure mode.
    THE FIXES: LeakyReLU (slope 0.01 for x < 0), GELU, SiLU.

/* --- SIGMOID --- */
    sigmoid(x)  = 1 / (1 + e^-x)                 range (0,1)
    sigmoid'(x) = sigmoid(x) * (1 - sigmoid(x))

    NOTE THE ELEGANCE: the derivative is expressed in terms
    of the OUTPUT, so a forward pass that saved its output
    gets the backward pass almost free. Every framework
    exploits this.

    THE PROBLEM: the maximum of s(1-s) is 0.25, at x = 0.
    Multiply that through ten layers and the gradient is
    0.25^10 = 1e-6. THIS IS THE VANISHING GRADIENT PROBLEM,
    and it is why sigmoid was abandoned for hidden layers
    (chapter 18). It survives for BINARY OUTPUTS and GATES.

/* --- TANH --- */
    tanh(x)  = (e^x - e^-x)/(e^x + e^-x)        range (-1,1)
    tanh'(x) = 1 - tanh(x)^2                    max 1.0

    Zero-centred, and a maximum gradient of 1 rather than
    0.25 - strictly better than sigmoid for hidden layers,
    still saturating. Used inside LSTMs (chapter 18).

/* --- GELU and SiLU: what transformers use --- */
    gelu(x) = x * Phi(x)      Phi = the Gaussian CDF
    silu(x) = x * sigmoid(x)  (also called swish)

    Smooth, non-monotonic near zero, and empirically better
    than ReLU in transformers. GELU is in GPT and BERT;
    SwiGLU (a gated SiLU variant) is in Llama and most
    recent models (chapter 22).

/* --- SOFTMAX: turning scores into a distribution --- */
    softmax(x)_i = e^(x_i) / sum_j e^(x_j)

    Outputs are positive and sum to 1. This is how a model
    produces "the probability of each next token".

    THE NUMERICAL RULE, AND IT IS NOT OPTIONAL:

        SUBTRACT THE MAXIMUM FIRST.

        e^1000 overflows to inf in float32. But
```

```
        softmax(x) == softmax(x - c) for any constant c, so
        subtracting max(x) makes the largest exponent e^0 = 1
        and nothing overflows.

    def softmax(x):
        x = x - np.max(x, axis=-1, keepdims=True)   # <<<
        e = np.exp(x)
        return e / np.sum(e, axis=-1, keepdims=True)

    THE JACOBIAN is a full matrix (every output depends on
    every input):
        d softmax_i / d x_j = s_i (delta_ij - s_j)

    BUT - and this is the practical mercy - COMBINED WITH
    CROSS-ENTROPY LOSS THE WHOLE THING COLLAPSES TO:

        dL/dx = predicted - target

    A subtraction. That is why every framework has a fused
    `cross_entropy_with_logits` and why you should never
    apply softmax before it. Chapter 10 derives this.     */
```

NEVER APPLY SOFTMAX AND THEN A SEPARATE CROSS-ENTROPY

Doing it in two steps computes logs of small probabilities and loses precision, and it discards the algebraic cancellation that makes the gradient a clean subtraction. Pass raw logits to `F.cross_entropy` (PyTorch) or `tf.nn.softmax_cross_entropy_with_logits`. Applying softmax first is one of the most common beginner bugs, and it usually shows as a model that trains but plateaus early.

How derivatives are actually computed

```
/* THREE OPTIONS, and only one is used.                    */

/* --- 1. SYMBOLIC (what you did in school) --- */
    Manipulate the expression algebraically.
    PROBLEM: EXPRESSION SWELL. The symbolic derivative of a
    deep composition grows exponentially in size. Unusable
    beyond a few layers.

/* --- 2. NUMERICAL (finite differences) --- */
    f'(x) ~= (f(x + h) - f(x - h)) / (2h)

    PROBLEM 1: O(n) function evaluations for n parameters.
      Seven billion parameters means fourteen billion
      forward passes per step. Absurd.
    PROBLEM 2: precision. Too large an h and truncation
      error dominates; too small and floating-point
      cancellation destroys the answer. The sweet spot is
      narrow.

    BUT IT HAS ONE ESSENTIAL USE - CHECKING YOUR ANALYTIC
    GRADIENT:

    def grad_check(f, x, analytic_grad, h=1e-5):
        num = np.zeros_like(x)
        for i in range(x.size):
            xp = x.copy(); xp.flat[i] += h
            xm = x.copy(); xm.flat[i] -= h
            num.flat[i] = (f(xp) - f(xm)) / (2*h)
        rel = (np.abs(num - analytic_grad) /
               (np.abs(num) + np.abs(analytic_grad) + 1e-12))
        return rel.max()          # want < 1e-6 in float64

    IF YOU WRITE A CUSTOM LAYER OR A CUSTOM BACKWARD PASS,
    RUN THIS. It is the unit test of this field, and it
    catches sign errors and transposes that would otherwise
    show up as "the model just does not train well".

/* --- 3. AUTOMATIC DIFFERENTIATION: what is used --- */
    Build a graph of elementary operations during the
    forward pass. Each operation knows its own local
    derivative. Then apply the chain rule mechanically
    backwards through the graph.

      · EXACT to machine precision - not an approximation
      · costs about the SAME as one forward pass, for ALL
        parameters simultaneously
      · works for arbitrary code with loops and branches

    THIS IS THE ALGORITHM THAT MADE DEEP LEARNING POSSIBLE,
    and chapter 07 builds one from scratch.

/* --- SEEING IT WORK --- */
import torch

x = torch.tensor([1.0, 2.0], requires_grad=True)
y = (x**2).sum() + 3*x[0]*x[1]
y.backward()
x.grad          # tensor([8., 7.])  - matches our hand
                # calculation above
```

```
/* FORWARD MODE vs REVERSE MODE, since the terms appear:
     FORWARD  cheap for FEW inputs, many outputs
     REVERSE  cheap for MANY inputs, ONE output
   A loss function is many parameters -> one scalar, so deep
   learning always uses REVERSE MODE. That is what
   "backpropagation" names.                              */
```

How it shows up

Symptom	Cause
`nan` in the loss immediately	Softmax overflow — the max was not subtracted
Loss plateaus early despite training	Softmax applied before cross-entropy
Some units always output zero	Dead ReLU — try LeakyReLU or a lower learning rate
Gradients near zero in early layers	Saturating activations — sigmoid in hidden layers
Model trains, but worse than it should	A sign or transpose error in a custom backward — run a gradient check
Gradient check fails at 1e-2	A real bug. Below 1e-6 in float64 is passing; float32 is noisier
Gradient check fails only at ReLU	Expected at exactly zero — the kink is not differentiable there
Finite differences give garbage	`h` too small — floating-point cancellation
Training stalls at a flat region	Saddle point — momentum helps (chapter 11)

Check yourself

- ✓ Define the derivative and interpret its sign in terms of which way to move.
- ✓ Compute the gradient of `x² + 3xy + y²` at (1, 2) by hand.
- ✓ State the two facts about the gradient that make gradient descent work.
- ✓ Write the update rule.
- ✓ Explain why nobody uses the Hessian for large models, with the number.
- ✓ Give the derivatives of ReLU, sigmoid and tanh, and the failure mode of each.
- ✓ Explain the vanishing gradient with the 0.25^{10} calculation.
- ✓ Write a numerically stable softmax and say why the shift is valid.
- ✓ State what softmax + cross-entropy collapses to, and why that matters.
- ✓ Compare symbolic, numerical and automatic differentiation.
- ✓ Write a gradient check and say when you must run one.

The chain rule and backpropagation

One rule from calculus, applied mechanically to a graph of operations. This is how every neural network that has ever been trained was trained, and it is simpler than its reputation.

The chain rule

```
IF  y = f(u)  AND  u = g(x)   THEN

     dy       dy     du
     --   =   --  *  --
     dx       du     dx

"RATES MULTIPLY ALONG A CHAIN."

THE INTUITION THAT MAKES IT OBVIOUS: gears.

  x turns 3x as fast as u,
  u turns 2x as fast as y
  -> x turns 6x as fast as y.

A WORKED EXAMPLE:
     y = (3x + 1)^2

     let u = 3x + 1     du/dx = 3
     then y = u^2       dy/du = 2u

     dy/dx = 2u * 3 = 6(3x + 1)

LONGER CHAINS JUST MULTIPLY MORE TERMS:

     x -> a -> b -> c -> L

     dL     dL   dc   db   da
     --  =  -- * -- * -- * --
     dx     dc   db   da   dx

AND THAT IS BACKPROPAGATION. A neural network IS a long
chain: input -> layer -> activation -> layer -> ... ->
loss. To find how the loss depends on a weight buried
twenty layers deep, multiply the local derivatives along
the path.

TWO CONSEQUENCES THAT EXPLAIN MOST TRAINING PATHOLOGIES:

  each factor < 1  ->  the product SHRINKS toward zero
                       -> VANISHING GRADIENTS
  each factor > 1  ->  the product GROWS
                       -> EXPLODING GRADIENTS

Twenty layers of sigmoid, each contributing at most 0.25:
     0.25^20 = 1e-12.
The first layer receives essentially no signal. That is
the entire reason deep networks were considered
untrainable before ReLU, careful initialisation, and
residual connections (chapters 15 and 22).
```

The computation graph

```
/* A neural network is a DIRECTED ACYCLIC GRAPH of simple
   operations. Backpropagation walks it backwards.

   TAKE  L = (w*x + b - y)^2   -  one neuron, squared error.

   FORWARD:
        x, w  -->  [*] --> u = w*x
        u, b  -->  [+] --> v = u + b
        v, y  -->  [-] --> e = v - y
        e     -->  [^2]--> L = e^2

   BACKWARD - start with dL/dL = 1 and walk back, applying
   each node's LOCAL derivative:

        dL/dL = 1
        dL/de = 2e                 (d(e^2)/de)
        dL/dv = dL/de * 1  = 2e    (d(v-y)/dv = 1)
        dL/db = dL/dv * 1  = 2e    (d(u+b)/db = 1)
        dL/du = dL/dv * 1  = 2e
        dL/dw = dL/du * x  = 2e*x  (d(w*x)/dw = x)

   NOTE THE TWO KINDS OF NODE BEHAVIOUR - this is the whole
   of backprop:

     ADDITION  PASSES THE GRADIENT THROUGH UNCHANGED to both
               inputs. It is a gradient DISTRIBUTOR.
     MULTIPLICATION SWAPS: the gradient to each input is
               multiplied by the OTHER input's forward value.
               Which is why THE FORWARD VALUES MUST BE SAVED
               - and why training uses far more memory than
               inference.

   Every other rule follows from those two plus the local
   derivative of each elementary function (chapter 06).
```

Autodiff from scratch

```
"""A complete reverse-mode automatic differentiation engine.
   About sixty lines. Everything PyTorch does for scalars is
   here; the rest is tensors and performance."""

    loss.backward()
    w.data -= 0.01 * w.grad
    b.data -= 0.01 * b.grad

# THE `+=` IN EVERY _backward IS DELIBERATE: a value used in
# two places receives gradient from BOTH paths, and they must
# ADD (the multivariable chain rule). That accumulation is
# also why you must ZERO GRADIENTS between steps - PyTorch's
# optimizer.zero_grad() does exactly this, and forgetting it
# is one of the most common bugs in the field.
```

THE THREE-LINE SUMMARY OF BACKPROPAGATION

```
1. FORWARD: compute the output, SAVING intermediate
   values.
2. BACKWARD: seed dL/dL = 1 and walk the graph in reverse
   topological order, each node multiplying by its local
   derivative and ACCUMULATING into its inputs.
3. UPDATE: step every parameter against its gradient.
```

The cost of the backward pass is roughly twice the forward pass, and it produces gradients for *every* parameter at once. That efficiency — one backward pass for billions of derivatives — is the entire reason this field exists.

Backprop through a layer

```
/* THE SCALAR CASE GENERALISES TO MATRICES DIRECTLY. These
   three formulas are worth memorising - they are most of
   what a framework computes.                              */

    FORWARD:   Y = X @ W + b
        X: (batch, d_in)
        W: (d_in, d_out)
        b: (d_out,)
        Y: (batch, d_out)

    BACKWARD, given dY (the gradient of the loss w.r.t. Y):

        dX = dY @ W.T           (batch, d_in)
        dW = X.T @ dY           (d_in, d_out)
        db = dY.sum(axis=0)     (d_out,)

/* HOW TO REMEMBER THEM WITHOUT DERIVING: THE SHAPES ONLY
   WORK ONE WAY. dX must have X's shape; the only product of
   dY and W with that shape is dY @ W.T. This is a genuinely
   reliable check - if your shapes work, your formula is
   almost certainly right.

/* AND NOTE THE TRANSPOSES: (AB)^T = B^T A^T from chapter 04
   is exactly why they appear.                             */

import numpy as np

class Linear:
    def __init__(self, d_in, d_out):
        # He initialisation - chapter 15 explains the scale
        self.W = (np.random.randn(d_in, d_out) *
                  np.sqrt(2.0 / d_in))
        self.b = np.zeros(d_out)

    def forward(self, X):
        self.X = X                  # SAVED for backward
        return X @ self.W + self.b

    def backward(self, dY):
        self.dW = self.X.T @ dY
        self.db = dY.sum(axis=0)
        return dY @ self.W.T        # gradient to pass down

class ReLU:
    def forward(self, X):
        self.mask = X > 0           # SAVED
        return X * self.mask
    def backward(self, dY):
        return dY * self.mask       # zero where input was
                                    # negative

# --- A TWO-LAYER NETWORK, COMPLETE ---
layers = [Linear(784, 128), ReLU(), Linear(128, 10)]

def forward(X):
    for layer in layers:
        X = layer.forward(X)
    return X

def backward(dY):
```

```
    for layer in reversed(layers):   # <<< REVERSED
        dY = layer.backward(dY)

# training step
logits = forward(X_batch)
probs  = softmax(logits)
dlogits = (probs - one_hot_targets) / len(X_batch)
                      # ^^ chapter 06's clean gradient
backward(dlogits)

for layer in layers:
    if hasattr(layer, 'W'):
        layer.W -= lr * layer.dW
        layer.b -= lr * layer.db

/* THAT IS A COMPLETE, WORKING NEURAL NETWORK TRAINER. Add a
   data loader and it learns MNIST. Everything after this
   chapter is better architectures, better optimisers and
   more scale - the training mechanism does not change. */
```

What this costs, and what goes wrong

```
/* --- MEMORY: THE REASON TRAINING NEEDS SO MUCH RAM --- */
    The backward pass needs the forward ACTIVATIONS. So
    training stores, per layer, per batch element, the full
    activation tensor.

    For a transformer: roughly
        activations ~ batch * seq_len * d_model * n_layers
                      * (a constant around 10-20)

    This usually exceeds the parameter memory, and it is why
    a model that fits in memory for inference will not train
    on the same card.

    THE MITIGATIONS:
      GRADIENT CHECKPOINTING  save only some activations;
                              RECOMPUTE the rest during the
                              backward pass. ~30% more
                              compute for a large memory
                              saving. Standard practice.
      SMALLER BATCHES, with gradient accumulation to keep the
                              effective batch size
      MIXED PRECISION         fp16/bf16 activations
                              (chapter 26)

/* --- THE BUGS, in order of frequency --- */

   1. FORGETTING TO ZERO GRADIENTS.
      Gradients accumulate by design. Miss zero_grad() and
      each step uses the sum of all previous gradients. The
      model appears to train, badly and erratically.

   2. NOT DETACHING WHEN YOU SHOULD.
      Keeping a reference to a tensor that is part of the
      graph keeps the WHOLE GRAPH alive. In an RNN loop this
      is an unbounded memory leak. Use .detach() or
      .item() for logging - never accumulate a raw loss
      tensor into a running total.

   3. BACKWARD THROUGH THE GRAPH TWICE.
      The graph is freed after backward(). Calling it again
      raises an error; retain_graph=True is usually papering
      over a design mistake.

   4. IN-PLACE OPERATIONS ON SAVED TENSORS.
      x += 1 can corrupt a value the backward pass needs.
      PyTorch usually detects this; numpy will not.

   5. GRADIENT FLOW BLOCKED.
      An argmax, a rounding, a hard threshold, a .detach()
      in the wrong place - all have zero or undefined
      gradient, and everything upstream of them stops
      learning silently. If a parameter's gradient is
      exactly zero every step, this is why.

   6. EXPLODING GRADIENTS.
      Clip them:
          torch.nn.utils.clip_grad_norm_(params, max_norm=1.0)
      Standard in transformer training, not optional.

/* --- THE DIAGNOSTIC HABIT --- */
```

```
    for name, p in model.named_parameters():
        if p.grad is None:
            print(f"{name}: NO GRADIENT")      # detached?
        else:
            print(f"{name}: {p.grad.norm():.3e}")

    Print this once at the start of training. Gradients that
    are None, exactly zero, nan, or wildly different in
    magnitude between layers all point at specific bugs, and
    all are invisible in the loss curve for a while.      */
```

How it shows up

Symptom	Cause
Loss decreases then oscillates wildly	Gradients not zeroed between steps
Memory grows every iteration	Accumulating a graph-attached tensor — detach it
`Trying to backward through the graph a second time`	The graph was freed — restructure rather than retaining
A parameter's gradient is always `None`	It is not on the path from the loss, or was detached
A parameter's gradient is always exactly zero	A non-differentiable operation upstream — argmax, rounding, hard threshold
Early layers barely change	Vanishing gradients — check activations and initialisation
Loss becomes `nan` after a few steps	Exploding gradients — clip the norm
Out of memory in training but not inference	Saved activations — use gradient checkpointing
Custom layer trains worse than expected	Wrong backward formula — run a gradient check (chapter 06)
Shapes fail in the backward pass	A missing transpose — the shapes only work one way

Check yourself

- ✓ State the chain rule and explain it with the gears analogy.
- ✓ Explain vanishing and exploding gradients as products of local derivatives.
- ✓ Backpropagate `L = (wx + b − y)²` by hand.
- ✓ State what addition and multiplication nodes do to gradients.
- ✓ Explain why the forward values must be saved.
- ✓ Write the three backward formulas for a linear layer and check them by shape.
- ✓ Explain why `_backward` uses `+=` and what that implies about `zero_grad`.
- ✓ Explain why a topological sort is needed before the backward walk.
- ✓ Estimate training activation memory and name three ways to reduce it.
- ✓ List six common backprop bugs and their symptoms.
- ✓ Write the gradient-norm diagnostic and say what each anomaly indicates.

Probability: distributions and expectation

A language model does not output text. It outputs a probability distribution over tokens, and something else turns that into text. This chapter is the vocabulary for what that distribution is and what you can do with it.

The pieces

```
RANDOM VARIABLE   a quantity whose value is uncertain.
                  X = the next token.

DISTRIBUTION      the assignment of probability to each
                  possible value.
                  P(X = "the") = 0.15, ...

THE TWO RULES, and everything follows from them:
     P(x) >= 0  for every x
     sum over all x of P(x) = 1

DISCRETE          countable outcomes; a PROBABILITY MASS
                  FUNCTION. Tokens, dice, classes.
CONTINUOUS        a PROBABILITY DENSITY FUNCTION. P(exact
                  value) = 0; only INTERVALS have
                  probability, and the DENSITY CAN EXCEED
                  1. Weights, activations, noise.

JOINT             P(X, Y)      both together
MARGINAL          P(X) = sum over y of P(X, y)
                  - "sum out" what you do not care about
CONDITIONAL       P(X | Y) = P(X, Y) / P(Y)
                  - "given that Y happened"

INDEPENDENCE      P(X, Y) = P(X) P(Y)
                  equivalently P(X | Y) = P(X)

AND THE CHAIN RULE OF PROBABILITY, which is the single
most important identity in this track:

     P(x1, x2, ..., xn)
       = P(x1) P(x2|x1) P(x3|x1,x2) ... P(xn|x1..x(n-1))

A LANGUAGE MODEL IS EXACTLY THIS FACTORISATION. The
probability of a document is the product of the
probability of each token given all preceding tokens, and
the model's only job is to estimate

     P(next token | everything so far)

Everything in chapters 16-25 is machinery for computing
that one conditional distribution well.
```

Expectation and variance

```
/* EXPECTATION: the probability-weighted average. */

        E[X] = sum over x of  x * P(x)

    A fair die:  E[X] = (1+2+3+4+5+6)/6 = 3.5
    Note it need not be an attainable value.

/* PROPERTIES THAT GET USED CONSTANTLY:
        E[aX + b]   = a E[X] + b
        E[X + Y]    = E[X] + E[Y]      ALWAYS - even if X
                                       and Y are dependent
        E[XY]       = E[X] E[Y]        ONLY IF INDEPENDENT

/* VARIANCE: the expected squared deviation. */

        Var[X] = E[(X - E[X])^2] = E[X^2] - E[X]^2

        Var[aX + b] = a^2 Var[X]       <- note the SQUARE,
                                          and that b
                                          vanishes
        Var[X + Y]  = Var[X] + Var[Y]  ONLY IF INDEPENDENT

    STANDARD DEVIATION = sqrt(Var), in the same units as X.

/* WHY THIS MATTERS DIRECTLY - WEIGHT INITIALISATION.

   A linear layer computes  y_i = sum over j of W_ij x_j.
   If the W are independent with variance v and there are
   n_in inputs with variance 1, then

        Var[y] = n_in * v

   To keep the variance at 1 through the layer - so signals
   neither explode nor vanish through depth (chapter 07) -
   you need

        v = 1 / n_in           XAVIER/GLOROT
        v = 2 / n_in           HE (for ReLU, which zeroes
                               half the outputs and so halves
                               the variance)

   THAT IS THE ENTIRE DERIVATION of the initialisation
   scheme every framework uses. It is variance arithmetic,
   nothing more (chapter 15).

/* --- IN CODE --- */
import numpy as np

x = np.random.randn(10000)
x.mean()            # ~0.0
x.var()             # ~1.0
x.std()             # ~1.0

W = np.random.randn(512, 512) * np.sqrt(2.0/512)   # He
h = np.random.randn(1000, 512)
out = h @ W
out.std()           # ~1.0 - the variance was PRESERVED

W_bad = np.random.randn(512, 512)                  # naive
```

```
(h @ W_bad).std()   # ~22.6 - and after ten layers,
                    # 22.6^10 = 1e13. Overflow.
```

The distributions you will meet

```
/* --- BERNOULLI: one binary trial --- */
    P(1) = p,  P(0) = 1-p
    E = p,  Var = p(1-p)
    USE: binary classification output; DROPOUT masks.

/* --- CATEGORICAL: one draw from k outcomes --- */
    P(i) = p_i,  with the p_i summing to 1
    USE: THE OUTPUT OF EVERY LANGUAGE MODEL. Softmax
    produces exactly this over the vocabulary, and sampling
    from it is how text is generated (chapter 25).

    np.random.choice(vocab_size, p=probs)

/* --- BINOMIAL: n independent Bernoulli trials --- */
    E = np,  Var = np(1-p)

/* --- UNIFORM --- */
    Equal density on [a, b]. E = (a+b)/2,
    Var = (b-a)^2 / 12.
    USE: initialisation ranges, random sampling.

/* --- GAUSSIAN (NORMAL): the important one --- */
    p(x) = (1 / sqrt(2 pi sigma^2))
           * exp(-(x - mu)^2 / (2 sigma^2))

    THE 68-95-99.7 RULE: that fraction of mass lies within
    1, 2 and 3 standard deviations.

    WHY IT IS EVERYWHERE:
      · THE CENTRAL LIMIT THEOREM: the sum of many
        independent random contributions tends to a Gaussian,
        WHATEVER their individual distributions. Neural
        network pre-activations are sums of hundreds of
        terms, so they are approximately Gaussian - which is
        why the variance arithmetic above works.
      · maximum entropy for a given mean and variance
        (chapter 10)
      · analytically convenient: sums of Gaussians are
        Gaussian, and the maths stays closed-form

    USE: weight initialisation, noise, VAE latents,
    diffusion models, and the assumption behind
    least-squares loss.

/* --- MULTIVARIATE GAUSSIAN --- */
    Parameterised by a mean VECTOR and a COVARIANCE MATRIX.
    The covariance's eigenvectors are the axes of the
    probability ellipsoid - chapter 05's machinery applied
    directly.

/* --- SOFTMAX AS A DISTRIBUTION-MAKER --- */
    Any vector of real "scores" becomes a categorical
    distribution:

        P(i) = exp(z_i / T) / sum_j exp(z_j / T)

    THE TEMPERATURE T IS THE SAMPLING CONTROL YOU WILL MEET
    IN EVERY LLM API:

        T -> 0     the distribution collapses onto the
```

```
                argmax. DETERMINISTIC, repetitive.
    T = 1       the model's own calibrated distribution.
    T > 1       FLATTENED. More surprising, more
                incoherent.
    T -> inf    uniform. Pure noise.

def softmax_T(z, T=1.0):
    z = z / T
    z = z - z.max()          # stability (chapter 06)
    e = np.exp(z)
    return e / e.sum()

THAT IS THE WHOLE MECHANISM behind the "temperature"
slider. Chapter 25 covers the rest of the sampling
toolkit.                                              */
```

LOG PROBABILITIES, ALWAYS

A 500-token sequence has a probability like 10^{-800}, which is zero in float32 and float64 alike. So everything is computed in **log space**: products become sums, tiny numbers become manageable negatives, and nothing underflows. When you see `log_softmax`, `logsumexp`, or a loss reported in "nats per token", this is why. The rule: *never multiply probabilities; add log probabilities.*

Sampling, and the practical side

```
import numpy as np

# --- SAMPLING FROM A CATEGORICAL DISTRIBUTION ---
probs = np.array([0.1, 0.7, 0.2])
np.random.choice(3, p=probs)

# HOW IT WORKS UNDERNEATH - inverse CDF sampling:
def sample(probs):
    r = np.random.rand()
    cum = 0.0
    for i, p in enumerate(probs):
        cum += p
        if r < cum:
            return i
    return len(probs) - 1
# One uniform random number, one cumulative walk. This is
# what runs in the inner loop of text generation.

# --- THE GUMBEL-MAX TRICK, which appears in real code ---
# Sampling from softmax(z) is equivalent to:
#     argmax_i (z_i + g_i),  g_i ~ Gumbel(0,1)
g = -np.log(-np.log(np.random.rand(len(z))))
sample_idx = np.argmax(z + g)
# NO SOFTMAX NEEDED. Numerically convenient, and the basis
# of the Gumbel-softmax relaxation used when you need a
# DIFFERENTIABLE approximation to sampling.

# --- LOG-SPACE ARITHMETIC ---
def logsumexp(x):
    m = np.max(x)
    return m + np.log(np.sum(np.exp(x - m)))
# The same max-subtraction trick as softmax, and the reason
# it exists: log(sum(exp(x))) computed naively overflows.

def log_softmax(z):
    return z - logsumexp(z)

# SEQUENCE LOG-PROBABILITY - how perplexity is computed:
total_logprob = sum(log_softmax(logits[t])[token[t]]
                    for t in range(T))
avg_nll = -total_logprob / T
perplexity = np.exp(avg_nll)
# PERPLEXITY is "the effective number of tokens the model is
# choosing between". A perplexity of 20 means the model is
# about as uncertain as if it were picking uniformly from 20
# options. Chapter 10 shows why it is exp of the
# cross-entropy.

# --- REPRODUCIBILITY, which you will need ---
np.random.seed(42)
# torch.manual_seed(42)
# AND NOTE: full determinism also needs deterministic GPU
# kernels and fixed data ordering. Seeding alone is not
# enough, and "it changed between runs" is usually this.

# --- ESTIMATING AN EXPECTATION BY SAMPLING ---
# E[f(X)] ~= (1/n) sum f(x_i)
samples = np.random.randn(10000)
np.mean(samples**2)      # ~1.0, since Var = E[X^2] - 0
# MONTE CARLO. The error shrinks as 1/sqrt(n), which is slow
```

```
# - 100x more samples for 10x more accuracy. This is why
# reinforcement learning from sampled rewards (chapter 24)
# is so much noisier than supervised training.
```

How it shows up

Symptom	Cause
Sequence probability is exactly 0.0	Underflow — work in log space
`inf` from `exp`	No max subtraction in softmax or logsumexp
Activations explode through depth	Initialisation variance not scaled by `1/n_in`
Activations vanish through depth	Initialisation variance too small
Generated text is repetitive	Temperature near zero — effectively greedy
Generated text is incoherent	Temperature too high — the distribution is flattened
`probabilities do not sum to 1`	Floating-point drift — renormalise, or sample in log space
Results differ between runs despite a seed	Non-deterministic kernels or data ordering
An RL or sampled estimate is very noisy	Monte Carlo error falls only as 1/√n
Density value greater than 1 looks wrong	Correct — densities are not probabilities

Check yourself

- ✓ State the two rules of a distribution and the difference between mass and density.
- ✓ Write the chain rule of probability and explain what a language model estimates.
- ✓ Give the linearity properties of expectation and say which require independence.
- ✓ Derive the He initialisation scale from variance arithmetic.
- ✓ Name four distributions and where each appears in a model.
- ✓ State the central limit theorem and why it justifies Gaussian assumptions in networks.
- ✓ Write temperature-scaled softmax and describe the behaviour at T→0, 1 and ∞.
- ✓ Explain why everything is done in log space.
- ✓ Write `logsumexp` and say why the max subtraction is needed.
- ✓ Define perplexity in words.
- ✓ Explain the Monte Carlo error rate and its consequence for RL.

Bayes, likelihood and estimation

How to update a belief when evidence arrives, and how to choose the parameters of a model from data. Maximum likelihood is the principle that justifies every loss function in this track.

Bayes' theorem

```
From the definition of conditional probability:

     P(A|B) P(B) = P(A, B) = P(B|A) P(A)

Rearranged:

                  P(B|A) P(A)
     P(A|B)  =  -------------
                     P(B)

THE NAMES, which are worth learning because papers use
them constantly:

     P(A)     PRIOR       what you believed before
     P(B|A)   LIKELIHOOD  how well A explains the
                          evidence B
     P(A|B)   POSTERIOR   what you believe after
     P(B)     EVIDENCE    a normalising constant

AND THE FORM THAT MATTERS IN PRACTICE:

     POSTERIOR  is proportional to  LIKELIHOOD x PRIOR

The denominator only makes it sum to 1, so it is often
ignored until the end.

THE CLASSIC WORKED EXAMPLE - a medical test, because the
result is genuinely surprising:

  disease prevalence          P(D)   = 0.001
  test sensitivity            P(+|D) = 0.99
  false positive rate         P(+|~D)= 0.05

  A patient tests positive. What is P(D|+)?

     P(+) = 0.99 * 0.001  +  0.05 * 0.999
          = 0.00099 + 0.04995 = 0.05094

     P(D|+) = 0.00099 / 0.05094 = 0.0194

  ABOUT 2%. Not 99%.

THE LESSON - and it is the one people get wrong: A RARE
CONDITION MEANS MOST POSITIVES ARE FALSE POSITIVES,
however good the test. The prior dominates.

THE SAME ARITHMETIC APPLIES TO ANY RARE-EVENT CLASSIFIER
YOU BUILD: fault detection on a machine that rarely
fails, intrusion detection, defect screening. A model
with 99% accuracy on a 0.1% base rate is generating
fifty false alarms for every true one, and reporting
"99% accurate" is actively misleading. Report PRECISION
AND RECALL instead (chapter 12).
```

Maximum likelihood

```
/* THE QUESTION: I have data. What parameters make that data
   most probable?

        theta_MLE = argmax  P(data | theta)

/* IN LOG SPACE, always (chapter 08) - products of many
   small numbers underflow, and sums are easier to
   differentiate:

        theta_MLE = argmax  sum_i log P(x_i | theta)

/* AND SINCE OPTIMISERS MINIMISE:

        theta_MLE = argmin  -sum_i log P(x_i | theta)
                             ^^^^^^^^^^^^^^^^^^^^^^^^
                             THE NEGATIVE LOG LIKELIHOOD

   THIS IS THE LOSS FUNCTION. Not an analogy - it is
   literally what "cross-entropy loss" computes
   (chapter 10).

/* --- WORKED: A COIN --- */
    n flips, k heads, parameter p.

        L(p) = p^k (1-p)^(n-k)
        log L = k log p + (n-k) log(1-p)
        d/dp  = k/p - (n-k)/(1-p) = 0
        =>  p = k/n

    The MLE is the observed frequency. Reassuringly obvious -
    but note it derived rigorously from a principle rather
    than being assumed.

/* --- WORKED: A GAUSSIAN, AND WHY MSE EXISTS --- */
    Assume  y_i = f(x_i) + noise,  noise ~ Normal(0, sigma^2)

        log P(y_i | x_i)
            = -(y_i - f(x_i))^2 / (2 sigma^2)
              - log(sigma sqrt(2 pi))

    Maximising this over the parameters of f means
    MINIMISING sum (y_i - f(x_i))^2.

    SO MEAN SQUARED ERROR IS NOT AN ARBITRARY CHOICE. IT IS
    MAXIMUM LIKELIHOOD UNDER AN ASSUMPTION OF GAUSSIAN
    NOISE.

    And that tells you when NOT to use it: if your errors are
    heavy-tailed, MSE's implicit Gaussian assumption makes it
    over-react to outliers. Huber loss or an L1 loss
    corresponds to a heavier-tailed noise model, which is
    exactly why they are more robust.

/* --- WORKED: CLASSIFICATION, AND WHY CROSS-ENTROPY
       EXISTS --- */
    The model outputs P(class | x) via softmax. The
    likelihood of the correct label is that probability, so

        NLL = -sum_i log P(y_i | x_i)
```

```
    which IS cross-entropy loss (chapter 10). One derivation
    produces both of the loss functions you will ever use.

/* --- MAP: MAXIMUM A POSTERIORI --- */
    Include a prior:

        theta_MAP = argmax  P(data|theta) P(theta)
                  = argmin  -log P(data|theta)
                            - log P(theta)
                                    ^^^^^^^^^^^^^
                                    A REGULARISATION TERM

    AND THE TWO STANDARD REGULARISERS FALL OUT DIRECTLY:

      a GAUSSIAN prior on the weights
          -> -log P(theta) proportional to ||theta||^2
          -> L2 REGULARISATION / WEIGHT DECAY

      a LAPLACE prior
          -> proportional to ||theta||_1
          -> L1 REGULARISATION, which drives weights to
             exactly zero (sparsity)

    So weight decay is not a hack. IT IS A STATEMENT THAT
    YOU BELIEVE SMALL WEIGHTS ARE MORE LIKELY A PRIORI
    (chapter 15).                                          */
```

THE SINGLE MOST USEFUL IDEA IN THIS CHAPTER

Every loss function is a negative log likelihood under some assumed noise model, and every regulariser is a negative log prior. If you know what distribution you are assuming, you know which loss to use — and if a loss is behaving strangely, ask what distributional assumption it encodes and whether your data actually satisfies it.

A worked classifier

```
"""NAIVE BAYES - the simplest useful application of Bayes'
   theorem, and still a strong baseline for text
   classification. Worth building once because it makes the
   abstract machinery concrete."""

import numpy as np
from collections import defaultdict

class NaiveBayes:
    """P(class | words) proportional to
       P(class) * product of P(word | class)

       "Naive" = assuming words are INDEPENDENT given the
       class. That assumption is obviously false, and the
       classifier works well anyway - a recurring lesson."""

    def fit(self, docs, labels):
        self.classes = set(labels)
        self.log_prior = {}
        self.log_lik = {}
        vocab = set(w for d in docs for w in d)
        V = len(vocab)

        for c in self.classes:
            c_docs = [d for d, l in zip(docs, labels)
                      if l == c]
            self.log_prior[c] = np.log(len(c_docs) /
                                       len(docs))

            counts = defaultdict(int)
            total = 0
            for d in c_docs:
                for w in d:
                    counts[w] += 1
                    total += 1

            # LAPLACE SMOOTHING: add 1 to every count.
            # WITHOUT IT, a word unseen in this class gives
            # P = 0, and one zero makes the WHOLE PRODUCT
            # zero - a single unseen word vetoes the class.
            # This is the same "never assign zero probability
            # to something possible" principle that appears
            # again in chapter 10.
            self.log_lik[c] = {
                w: np.log((counts[w] + 1) / (total + V))
                for w in vocab
            }
            self.log_lik[c]['<UNK>'] = np.log(1 /
                                              (total + V))

    def predict(self, doc):
        best, best_score = None, -np.inf
        for c in self.classes:
            # SUM OF LOGS, never a product of probabilities
            score = self.log_prior[c]
            for w in doc:
                score += self.log_lik[c].get(
                             w, self.log_lik[c]['<UNK>'])
            if score > best_score:
                best, best_score = c, score
```

```
        return best

docs = [["buy", "now", "cheap"], ["meeting", "at", "three"],
        ["cheap", "offer", "now"], ["project", "meeting"]]
labels = ["spam", "ham", "spam", "ham"]

nb = NaiveBayes()
nb.fit(docs, labels)
nb.predict(["cheap", "meeting"])

/* WHY THIS IS WORTH KNOWING IN 2026:
   · it is a genuine probabilistic model you can read in
     full
   · it trains in one pass and runs in microseconds - which
     makes it a real option on an MCU where a transformer is
     not
   · the smoothing problem it exposes is universal
   · and it is the honest baseline: if a neural network
     cannot beat naive Bayes on your task, the network is
     not the problem, the data is.                      */
```

Uncertainty, and why models are overconfident

```
/* TWO KINDS OF UNCERTAINTY, and the distinction matters:

   ALEATORIC   irreducible randomness in the data itself.
               A coin flip. Sensor noise. MORE DATA DOES NOT
               HELP.
   EPISTEMIC   uncertainty about the model or its
               parameters, from limited data. MORE DATA
               REDUCES IT.

   A model far outside its training distribution has huge
   EPISTEMIC uncertainty - and a standard softmax has NO WAY
   TO EXPRESS IT. It will report 99% confidence on an input
   unlike anything it has ever seen. That is not a bug in
   the training; it is a limitation of the output
   parameterisation.

/* CALIBRATION: does "70% confident" mean right 70% of the
   time?

   Modern neural networks are systematically OVERCONFIDENT.
   The standard measurement is a RELIABILITY DIAGRAM - bin
   predictions by confidence, plot accuracy per bin against
   the bin's confidence, and look for the diagonal.

   THE CHEAP FIX - TEMPERATURE SCALING:
     after training, fit ONE scalar T on a validation set to
     minimise NLL:
         p = softmax(logits / T)
     T > 1 softens overconfident predictions. One parameter,
     no retraining, and it works remarkably well.

/* ESTIMATING EPISTEMIC UNCERTAINTY, in increasing cost:
     MC DROPOUT       keep dropout on at inference, run n
                      forward passes, look at the spread.
                      Cheap and approximate.
     DEEP ENSEMBLES   train k models, compare. Expensive,
                      and the most reliable method in
                      practice.
     BAYESIAN NNs     distributions over weights.
                      Principled, rarely practical at scale.

/* AND FOR LANGUAGE MODELS SPECIFICALLY:
   The token-level probabilities are a poor guide to factual
   correctness. A model can be highly confident in each token
   of a fabricated citation, because each token is a
   plausible continuation of the previous ones - the
   confidence is about FLUENCY, not TRUTH. This is worth
   understanding precisely, because it explains why
   "just check the model's confidence" does not solve
   hallucination.

   WHAT DOES HELP: sampling several answers and checking
   agreement (self-consistency), retrieving evidence and
   requiring citation, and constraining the output format so
   invalid answers are unrepresentable. All engineering, not
   probability.                                          */
```

How it shows up

Symptom	Cause
A 99%-accurate detector floods you with false alarms	Low base rate — most positives are false
Accuracy looks great, the model is useless	Imbalanced classes — report precision and recall
One unseen word forces a class to zero	No smoothing — a zero probability vetoes the product
Probabilities underflow to zero	Multiplying instead of summing logs
MSE dominated by a few outliers	Its Gaussian assumption — use Huber or L1
Model is 99% confident on nonsense input	Softmax cannot express epistemic uncertainty
Confidence does not match accuracy	Miscalibration — apply temperature scaling
Weight decay described as a hack	It is a Gaussian prior — MAP estimation
Confident, fluent, fabricated output	Token confidence measures fluency, not truth

Check yourself

- ✓ State Bayes' theorem and name all four terms.
- ✓ Work the medical-test example and explain why the answer is 2%.
- ✓ Explain what this implies for any rare-event detector you build.
- ✓ Define maximum likelihood and show why it becomes a minimisation.
- ✓ Derive the MLE for a coin.
- ✓ Derive MSE from a Gaussian noise assumption, and say when that assumption fails.
- ✓ Explain how MAP estimation produces L1 and L2 regularisation.
- ✓ Explain Laplace smoothing and the failure it prevents.
- ✓ Distinguish aleatoric and epistemic uncertainty.
- ✓ Describe temperature scaling and what a reliability diagram shows.
- ✓ Explain why token confidence is a poor guide to factual correctness.

Information theory: entropy and cross-entropy

How to measure surprise, and how to measure the gap between two distributions. Cross-entropy is the loss function used to train essentially every model in this track, and it deserves to be understood rather than imported.

Information as surprise

```
THE SELF-INFORMATION of an outcome:

     I(x) = -log P(x)

WHY THAT FORM? Because it is the only one satisfying
three requirements anyone would want:

  · a CERTAIN event carries no information:
       P = 1 -> I = 0
  · a RARER event carries more:
       P smaller -> I larger
  · INDEPENDENT events ADD:
       I(x, y) = I(x) + I(y)
    and log is the function that turns the product
    P(x)P(y) into a sum.

UNITS DEPEND ON THE LOG BASE:
     log2  -> BITS       (the natural unit for storage)
     ln    -> NATS       (the natural unit for maths and
                          for every ML framework)

EXAMPLES:
     a fair coin        -log2(0.5)     = 1 bit
     a fair die         -log2(1/6)     = 2.58 bits
     one of 50,000
       tokens, uniform  -log2(1/50000) = 15.6 bits
     "the" after
       "once upon"      -log2(0.0001)  = 13.3 bits
     "time" after
       "once upon a"    -log2(0.95)    = 0.07 bits

THAT LAST PAIR IS THE WHOLE IDEA OF A LANGUAGE MODEL: a
good model assigns high probability to what actually
comes next, so real text carries LOW surprise under it.
Training minimises average surprise. Nothing more
mysterious than that.

ENTROPY is the AVERAGE surprise of a distribution:

     H(P) = -sum_x P(x) log P(x)  =  E[-log P(x)]

  fair coin           H = 1 bit          (maximum for 2
                                          outcomes)
  biased coin p=0.9   H = 0.469 bits
  certain outcome     H = 0 bits         (no surprise
                                          ever)
  uniform over n      H = log2(n)        (MAXIMUM)

AND THE INTERPRETATION THAT MAKES IT CONCRETE: H(P) IS
THE MINIMUM AVERAGE NUMBER OF BITS NEEDED TO ENCODE
SAMPLES FROM P. That is Shannon's source coding theorem,
and it is why this subject and data compression are the
same subject.

WHICH LEADS DIRECTLY TO A CLAIM WORTH SITTING WITH:
A LANGUAGE MODEL IS A COMPRESSOR. A model that predicts
the next token well can encode text in few bits. The
better the prediction, the better the compression - and
the training objective is literally "minimise the
compressed size of the training data".
```

Cross-entropy and KL divergence

```
/* --- CROSS-ENTROPY: encoding P's data with Q's code --- */

        H(P, Q) = -sum_x P(x) log Q(x)

    P is the TRUE distribution, Q is the MODEL's.

    If Q = P, cross-entropy equals entropy - you cannot do
    better. Any mismatch costs extra bits.

/* --- KL DIVERGENCE: exactly that extra cost --- */

        KL(P || Q) = H(P, Q) - H(P)
                   = sum_x P(x) log( P(x) / Q(x) )

    PROPERTIES:
      KL >= 0, always              (Gibbs' inequality)
      KL = 0 if and only if P = Q
      NOT SYMMETRIC: KL(P||Q) != KL(Q||P)
      NOT a distance - it violates the triangle inequality

    THE ASYMMETRY IS MEANINGFUL AND WORTH KNOWING:

      KL(P || Q)  "FORWARD", MODE-COVERING.
                  Heavily penalises Q(x) being near zero
                  where P(x) is not. Q is forced to spread
                  out and cover everything P does.
                  THIS IS WHAT MAXIMUM LIKELIHOOD MINIMISES
                  (chapter 09) - which is why generative
                  models trained this way produce some
                  low-quality samples: they would rather
                  cover everything than be sharp.

      KL(Q || P)  "REVERSE", MODE-SEEKING.
                  Q can safely ignore parts of P; it just
                  must not put mass where P has none.
                  Produces sharp but narrow results.
                  Used in variational inference and in the
                  RLHF objective (chapter 24).

/* --- WHY CROSS-ENTROPY IS THE LOSS FUNCTION --- */

    For a classification problem the true distribution is
    ONE-HOT: P(correct class) = 1, everything else 0.

    So the sum collapses to a single term:

        H(P, Q) = -log Q(correct class)

    AND THAT IS THE NEGATIVE LOG LIKELIHOOD from chapter 09.
    Cross-entropy loss, negative log likelihood, and
    minimising KL divergence from the data distribution are
    THE SAME OBJECTIVE seen from three angles.

    Also note: since H(P) is fixed by the data,
        minimise cross-entropy  ==  minimise KL(P||Q).
    The entropy of the data is a constant floor you cannot
    get below, which is why a well-trained model's loss
    plateaus at a non-zero value - that floor is the
    irreducible ambiguity of language.                    */
```

Implementing it

```
import numpy as np

def cross_entropy(logits, target_idx):
    """Numerically stable, from raw logits."""
    logits = logits - np.max(logits)          # chapter 06
    log_probs = logits - np.log(np.sum(np.exp(logits)))
    return -log_probs[target_idx]

# EQUIVALENTLY, and this is what frameworks do:
#     loss = logsumexp(logits) - logits[target]
# ONE SUBTRACTION AND ONE STABLE REDUCTION. No softmax, no
# log of a probability, no chance of log(0).

# --- THE GRADIENT, and why it is beautiful ---
#
#   dL/dlogits = softmax(logits) - one_hot(target)
#
# The messy softmax Jacobian (chapter 06) cancels against
# the log in cross-entropy, leaving a SUBTRACTION.
#
#   Interpretation: the gradient is the PREDICTION ERROR.
#   Push down the probability of everything you predicted,
#   push up the probability of what was correct, in
#   proportion to how wrong you were.

def cross_entropy_backward(probs, target_idx):
    grad = probs.copy()
    grad[target_idx] -= 1.0
    return grad

# --- BATCHED, in PyTorch ---
import torch
import torch.nn.functional as F

logits  = torch.randn(32, 50000)     # batch, vocab
targets = torch.randint(0, 50000, (32,))

loss = F.cross_entropy(logits, targets)     # RAW LOGITS

# NEVER:
#   probs = F.softmax(logits, -1)
#   loss = F.nll_loss(torch.log(probs), targets)
# It works, and it is less accurate and slower, and it
# throws away the cancellation above.

# --- LABEL SMOOTHING ---
loss = F.cross_entropy(logits, targets, label_smoothing=0.1)
# Instead of a one-hot target, use 0.9 for the correct class
# and 0.1/(V-1) spread over the rest.
#
# WHY: a one-hot target asks the model to output probability
# exactly 1, which requires an INFINITE logit. The model
# pushes logits ever larger, becomes overconfident
# (chapter 09) and generalises worse. Smoothing gives it a
# finite target to reach. Standard in vision and machine
# translation; used more selectively for LLM pretraining.

# --- PERPLEXITY ---
perplexity = torch.exp(loss)
# The exponential of the cross-entropy in NATS.
```

```
#
# THE INTERPRETATION: "the model is as uncertain as if it
# were choosing uniformly among this many options."
#   perplexity 1      perfect prediction
#   perplexity 20     a good modern LLM on general text
#   perplexity 50000  no better than uniform over the
#                     vocabulary
#
# AND THE CAVEAT THAT INVALIDATES MOST COMPARISONS:
# PERPLEXITY DEPENDS ON THE TOKENISER. A model with a larger
# vocabulary spreads the same text over fewer tokens, so its
# per-token perplexity is not comparable to a model with a
# different vocabulary. Compare BITS PER BYTE instead
# (chapter 16).
```

THE ONE IDENTITY TO REMEMBER

```
minimise cross-entropy
  == maximise likelihood        (chapter 09)
  == minimise KL(data || model)
  == minimise the compressed size of the data
  == minimise the model's average surprise
```

Five descriptions of the same optimisation. Which one you use depends on which makes the current problem obvious.

The other quantities worth knowing

```
/* --- MUTUAL INFORMATION --- */
        I(X; Y) = H(X) - H(X|Y)
                = KL( P(X,Y) || P(X)P(Y) )

    "How many bits does knowing Y save you about X?"
    Zero exactly when X and Y are independent. SYMMETRIC,
    unlike KL.

    WHERE IT APPEARS: feature selection, InfoNCE and
    contrastive learning objectives, analysing what a
    network layer retains about its input, and the
    information-bottleneck view of representation learning.

/* --- CONDITIONAL ENTROPY --- */
        H(X|Y) = H(X, Y) - H(Y)
    "Remaining uncertainty about X once Y is known."
    A LANGUAGE MODEL ESTIMATES exactly
        H(next token | context)
    and reducing it is the whole training objective.

/* --- THE ENTROPY OF ENGLISH --- */
    Shannon estimated ~1.0-1.3 bits per character for
    English text, using human prediction experiments.

    Modern large models achieve roughly 0.6-0.8 BITS PER
    BYTE on general text - BELOW Shannon's human estimate.
    That is a genuinely meaningful benchmark, because it is
    tokeniser-independent and directly comparable across
    models and across decades.

/* --- CHANNEL CAPACITY, for completeness --- */
    Shannon's other great result: a noisy channel has a
    maximum reliable rate, and codes exist that approach it.
    Not directly used in this track, but it is the same
    mathematics, and it is why error-correcting codes and
    machine learning keep borrowing each other's tools.

/* --- ENTROPY AS A DIAGNOSTIC, which is genuinely
       useful --- */

    def output_entropy(probs):
        return -np.sum(probs * np.log(probs + 1e-12))

    · HIGH entropy in the output distribution -> the model is
      uncertain about this token. Often a good place to
      branch, to ask for confirmation, or to spend more
      compute.
    · ENTROPY COLLAPSING TOWARD ZERO during training ->
      overconfidence, or a degenerate solution.
    · ENTROPY OF THE ATTENTION WEIGHTS -> whether a head is
      focused on one position or spread across many
      (chapter 19). A useful interpretability probe.
    · AND FOR DATA: the entropy of your label distribution
      tells you the accuracy a trivial "always predict the
      majority class" model would get. Compare against that,
      not against zero.                                  */
```

How it shows up

Symptom	Cause
`nan` loss	`log(0)` — softmax applied before cross-entropy, or no epsilon
Loss plateaus at a non-zero value	Expected — that floor is the data's own entropy
Loss of exactly `log(vocab_size)` at step 0	Correct — a uniform distribution. A useful sanity check
Loss much higher than `log(V)` at step 0	Initialisation is too large, or labels are misaligned
Model becomes overconfident and generalises worse	One-hot targets push logits to infinity — try label smoothing
Perplexity comparisons disagree with quality	Different tokenisers — use bits per byte
Generative samples are blurry or generic	Forward KL is mode-covering
A model collapses to one output mode	Reverse KL is mode-seeking
Accuracy beats a baseline by little	Compare against the majority-class entropy, not zero

Check yourself

- ✓ Give the three requirements that force `-log P` as the measure of information.
- ✓ Compute the entropy of a fair coin and of a uniform distribution over n outcomes.
- ✓ State the source coding theorem and explain why a language model is a compressor.
- ✓ Define cross-entropy and KL divergence, and state the relationship.
- ✓ Explain the difference between forward and reverse KL and where each is used.
- ✓ Show why cross-entropy collapses to negative log likelihood for a one-hot target.
- ✓ Write a numerically stable cross-entropy from logits.
- ✓ State the gradient of cross-entropy with respect to logits and interpret it.
- ✓ Explain label smoothing and the problem it solves.
- ✓ Define perplexity and say why it is not comparable across tokenisers.
- ✓ Give three diagnostic uses of entropy.

Gradient descent and its variants

The loop that actually trains everything. Ten lines of arithmetic, a handful of hyperparameters, and more practical folklore than any other part of the subject.

The algorithm

```
REPEAT:
   1. compute the loss on some data
   2. compute the gradient of the loss w.r.t. every
      parameter        (chapter 07)
   3. step every parameter AGAINST its gradient

     theta  <-  theta - lr * grad

THAT IS ALL. Everything below is about doing step 3
better.

THE THREE FLAVOURS, by how much data step 1 uses:

  BATCH (full)      the whole dataset per step.
                    Accurate gradient, impossibly slow,
                    and it gets stuck in whatever basin it
                    starts in.
  STOCHASTIC (SGD)  one sample per step.
                    Noisy, fast per step, and the noise
                    helps escape bad regions.
  MINI-BATCH        32-2048 samples. WHAT EVERYONE
                    ACTUALLY USES: a good gradient
                    estimate, and it saturates the
                    hardware's parallelism.

THE LEARNING RATE IS THE MOST IMPORTANT HYPERPARAMETER
IN THE FIELD:

  TOO SMALL     training crawls; may never arrive
  TOO LARGE     the loss oscillates, or diverges to nan
  JUST RIGHT    steady decrease

  loss                    loss                 loss
   |\                      |  /\  /\            |\
   | \____                 | /  \/  \           | \
   |      \____            |/         \         |  \___
   +---------- good        +---------- too     +------
                                       large     too small
                                       (bouncing) (crawling)

AND THE UNCOMFORTABLE TRUTH: THERE IS NO WAY TO KNOW THE
RIGHT VALUE WITHOUT TRYING. The standard method is an
LR RANGE TEST - increase the learning rate exponentially
over a few hundred steps, plot the loss, and pick roughly
an order of magnitude below where it starts rising.
```

Momentum and adaptivity

```
/* --- PLAIN SGD --- */
    theta -= lr * g

    Problems: it oscillates across narrow valleys, crawls
    along flat directions, and treats every parameter
    identically regardless of how large its gradients
    usually are.

/* --- MOMENTUM --- */
    v = beta * v + g              /* beta typically 0.9 */
    theta -= lr * v

    An exponentially weighted average of past gradients.
    THE PHYSICAL PICTURE: a ball rolling downhill has
    inertia. It builds speed in consistent directions and
    averages away oscillation across the valley.

    beta = 0.9 means the effective average covers roughly the
    last 1/(1-beta) = 10 gradients.

/* --- NESTEROV MOMENTUM --- */
    Evaluate the gradient at where momentum is ABOUT to take
    you, rather than where you are. A "look-ahead" correction
    that slightly improves convergence.

/* --- ADAGRAD: per-parameter learning rates --- */
    s += g^2                       /* elementwise */
    theta -= lr * g / (sqrt(s) + eps)

    Parameters with historically large gradients get smaller
    steps. Good for sparse features.
    FATAL FLAW: s only grows, so the effective learning rate
    decays monotonically to zero and training stops.

/* --- RMSPROP: fix the decay --- */
    s = beta2 * s + (1 - beta2) * g^2
    theta -= lr * g / (sqrt(s) + eps)

    An exponential average instead of a running sum, so it
    adapts to the RECENT gradient scale and never dies.

/* --- ADAM: momentum + RMSProp. THE DEFAULT. --- */
    m = beta1 * m + (1 - beta1) * g          /* 1st moment */
    v = beta2 * v + (1 - beta2) * g**2       /* 2nd moment */

    m_hat = m / (1 - beta1**t)               /* BIAS
                                                CORRECTION */
    v_hat = v / (1 - beta2**t)

    theta -= lr * m_hat / (sqrt(v_hat) + eps)

    DEFAULTS: beta1 = 0.9, beta2 = 0.999, eps = 1e-8.
    For transformers, beta2 = 0.95 is common and more
    stable.

    WHY THE BIAS CORRECTION: m and v start at zero, so early
    estimates are biased toward zero. Dividing by
    (1 - beta^t) - which is small early and approaches 1 -
    removes exactly that bias. Without it the first hundred
    steps take almost no movement.
```

```
    THE MEMORY COST: TWO EXTRA FULL-SIZE STATE TENSORS.
    Training a 7-billion-parameter model in fp32 needs
        28 GB weights + 28 GB gradients + 56 GB Adam state
        = 112 GB
    before activations. THIS IS WHY OPTIMISER STATE
    SHARDING (ZeRO, FSDP) exists, and why 8-bit optimisers
    are used.

/* --- ADAMW: use this one --- */
    theta -= lr * (m_hat / (sqrt(v_hat) + eps)
                   + weight_decay * theta)
                   ^^^^^^^^^^^^^^^^^^^^^^^
                   DECOUPLED from the adaptive scaling

    In plain Adam, L2 regularisation added to the gradient
    gets divided by sqrt(v) like everything else - so
    parameters with large gradients receive LESS
    regularisation, which is backwards. AdamW applies decay
    directly to the weights.

    ADAMW IS THE STANDARD FOR TRANSFORMERS. If you are
    choosing an optimiser and have no specific reason
    otherwise, use AdamW with lr around 3e-4 for a small
    model and weight_decay = 0.1.

/* --- THE NEWER ONES, briefly --- */
    LION       sign-based updates, less memory (one state
               tensor), competitive results
    SHAMPOO / SOAP   approximate second-order preconditioning
    ADAFACTOR  factorises the second-moment matrix to save
               memory; used for very large models
    MUON       orthogonalised momentum, strong recent results
               on transformer training

   None of these has displaced AdamW as the safe default.  */
```

Learning rate schedules

```
/* A CONSTANT LEARNING RATE IS ALMOST NEVER OPTIMAL. Large
   early to make progress, small later to settle.        */

import numpy as np

# --- WARMUP: essential for transformers ---
def warmup_cosine(step, warmup=2000, total=100000,
                  peak=3e-4, final=3e-5):
    if step < warmup:
        return peak * step / warmup          # LINEAR RAMP
    p = (step - warmup) / (total - warmup)
    return final + 0.5 * (peak - final) * (1 +
                                        np.cos(np.pi * p))

/* WHY WARMUP IS NOT OPTIONAL FOR ADAM + TRANSFORMERS:
   at step 1, Adam's second-moment estimate is based on a
   single gradient and is unreliable, so the adaptive
   denominator is meaningless and the first few steps can be
   enormous. That destabilises LayerNorm statistics and
   attention patterns before they have formed. Ramping from
   zero over 1-2k steps avoids it. Skipping warmup is one of
   the most common causes of "my transformer will not train".

/* THE SCHEDULES YOU WILL MEET:
     COSINE          smooth decay to near zero. THE DEFAULT
                     for LLM pretraining.
     LINEAR DECAY    simple, works well for fine-tuning
     STEP            drop by 10x at fixed milestones.
                     Classic vision training.
     ONE-CYCLE       up then down, with high peak LR.
                     Fast convergence for smaller models.
     CONSTANT + COOLDOWN   hold, then decay at the end.
                     Convenient when the total number of
                     steps is not known in advance, which is
                     increasingly common.

/* --- GRADIENT CLIPPING: not optional either --- */
    torch.nn.utils.clip_grad_norm_(model.parameters(), 1.0)

    If the total gradient norm exceeds the threshold, scale
    the WHOLE gradient down to that norm - preserving its
    direction. A single bad batch can otherwise produce a
    gradient large enough to destroy the model in one step,
    and recovery may take thousands of steps or never
    happen.

/* --- THE COMPLETE TRAINING LOOP --- */
import torch

model = MyModel()
opt = torch.optim.AdamW(model.parameters(), lr=3e-4,
                        weight_decay=0.1,
                        betas=(0.9, 0.95))

for step, (x, y) in enumerate(dataloader):
    lr = warmup_cosine(step)
    for g in opt.param_groups:
        g['lr'] = lr

    logits = model(x)
```

```
    loss = F.cross_entropy(logits.view(-1, V), y.view(-1))

    opt.zero_grad(set_to_none=True)   # <<< chapter 07
    loss.backward()
    torch.nn.utils.clip_grad_norm_(model.parameters(), 1.0)
    opt.step()

    if step % 100 == 0:
        print(f"{step} loss {loss.item():.4f} lr {lr:.2e}")

/* THAT LOOP TRAINS ANY MODEL IN THIS TRACK, INCLUDING THE
   TRANSFORMER IN CHAPTER 28. The architecture changes; this
   does not.

/* --- GRADIENT ACCUMULATION, when the batch will not fit --- */
    for i, (x, y) in enumerate(dataloader):
        loss = compute_loss(x, y) / accum_steps
        loss.backward()                    # ACCUMULATES
        if (i + 1) % accum_steps == 0:
            clip_grad_norm_(...)
            opt.step()
            opt.zero_grad(set_to_none=True)

    Effective batch size = batch_size * accum_steps.
    NOTE THE DIVISION BY accum_steps - without it the
    effective learning rate is multiplied by accum_steps.  */
```

DEBUGGING A TRAINING RUN, IN ORDER

```
1. OVERFIT ONE BATCH. Take 8 samples, turn off
   regularisation, and train until the loss is ~0. If it
   cannot, the bug is in the model or the data
   pipeline, not the optimiser. Do this FIRST, always.
2. Check the step-0 loss against the theoretical value
   (log V for a V-way classifier - chapter 10).
3. Print gradient norms per layer (chapter 07).
4. Run an LR range test.
5. Only then tune anything else.
```

What the loss landscape is actually like

```
/* THE PICTURE IN TEXTBOOKS - a smooth bowl with one minimum
   and some traps - is misleading for high-dimensional
   networks.

/* --- LOCAL MINIMA ARE NOT THE PROBLEM --- */
    In n dimensions, a local minimum requires ALL n
    eigenvalues of the Hessian to be positive. For large n
    that is astronomically unlikely at a random critical
    point. SADDLE POINTS - some directions up, some down -
    dominate instead.

    And saddles are escapable: gradient descent with any
    noise eventually finds a descending direction. This is
    part of why SGD's noise is a feature, and why the
    "getting stuck in a local minimum" worry from classical
    optimisation largely does not apply here.

/* --- MOST MINIMA ARE EQUIVALENT --- */
    Empirically, the many minima that gradient descent finds
    in a large network have similar loss. You are not
    searching for THE optimum; you are finding one of
    enormously many adequate ones.

/* --- FLAT MINIMA GENERALISE BETTER --- */
    A wide, flat basin means small parameter perturbations
    barely change the loss - so the solution is robust, and
    it tends to transfer to unseen data. Sharp minima do not.

    THIS EXPLAINS SEVERAL PRACTICES:
      · SMALL BATCHES generalise better than very large ones:
        their gradient noise cannot settle into a narrow
        basin
      · SAM (sharpness-aware minimisation) explicitly seeks
        flat regions
      · weight averaging (SWA, EMA of weights) lands in the
        middle of a basin rather than on its wall, and is
        nearly free

/* --- THE PRACTICAL CONSEQUENCES --- */
    · noise HELPS. Do not try to eliminate it.
    · the batch size and learning rate are COUPLED. The
      common heuristic: scale lr with the square root of the
      batch size for Adam, linearly for SGD.
    · a "bad run" is often just an unlucky initialisation or
      data order. Try a different seed before redesigning.
    · AND WATCH FOR LOSS SPIKES in large-model training.
      They are common, usually recoverable, and the standard
      response is to roll back to a checkpoint and skip the
      offending data batch - which is a real operational
      procedure, not a joke.                              */
```

How it shows up

Symptom	Cause
Loss is `nan` after a few steps	Learning rate too high, no clipping, or no warmup
Loss oscillates without decreasing	Learning rate too high

Symptom	Cause
Loss barely moves	Learning rate too low, or gradients not flowing
Transformer will not train at all	Missing warmup with Adam
Training is unstable early, fine later	Adam's second-moment estimate is unreliable at first — warm up
Cannot overfit 8 samples	A bug in the model or data pipeline, not the optimiser
Out of memory with Adam but not SGD	Two extra state tensors per parameter
Weight decay has no effect	Plain Adam, not AdamW — decay was scaled away
Effective learning rate too high with accumulation	Loss not divided by `accum_steps`
Large-batch training generalises worse	Sharp minima — reduce batch or add noise
A sudden loss spike mid-run	Common at scale — roll back and skip the batch

Check yourself

- ✓ Write the gradient descent update and the three batching flavours.
- ✓ Describe the loss curve for a learning rate that is too high, too low and correct.
- ✓ Explain momentum and what `beta = 0.9` means in terms of averaging.
- ✓ Write Adam from memory, including bias correction, and say why it is needed.
- ✓ Compute the memory cost of AdamW for a 7B model in fp32.
- ✓ Explain what AdamW decouples and why plain Adam's L2 is backwards.
- ✓ Explain why transformers need learning-rate warmup.
- ✓ Explain gradient clipping and what it preserves.
- ✓ Write the complete training loop from memory.
- ✓ Give the five debugging steps in order, starting with overfitting one batch.
- ✓ Explain why saddle points, not local minima, dominate high-dimensional landscapes.
- ✓ Say why flat minima generalise better and name two practices that exploit it.

What machine learning is

Fitting a function to data instead of writing it. That is the whole idea — and knowing when *not* to do it is as valuable as knowing how.

The shift

```
TRADITIONAL PROGRAMMING
     rules + data  ->  [program]  ->  answers

MACHINE LEARNING
     data + answers -> [training] ->  RULES
     then:  new data + rules      ->  answers

YOU SPECIFY WHAT, NOT HOW.

THE FORMAL SETUP:
  · a HYPOTHESIS SPACE - the set of functions the model
    can represent, determined by its architecture and
    parameters
  · a LOSS FUNCTION - how wrong a given function is on
    the data (chapters 09, 10)
  · an OPTIMISER - a search procedure over the hypothesis
    space (chapter 11)

TRAINING = SEARCHING FOR THE FUNCTION IN THAT SPACE THAT
MINIMISES THE LOSS.

THE THREE CLASSICAL SETTINGS:

SUPERVISED       inputs WITH labels.
                 classification (discrete labels),
                 regression (continuous).
                 The overwhelming majority of deployed
                 systems.

UNSUPERVISED     inputs, no labels. Clustering,
                 dimensionality reduction (chapter 05),
                 density estimation.

REINFORCEMENT    an agent acting in an environment,
                 receiving rewards. Games, robotics, and
                 RLHF (chapter 24).

AND THE ONE THAT MATTERS MOST NOW:

SELF-SUPERVISED  labels DERIVED FROM THE DATA ITSELF.
                 "Predict the next token" needs no
                 annotation - the next token IS the
                 label, and every document is millions of
                 training examples.

                 THIS IS WHY LARGE LANGUAGE MODELS WERE
                 POSSIBLE. Labelled data is scarce and
                 expensive; raw text is essentially free
                 and effectively unlimited. The entire
                 scaling story (chapter 23) rests on
                 removing the labelling bottleneck.
```

Generalisation: the actual problem

```
/* MEMORISING THE TRAINING DATA IS TRIVIAL. A lookup table
   achieves zero training error. IT IS ALSO USELESS.

   THE GOAL IS PERFORMANCE ON DATA YOU HAVE NEVER SEEN.

/* --- THE SPLIT, and it is non-negotiable --- */
    TRAIN        60-80%   the model fits this
    VALIDATION   10-20%   you choose hyperparameters using
                          this
    TEST         10-20%   YOU LOOK AT THIS ONCE, AT THE END

    IF YOU TUNE ON THE TEST SET, YOU HAVE NO TEST SET. Each
    decision you make based on test performance leaks a
    little information, and after fifty experiments your
    test score is an optimistic fiction. This is the most
    common methodological failure in applied work, and it is
    invisible until deployment.

/* --- UNDERFITTING AND OVERFITTING --- */

    UNDERFIT       high train error, high test error.
                   The model is too simple, or undertrained.
    GOOD FIT       low train error, low test error.
    OVERFIT        LOW train error, HIGH test error.
                   The model memorised noise.

      error
        |  \                    /   test
        |   \                  /
        |    \        ________/
        |     \______/
        |      \_______________ train
        +---------------------------> model capacity
                    ^
                the sweet spot

/* --- BIAS AND VARIANCE --- */
    BIAS       error from wrong assumptions. A linear model
               fitting a curve. -> UNDERFITTING.
    VARIANCE   sensitivity to the particular training sample.
               -> OVERFITTING.

    Classically these trade off. IN DEEP LEARNING THEY
    LARGELY DO NOT, and this is worth knowing because it
    contradicts the textbooks:

/* --- DOUBLE DESCENT --- */
      test
      error |    /\
            |   /  \        <- classical U-curve
            |  /    \
            | /      \    /-------____
            |/        \__/            ---____
            +-------------------------------------->
                       ^         model capacity
                  INTERPOLATION THRESHOLD
                  (enough capacity to fit the training data
                   exactly)

    Past the point where a model can fit the training data
```

```
    perfectly, test error DROPS AGAIN - often below the
    classical minimum. Bigger models generalise BETTER, not
    worse, which is the opposite of what classical
    statistical learning theory predicts.

    NOBODY HAS A COMPLETE EXPLANATION. The leading intuition
    involves implicit regularisation from SGD and the
    flat-minima argument (chapter 11). This is one of
    several places where the practice ran ahead of the
    theory and the theory has not caught up.

/* --- WHAT ACTUALLY CONTROLS OVERFITTING (chapter 15) --- */
      MORE DATA           the most effective by a wide
                          margin
      data AUGMENTATION   more data, cheaply
      REGULARISATION      weight decay, dropout
      EARLY STOPPING      stop when validation loss rises
      a SMALLER model     the classical answer, and often
                          the wrong one now               */
```

Measuring it properly

```
/* ACCURACY IS USUALLY THE WRONG METRIC, for the reason in
   chapter 09: with a 0.1% positive rate, a model that always
   says "no" is 99.9% accurate and worthless.             */

    THE CONFUSION MATRIX:
                      PREDICTED
                    pos       neg
        ACTUAL pos   TP        FN     (missed)
               neg   FP        TN
                    (false alarm)

    PRECISION = TP / (TP + FP)
        "Of the ones I flagged, how many were real?"
        Matters when a FALSE ALARM IS EXPENSIVE - shutting
        down a production line, blocking a legitimate
        transaction.

    RECALL    = TP / (TP + FN)
        "Of the real ones, how many did I catch?"
        Matters when a MISS IS EXPENSIVE - a missed fault, a
        missed diagnosis.

    F1 = 2 * P * R / (P + R)      the harmonic mean

    ROC-AUC       ranking quality across all thresholds
    PR-AUC        BETTER FOR IMBALANCED DATA than ROC-AUC,
                  which looks deceptively good when
                  negatives dominate

/* THE PRECISION-RECALL TRADE-OFF IS A THRESHOLD CHOICE, not
   a model property. One model gives a whole curve; where you
   sit on it is a PRODUCT decision, and it should be made
   with whoever owns the consequences.

/* --- REGRESSION METRICS --- */
    MSE / RMSE    penalises large errors quadratically;
                  sensitive to outliers (chapter 09)
    MAE           linear penalty, robust
    R^2           fraction of variance explained
    MAPE          percentage error - and it EXPLODES when
                  true values are near zero

/* --- CROSS-VALIDATION, when data is scarce --- */
    Split into k folds; train k times, each time holding out
    one fold. Average the results.
    k = 5 or 10 is standard.

    AND THE TRAPS:
      · TIME SERIES: never shuffle. Use forward-chaining
        splits, or you train on the future and predict the
        past.
      · GROUPED DATA: if the same patient, device or user
        appears in both train and test, you are measuring
        memorisation. Split by GROUP.
      · IMBALANCED CLASSES: stratify, so each fold has the
        same class ratio.

/* --- DATA LEAKAGE: the failure that ruins projects --- */
    Information in the training data that will not exist at
    prediction time. The model learns it, scores brilliantly
```

```
    in evaluation, and fails completely in production.

    REAL EXAMPLES:
      · a feature computed AFTER the outcome (an "account
        closed" flag when predicting churn)
      · normalising using statistics from the FULL dataset
        before splitting — the test set's mean has leaked
        into training
      · duplicate records across the train/test boundary
      · an ID that correlates with the label because of how
        the data was collected
      · IN LLM EVALUATION: the benchmark's test set is in
        the pretraining corpus. This is now a serious and
        widespread measurement problem, and it is why
        contamination checks and held-out private evals
        matter.

    THE SMELL TEST: IF YOUR RESULTS LOOK TOO GOOD, THEY ARE.
    Go looking for the leak; you will usually find it.    */
```

WHEN NOT TO USE MACHINE LEARNING

```
· THE RULES ARE KNOWN. Write them. A deterministic
  algorithm is faster, testable, explainable, and does
  not degrade silently.
· YOU LACK DATA. A few hundred examples rarely
  supports a learned model.
· ERRORS ARE UNACCEPTABLE. ML systems are wrong
  sometimes, by construction.
· YOU NEED AN EXPLANATION. Regulated decisions often
  require a reason, not a probability.
· THE DISTRIBUTION SHIFTS CONSTANTLY. A model trained
  on last month's data may be worse than a simple
  heuristic on this month's.
· A SIMPLE BASELINE ALREADY WORKS. Threshold, moving
  average, lookup table, linear model.
```

Always build the trivial baseline first — majority class, last value, a hand-tuned threshold. If your model does not clearly beat it, it does not justify its complexity, its latency, or its maintenance cost. This is the single most useful habit in applied machine learning.

The real workflow

```
/* THE PROPORTIONS SURPRISE PEOPLE:

     define the problem and the metric      5%
     get and clean the data                40%     <<<
     feature engineering / preprocessing   20%
     model selection and training          10%
     evaluation and error analysis         15%
     deployment and monitoring             10%

   THE MODEL IS THE SMALL PART. Anyone telling you
   otherwise has not shipped one.

/* --- 1. DEFINE THE PROBLEM AND THE METRIC FIRST --- */
    What decision does this output feed?
    What does a false positive cost? A false negative?
    What performance would make this worth deploying?
    AGREE THE METRIC BEFORE YOU START, or you will pick the
    metric that flatters the result you got.

/* --- 2. DATA --- */
    Is it representative of production?
    How is it labelled, and how good are the labels? (Label
      noise sets a ceiling on achievable accuracy.)
    Is it balanced? Biased? Does it encode a historical
      decision you should not replicate?
    HOW MUCH IS THERE? This determines what is possible more
      than any architectural choice.

/* --- 3. BASELINE --- */
    The trivial one. Then a simple model - logistic
    regression, gradient-boosted trees. FOR TABULAR DATA,
    GRADIENT BOOSTING (XGBoost, LightGBM) STILL BEATS NEURAL
    NETWORKS MOST OF THE TIME. Deep learning wins on
    perceptual and sequential data - images, audio, text -
    not on spreadsheets.

/* --- 4. ITERATE ON ERRORS, NOT ON ARCHITECTURE --- */
    LOOK AT THE MISTAKES. Sort by loss, read the worst
    hundred examples by hand. You will find mislabelled
    data, a preprocessing bug, or a systematic gap - and any
    of those is worth more than a hyperparameter sweep.

    This is the highest-value hour in any ML project and it
    is the one most often skipped.

/* --- 5. DEPLOY AND MONITOR --- */
    LATENCY, memory, throughput - the embedded constraints
      (chapter 27)
    INPUT DISTRIBUTION MONITORING: is production data
      drifting from training data?
    OUTPUT MONITORING: is the prediction distribution
      changing?
    A FALLBACK PATH for when the model is unavailable or
      obviously wrong
    AND A RETRAINING PLAN, because the world moves.

    MODELS DEGRADE SILENTLY. Unlike a crashed service,
    a model that has become wrong keeps returning confident
    answers. YOU WILL NOT NOTICE WITHOUT MONITORING.      */
```

How it shows up

Symptom	Cause
99% accuracy, useless in production	Imbalanced classes — use precision and recall
Excellent evaluation, poor deployment	Data leakage, or a train/production distribution gap
Test score drifts up over a project	Tuning on the test set — it is no longer held out
Perfect training loss, poor validation	Overfitting — more data or more regularisation
Both losses high	Underfitting — more capacity or longer training
Time-series model looks perfect	Shuffled split — the model saw the future
Great cross-validation, bad on new users	Same group in train and test — split by group
Benchmark scores far above real-world quality	Test-set contamination in the training corpus
Bigger model generalises better than theory predicts	Double descent — expected past the interpolation threshold
Model quality decays over months	Distribution drift with no monitoring
Neural network loses to gradient boosting	Tabular data — that is the normal result

Check yourself

- ✓ Contrast traditional programming and machine learning in one line each.
- ✓ Name the three components of a learning setup.
- ✓ Explain self-supervision and why it enabled large language models.
- ✓ Explain the three-way split and why tuning on the test set destroys it.
- ✓ Define underfitting, overfitting, bias and variance.
- ✓ Describe double descent and say why it contradicts classical theory.
- ✓ Define precision and recall and give a situation where each dominates.
- ✓ Give four concrete examples of data leakage.
- ✓ List six situations where machine learning is the wrong tool.
- ✓ State the workflow proportions and which step is most often skipped.
- ✓ Say why models degrade silently and what monitoring must cover.

Linear and logistic regression

The two simplest useful models, built end to end. Everything in the rest of this track is a variation on what happens here — and a single logistic regression unit *is* a neuron.

Linear regression

```
THE MODEL:
     y = w1 x1 + w2 x2 + ... + wn xn + b
       = w · x + b

ONE DOT PRODUCT (chapter 02) plus an offset. That is the
entire hypothesis space: all the hyperplanes.

THE LOSS - mean squared error, which chapter 09 derived
from a Gaussian noise assumption:

     L = (1/N) sum_i (y_i - y_hat_i)^2

THE GRADIENTS, derived with the chain rule (chapter 07):

     dL/dw = -(2/N) sum_i (y_i - y_hat_i) x_i
     dL/db = -(2/N) sum_i (y_i - y_hat_i)

IN MATRIX FORM, which is what you implement:

     y_hat = X @ w + b            X: (N, d)
     err   = y_hat - y
     dw    = (2/N) * X.T @ err
     db    = (2/N) * err.sum()

AND THERE IS A CLOSED-FORM SOLUTION - the NORMAL
EQUATIONS:

     w = (X^T X)^-1 X^T y

WHEN TO USE IT: small d (up to a few thousand features),
when you want the exact answer in one step.
WHEN NOT TO: large d - inverting a (d, d) matrix is
O(d^3); when X^T X is singular or ill-conditioned
(chapter 03); when the data does not fit in memory. And
in practice, use np.linalg.lstsq rather than forming the
inverse yourself.

GRADIENT DESCENT SCALES WHERE THE CLOSED FORM DOES NOT,
which is why every model past this chapter uses it.
```

```
import numpy as np

class LinearRegression:
    def fit(self, X, y, lr=0.01, epochs=1000):
        N, d = X.shape
        self.w = np.zeros(d)
        self.b = 0.0
        self.history = []

        for epoch in range(epochs):
            y_hat = X @ self.w + self.b
            err = y_hat - y
            loss = np.mean(err**2)
            self.history.append(loss)

            self.w -= lr * (2/N) * (X.T @ err)
            self.b -= lr * (2/N) * err.sum()
        return self

    def predict(self, X):
        return X @ self.w + self.b

# --- FEATURE SCALING IS NOT OPTIONAL ---
# If x1 is in [0, 1] and x2 is in [0, 100000], the loss
# surface is an extremely elongated valley. Gradient descent
# zig-zags across the narrow direction and crawls along the
# long one - the conditioning problem from chapter 03,
# appearing as a training problem.
X_scaled = (X - X.mean(axis=0)) / (X.std(axis=0) + 1e-8)

# COMPUTE THE STATISTICS ON THE TRAINING SET ONLY, and apply
# them to validation and test. Using the full dataset's mean
# is data leakage (chapter 12).

# --- POLYNOMIAL FEATURES: linear in the PARAMETERS ---
X_poly = np.column_stack([x, x**2, x**3])
# The model is still "linear regression" - the linearity that
# matters is in w, not in x. This is how a linear model fits
# a curve, and it is the same trick kernel methods
# generalise.

# --- REGULARISED VARIANTS (chapter 09's MAP view) ---
# RIDGE (L2):  loss + alpha * ||w||^2
#     shrinks all weights; handles correlated features
#     gracefully; has a closed form:
#         w = (X.T @ X + alpha*I)^-1 @ X.T @ y
#     Note the +alpha*I: it also FIXES SINGULARITY, which is
#     why ridge is numerically better behaved than plain
#     least squares.
#
# LASSO (L1):  loss + alpha * ||w||_1
#     drives weights to EXACTLY zero -> automatic feature
#     selection. No closed form; needs iterative solvers.
#
# ELASTIC NET: both.
```

Logistic regression

```
/* CLASSIFICATION, NOT REGRESSION - the name is historical
   and unhelpful.

   THE PROBLEM WITH USING LINEAR REGRESSION FOR
   CLASSIFICATION: it outputs unbounded values. What does
   -3.7 mean when the label is 0 or 1?

   THE FIX: SQUASH IT THROUGH A SIGMOID (chapter 06).

        z = w · x + b                  the LOGIT
        p = sigmoid(z) = 1/(1 + e^-z)  a PROBABILITY in (0,1)

   THE LOSS - binary cross-entropy, which chapter 10 derived
   as the negative log likelihood:

        L = -(1/N) sum_i [ y_i log(p_i)
                         + (1-y_i) log(1-p_i) ]

   Read it: when y = 1 only the first term survives, so the
   loss is -log(p) - pushing p up. When y = 0 only the
   second survives. It is exactly "the negative log
   probability of the correct answer".

/* AND THE GRADIENT, WHICH IS THE SAME AS LINEAR
   REGRESSION'S: */

        dL/dw = (1/N) X.T @ (p - y)
        dL/db = (1/N) sum(p - y)

   THE SIGMOID DERIVATIVE CANCELS AGAINST THE LOG IN THE
   LOSS, leaving PREDICTION MINUS TARGET - the same clean
   form as softmax + cross-entropy (chapter 06). This
   cancellation is not a coincidence: it happens for every
   member of the exponential family paired with its natural
   loss.

/* WHY YOU MUST NOT USE MSE FOR CLASSIFICATION:
     with MSE the gradient carries a factor of
     sigmoid'(z) = p(1-p), which is nearly ZERO when the
     model is confidently WRONG (p near 0 with y = 1). The
     model gets almost no gradient exactly when it most needs
     one. Cross-entropy has no such factor - a confidently
     wrong prediction produces a LARGE gradient. This is one
     of the clearest cases where the right loss function is
     not a matter of taste.                              */

import numpy as np

def sigmoid(z):
    # STABLE: exp of a large positive number overflows
    return np.where(z >= 0,
                    1 / (1 + np.exp(-z)),
                    np.exp(z) / (1 + np.exp(z)))

class LogisticRegression:
    def fit(self, X, y, lr=0.1, epochs=1000, l2=0.0):
        N, d = X.shape
        self.w = np.zeros(d)
        self.b = 0.0
        for _ in range(epochs):
```

```
            p = sigmoid(X @ self.w + self.b)
            grad = p - y                        # <<< that is
                                                #     all of it
            self.w -= lr * ((X.T @ grad) / N + l2 * self.w)
            self.b -= lr * grad.mean()
        return self

    def predict_proba(self, X):
        return sigmoid(X @ self.w + self.b)

    def predict(self, X, threshold=0.5):
        return (self.predict_proba(X) >= threshold).astype(int)

/* THE THRESHOLD IS A SEPARATE DECISION FROM THE MODEL. 0.5
   is a default, not a law. Move it to trade precision
   against recall according to what a false positive costs
   (chapter 12).

/* --- MULTI-CLASS: SOFTMAX REGRESSION --- */
    W: (d, K) instead of (d,). Softmax instead of sigmoid.
    Categorical cross-entropy instead of binary.

        logits = X @ W + b          # (N, K)
        probs  = softmax(logits)
        grad   = probs - one_hot(y) # (N, K) - SAME FORM
        dW     = X.T @ grad / N

    AND NOTE WHAT THIS IS: a single linear layer followed by
    softmax. IT IS THE OUTPUT HEAD OF EVERY CLASSIFIER IN
    THIS TRACK, including a language model's projection to
    the vocabulary (chapter 20). You have now written it.  */
```

A LOGISTIC REGRESSION UNIT IS A NEURON

```
weighted sum -> non-linearity -> output
   w · x + b  ->   sigmoid     ->   p
```

Stack many of these in parallel and you have a layer. Stack layers and you have a neural network (chapter 14). The forward pass, the loss, the gradient and the update loop you just wrote do not change — only the number of layers between input and output. That is genuinely the whole conceptual step from here to a transformer.

Interpretation, and the limits

```
/* --- WHAT THE COEFFICIENTS MEAN --- */
    LINEAR:   w_j is the change in y for a one-unit change in
              x_j, holding the others fixed.
    LOGISTIC: w_j is the change in the LOG-ODDS. exp(w_j) is
              the ODDS RATIO - "this feature multiplies the
              odds by exp(w_j)".

    THIS INTERPRETABILITY IS THE MAIN REASON THESE MODELS
    ARE STILL EVERYWHERE in medicine, finance and any
    regulated domain. You can hand a coefficient table to a
    domain expert and they can tell you whether it is
    sensible. You cannot do that with a transformer.

    THE CAVEATS:
      · coefficients are only comparable if the features are
        SCALED
      · CORRELATED FEATURES split their weight
        unpredictably; the individual values become
        meaningless even though predictions are fine
      · AND THE BIG ONE: CORRELATION IS NOT CAUSATION. A
        positive coefficient does not mean intervening on
        that feature will change the outcome. Models trained
        on observational data cannot answer interventional
        questions, and treating them as though they can has
        caused real harm.

/* --- WHAT LINEAR MODELS CANNOT DO --- */
    XOR:
        x1 x2 | y
         0  0 | 0
         0  1 | 1
         1  0 | 1
         1  1 | 0

    NO LINE SEPARATES THESE POINTS. This is Minsky and
    Papert's 1969 result, and it stalled neural network
    research for over a decade.

    THE RESOLUTIONS:
      · engineer a feature: add x1*x2 and it becomes
        separable
      · OR LEARN THE FEATURES - which is exactly what a
        hidden layer does, and why chapter 14 exists.

    The historical lesson worth carrying: the limitation was
    real, the conclusion drawn from it was wrong, and the fix
    (a hidden layer plus a way to train it) had to wait for
    backpropagation to become widely understood.

/* --- WHEN A LINEAR MODEL IS STILL THE RIGHT ANSWER --- */
      · few samples relative to features
      · you need an explanation, not just a prediction
      · the relationship really is roughly linear
      · you need microsecond inference in a few hundred bytes
        of code - which on an MCU is a decisive argument
        (chapter 27)
      · as a BASELINE. Always (chapter 12).

/* --- AND THE HONEST NOTE ON TABULAR DATA --- */
    For structured/tabular problems, the ladder that usually
```

```
    works is:
        linear/logistic  ->  gradient-boosted trees
        (XGBoost, LightGBM)  ->  and only then neural
        networks, which frequently do not win at all.
    Deep learning's advantage is on perceptual and
    sequential data. Knowing this saves months.          */
```

How it shows up

Symptom	Cause
Training diverges immediately	Features unscaled — an ill-conditioned loss surface
Loss decreases painfully slowly	Same cause, or the learning rate is too low
`nan` from `exp`	Unstable sigmoid — use the branch-free stable form
Confidently wrong predictions never improve	MSE used for classification — the gradient vanishes
Coefficients are huge and unstable	Collinear features — use ridge
`Singular matrix` in the normal equations	Rank-deficient `X` — add ridge, or use `lstsq`
Model cannot learn XOR	Correct — linear models cannot. Add a hidden layer
Validation worse than training by a lot	Overfitting — regularise or get more data
Predictions all one class	Imbalanced data at threshold 0.5 — move the threshold
Coefficients contradict domain knowledge	Correlated features splitting weight, or leakage
Test performance drops after scaling	Statistics computed on the full dataset — leakage

Check yourself

- ✓ Write the linear model, its loss and its gradients in matrix form.
- ✓ Give the normal equations and say when not to use them.
- ✓ Explain why feature scaling matters, in terms of the loss surface.
- ✓ Explain how polynomial features keep a model "linear".
- ✓ Contrast ridge and lasso, including what ridge does to singularity.
- ✓ Write binary cross-entropy and read both terms aloud.
- ✓ State the logistic gradient and explain why the sigmoid derivative cancels.
- ✓ Explain why MSE is the wrong loss for classification.
- ✓ Interpret a logistic coefficient as an odds ratio, with the three caveats.
- ✓ Show why XOR is not linearly separable and give two fixes.
- ✓ Say when a linear model is still the right choice, including on an MCU.

Neural networks: the multilayer perceptron

Stack the units from the last chapter, put a non-linearity between the layers, and the model can represent anything. This is the architecture every later one is a specialisation of.

The architecture

```
INPUT      HIDDEN 1     HIDDEN 2      OUTPUT
(784)       (128)        (64)          (10)

  o ---\   /-- o ---\   /-- o ---\   /-- o
  o ----\ /--- o ----\ /--- o ----\ /--- o
  o -----X---- o -----X---- o -----X---- o
  o ----/ \--- o ----/ \--- o ----/ \--- o
  o ---/   \-- o ---/   \-- o ---/   \-- o
           W1,b1       W2,b2        W3,b3
           ReLU        ReLU         softmax

EVERY LAYER IS:
     h = activation(W @ x + b)

THE FORWARD PASS, in full:
     h1 = relu(x  @ W1 + b1)      (784,) -> (128,)
     h2 = relu(h1 @ W2 + b2)      (128,) -> ( 64,)
     y  = softmax(h2 @ W3 + b3)   ( 64,) -> ( 10,)

PARAMETER COUNT:
     784*128 + 128   = 100,480
     128*64  +  64   =   8,256
     64*10   +  10   =     650
                     = 109,386 total

THE ACTIVATION IS THE WHOLE POINT. Without it:
     W3 (W2 (W1 x)) = (W3 W2 W1) x = W x
Three layers collapse into one matrix (chapter 03). THE
DEPTH WOULD BUY NOTHING AT ALL. A non-linearity between
layers is what makes composition meaningful.

THE UNIVERSAL APPROXIMATION THEOREM says a network with
ONE hidden layer can approximate any continuous function
on a bounded domain, to any accuracy, given enough units.

AND THE THEOREM IS ALMOST USELESS IN PRACTICE, which is
worth being clear about:
  · "enough units" may be exponentially many
  · it says nothing about whether TRAINING will FIND those
    weights
  · it says nothing about GENERALISATION

DEPTH IS WHAT ACTUALLY WORKS. Deep networks represent
many functions exponentially more compactly than shallow
ones, and they are the ones gradient descent can
successfully train. That empirical fact, not the theorem,
is why the field is called DEEP learning.
```

A complete implementation

```
"""A full MLP in numpy. Every line here was derived in
   chapters 06, 07, 10 and 11 - this is just assembly."""

import numpy as np

# ~98% ON MNIST. About sixty lines, no framework, and every
# line traceable to a chapter in this track.

# --- THE SAME THING IN PYTORCH ---
import torch.nn as nn

model = nn.Sequential(
    nn.Linear(784, 128), nn.ReLU(),
    nn.Linear(128, 64),  nn.ReLU(),
    nn.Linear(64, 10),
)
# The framework provides autodiff (chapter 07),
# initialisation, optimisers (chapter 11) and GPU
# execution. IT COMPUTES EXACTLY WHAT THE CODE ABOVE
# COMPUTES.
```

Choosing an activation

Function	Formula	Use
ReLU	`max(0, x)`	**The default.** Cheap, no saturation for positive inputs
LeakyReLU	`max(0.01x, x)`	When units are dying
GELU	`x · Φ(x)`	Transformers — GPT, BERT
SiLU / Swish	`x · σ(x)`	Modern LLMs, usually gated as SwiGLU
Sigmoid	$1/(1+e^{-x})$	**Output only** — binary probability, or a gate
Tanh	—	LSTM internals; zero-centred
Softmax	—	Output layer for multi-class
None (identity)	—	Regression output, and every logit layer

```
/* THE DECISION IN PRACTICE:
     hidden layers, general        -> ReLU
     hidden layers, transformer    -> GELU or SwiGLU
     output, binary classification -> sigmoid
     output, multi-class           -> softmax (fused into
                                      the loss)
     output, regression            -> NONE

/* THE MOST COMMON ERROR: PUTTING AN ACTIVATION ON THE
   OUTPUT LAYER OF A CLASSIFIER AND THEN USING A LOSS THAT
   EXPECTS LOGITS. It halves your effective gradient and
   costs accuracy, and it produces no error message
   (chapter 06).

/* --- DEAD ReLUs, concretely --- */
    A unit whose pre-activation is negative for EVERY input
    outputs zero always, and its gradient is zero always, so
    it never recovers. Usually caused by too high a learning
    rate driving a large negative bias.

    DIAGNOSE:
        frac_dead = (activations == 0).all(axis=0).mean()
    A few percent is normal - ReLU sparsity is useful.
    Thirty percent means something is wrong.

    FIX: lower the learning rate, use LeakyReLU or GELU,
    check the initialisation.

/* --- AND FOR THE EMBEDDED READER (chapter 27) --- */
    ReLU is ONE COMPARISON. GELU involves a tanh or an erf
    approximation - roughly 10-20x the cost, and it needs a
    lookup table or a polynomial on a device without an FPU.
    On an MCU, ReLU (or ReLU6, which clamps at 6 and
    quantises cleanly) is almost always the right choice,
    and every embedded inference library optimises for
    it.                                                  */
```

WHAT THE LAYERS ARE DOING

Each hidden layer computes a new *representation* of the input — a set of learned features. The first layer of an image network learns edges; the next, corners and textures; the next, object parts. You did not specify any of those. **Representation learning is the actual contribution of deep learning**: instead of hand-engineering features and then fitting a linear model on top, the network learns the features and the classifier together, end to end. Every architecture after this chapter is a different structural prior about what representations are useful — convolution for spatial locality, attention for relevance across a sequence.

Why depth, and what the priors are

```
/* --- AN MLP HAS NO STRUCTURAL PRIOR --- */
    Every input connects to every unit. The model has no
    notion that pixel (3,4) is next to pixel (3,5), or that
    token 7 came before token 8. It must learn any such
    structure from data - which needs vastly more data than
    building the assumption in.

/* --- CONVOLUTIONAL NETWORKS: the spatial prior --- */
    A small kernel slides over the input, SHARING WEIGHTS
    across positions.

      · TRANSLATION EQUIVARIANCE: a feature detector that
        works at one position works at all of them
      · LOCALITY: nearby pixels are related
      · PARAMETER SHARING: a 3x3 kernel is 9 weights,
        regardless of image size

    A 224x224 image into a 1000-unit MLP layer needs 50
    million weights for one layer. A conv layer needs
    hundreds. THE PRIOR IS THE POINT - and it is why CNNs
    beat MLPs on images by an enormous margin.

    STILL THE RIGHT CHOICE for vision on embedded hardware:
    MobileNet, EfficientNet-Lite and their kin run on
    microcontrollers (chapter 27) where a vision transformer
    does not.

/* --- RECURRENT NETWORKS: the sequential prior --- */
    A hidden state carried from step to step. Chapter 18
    covers them and why they were superseded.

/* --- TRANSFORMERS: the relevance prior --- */
    Attention lets every position look at every other
    position, WEIGHTED BY LEARNED RELEVANCE (chapter 19).
    A weaker prior than convolution - which is why
    transformers need more data, and why, with enough data,
    they win.

    THE PATTERN ACROSS ALL THREE: A STRONGER PRIOR NEEDS
    LESS DATA BUT CAPS PERFORMANCE; A WEAKER PRIOR NEEDS
    MORE DATA AND SCALES FURTHER. That trade-off is the
    single most useful lens for reading architecture papers.

/* --- WHY DEEP RATHER THAN WIDE --- */
    · COMPOSITIONAL efficiency: some functions need
      exponentially more units in a shallow network than in
      a deep one
    · HIERARCHY: features build on features
    · EMPIRICALLY, depth wins - and residual connections
      (chapter 22) made very deep networks trainable, which
      was the unlock.

/* --- THE PROBLEMS DEPTH INTRODUCES, and their fixes --- */
      vanishing/exploding gradients  -> careful init,
                                        residual connections
      internal covariate shift       -> normalisation layers
      overfitting                    -> more data, dropout,
                                        weight decay
      compute cost                   -> the entire hardware
                                        industry
```

```
    Chapters 15 and 22 cover the first three. The fourth is
    someone else's problem.                                  */
```

How it shows up

Symptom	Cause
Deep network performs like a linear model	Missing activation between layers — they collapsed
Loss stuck at `log(n_classes)`	No learning — check initialisation and gradient flow
Many units always output zero	Dead ReLUs — lower the learning rate or switch activation
Accuracy lower than expected, no error	Softmax applied before a logit-expecting loss
Gradients vanish in the first layers	Depth without residuals or proper initialisation
Loss is `nan` from step 1	Initialisation scale far too large
MLP needs enormous data for images	No spatial prior — use convolution
Transformer underperforms a CNN on a small dataset	Weaker prior — expected below a data threshold
Wider network does not help	Depth, not width, is usually the lever
GELU is slow on an MCU	Transcendental function — use ReLU or ReLU6

Check yourself

- ✓ Write the forward pass of a three-layer MLP and count its parameters.
- ✓ Explain why layers collapse without a non-linearity.
- ✓ State the universal approximation theorem and three reasons it is not practically useful.
- ✓ Implement the backward pass for a two-layer MLP from memory.
- ✓ Explain why the output layer has no activation when using cross-entropy.
- ✓ Choose activations for hidden layers, binary output, multi-class output and regression.
- ✓ Diagnose and fix dead ReLUs.
- ✓ Explain representation learning in one paragraph.
- ✓ Give the structural prior of a CNN, an RNN and a transformer.
- ✓ State the prior-strength versus data-requirement trade-off.
- ✓ List four problems depth introduces and their standard fixes.

Training: loss, initialisation and regularisation

The practical craft. Everything that determines whether a correct architecture actually learns anything — and the diagnostic procedure for when it does not.

Initialisation

```
THE PROBLEM: the initial weights determine whether
signals and gradients survive their trip through the
network.

ALL ZEROS       every unit in a layer computes the same
                thing, receives the same gradient, and
                stays identical forever. THE NETWORK HAS
                ONE EFFECTIVE UNIT PER LAYER. Symmetry
                must be broken.

TOO LARGE       activations grow layer by layer;
                gradients explode; loss goes to nan
                within a few steps.

TOO SMALL       activations shrink to zero; gradients
                vanish; nothing learns.

THE RULE, derived from variance arithmetic in chapter 08:
KEEP THE VARIANCE OF THE ACTIVATIONS ROUGHLY CONSTANT
THROUGH DEPTH.

  XAVIER / GLOROT     Var(W) = 1 / n_in
                      (or 2/(n_in+n_out))
                      for tanh and sigmoid

  HE / KAIMING        Var(W) = 2 / n_in
                      for ReLU - the factor of 2
                      compensates for ReLU zeroing half
                      the outputs

  ORTHOGONAL          Q from a QR decomposition.
                      Preserves norms exactly
                      (chapter 03). Good for RNNs and
                      very deep stacks.

  BIASES              zero. Almost always.

AND FOR TRANSFORMERS SPECIFICALLY:
  · a SMALL initialisation (std 0.02) on all weights
  · the RESIDUAL PROJECTIONS scaled down by
    1/sqrt(2*n_layers), so the residual stream does not
    grow with depth (chapter 22)
  · embeddings drawn from N(0, 0.02)

THIS IS NOT FOLKLORE - it is the same variance argument,
applied to a specific topology. GPT-2's initialisation
scheme is three lines of code and it is load-bearing.
```

```
import numpy as np
import torch.nn as nn

# NUMPY
W = np.random.randn(n_in, n_out) * np.sqrt(2.0 / n_in)   # He

# PYTORCH - the defaults are reasonable but not optimal for
# every architecture, so set them explicitly:
def init_weights(m):
    if isinstance(m, nn.Linear):
        nn.init.normal_(m.weight, mean=0.0, std=0.02)
        if m.bias is not None:
            nn.init.zeros_(m.bias)
    elif isinstance(m, nn.Embedding):
        nn.init.normal_(m.weight, mean=0.0, std=0.02)

model.apply(init_weights)

# THE DIAGNOSTIC - run this ONCE before training. It takes
# thirty seconds and it has saved more debugging time than
# any other habit in this chapter:
def check_activations(model, x):
    acts = {}
    hooks = [m.register_forward_hook(
                lambda mod, i, o, n=n: acts.__setitem__(
                    n, o.detach()))
             for n, m in model.named_modules()]
    model(x)
    for name, a in acts.items():
        print(f"{name:30s} std={a.std():.4f} "
              f"mean={a.mean():+.4f} "
              f"dead={(a == 0).float().mean():.2%}")
    for h in hooks: h.remove()

# WHAT YOU WANT TO SEE: std roughly CONSTANT across layers,
# somewhere near 1 (or near 1 after each normalisation
# layer). A std that shrinks 10x per layer, or grows 10x,
# tells you the problem before you waste an hour on the
# loss curve.
```

Choosing the loss

Task	Loss	Output layer
Binary classification	`BCEWithLogitsLoss`	1 logit, **no sigmoid**
Multi-class	`CrossEntropyLoss`	K logits, **no softmax**
Multi-label	`BCEWithLogitsLoss`	K logits
Regression	`MSELoss`	Linear
Regression with outliers	`HuberLoss` / `SmoothL1`	Linear
Language modelling	`CrossEntropyLoss`	V logits per position
Ranking / retrieval	Contrastive, InfoNCE, triplet	Embeddings
Imbalanced classification	Focal loss, or class weights	Logits

```
/* THE "WithLogits" VARIANTS ARE NOT A CONVENIENCE. They
   fuse the activation and the loss to gain numerical
   stability and the clean gradient (chapter 06). Using the
   separated version is measurably worse and occasionally
   produces nan.

/* --- HANDLING IMBALANCE --- */
    class weights:
        w = torch.tensor([1.0, 10.0])       # 10x on the
                                            # rare class
        F.cross_entropy(logits, y, weight=w)

    FOCAL LOSS down-weights easy examples so training
    focuses on the hard ones:
        FL = -(1 - p_t)^gamma * log(p_t)      gamma = 2
    Designed for extreme imbalance in object detection;
    useful whenever the easy negatives swamp the signal.

    AND THE SIMPLER OPTIONS THAT OFTEN WIN: resample the
    data, or just move the decision threshold after training
    (chapter 13). Try those first.

/* --- AUXILIARY AND COMBINED LOSSES --- */
    loss = main_loss + 0.1 * auxiliary_loss

    THE WEIGHT MATTERS ENORMOUSLY and is a real
    hyperparameter. Check the MAGNITUDES of the terms - if
    one is 100x the other, the small one is decoration. Print
    both separately during training; a combined loss that
    only ever reflects one term is a common silent failure.

/* --- THE SANITY CHECK YOU SHOULD ALWAYS RUN --- */
    At step 0, before any learning:
      · K-way classification -> loss should be ~log(K)
        (10 classes -> 2.303; 50k vocabulary -> 10.82)
      · regression -> loss should be ~the variance of y

    IF THE INITIAL LOSS IS WRONG, THE BUG IS IN THE MODEL,
    THE LABELS OR THE LOSS - not in the training. Finding it
    now costs minutes; finding it after a day of training
    costs a day.                                          */
```

Regularisation

```
/* --- MORE DATA. Always first, always best. --- */
    Nothing on this list comes close to the effect of
    doubling the dataset.

/* --- DATA AUGMENTATION: more data, for free --- */
    images  flips, crops, rotations, colour jitter,
            mixup, cutmix
    audio   time/pitch shift, noise, SpecAugment
    text    back-translation, synonym swap, token dropout -
            all much weaker than the vision equivalents,
            because language is less tolerant of
            perturbation
    sensor  jitter, scaling, window shifting, and SYNTHETIC
            FAULT INJECTION - which for embedded anomaly
            detection is often the only way to get positive
            examples at all

/* --- WEIGHT DECAY (L2) --- */
    opt = torch.optim.AdamW(params, weight_decay=0.1)
    A Gaussian prior on the weights (chapter 09). USE ADAMW,
    not Adam with L2 in the loss (chapter 11).

    AND EXCLUDE BIASES AND NORMALISATION PARAMETERS from
    decay - decaying a LayerNorm gain toward zero actively
    hurts:
        decay    = [p for n,p in model.named_parameters()
                    if p.dim() >= 2]
        no_decay = [p for n,p in model.named_parameters()
                    if p.dim() < 2]

/* --- DROPOUT --- */
    nn.Dropout(0.1)
    Randomly zero a fraction of activations during training;
    scale the rest by 1/(1-p) so the expected value is
    unchanged. At inference it is a no-op.

    THE INTUITION: units cannot rely on any particular other
    unit being present, so they learn redundant, distributed
    representations. Also approximately an ensemble over
    exponentially many sub-networks.

    RATES: 0.5 for old-style MLPs, 0.1 for transformers,
    OFTEN ZERO FOR LARGE-SCALE PRETRAINING - when the data
    is effectively unlimited and each example is seen once,
    there is nothing to overfit, and dropout only slows
    learning. It comes back for fine-tuning on small
    datasets.

    AND THE CLASSIC BUG: FORGETTING model.eval(). Dropout
    stays active, and your validation numbers are noisy and
    pessimistic. The same call switches BatchNorm to its
    running statistics.

/* --- EARLY STOPPING --- */
    best, patience, wait = inf, 10, 0
    for epoch in ...:
        val = validate()
        if val < best:
            best, wait = val, 0
            torch.save(model.state_dict(), "best.pt")
```

```
        else:
            wait += 1
            if wait >= patience:
                break
    Free, effective, and it also gives you the checkpoint.

/* --- LABEL SMOOTHING --- */
    Chapter 10. Prevents the model chasing infinite logits.

/* --- NORMALISATION LAYERS --- */
    BATCHNORM  normalise across the BATCH. Great for CNNs.
               DEPENDS ON BATCH SIZE, behaves differently in
               train and eval, and is awkward for sequences
               and for batch size 1 - which is exactly the
               embedded inference case.
    LAYERNORM  normalise across the FEATURES of each sample
               independently. NO BATCH DEPENDENCE, identical
               in train and eval. THE TRANSFORMER CHOICE
               (chapter 22).
    RMSNORM    LayerNorm without the mean subtraction.
               Cheaper, and what most recent LLMs use.

/* --- AND THE CHEAPEST WIN OF ALL: EMA OF THE WEIGHTS --- */
    ema = 0.999 * ema + 0.001 * weights
    Evaluate with the averaged weights. Costs one extra copy
    of the model and frequently gives a free accuracy
    improvement, because it lands in the middle of a basin
    rather than on its wall (chapter 11).                */
```

THE ORDER TO REACH FOR THESE

```
1. More data.
2. Data augmentation.
3. Early stopping (free, do it anyway).
4. Weight decay.
5. Dropout.
6. A smaller model.
```

And measure after each one. Stacking regularisers blindly is how you end up with a model that underfits and a hyperparameter search that cannot recover.

The debugging procedure

```
/* IN ORDER. Do not skip steps; each one rules out a whole
   class of bug and takes minutes.                          */

/* --- 1. OVERFIT A SINGLE BATCH --- */
    x, y = next(iter(dataloader))
    x, y = x[:8], y[:8]
    for i in range(500):
        loss = criterion(model(x), y)
        opt.zero_grad(); loss.backward(); opt.step()
        if i % 50 == 0: print(i, loss.item())

    THE LOSS MUST REACH APPROXIMATELY ZERO. If it does not,
    the bug is in the model, the data pipeline or the loss -
    NOT in the hyperparameters. Nothing else you do matters
    until this passes.

/* --- 2. CHECK THE INITIAL LOSS --- */
    ~log(K) for K classes. Wrong value -> wrong labels,
    wrong loss, or a broken output layer.

/* --- 3. VISUALISE THE INPUT AT THE MODEL BOUNDARY --- */
    Print or plot exactly what the model receives, after all
    preprocessing. Wrong normalisation, channels in the wrong
    order, off-by-one label indexing, and a shuffled
    label/feature correspondence are all VISIBLE HERE and
    invisible everywhere else.

/* --- 4. CHECK GRADIENT FLOW --- */
    for n, p in model.named_parameters():
        print(n, None if p.grad is None
                 else p.grad.norm().item())
    None -> disconnected from the loss.
    0.0  -> a non-differentiable operation upstream.
    1e-8 -> vanishing. 1e+8 -> exploding. (chapter 07)

/* --- 5. CHECK ACTIVATION STATISTICS --- */
    The hook from the top of this chapter.

/* --- 6. LR RANGE TEST --- */
    Chapter 11.

/* --- 7. ONLY NOW: TUNE --- */
    And tune ONE THING AT A TIME, with a fixed seed, logging
    everything.

/* ================= THE SYMPTOM TABLE ================= */

   LOSS IS nan
     -> lr too high; log(0); division by zero; bad input
        data; missing gradient clipping; fp16 overflow

   LOSS DOES NOT MOVE AT ALL
     -> lr too low; gradients not flowing; optimizer.step()
        never called; parameters not passed to the optimiser
        (a real and common mistake when a submodule is
        created after the optimiser)

   LOSS DECREASES THEN EXPLODES
     -> lr too high for the later, sharper region; add a
        schedule and clipping
```

```
TRAIN LOSS DOWN, VAL LOSS UP
  -> overfitting. See the list above.

BOTH LOSSES PLATEAU HIGH
  -> underfitting: more capacity, longer training, higher
     lr, or the features genuinely do not contain the
     signal

VAL LOSS LOWER THAN TRAIN LOSS
  -> normal early on with dropout (train is measured with
     regularisation on); if persistent, suspect a data
     split problem

RESULTS VARY WILDLY BETWEEN SEEDS
  -> the model is too small, the data too little, or the
     lr too high. Report a mean over seeds, not your best
     run.

GREAT VALIDATION, POOR PRODUCTION
  -> leakage, or distribution shift (chapter 12)      */
```

How it shows up

Symptom	Cause
All units in a layer identical	Zero initialisation — symmetry never broken
Activation std shrinks 10× per layer	Initialisation scale too small
Loss `nan` at step 1	Initialisation too large, or bad input data
Initial loss not `log(K)`	Wrong labels, wrong loss, or a broken output layer
Cannot overfit 8 samples	A bug in the model, data pipeline or loss
Validation noisy and pessimistic	`model.eval()` not called — dropout still active
Weight decay hurts accuracy	Applied to biases and norm parameters — exclude them
A parameter never changes	Not passed to the optimiser
An auxiliary loss has no effect	Its magnitude is dwarfed by the main term
BatchNorm behaves differently at inference	By design — use LayerNorm for batch size 1
Results depend heavily on the seed	Model or data too small — report means across seeds

Check yourself

- ✓ Explain why zero initialisation fails and what "breaking symmetry" means.
- ✓ Give the Xavier and He variances and say why He has a factor of 2.
- ✓ Describe the transformer initialisation scheme, including the residual scaling.
- ✓ Write the activation-statistics diagnostic and say what good output looks like.
- ✓ Choose the loss and output layer for six task types.
- ✓ Explain why `WithLogits` losses are not merely convenient.
- ✓ Give three approaches to class imbalance and say which to try first.
- ✓ State the step-0 loss sanity check for classification and regression.
- ✓ Explain dropout, its scaling, and why large-scale pretraining often omits it.

- ✓ Contrast BatchNorm, LayerNorm and RMSNorm, and say which suits batch size 1.
- ✓ Recite the seven debugging steps in order.
- ✓ Diagnose: `nan`, flat loss, exploding loss, diverging validation, high plateau.

Tokenisation

Text becomes integers before a model sees any of it. This unglamorous preprocessing step is the origin of a surprising number of the strange behaviours people attribute to the model itself.

The problem

```
A NEURAL NETWORK CONSUMES NUMBERS. Text is a string. Some
mapping is required, and the choice has consequences.

OPTION 1 - CHARACTERS
  "hello" -> [104, 101, 108, 108, 111]
  + tiny vocabulary (~256 with bytes)
  + NO out-of-vocabulary words, ever
  - LONG sequences: attention is quadratic in length
    (chapter 19), so 5x longer input is 25x the attention
    cost
  - the model must learn spelling before it learns
    meaning

OPTION 2 - WORDS
  "hello world" -> [4821, 923]
  + short sequences, semantically meaningful units
  - HUGE vocabulary: 500k+ for English, and the output
    layer is (d_model x vocab) - the largest matrix in a
    small model
  - out-of-vocabulary words become <UNK> and their
    information is DESTROYED
  - "run", "runs", "running", "ran" are four unrelated
    entries
  - and it is not even well-defined for Chinese, Japanese
    or Thai, which do not delimit words with spaces

OPTION 3 - SUBWORDS. WHAT EVERYONE USES.
  "tokenisation" -> ["token", "isation"]
  "unhappiness"  -> ["un", "happiness"]
  "GPT-4"        -> ["G", "PT", "-", "4"]

  · common words stay whole
  · rare words split into meaningful pieces
  · NO out-of-vocabulary case at all - anything
    decomposes to bytes in the worst case
  · vocabulary of 30k-200k: a workable output layer
  · morphology is partially captured for free

THE PRACTICAL RATIO FOR ENGLISH: about 4 CHARACTERS PER
TOKEN, or roughly 0.75 words per token. 1,000 tokens is
about 750 words. This is the arithmetic behind every
context-length and pricing calculation you will do.
```

Byte-pair encoding

```
"""BPE, the dominant algorithm. Originally a 1994
   compression method, repurposed for NLP in 2015.

   TRAINING: start from individual bytes, repeatedly merge
   the most frequent adjacent pair, until the vocabulary
   reaches the target size."""

from collections import Counter

def train_bpe(corpus_words, num_merges):
    # start: every word as a tuple of bytes/characters
    vocab = {tuple(w): c for w, c in
             Counter(corpus_words).items()}
    merges = []

    for _ in range(num_merges):
        # 1. COUNT ADJACENT PAIRS, weighted by word frequency
        pairs = Counter()
        for word, freq in vocab.items():
            for i in range(len(word) - 1):
                pairs[(word[i], word[i+1])] += freq
        if not pairs:
            break

        # 2. MERGE THE MOST FREQUENT PAIR
        best = max(pairs, key=pairs.get)
        merges.append(best)

        new_vocab = {}
        for word, freq in vocab.items():
            w, i = [], 0
            while i < len(word):
                if (i < len(word) - 1 and
                        (word[i], word[i+1]) == best):
                    w.append(word[i] + word[i+1])
                    i += 2
                else:
                    w.append(word[i])
                    i += 1
            new_vocab[tuple(w)] = freq
        vocab = new_vocab

    return merges

def encode(word, merges):
    """Apply the learned merges IN THE ORDER THEY WERE
       LEARNED. That ordering is the model - it is why the
       merge list, not just the vocabulary, must be
       shipped."""
    tokens = list(word)
    for a, b in merges:
        i = 0
        while i < len(tokens) - 1:
            if tokens[i] == a and tokens[i+1] == b:
                tokens[i:i+2] = [a + b]
            else:
                i += 1
    return tokens

# WORKED, on a corpus of "low low lower newest widest":
```

```
#   merge 1: ('e','s') -> 'es'      (in newest, widest)
#   merge 2: ('es','t') -> 'est'
#   merge 3: ('l','o') -> 'lo'
#   ...
# Frequent substrings become single tokens; rare ones stay
# split.

/* --- THE VARIANTS YOU WILL MEET --- */
    BPE            merge by FREQUENCY. GPT-2/3/4, Llama,
                   most models.
    BYTE-LEVEL BPE Operate on RAW BYTES, not Unicode
                   characters. 256 base tokens covers
                   EVERYTHING - every language, every emoji,
                   every binary blob - with no unknown
                   token possible. GPT-2 onwards.
    WORDPIECE      merge by LIKELIHOOD GAIN rather than
                   raw frequency. BERT. Marks continuations
                   with "##".
    UNIGRAM / SentencePiece
                   start LARGE and prune tokens that cost
                   least likelihood. Handles languages
                   without spaces natively, and is
                   REVERSIBLE - it encodes whitespace as a
                   visible marker, so decode(encode(x)) == x
                   exactly. T5, Llama, Gemma.

/* --- USING ONE --- */
from tokenizers import Tokenizer
tok = Tokenizer.from_pretrained("gpt2")

ids = tok.encode("Hello, world!").ids   # [15496, 11, 995, 0]
tok.decode(ids)                          # "Hello, world!"

/* NOTE THE FOUR TOKENS FOR THREE WORDS AND TWO PUNCTUATION
   MARKS. And note that " world" (with the leading space)
   is a DIFFERENT TOKEN from "world". The space belongs to
   the following token in GPT-style tokenisers, which is the
   source of a whole family of surprises below.          */
```

Why models behave strangely

```
/* A large fraction of "the model is bad at X" is really
   "the tokeniser makes X hard", and knowing which is which
   saves a great deal of confusion.                        */

/* --- 1. COUNTING LETTERS --- */
    "How many r's in strawberry?"
    The model sees ["str", "aw", "berry"]. IT NEVER SEES
    INDIVIDUAL LETTERS. Asking it to count characters is
    like asking you to count the pixels in a word you read.
    It can sometimes do it by memorised association; it has
    no direct access.

/* --- 2. ARITHMETIC --- */
    Numbers tokenise inconsistently:
        "1234"  might be one token, or ["12","34"],
                or ["1","234"]
        "1235"  might split completely differently
    Digit-position alignment - which is what column
    arithmetic requires - is destroyed. THE FIX, used by
    several recent models: force digits to tokenise
    individually, or in fixed groups of three. It measurably
    improves arithmetic, which is strong evidence the
    tokeniser was the problem.

/* --- 3. REVERSING STRINGS, RHYMING, WORDPLAY --- */
    All require character-level access. Same cause.

/* --- 4. WHITESPACE SENSITIVITY --- */
    "hello" and " hello" are different tokens with different
    embeddings. A prompt ending in a trailing space puts the
    model in a strange state, because it now expects a
    continuation of a token rather than a new word. THIS IS
    A REAL SOURCE OF DEGRADED OUTPUT and it is invisible
    when you read the prompt.

/* --- 5. NON-ENGLISH TEXT COSTS MORE --- */
    Tokenisers are trained on corpora dominated by English.
        English   ~4 characters per token
        Chinese   ~1-1.5 characters per token
        Thai, Burmese, many African languages: sometimes
        1 token PER BYTE
    So the same document costs 2-5x more tokens, fits in
    less context, and costs more money. This is a genuine
    equity issue in deployed systems, not a curiosity.

/* --- 6. GLITCH TOKENS --- */
    " SolidGoldMagikarp" and a handful of others appeared in
    GPT-2's tokeniser training data (scraped from Reddit
    usernames) but were almost absent from the model's
    training data. Their embeddings were never meaningfully
    trained, so they sit at essentially random positions in
    embedding space, and prompting with them produced
    bizarre, evasive or nonsensical output.

    THE GENERAL LESSON: A TOKEN THAT EXISTS IN THE VOCABULARY
    BUT NOT IN THE TRAINING DATA IS AN UNTRAINED PARAMETER
    SITTING IN YOUR MODEL. Tokeniser and model must be
    trained on consistent data.

/* --- 7. CODE --- */
```

```
    Indentation matters in Python, and a tokeniser trained
    mostly on prose splits whitespace poorly. Code-focused
    models add explicit tokens for runs of 2, 4, 8, 16
    spaces - a small change with a large effect on code
    quality and on token count.                          */
```

THE RULE

The tokeniser and the model are a matched pair. Changing the tokeniser invalidates every embedding and requires retraining from scratch. Vocabulary size, digit handling and whitespace treatment are architectural decisions made *before* pretraining and effectively permanent afterwards — which is why tokeniser choices from 2019 are still shaping model behaviour today.

Practical matters

```
/* --- SPECIAL TOKENS --- */
    <|endoftext|>    document boundary; also used as
                     padding and as BOS in GPT-2
    [CLS] [SEP]      BERT's classification and separator
    <|im_start|>
    <|im_end|>       chat message boundaries in
                     instruction-tuned models
    <PAD>            padding, and it MUST BE MASKED OUT of
                     both attention and loss
    <|fim_prefix|>   fill-in-the-middle, for code models

    THE CHAT TEMPLATE MATTERS. An instruction-tuned model
    was fine-tuned on a specific format, and using a
    different one degrades it substantially:

        tok.apply_chat_template(messages, tokenize=False)

    USE THE LIBRARY FUNCTION rather than assembling the
    string yourself - this is a common and silent source of
    poor results.

/* --- VOCABULARY SIZE: THE TRADE-OFF --- */
    LARGER vocabulary
      + shorter sequences -> cheaper attention (quadratic!)
      + more semantics per token
      - a bigger embedding table and output projection
      - each token is seen less often during training
      - and a slower softmax over the vocabulary

    TYPICAL: 32k (Llama 2), 50k (GPT-2), 100k (GPT-4),
    128k-256k (Llama 3, Gemma). THE TREND IS UPWARD,
    because attention cost dominates and multilingual
    coverage matters.

/* --- COUNTING TOKENS, which you will do constantly --- */
    ids = tok.encode(text).ids
    n = len(ids)

    RULES OF THUMB FOR ENGLISH:
        1 token   ~= 4 characters ~= 0.75 words
        1,000 tokens ~= 750 words ~= 1.5 pages
    ALWAYS MEASURE for other languages and for code.

/* --- BATCHING AND PADDING --- */
    Sequences in a batch must be the same length.
      PAD to the longest in the batch (dynamic padding),
        not to the model maximum - padding to 2048 when your
        longest sample is 100 tokens wastes 95% of the
        compute
      MASK the padding in attention
      IGNORE it in the loss:
          F.cross_entropy(logits, targets,
                          ignore_index=PAD_ID)
      SORT BY LENGTH into buckets to minimise padding
      AND FOR PRETRAINING, don't pad at all: concatenate
        documents with a separator and slice into fixed
        blocks. Zero waste, and it is what every large
        pretraining run does.

/* --- FOR EMBEDDED DEPLOYMENT (chapter 27) --- */
```

```
    The tokeniser must ship with the model and run on the
    device. A 128k-entry vocabulary with its merge list is
    a few megabytes of data and needs a real string
    implementation.

    ON A CONSTRAINED DEVICE, CONSIDER:
      · a SMALL DOMAIN-SPECIFIC VOCABULARY trained on your
        actual data - 1-4k tokens is often plenty for a
        command or intent model, and shrinks the embedding
        table dramatically
      · CHARACTER-LEVEL, if sequences are short. No
        vocabulary file at all.
      · doing tokenisation on the HOST and sending IDs, if
        the device is not the entry point.
    The output projection is proportional to vocabulary
    size, so on an MCU this is frequently the single
    largest layer in the model.                          */
```

How it shows up

Symptom	Cause
Model miscounts letters in a word	It never sees characters — subword tokens
Arithmetic errors on multi-digit numbers	Inconsistent digit tokenisation destroys place alignment
Output degrades with a trailing space in the prompt	Whitespace belongs to the following token
Non-English text costs 3× more tokens	Tokeniser trained mostly on English
A rare string produces bizarre output	Glitch token — an untrained embedding
Instruction model responds poorly	Chat template not applied, or applied wrongly
Loss includes garbage	Padding not excluded via `ignore_index`
Attention attends to padding	No attention mask
Training is 10× slower than expected	Padding to the model maximum instead of dynamic batching
Model outputs nonsense after a tokeniser swap	Embeddings are tied to the tokeniser — retrain
Code model handles indentation badly	No whitespace-run tokens

Check yourself

- ✓ Give the trade-offs of character, word and subword tokenisation.
- ✓ State the characters-per-token and words-per-token rules for English.
- ✓ Describe the BPE training algorithm and why the merge *order* must be preserved.
- ✓ Contrast BPE, byte-level BPE, WordPiece and Unigram.
- ✓ Explain why byte-level tokenisation makes unknown tokens impossible.
- ✓ Explain the strawberry problem and the arithmetic problem in terms of tokens.
- ✓ Explain glitch tokens and the general lesson about untrained parameters.
- ✓ Give the vocabulary-size trade-off in both directions.
- ✓ Explain why non-English text costs more and why that matters.
- ✓ Describe correct padding, masking and loss exclusion — and the pretraining alternative.
- ✓ Give three tokenisation strategies for a constrained device.

Embeddings and vector semantics

Token IDs are arbitrary integers with no meaning. An embedding table turns each one into a learned vector whose *position* carries meaning — and that is the input to every model in the rest of this track.

Why a lookup table

```
TOKEN ID 4821 IS NOT A NUMBER YOU CAN COMPUTE WITH.
ID 4821 is not "more" than ID 4820, and their difference
means nothing.

ONE-HOT ENCODING makes them comparable but is useless:
    "cat"  -> [0,0,...,1,...,0]     50,000 entries
    "dog"  -> [0,0,...,0,...,1]
  · 50,000 dimensions per token
  · EVERY PAIR IS EQUALLY DISSIMILAR - "cat" and "dog"
    are exactly as unrelated as "cat" and "hydraulic"
  · almost all zeros

AN EMBEDDING is a LEARNED DENSE VECTOR:

    "cat"  -> [0.2, -0.5, 0.8, ..., 0.1]   768 numbers
    "dog"  -> [0.3, -0.4, 0.7, ..., 0.2]   NEARBY
    "hydraulic" -> [-0.9, 0.1, -0.3, ...]  FAR AWAY

THE EMBEDDING TABLE is simply a (vocab_size, d_model)
matrix, and "embedding a token" is a ROW LOOKUP:

    E = matrix of shape (50000, 768)
    embed(4821) = E[4821]

AND NOTICE: THIS IS EXACTLY EQUIVALENT to multiplying the
one-hot vector by E. The lookup is just the efficient
implementation of that matrix product - which is why the
gradient of an embedding lookup is "add the incoming
gradient to that row" and nothing else.

THE PARAMETERS ARE LEARNED. Nobody assigns coordinates.
Backpropagation moves each row so that the model predicts
better, and semantic structure EMERGES from that pressure.

SIZE MATTERS: a 128k vocabulary at d_model = 4096 is
524 million parameters IN THE EMBEDDING TABLE ALONE -
often 10-20% of a mid-sized model, and the largest single
tensor in a small one.
```

What the space looks like

```
/* THE DISTRIBUTIONAL HYPOTHESIS (Firth, 1957):
   "You shall know a word by the company it keeps."

   Words appearing in similar contexts get similar vectors,
   because the training objective pushes them there. That is
   the entire mechanism - no semantics were programmed in. */

import numpy as np

def cosine(a, b):                              # chapter 02
    return (a @ b) / (np.linalg.norm(a) * np.linalg.norm(b))

cosine(E["cat"], E["dog"])        # ~0.7   related
cosine(E["cat"], E["kitten"])     # ~0.8   closely related
cosine(E["cat"], E["hydraulic"])  # ~0.05  unrelated

/* --- THE ANALOGY RESULT --- */
    vec("king") - vec("man") + vec("woman")  ~=  vec("queen")
    vec("Paris") - vec("France") + vec("Italy")
                                           ~=  vec("Rome")

    DIRECTIONS IN THE SPACE CORRESPOND TO RELATIONSHIPS.
    Gender is a direction. Capital-of is a direction. Plural
    is a direction.

    THE HONEST CAVEAT, because this result is over-sold: the
    analogy typically only works when you EXCLUDE the three
    input words from the nearest-neighbour search, and it is
    sensitive to normalisation. The underlying claim -
    that linear structure exists - is solid; the party trick
    is fragile.

/* --- WHAT ELSE IS ENCODED --- */
    · syntax: nouns cluster, verbs cluster, tenses align
    · sentiment: a direction separating positive from
      negative
    · morphology: "run"/"running" offset resembles
      "walk"/"walking"
    · AND SOCIAL BIAS. Embeddings trained on human text
      encode human associations, including harmful ones:
      occupations align with gender directions,
      names align with sentiment by ethnicity. This is not a
      training bug - it is an accurate reflection of the
      corpus, and it propagates into any downstream system
      that uses the embeddings. MEASURE IT (WEAT and similar
      tests) IF YOUR SYSTEM MAKES DECISIONS ABOUT PEOPLE.

/* --- SUPERPOSITION: how so much fits in so few
       dimensions --- */
    A model with 768 dimensions appears to represent far
    more than 768 distinct features. It can, because in high
    dimensions there are exponentially many ALMOST-orthogonal
    directions (chapter 02). Features are stored in
    superposition, with small interference.

    THIS IS THE LEADING EXPLANATION for why bigger models
    are disproportionately better - more dimensions means
    exponentially more room - and it is the basis of the
    sparse-autoencoder work in mechanistic interpretability,
```

```
 which tries to decompose those superposed directions back
 into individual interpretable features.              */
```

Static versus contextual

```
STATIC EMBEDDINGS - word2vec (2013), GloVe, fastText
  ONE VECTOR PER WORD, FIXED.

  "I went to the BANK to deposit money"
  "I sat on the river BANK"
     -> the SAME vector. The model cannot distinguish
        them.

  word2vec's two training objectives:
    SKIP-GRAM   predict context words from the centre
                word
    CBOW        predict the centre word from its context
  plus NEGATIVE SAMPLING, which turns an expensive softmax
  over the whole vocabulary into a handful of binary
  classifications.

  STILL USEFUL: they are tiny, fast, need no GPU, and for
  a keyword or intent classifier on a microcontroller they
  may be the only option that fits (chapter 27).

CONTEXTUAL EMBEDDINGS - ELMo, BERT, GPT, everything since
  THE VECTOR DEPENDS ON THE SURROUNDING TEXT.

  The embedding TABLE still gives a static starting
  vector, but each transformer layer MIXES INFORMATION
  FROM OTHER POSITIONS via attention (chapter 19). By the
  final layer, "bank" in the two sentences has two very
  different representations.

  THE INPUT EMBEDDING IS THE STARTING POINT, NOT THE
  ANSWER. This distinction is the single most important
  thing in this chapter: everything a transformer does is
  progressively refining these vectors using context.

SENTENCE / DOCUMENT EMBEDDINGS
  One vector for a whole passage, for retrieval and
  similarity.
  · mean-pool the token embeddings (simple, decent)
  · use the [CLS] position (BERT-style)
  · OR TRAIN FOR IT: sentence-transformers, E5, BGE, and
    similar models are fine-tuned with a CONTRASTIVE
    objective so that cosine similarity actually
    corresponds to semantic similarity.

  AND THIS MATTERS: raw mean-pooled BERT embeddings are
  notoriously poor at similarity. Use a model TRAINED for
  embedding, not a language model's hidden states.
```

Implementation

```
import torch
import torch.nn as nn

# --- THE LAYER ---
emb = nn.Embedding(num_embeddings=50000, embedding_dim=768)

ids = torch.tensor([[15496, 11, 995]])   # (batch=1, seq=3)
vecs = emb(ids)                           # (1, 3, 768)

# THAT IS THE ENTIRE INPUT PIPELINE OF A TRANSFORMER:
# integers in, vectors out.

# --- WEIGHT TYING: a free improvement ---
model.lm_head.weight = model.embed_tokens.weight
# Share the input embedding table with the output projection
# to the vocabulary. THE INTUITION: both matrices map
# between token space and vector space, in opposite
# directions.
#
#   · SAVES vocab*d_model PARAMETERS - 524M for the example
#     above, which is enormous
#   · usually IMPROVES quality for small and mid-sized
#     models
#   · standard in GPT-2 and many others
#
# Very large models sometimes untie them, having enough
# capacity that the constraint costs more than it saves.

# --- PADDING ---
emb = nn.Embedding(50000, 768, padding_idx=0)
# Row 0 is fixed at zero and receives NO GRADIENT. Without
# this, the pad token accumulates updates and drifts into a
# meaningless but non-zero position.

# --- FROZEN PRETRAINED EMBEDDINGS ---
emb = nn.Embedding.from_pretrained(vectors, freeze=True)
# Useful with small datasets: you inherit semantics learned
# from a large corpus without the data to relearn them.

# --- A RETRIEVAL SYSTEM, end to end ---
from sentence_transformers import SentenceTransformer
model = SentenceTransformer('all-MiniLM-L6-v2')

docs = ["The cat sat on the mat", "Dogs are loyal",
        "Python is a programming language"]
doc_vecs = model.encode(docs, normalize_embeddings=True)

q = model.encode("feline on a rug", normalize_embeddings=True)
scores = doc_vecs @ q          # NORMALISED -> the dot
                               # product IS cosine similarity
best = scores.argmax()         # -> document 0

# THIS IS THE WHOLE OF SEMANTIC SEARCH, and the retrieval
# half of RAG (retrieval-augmented generation). At scale,
# the linear scan is replaced by an APPROXIMATE NEAREST
# NEIGHBOUR index - HNSW or IVF-PQ, in FAISS or a vector
# database - which trades a little recall for logarithmic
# search time.

# --- AND THE THING TO GET RIGHT ---
```

```
# NORMALISE ONCE AT INSERT TIME (chapter 02). Then querying
# is pure matrix-vector multiplication, which is exactly the
# memory-bound operation from chapter 04 - so a vector
# search over a million documents is a BANDWIDTH problem,
# and quantising the stored vectors to int8 makes it 4x
# faster. The same reasoning as LLM inference, applied to a
# database.
```

EMBEDDINGS ARE THE INTERFACE

Every modality reaches a transformer the same way: as a sequence of vectors. Text goes through a token embedding table. Images are split into patches and each patch is linearly projected. Audio becomes spectrogram frames. Once anything is a sequence of `d_model`-dimensional vectors, the architecture in the next chapters does not care where it came from — which is precisely why multimodal models were an incremental change rather than a redesign.

How it shows up

Symptom	Cause
`IndexError` in the embedding layer	A token ID at or above `num_embeddings` — tokeniser/model mismatch
Pad token acquires meaning	`padding_idx` not set
Similarity scores are all near 0.8	Anisotropic space — use a model trained for embedding, or centre the vectors
Semantic search returns poor matches	Raw LM hidden states instead of a contrastively trained encoder
Cosine similarity does not match the dot product	Vectors not normalised
Homonyms confused	Static embeddings — one vector per word by design
Model is 30% embedding parameters	Large vocabulary — consider weight tying
Occupation predictions correlate with gender	Corpus bias encoded in the embeddings — measure it
Analogy arithmetic fails	Input words not excluded from the neighbour search
Vector search is slow at a million documents	Linear scan — use an ANN index, and quantise

Check yourself

- ✓ Explain why one-hot encoding is useless and what an embedding table replaces it with.
- ✓ Say why an embedding lookup is equivalent to a matrix product, and what its gradient is.
- ✓ Compute the parameter count of a 128k × 4096 embedding table.
- ✓ State the distributional hypothesis and how it becomes a training signal.
- ✓ State the analogy result and its honest caveat.
- ✓ Explain superposition and why it favours larger models.
- ✓ Contrast static and contextual embeddings with the "bank" example.
- ✓ Say why a language model's hidden states make poor sentence embeddings.
- ✓ Explain weight tying and quantify what it saves.
- ✓ Write a semantic search from encoding to ranking.
- ✓ Explain why embeddings are the universal interface for multimodal models.

Sequence models before transformers

Recurrent networks dominated sequence modelling for twenty-five years. Understanding what they did well and exactly why they were displaced is the clearest possible motivation for attention — and they are quietly coming back on embedded hardware.

The recurrent neural network

```
THE IDEA: carry a HIDDEN STATE from step to step.

     h_t = tanh(W_hh @ h_{t-1} + W_xh @ x_t + b)
     y_t = W_hy @ h_t

UNROLLED OVER TIME:

  x1      x2      x3      x4
   |       |       |       |
   v       v       v       v
 [RNN]->[RNN]->[RNN]->[RNN]->
   |  h1   |  h2   |  h3   |  h4
   v       v       v       v
  y1      y2      y3      y4

THE SAME WEIGHTS AT EVERY STEP. That parameter sharing is
the sequential prior (chapter 14): the model assumes the
same computation applies at every position.

WHAT IS APPEALING ABOUT THIS:
  · O(1) MEMORY PER STEP - the state is fixed size
    regardless of how much text has been seen
  · O(n) TOTAL COMPUTE for a sequence of length n
  · handles ARBITRARY LENGTH input
  · it is the obvious, natural model of a sequence

WHAT KILLS IT:

1. NO PARALLELISM. h_t depends on h_{t-1}. You cannot
   compute step 5 before step 4. TRAINING IS INHERENTLY
   SEQUENTIAL, which wastes almost all of a GPU. This,
   more than accuracy, is why transformers won: a
   transformer processes an entire sequence in parallel
   during training.

2. VANISHING GRADIENTS. Backpropagation through time
   multiplies by W_hh at every step (chapters 05, 07):

      dL/dh_1 involves  (W_hh)^n

   Largest eigenvalue below 1 -> the gradient vanishes
   exponentially. Above 1 -> it explodes. IN PRACTICE A
   PLAIN RNN CANNOT LEARN DEPENDENCIES BEYOND ABOUT 10
   STEPS.

3. THE INFORMATION BOTTLENECK. Everything about the past
   must fit in one fixed-size vector. For a 1,000-token
   document compressed into 512 numbers, most of it is
   simply gone.
```

LSTM and GRU

```
/* LONG SHORT-TERM MEMORY (Hochreiter and Schmidhuber,
   1997). The fix that made recurrence work, and it held the
   field for two decades.

   THE KEY IDEA: A SEPARATE CELL STATE WITH AN ADDITIVE PATH,
   controlled by learned GATES.                          */

    f_t = sigmoid(W_f @ [h_{t-1}, x_t] + b_f)  /* FORGET  */
    i_t = sigmoid(W_i @ [h_{t-1}, x_t] + b_i)  /* INPUT   */
    o_t = sigmoid(W_o @ [h_{t-1}, x_t] + b_o)  /* OUTPUT  */
    g_t = tanh(   W_g @ [h_{t-1}, x_t] + b_g)  /* CANDIDATE */

    c_t = f_t * c_{t-1} + i_t * g_t     /* THE CELL STATE */
    h_t = o_t * tanh(c_t)               /* the hidden state */

/* WHY THIS SOLVES VANISHING GRADIENTS:

   Look at the cell state update. The path from c_{t-1} to
   c_t is MULTIPLICATION BY f_t AND AN ADDITION. If the
   forget gate is near 1, the gradient flows back
   essentially UNCHANGED - no repeated multiplication by a
   weight matrix.

   This is called the CONSTANT ERROR CARROUSEL, and it is
   the same structural idea as a RESIDUAL CONNECTION
   (chapter 22): give the gradient a path that does not go
   through a transformation.

   THE GATES ARE LEARNED, SOFT SWITCHES:
     forget gate near 0 -> discard the past
     input gate near 1  -> write the new candidate
     output gate        -> decide what to expose

   AND THE ONE PRACTICAL TRICK: INITIALISE THE FORGET GATE
   BIAS TO 1 (or 2). It starts the network in
   "remember everything" mode, and it measurably improves
   training. A one-line change that was a small paper.

/* --- GRU: the simplified version --- */
    z_t = sigmoid(W_z @ [h_{t-1}, x_t])     /* UPDATE gate */
    r_t = sigmoid(W_r @ [h_{t-1}, x_t])     /* RESET  gate */
    h~  = tanh(W @ [r_t * h_{t-1}, x_t])
    h_t = (1 - z_t) * h_{t-1} + z_t * h~

    Two gates instead of three, no separate cell state,
    ~25% fewer parameters. Usually comparable in accuracy
    and faster. WHEN CHOOSING BETWEEN THEM ON A CONSTRAINED
    DEVICE, START WITH GRU.

/* --- IN CODE --- */
import torch.nn as nn

lstm = nn.LSTM(input_size=128, hidden_size=256,
               num_layers=2, batch_first=True,
               dropout=0.1, bidirectional=False)

out, (h_n, c_n) = lstm(x)     # x: (batch, seq, 128)
                              # out: (batch, seq, 256)

/* BIDIRECTIONAL: run one LSTM forwards and one backwards,
```

```
    concatenate. Every position then sees the whole sequence.
    USE FOR CLASSIFICATION AND TAGGING; IMPOSSIBLE FOR
    GENERATION, because you cannot look at the future you
    have not generated yet.                                */
```

Where attention came from

```
/* THE SETTING: SEQUENCE-TO-SEQUENCE TRANSLATION (2014).

   ENCODER LSTM reads the source sentence -> a single
   context vector
   DECODER LSTM generates the target from that vector

      "the cat sat on the mat"
              |
              v
        [ONE VECTOR]        <-- EVERYTHING must fit here
              |
              v
      "le chat s'est assis sur le tapis"

   AND IT WORKED - until sentences got long. Translation
   quality fell off a cliff past about 30 words, because the
   whole source had to be compressed into one fixed vector.

/* BAHDANAU ET AL., 2015: LET THE DECODER LOOK BACK.

   Instead of one context vector, keep ALL the encoder
   states, and at each decoding step compute a WEIGHTED SUM
   of them:

     score_i   = alignment(decoder_state, encoder_state_i)
     alpha     = softmax(scores)          /* weights summing
                                             to 1 */
     context   = sum_i alpha_i * encoder_state_i

   THE WEIGHTS ARE LEARNED AND DYNAMIC. When generating
   "chat", the model attends to "cat". When generating
   "tapis", it attends to "mat". You can PLOT the alignment
   matrix and it looks like a translation dictionary -
   which was the moment the field realised something
   important had happened.

/* THIS IS ATTENTION, and note what it fixed:
     · no fixed-size bottleneck
     · a DIRECT PATH from any output position to any input
       position - so gradients do not have to travel through
       n recurrent steps
     · and it is INTERPRETABLE

/* --- LUONG (2015) simplified the scoring to a dot
       product --- */
        score = decoder_state · encoder_state

   Cheaper, and it is one step from the scaled dot-product
   attention of chapter 19.

/* --- AND THEN THE OBSERVATION THAT CHANGED EVERYTHING --- */

   Vaswani et al., 2017: "ATTENTION IS ALL YOU NEED".

   If attention gives every position direct access to every
   other position, WHAT IS THE RECURRENCE FOR?

   REMOVE IT. Keep only attention, plus a feed-forward
   network and positional information.
```

```
   THE PAYOFF WAS NOT PRIMARILY ACCURACY - IT WAS
   PARALLELISM. Without the sequential dependency, an entire
   sequence trains in ONE parallel pass. That turned
   sequence modelling into a big matrix multiplication
   (chapter 04), which is exactly what GPUs do, and it made
   scaling to hundreds of billions of parameters an
   engineering problem rather than an impossible one.     */
```

THE COMPARISON THAT EXPLAINS THE SWITCH

	RNN/LSTM	TRANSFORMER
training parallelism	NONE	FULL
path between two positions	O(distance)	O(1)
compute per layer	O(n·d²)	O(n²·d + n·d²)
memory at inference	O(1)	O(n) (the KV cache)
max useful context	hundreds	hundreds of thousands

The transformer is *worse* asymptotically in sequence length and *worse* in inference memory. It won because training parallelism and the O(1) path length mattered far more — a reminder that the right complexity measure is the one that matches your hardware.

Where recurrence stands now

```
/* RNNs ARE NOT ONLY OF HISTORICAL INTEREST, and this is the
   part that matters most for an embedded engineer.       */

/* --- THE TRANSFORMER'S WEAKNESS IS INFERENCE MEMORY --- */
    A transformer must keep a KV CACHE that GROWS WITH
    SEQUENCE LENGTH (chapter 25). An RNN keeps a fixed-size
    state, forever.

    FOR STREAMING INFERENCE ON A DEVICE - continuous audio,
    a sensor stream, always-on keyword spotting - a
    fixed-size state is a decisive advantage. The memory
    budget is known at compile time.

/* --- THE MODERN RECURRENT MODELS --- */
    STATE SPACE MODELS (S4, MAMBA)
      A linear recurrence, formulated so that TRAINING can be
      parallelised with a scan (or a convolution) while
      INFERENCE remains a constant-memory recurrence.

      THAT COMBINATION IS THE POINT: it recovers the
      transformer's training parallelism WITHOUT the growing
      inference state. Mamba's selective mechanism makes the
      recurrence input-dependent, which was the missing
      ingredient for language.

    RWKV, RETNET, GRIFFIN, xLSTM
      Various routes to the same goal - "transformer-quality
      training, RNN-quality inference".

    HYBRID ARCHITECTURES
      Most recent efficient models interleave a few attention
      layers among many recurrent or linear ones. Attention
      where precise recall matters; recurrence for
      everything else. This is currently the most practical
      answer.

/* --- AND THE CLASSIC RNN IS STILL DEPLOYED --- */
    On microcontrollers, a small GRU or LSTM remains a
    sensible choice for:
      · keyword spotting ("hey device")
      · sensor time-series classification and anomaly
        detection
      · gesture recognition from an IMU
      · predictive maintenance from vibration data

    WHY: a 2-layer GRU with 64 hidden units is a few tens of
    kilobytes, runs in constant memory, has no attention
    matrix to materialise, and every embedded inference
    library supports it. CMSIS-NN and TFLite Micro both have
    optimised LSTM/GRU kernels. Chapter 27 covers the
    deployment.

    THE ENGINEERING JUDGEMENT: FOR SHORT SEQUENCES AND TIGHT
    MEMORY, RECURRENCE IS OFTEN STILL CORRECT. Do not reach
    for a transformer because it is fashionable; reach for
    it when you need long-range precise recall and you have
    the memory for the cache.                              */
```

How it shows up

Symptom	Cause
RNN cannot learn dependencies past ~10 steps	Vanishing gradients — use an LSTM or GRU
Loss becomes `nan` during BPTT	Exploding gradients — clip the norm
GPU utilisation is low when training an RNN	Inherently sequential — expected
Translation quality collapses on long sentences	The fixed-size context bottleneck — add attention
Bidirectional model cannot generate	It sees the future — use unidirectional for generation
LSTM forgets everything early in training	Forget-gate bias not initialised to 1
Transformer runs out of memory on long streams	KV cache grows with length — consider a recurrent model
Transformer will not fit on an MCU	Attention working set — a GRU may be the right answer
Padded steps corrupt the hidden state	No `pack_padded_sequence` or mask

Check yourself

- ✓ Write the RNN recurrence and say what parameter sharing assumes.
- ✓ Give the three reasons plain RNNs fail, and say which one mattered most commercially.
- ✓ Write the LSTM equations and explain the constant error carrousel.
- ✓ Connect the LSTM cell path to residual connections.
- ✓ Say what the forget-gate bias initialisation does.
- ✓ Contrast LSTM and GRU and pick one for a microcontroller.
- ✓ Explain the seq2seq bottleneck and how Bahdanau attention removed it.
- ✓ State what "attention is all you need" removed and what the real payoff was.
- ✓ Fill in the RNN-versus-transformer comparison table from memory.
- ✓ Explain what state space models recover and why it matters for streaming.
- ✓ Give four embedded tasks where a small GRU is still the right choice.

Attention

Every position looks at every other position and takes a weighted average of what it finds, with the weights computed from the content itself. One equation, and it is the central mechanism of every modern language model.

The idea, before the equation

```
THE PROBLEM: "The animal didn't cross the street because
IT was too tired."

What does "it" refer to? To represent "it" properly, the
model must incorporate information from "animal" -
which is six positions away, and which position varies
from sentence to sentence.

THE MECHANISM - a soft, differentiable dictionary lookup:

  QUERY   what this position is LOOKING FOR
  KEY     what each position OFFERS
  VALUE   what each position CONTRIBUTES if selected

A HARD DICTIONARY: find the key that matches exactly,
                   return its value.
ATTENTION:         compare the query to EVERY key, get a
                   similarity score for each, softmax the
                   scores into weights, and return the
                   WEIGHTED AVERAGE OF ALL VALUES.

IT IS DIFFERENTIABLE, so it can be learned.

FOR THE TOKEN "it":
   query("it") · key("animal")  -> HIGH
   query("it") · key("street")  -> medium
   query("it") · key("because") -> low
   ...
   softmax  ->  [0.6, 0.2, 0.05, ...]
   output   =  0.6*value("animal") + 0.2*value("street")
               + ...

The representation of "it" now CONTAINS information about
"animal". That is what "contextual embedding"
(chapter 17) means, mechanically.

AND THE THREE PROPERTIES THAT MATTER:
  · CONTENT-BASED. The weights depend on what the tokens
    ARE, not on their positions. Attention itself is
    PERMUTATION-INVARIANT - which is why positional
    encoding must be added separately (chapter 21).
  · O(1) PATH LENGTH between any two positions. Contrast
    the RNN's O(distance) (chapter 18).
  · FULLY PARALLEL. Every position's output is computed
    simultaneously - one matrix multiply.
```

Scaled dot-product attention

```
/* THE EQUATION. Memorise it. */

    Attention(Q, K, V) = softmax( Q K^T / sqrt(d_k) ) V

    Q: (n, d_k)     queries   - one per position
    K: (n, d_k)     keys
    V: (n, d_v)     values
    output: (n, d_v)

/* STEP BY STEP, WITH SHAPES - the only way to read
   attention code:

    1. SCORES = Q @ K.T              (n, n)
       Every query dotted with every key. THIS MATRIX IS THE
       QUADRATIC COST.

    2. SCALE by 1/sqrt(d_k)          (n, n)

    3. MASK (optional)               (n, n)
       set forbidden positions to -inf

    4. WEIGHTS = softmax(scores, dim=-1)   (n, n)
       each ROW sums to 1

    5. OUTPUT = WEIGHTS @ V          (n, d_v)
       a weighted average of the values

/* WHY DIVIDE BY sqrt(d_k) - AND THIS IS NOT ARBITRARY:

   If q and k have independent components with mean 0 and
   variance 1, then their dot product over d_k dimensions
   has variance d_k (chapter 08). So for d_k = 64 the scores
   have a standard deviation of 8, and for d_k = 128, about
   11.

   LARGE SCORES SATURATE THE SOFTMAX: it approaches a
   one-hot distribution, the gradient becomes almost zero,
   and the layer stops learning. Dividing by sqrt(d_k)
   returns the variance to 1 and keeps the softmax in its
   useful range.

   SKIP THE SCALING AND DEEP TRANSFORMERS SIMPLY DO NOT
   TRAIN. It is one line and it is load-bearing.

/* --- WHERE Q, K AND V COME FROM --- */
    They are LEARNED LINEAR PROJECTIONS of the same input:

        Q = X @ W_Q
        K = X @ W_K
        V = X @ W_V

    W_Q, W_K, W_V are (d_model, d_k) parameter matrices.

    SELF-ATTENTION:  Q, K, V all from the SAME sequence.
                     "How do these tokens relate to each
                     other?"
    CROSS-ATTENTION: Q from one sequence, K and V from
                     another. Used in encoder-decoder
                     translation, and in multimodal models
                     where text queries attend to image
```

```
                      patches.

/* --- THE IMPLEMENTATION --- */
import torch
import torch.nn.functional as F
import math

def attention(Q, K, V, mask=None):
    d_k = Q.size(-1)
    scores = Q @ K.transpose(-2, -1) / math.sqrt(d_k)
    if mask is not None:
        scores = scores.masked_fill(mask == 0,
                                    float('-inf'))
    weights = F.softmax(scores, dim=-1)
    return weights @ V, weights

/* SEVEN LINES. That is the mechanism that made large
   language models possible.                              */
```

Masking

```
/* --- CAUSAL MASKING: the one that makes generation
       possible --- */

    A language model predicts the next token. If position 3
    could see position 4, it would be reading the answer -
    and the model would learn nothing useful and fail
    completely at inference, when the future does not exist.

    SO POSITION i MAY ATTEND ONLY TO POSITIONS 0..i.

    THE MASK (chapter 03's tril):

        [1 0 0 0]        the score matrix becomes
        [1 1 0 0]        [ s00  -inf -inf -inf ]
        [1 1 1 0]        [ s10   s11 -inf -inf ]
        [1 1 1 1]        [ s20   s21  s22 -inf ]
                         [ s30   s31  s32  s33 ]

    -inf becomes exactly 0 after softmax. NOT a small
    number - exactly zero, because exp(-inf) = 0.

    mask = torch.tril(torch.ones(n, n))
    scores = scores.masked_fill(mask == 0, float('-inf'))

/* WHY THIS IS BRILLIANT FOR TRAINING: with the causal mask,
   ONE forward pass over a sequence of length n produces n
   training examples simultaneously - each position predicts
   its own next token, and none of them can cheat. That is
   the parallelism the RNN could not offer (chapter 18), and
   it is the whole efficiency argument for transformers.

/* --- PADDING MASKS --- */
    Batched sequences are padded (chapter 16). Attending to
    padding pollutes the representation, so pad positions
    must also be masked to -inf.

    THE TWO MASKS COMBINE:
        mask = causal_mask & padding_mask

/* --- THE NUMERICAL TRAP --- */
    A row that is ENTIRELY -inf gives softmax(all -inf) =
    nan. This happens when a sequence is all padding, or
    when a mask is constructed wrongly.

    USE A LARGE FINITE NEGATIVE NUMBER instead of -inf if
    you cannot guarantee otherwise:
        scores.masked_fill(mask == 0, -1e9)
    And in fp16, -1e9 overflows - use -65504 or the dtype's
    minimum. This is a real and frequently-hit bug when
    moving a model to half precision.

/* --- BIDIRECTIONAL: NO CAUSAL MASK --- */
    BERT-style encoders let every position see every other
    position. Better representations for classification and
    retrieval, IMPOSSIBLE FOR GENERATION.

    THE FAMILIES:
      DECODER-ONLY (causal)    GPT, Llama, Mistral, Claude.
                               Generation.
      ENCODER-ONLY (bidir.)    BERT, RoBERTa. Classification,
```

```
                              embeddings.
    ENCODER-DECODER           T5, BART. Translation,
                              summarisation.
  DECODER-ONLY HAS WON for general-purpose models, largely
  because one simple objective plus scale beat
  architectural specialisation.                          */
```

THE COST, AND WHY CONTEXT LENGTH IS EXPENSIVE

```
The (n, n) score matrix means attention is
O(n² · d) in compute and O(n²) in memory.

  n =  1,000    1,000,000 scores      4 MB in fp32
  n = 10,000  100,000,000 scores    400 MB
  n = 100,000  10 BILLION scores      40 GB, per head,
                                      per layer

That is why context length was stuck at 512-2048 for
years, and why every efficiency technique in this
field is ultimately an attack on this quadratic.
```

Making it cheaper

```
/* --- FLASH ATTENTION: the one that actually mattered --- */
    THE INSIGHT: the (n, n) matrix is never needed in full.
    Process it in TILES that fit in on-chip SRAM, computing
    a running softmax with the online-normalisation trick, so
    the full score matrix is NEVER WRITTEN TO MAIN MEMORY.

      · MATHEMATICALLY IDENTICAL output - not an
        approximation
      · MEMORY becomes O(n) instead of O(n^2)
      · 2-4x FASTER, because attention is MEMORY BOUND
        (chapter 04) and this removes most of the traffic

    THIS IS A PURE SYSTEMS OPTIMISATION - cache blocking,
    exactly as in chapter 04's matmul - and it is the single
    largest practical advance in transformer efficiency. It
    is why long contexts became affordable.

    In PyTorch you get it for free:
        F.scaled_dot_product_attention(q, k, v,
                                       is_causal=True)

/* --- SPARSE ATTENTION PATTERNS --- */
    Do not attend to everything.
      SLIDING WINDOW   only the last w tokens. O(n*w).
                       Mistral uses this.
      DILATED          every k-th token, for a wider
                       receptive field
      GLOBAL + LOCAL   a few global tokens everyone sees,
                       plus a local window (Longformer,
                       BigBird)
      BLOCK-SPARSE     structured blocks that map well onto
                       hardware

/* --- LINEAR ATTENTION --- */
    Replace softmax with a kernel so the operation
    reassociates:
        (Q K^T) V   becomes   Q (K^T V)
    O(n^2 d) becomes O(n d^2). This is chapter 04's
    associativity argument, applied to make the sequence
    length linear.
    THE CATCH: quality has consistently lagged. Related to
    the state-space models of chapter 18.

/* --- MULTI-QUERY AND GROUPED-QUERY ATTENTION --- */
    Share K and V across attention heads.
      MHA   every head has its own K, V
      MQA   ALL heads share ONE K, V
      GQA   groups of heads share - the middle ground, and
            what Llama 2/3 and most current models use

    THIS DOES NOT REDUCE TRAINING COMPUTE. It reduces the KV
    CACHE SIZE AT INFERENCE by the sharing factor - often 8x
    - and since generation is memory-bandwidth bound
    (chapters 04, 25), that is a direct throughput win.

/* --- AND THE PRACTICAL SUMMARY --- */
    · use F.scaled_dot_product_attention, always. It selects
      the best available kernel.
    · GQA for inference-heavy deployments
    · sliding-window if you need very long contexts cheaply
```

```
    · and do not implement attention by hand in production -
      write it once, as in this chapter, to understand it,
      then use the fused kernel.                          */
```

What attention learns

```
/* THE WEIGHTS ARE INSPECTABLE, which makes this one of the
   few interpretable parts of a modern model.            */

    out, weights = attention(Q, K, V)
    # weights: (n, n) - row i shows what position i
    # attended to

    import matplotlib.pyplot as plt
    plt.imshow(weights.detach(), cmap='Blues')

/* PATTERNS THAT SHOW UP CONSISTENTLY ACROSS MODELS:

   POSITIONAL HEADS      attend to the previous token, or
                         the one before that. Effectively
                         learned n-gram features.
   SYNTACTIC HEADS       verbs to their subjects, adjectives
                         to their nouns, and matching
                         brackets in code
   COREFERENCE HEADS     pronouns to their antecedents -
                         exactly the "it" example above
   DELIMITER HEADS       attend heavily to the first token
                         or to punctuation. Often an
                         ATTENTION SINK: a place to dump
                         probability mass when the head has
                         nothing useful to do, since softmax
                         forces the row to sum to 1.
   INDUCTION HEADS       the important one. They implement
                         "[A][B] ... [A] -> predict [B]" -
                         copying a pattern seen earlier in
                         the context. They FORM ABRUPTLY
                         during training, and their
                         appearance coincides with the model
                         acquiring IN-CONTEXT LEARNING -
                         the ability to pick up a pattern
                         from examples in the prompt.

   THE INDUCTION HEAD RESULT IS WORTH KNOWING because it is
   one of the clearest cases where a specific circuit was
   identified and connected to a capability. Most
   interpretability is not this clean.

/* AND THE CAVEAT, because attention maps are over-read:
   ATTENTION WEIGHTS ARE NOT AN EXPLANATION. A head can
   attend strongly to a token whose value vector contributes
   almost nothing, and information also flows through the
   residual stream and the feed-forward layers (chapter 22).
   "The model attended to X, therefore it used X" is not a
   valid inference. Attention maps are a useful signal and a
   poor proof.                                           */
```

How it shows up

Symptom	Cause
Deep transformer will not train	Missing `1/√d_k` scaling — the softmax saturates
Loss near zero, generation is garbage	No causal mask — the model read the answer
`nan` in attention weights	A fully masked row — softmax of all `-inf`
`nan` only in fp16	`-1e9` overflows — use the dtype minimum
Out of memory at long sequence length	The (n, n) matrix — use Flash Attention
Model attends to padding	Padding mask missing or not combined with the causal mask
Attention is slower than the FLOPs suggest	Memory bound — use the fused kernel
Generation throughput collapses at long context	KV cache bandwidth — consider GQA
Shuffling input tokens changes nothing	No positional encoding — attention is permutation-invariant
A head attends almost entirely to token 0	An attention sink — usually normal, not a bug

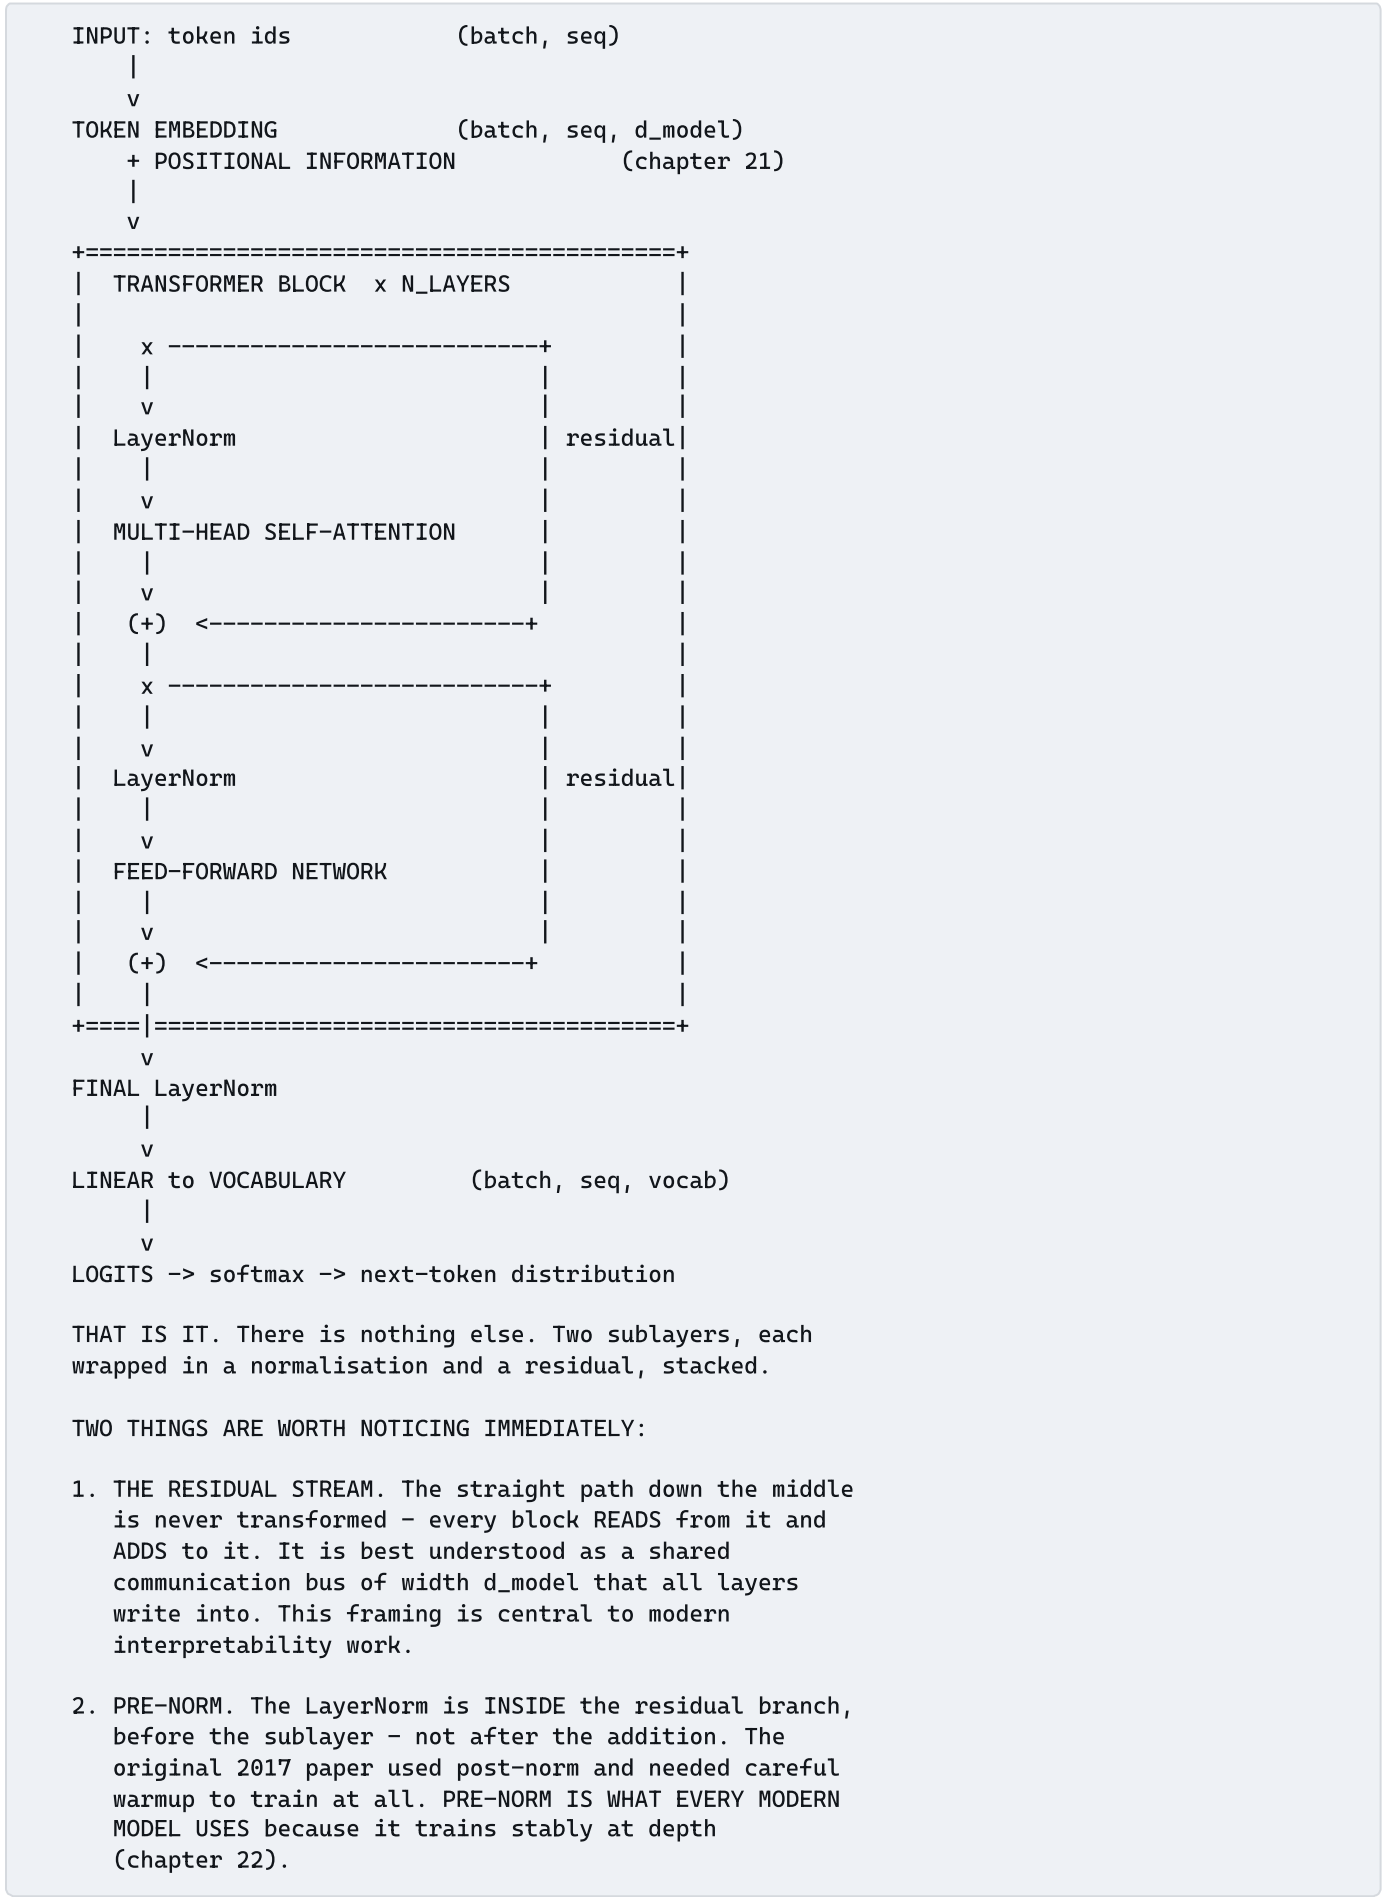
Check yourself

- ✓ Explain query, key and value as a soft dictionary lookup.
- ✓ Write the attention equation from memory with shapes at every step.
- ✓ Derive why the scaling factor is `1/√d_k` and say what happens without it.
- ✓ Distinguish self-attention from cross-attention.
- ✓ Draw the causal mask and explain why `-inf` becomes exactly zero.
- ✓ Explain why causal masking yields n training examples from one forward pass.
- ✓ Explain the fully-masked-row `nan` and the fp16 variant.
- ✓ Compute the attention memory cost at n = 100,000.
- ✓ Explain what Flash Attention does and why it is exact rather than approximate.
- ✓ Explain what GQA reduces and why that helps generation specifically.
- ✓ Name five attention patterns, and say what induction heads do.
- ✓ State why attention weights are not an explanation.

The transformer architecture

Attention, a feed-forward network, normalisation and a residual connection, repeated N times. Every large language model in existence is this diagram with different numbers in it.

The whole thing



THAT IS IT. There is nothing else. Two sublayers, each
wrapped in a normalisation and a residual, stacked.

TWO THINGS ARE WORTH NOTICING IMMEDIATELY:

1. THE RESIDUAL STREAM. The straight path down the middle
   is never transformed - every block READS from it and
   ADDS to it. It is best understood as a shared
   communication bus of width d_model that all layers
   write into. This framing is central to modern
   interpretability work.

2. PRE-NORM. The LayerNorm is INSIDE the residual branch,
   before the sublayer - not after the addition. The
   original 2017 paper used post-norm and needed careful
   warmup to train at all. PRE-NORM IS WHAT EVERY MODERN
   MODEL USES because it trains stably at depth
   (chapter 22).

The numbers

Model	d_model	Layers	Heads	Params
Original (2017)	512	6	8	65 M
BERT-base	768	12	12	110 M
GPT-2 small	768	12	12	124 M
GPT-2 XL	1600	48	25	1.5 B
GPT-3	12288	96	96	175 B
Llama 3 8B	4096	32	32 (8 KV)	8 B
Llama 3 70B	8192	80	64 (8 KV)	70 B

```
/* THE PARAMETER COUNT, per layer, in terms of d = d_model:

    ATTENTION
      W_Q, W_K, W_V, W_O    4 * d * d      = 4 d^2
    FEED-FORWARD (d_ff = 4d, the standard ratio)
      W_1: d x 4d, W_2: 4d x d             = 8 d^2
    LayerNorms                              ~ negligible
                                            ----------
                           PER LAYER       = 12 d^2

    TOTAL ~= 12 * n_layers * d^2  +  vocab * d

    CHECK IT AGAINST GPT-3:
      12 * 96 * 12288^2 = 174 billion.  Correct.

    NOTE THE PROPORTIONS: the FEED-FORWARD NETWORK IS TWO
    THIRDS OF THE PARAMETERS. Attention gets the attention;
    the FFN holds the weights. Chapter 22 discusses what it
    is believed to be doing.

/* SOME CONVENTIONS THAT ARE ALMOST ALWAYS TRUE:
     d_head  = d_model / n_heads      (usually 64 or 128)
     d_ff    = 4 * d_model            (or 8/3 * d for gated
                                       SwiGLU variants,
                                       which keeps the
                                       parameter count
                                       equal)
     depth and width scale together as models grow

/* AND THE MEMORY, which is what you actually plan around:
     WEIGHTS, fp16          2 bytes/param
       7B model  -> 14 GB
       70B model -> 140 GB   (chapter 26 halves or quarters
                              this)
     KV CACHE per token:
       2 * n_layers * n_kv_heads * d_head * 2 bytes
       Llama-3-8B: 2*32*8*128*2 = 131 KB PER TOKEN
       -> 8k context = 1 GB. This is why GQA exists
          (chapter 19).                                  */
```

The complete implementation

```

                logits.view(-1, logits.size(-1)),
                targets.view(-1),
                ignore_index=-1)
        return logits, loss

model = GPT(Config())
```

```
n = sum(p.numel() for p in model.parameters())
print(f"{n/1e6:.1f}M parameters")     # ~124M - GPT-2 small
```

THE WHOLE TRAINING OBJECTIVE

```
input:   [The, cat, sat, on, the]
targets: [cat, sat, on, the, mat]

Shift by one. Cross-entropy at every position. That is
the entire pretraining objective of every large language
model - no labels, no annotation, just text
(chapter 23).
```

The families, and what changed since 2017

```
/* --- THE THREE ARCHITECTURES --- */
    ENCODER-ONLY     bidirectional attention, masked-token
                     objective. BERT, RoBERTa, DeBERTa.
                     Classification, NER, EMBEDDINGS
                     (chapter 17).
    DECODER-ONLY     causal attention, next-token objective.
                     GPT, Llama, Mistral, Claude, Gemma.
                     GENERATION - and, it turned out,
                     everything else too.
    ENCODER-DECODER  cross-attention from decoder to
                     encoder. T5, BART, Whisper.
                     Translation, summarisation,
                     speech-to-text.

    DECODER-ONLY DOMINATES general-purpose models. The
    lesson the field drew: one simple objective plus scale
    outperformed architectural specialisation - the same
    lesson as chapter 14's prior-strength trade-off.

/* --- WHAT ACTUALLY CHANGED BETWEEN 2017 AND NOW --- */

    2017 ORIGINAL              MODERN (Llama 3 and similar)
    ------------------------------------------------------
    post-norm                  PRE-NORM
    LayerNorm                  RMSNORM (cheaper, no mean)
    learned absolute positions  ROPE (rotary, relative)
    ReLU FFN                   SWIGLU (gated)
    MHA                        GQA (smaller KV cache)
    d_ff = 4d                  d_ff = 8/3 d (to keep the
                               parameter count with gating)
    dropout 0.1                often 0 for pretraining
    biases everywhere          MOSTLY NO BIASES
    2k context                 128k+ context

    EVERY ONE OF THESE IS A SMALL CHANGE. There has been no
    architectural revolution since 2017 - the transformer
    block is essentially unchanged, and the gains have come
    from SCALE, DATA and SYSTEMS ENGINEERING. That is worth
    stating plainly, because it is not the impression the
    press gives.

/* --- MIXTURE OF EXPERTS, the one structural change --- */
    Replace the FFN with N expert FFNs and a router that
    sends each token to the top-k of them (usually k = 2).

      · TOTAL parameters go up enormously
      · ACTIVE parameters per token stay small
      · so capacity grows without proportional compute

    Mixtral 8x7B: 47B total, ~13B active per token.
    THE COSTS: all experts must be in memory, load balancing
    across experts needs an auxiliary loss, and distributed
    training becomes considerably harder.

/* --- AND THE MULTIMODAL EXTENSION --- */
    Nothing about the block is text-specific. Feed it image
    patches (ViT), audio frames (Whisper), or a mixture, and
    the same architecture applies. Chapter 17's point
```

```
    exactly: once everything is a sequence of vectors, the
    transformer does not care.                          */
```

How it shows up

Symptom	Cause
Training diverges past ~12 layers	Post-norm without warmup — use pre-norm
Loss drops to near zero, generation fails	No causal mask
Parameter count is far off the expected value	Check the $12 \cdot n_{layer} \cdot d^2$ estimate — usually a wrong `d_ff` or untied weights
Output is identical for shuffled input	Positional embedding missing or not added
Sequence longer than `block_size` crashes	Learned absolute positions have a hard limit
Activations grow with depth	Residual projections not scaled at initialisation
KV cache dominates memory	Full MHA — use GQA
Attention is slower than expected	Manual implementation instead of the fused kernel
MoE model has idle experts	No load-balancing auxiliary loss
Model is huge but the FFN is small	Wrong `d_ff` ratio — it should be two thirds of the parameters

Check yourself

- ✓ Draw the transformer block from memory, including both residuals.
- ✓ Explain the residual stream as a communication bus.
- ✓ Explain pre-norm versus post-norm and which trains at depth.
- ✓ Derive the $12 \cdot d^2$ per-layer parameter count and verify it against GPT-3.
- ✓ Say which sublayer holds two thirds of the parameters.
- ✓ Compute the KV cache per token for Llama-3-8B.
- ✓ Implement causal self-attention including the head reshape.
- ✓ Explain the input/target shift and why one pass gives T examples.
- ✓ Name the three architecture families and what each is used for.
- ✓ List eight changes between the 2017 transformer and a modern one.
- ✓ Explain mixture of experts and its three costs.

Multi-head attention and positional encoding

Two details that the previous chapter glossed over, and both matter more than their size suggests. One gives attention its expressive power; the other is the only thing telling the model that word order exists.

Multi-head attention

```
ONE ATTENTION HEAD PRODUCES ONE WEIGHTED AVERAGE. But a
token often needs several unrelated things at once:

  "The bank by the river was steep."

  · what is the SUBJECT of "was"?          -> "bank"
  · which sense of "bank" is this?         -> "river"
  · what is the previous token?            -> "was"

THREE DIFFERENT QUESTIONS, THREE DIFFERENT WEIGHTINGS.
One softmax-weighted average cannot express all of them -
whatever it emphasises, it de-emphasises the rest.

THE SOLUTION: RUN h ATTENTION OPERATIONS IN PARALLEL,
EACH IN A LOWER-DIMENSIONAL SUBSPACE, AND CONCATENATE.

     d_head = d_model / h

  x --> [W_Q1,W_K1,W_V1] --> attention --> head_1 \
    --> [W_Q2,W_K2,W_V2] --> attention --> head_2  \
    --> ...                                         >-- concat --> W_O --> out
    --> [W_Qh,W_Kh,W_Vh] --> attention --> head_h  /

THE PARAMETER COUNT IS UNCHANGED. Splitting 768
dimensions into 12 heads of 64 costs exactly the same as
one head of 768 - you are reshaping, not adding.

WHAT YOU BUY: h INDEPENDENT ATTENTION PATTERNS instead
of one. Empirically this matters a great deal; ablating
to a single head degrades models badly.

AND THE OUTPUT PROJECTION W_O IS NOT DECORATION. The
concatenated heads are just stacked subspaces; W_O mixes
them back into the residual stream and decides how each
head's contribution is written. Interpretability work
often factors attention as (W_Q W_K^T) for "where to
look" and (W_V W_O) for "what to write".

TYPICAL: d_head is 64 or 128, essentially always. Models
grow by adding HEADS and LAYERS, not by widening heads.
```

```
import torch
import torch.nn as nn
import torch.nn.functional as F

class MultiHeadAttention(nn.Module):
    def __init__(self, d_model, n_head, dropout=0.1):
        super().__init__()
        assert d_model % n_head == 0
        self.n_head = n_head
        self.d_head = d_model // n_head
        # ONE fused projection for Q, K, V (chapter 04:
        # one big matmul beats three small ones)
        self.qkv  = nn.Linear(d_model, 3 * d_model,
                              bias=False)
        self.proj = nn.Linear(d_model, d_model, bias=False)
        self.dropout = dropout

    def forward(self, x, is_causal=True):
        B, T, C = x.shape
        q, k, v = self.qkv(x).chunk(3, dim=-1)

        # THE RESHAPE THAT MAKES HEADS WORK:
        # (B, T, C) -> (B, n_head, T, d_head)
        # The head dimension becomes a BATCH dimension, so
        # one batched matmul runs every head simultaneously.
        def split(t):
            return t.view(B, T, self.n_head,
                          self.d_head).transpose(1, 2)
        q, k, v = split(q), split(k), split(v)

        y = F.scaled_dot_product_attention(
                q, k, v, is_causal=is_causal,
                dropout_p=self.dropout if self.training
                          else 0.0)

        # (B, n_head, T, d_head) -> (B, T, C)
        y = y.transpose(1, 2).contiguous().view(B, T, C)
        return self.proj(y)

# THE .contiguous() IS NOT OPTIONAL. transpose() returns a
# VIEW with permuted strides; view() requires contiguous
# memory. Omitting it raises an error - and if you use
# reshape() instead, it silently copies, which works but
# hides the cost.

# --- GROUPED-QUERY ATTENTION (chapter 19) ---
class GQA(nn.Module):
    """n_head query heads, n_kv_head key/value heads.
       n_kv_head = n_head    -> standard MHA

        return self.proj(y)
```

Why position must be added

```
/* ATTENTION IS PERMUTATION-EQUIVARIANT.

   Shuffle the input tokens and the outputs shuffle
   identically - the VALUES do not change. Look at the
   equation (chapter 19): it is a set of dot products and a
   weighted sum. NOTHING IN IT REFERS TO POSITION.

   So without positional information:

        "dog bites man"  ==  "man bites dog"

   The model literally cannot distinguish them. POSITION
   MUST BE INJECTED EXPLICITLY, and how you do it turns out
   to determine how far the model can extrapolate beyond its
   training length.                                        */

/* --- 1. LEARNED ABSOLUTE (GPT-2, BERT) --- */
    self.wpe = nn.Embedding(max_len, d_model)
    x = self.wte(idx) + self.wpe(positions)

    A lookup table, one vector per position, learned like
    any other parameter.
      + simple, and it works
      - HARD LIMIT at max_len. Position 1025 has no
        embedding. Cannot extrapolate at all.
      - positions are learned independently, so nothing
        forces position 5 and position 6 to be related

/* --- 2. SINUSOIDAL (the 2017 paper) --- */
    PE(pos, 2i)   = sin(pos / 10000^(2i/d))
    PE(pos, 2i+1) = cos(pos / 10000^(2i/d))

    Different dimensions oscillate at different frequencies -
    a binary-counter-like encoding in continuous form. The
    intended property: PE(pos+k) is a LINEAR FUNCTION of
    PE(pos), so relative offsets are learnable.
      + no parameters, defined for any position
      - extrapolation is poor in practice despite the theory

/* --- 3. ROPE: ROTARY POSITION EMBEDDING. THE STANDARD. --- */

    THE IDEA: do not ADD anything to the embeddings. ROTATE
    the query and key vectors by an angle proportional to
    their position.

      Treat each pair of dimensions as a 2-D vector and
      rotate it by (position * theta_i), with theta_i
      decreasing across dimension pairs.

    WHY IT IS ELEGANT: after rotation, the dot product
    between a query at position m and a key at position n
    depends only on (m - n).

        q_m · k_n  =  f(q, k, m - n)

    RELATIVE POSITION FALLS OUT OF THE ARITHMETIC. No
    relative-position bias table, no extra parameters, and
    it applies to Q and K only - the values and the residual
    stream are untouched.
```

```
    · used by Llama, Mistral, Gemma, Qwen, and essentially
      every recent open model
    · extrapolates better than the alternatives
    · and CONTEXT EXTENSION IS POSSIBLE AFTER TRAINING by
      scaling the frequencies - "NTK-aware" scaling, YaRN,
      position interpolation. This is how an 8k model
      becomes a 128k model with modest fine-tuning, and it
      is the main reason context lengths grew so fast.

def rope(x, positions, base=10000.0):
    """x: (B, n_head, T, d_head), d_head even."""
    B, H, T, D = x.shape
    half = D // 2
    freqs = 1.0 / (base ** (torch.arange(0, half,
                    device=x.device).float() / half))
    angles = positions[:, None].float() * freqs[None, :]
    cos, sin = angles.cos(), angles.sin()      # (T, half)

    x1, x2 = x[..., :half], x[..., half:]
    return torch.cat([x1 * cos - x2 * sin,
                      x1 * sin + x2 * cos], dim=-1)

# APPLY TO Q AND K ONLY, NOT V:
#     q = rope(q, pos);  k = rope(k, pos)

/* --- 4. ALiBi --- */
    Add a linear penalty to the attention scores based on
    distance, with a different slope per head:
        score = q·k - m_head * |i - j|
    No embeddings at all. Extrapolates well; nearer tokens
    are simply favoured. Used by BLOOM and MPT.

/* --- 5. NoPE --- */
    And a genuinely surprising result: DECODER-ONLY models
    with NO POSITIONAL ENCODING AT ALL still learn position,
    because the causal mask itself is positional information
    - position i can see exactly i+1 tokens, and that count
    is recoverable. Performance is competitive at small
    scale. A good reminder that architectural "necessities"
    deserve testing.                                      */
```

WHAT TO USE

```
new model, any size        -> RoPE
need long extrapolation    -> RoPE with frequency
                              scaling, or ALiBi
reproducing GPT-2/BERT     -> learned absolute
encoder for fixed-length
  classification           -> learned absolute is fine
tiny embedded model,
  short sequences          -> learned absolute; it is one
                              small table and the cheapest
                              to run
```

What the heads do

```
/* HEADS SPECIALISE, without being told to. The patterns
   from chapter 19, seen through the multi-head lens:

     · POSITIONAL heads   attend to the previous token, or
                          n back. Early layers.
     · SYNTACTIC heads    subject-verb, adjective-noun,
                          matching brackets
     · COREFERENCE heads  pronoun to antecedent
     · INDUCTION heads    copy a pattern seen earlier in
                          context. Requires TWO heads
                          working together across layers -
                          one to record "what followed this
                          token last time", one to use it.
                          Their formation coincides with
                          in-context learning appearing.
     · SINK heads         dump attention on token 0

/* --- HEAD REDUNDANCY --- */
    A well-known result: MANY HEADS CAN BE PRUNED with
    little loss. Some layers work fine with a single head.
    Others have one critical head whose removal breaks a
    capability entirely.

    THIS IS PRACTICALLY USEFUL: head pruning is a real
    compression technique (chapter 26), and it is structured
    - removing a whole head removes whole rows and columns,
    which actually speeds up the matmul, unlike unstructured
    sparsity (chapter 03).

/* --- INSPECTING THEM --- */
    def get_attention_maps(model, ids):
        maps = []
        def hook(mod, inp, out):
            q, k, _ = mod.qkv(inp[0]).chunk(3, dim=-1)
            # recompute the scores just to look at them
            ...
            maps.append(weights.detach())
        handles = [b.attn.register_forward_hook(hook)
                   for b in model.blocks]
        model(ids)
        for h in handles: h.remove()
        return maps       # (n_layer, B, n_head, T, T)

    AND THE CAVEAT FROM CHAPTER 19 STILL APPLIES: an
    attention map shows where a head LOOKED, not what the
    model USED. Treat it as a hypothesis generator, not
    evidence.                                              */
```

How it shows up

Symptom	Cause
Word order has no effect on output	No positional encoding
Crash at sequence length above the trained maximum	Learned absolute positions — no embedding exists
Quality collapses beyond the training length	Poor extrapolation — use RoPE with scaling or ALiBi
`view size is not compatible`	Missing `.contiguous()` after `transpose`

Symptom	Cause
Heads produce identical patterns	Initialisation or a reshape bug collapsing the head dimension
Output is scrambled across heads	Wrong reshape order — check `(B, T, H, D)` then transpose
RoPE applied to values	It belongs on Q and K only
KV cache far larger than expected	Full MHA rather than GQA
Extended context degrades badly	Frequencies not rescaled for the new length
Pruning heads gives no speedup	Masked rather than physically removed

Check yourself

- ✓ Explain why one attention head is insufficient, with a concrete sentence.
- ✓ Show that multi-head attention costs the same parameters as single-head.
- ✓ Explain what `W_O` does and the (W_Q W_K) / (W_V W_O) factorisation.
- ✓ Write the reshape that turns heads into a batch dimension, and say why `.contiguous()` is needed.
- ✓ Explain GQA's repeat step and what it saves.
- ✓ Explain why attention is permutation-equivariant and what that implies.
- ✓ Compare learned absolute, sinusoidal, RoPE and ALiBi.
- ✓ State RoPE's key property and why it gives relative position for free.
- ✓ Explain how context extension works after training.
- ✓ Say why decoder-only models can work with no positional encoding at all.
- ✓ Name five head specialisations and say what induction heads require.
- ✓ Explain why head pruning is structured sparsity and why that matters.

Normalisation, residuals and the feed-forward block

The unglamorous two thirds of a transformer. Residual connections are what make depth trainable, normalisation is what keeps it stable, and the feed-forward network holds most of the parameters and, probably, most of the knowledge.

Residual connections

```
      x ------------------+
      |                   |
      v                   |
   [ sublayer ]           |
      |                   |
      v                   |
     (+) <----------------+
      |
      v
    output = x + sublayer(x)

THE GRADIENT ARGUMENT, and it is the whole reason:

      d(output)/dx = 1 + d(sublayer)/dx
                     ^
                     THE IDENTITY PATH

Backpropagating through n layers multiplies n such terms.
Without the residual, the product is of n Jacobians and
vanishes or explodes exponentially (chapter 07). WITH IT,
the "1" guarantees a path along which the gradient
arrives essentially UNCHANGED, however deep the stack.

This is the same structural trick as the LSTM's cell
state (chapter 18) - give the gradient a route that does
not pass through a transformation.

BEFORE RESNET (2015), 20 layers was hard. AFTER, 1000+
layers train. IT IS THE SINGLE MOST IMPORTANT
ARCHITECTURAL IDEA OF THE DECADE, and it is one addition.

THE OTHER READING - THE RESIDUAL STREAM:

  Think of x as a SHARED BUS of width d_model that runs
  the full depth of the model. Each sublayer:
     · READS from the bus (through its LayerNorm)
     · COMPUTES something
     · ADDS its result back

  Nothing overwrites. Information written by layer 3
  survives to layer 40 unless something explicitly
  subtracts it. Layers can therefore communicate at a
  distance, and interpretability work treats the residual
  stream as the model's working memory.

  A CONSEQUENCE WORTH KNOWING: THE RESIDUAL STREAM'S NORM
  GROWS WITH DEPTH, because every layer adds to it. That
  is why the residual projections are initialised scaled
  down by 1/sqrt(2*n_layers) (chapter 15), and why the
  final LayerNorm before the output head is necessary.
```

Normalisation

```
/* --- LAYERNORM --- */
    mu    = mean(x, over the FEATURE dimension)
    sigma = std(x,  over the FEATURE dimension)
    y     = gamma * (x - mu) / (sigma + eps) + beta

    gamma and beta are LEARNED per-feature scale and shift,
    so the layer can undo the normalisation if that is
    useful.

    NORMALISED PER SAMPLE, PER POSITION, ACROSS FEATURES.
    No dependence on the batch at all - which is why
    transformers use it (chapter 15).

    nn.LayerNorm(d_model)      # (B, T, d) -> normalises
                               # over d

/* --- RMSNORM: what modern models use --- */
    y = gamma * x / sqrt(mean(x^2) + eps)

    NO MEAN SUBTRACTION, NO BETA. Just rescale to unit root
    mean square.

      · ~10-15% faster (one reduction instead of two)
      · fewer parameters
      · EMPIRICALLY JUST AS GOOD - which suggests the
        re-CENTRING was never the active ingredient; the
        re-SCALING was.

    Llama, Mistral, Gemma, T5 and most recent models use it.

    class RMSNorm(nn.Module):
        def __init__(self, d, eps=1e-6):
            super().__init__()
            self.weight = nn.Parameter(torch.ones(d))
            self.eps = eps
        def forward(self, x):
            rms = x.pow(2).mean(-1,
                                keepdim=True).add(self.eps).rsqrt()
            return self.weight * (x * rms)

/* --- PRE-NORM VERSUS POST-NORM. THIS ONE MATTERS. --- */

    POST-NORM (the 2017 paper):
        x = LayerNorm(x + sublayer(x))

        The normalisation is ON the residual path. So the
        gradient must pass through a LayerNorm at EVERY
        layer, and the clean identity path is destroyed.
        RESULT: deep post-norm transformers are hard to
        train and need careful warmup, and past ~12-18
        layers they frequently diverge.

    PRE-NORM (everything modern):
        x = x + sublayer(LayerNorm(x))

        The normalisation is INSIDE the branch. The residual
        path is a pure addition, so the identity gradient
        survives intact.
        RESULT: stable training at any depth, far less
        sensitivity to warmup and learning rate.
```

```
    THIS IS A ONE-LINE DIFFERENCE THAT DETERMINES WHETHER A
    100-LAYER MODEL TRAINS AT ALL. If you are reading old
    code and it will not converge, check this first.

    (Pre-norm's cost: the residual stream grows unnormalised
    with depth, which is why a FINAL LayerNorm before the
    output head is required. Some models add extra norms -
    "sandwich" or QK-norm - for stability at very large
    scale.)

/* --- WHY NORMALISATION HELPS AT ALL --- */
    The original claim was "reducing internal covariate
    shift". That explanation has not held up well.

    THE BETTER-SUPPORTED VIEW: it SMOOTHS THE LOSS
    LANDSCAPE, so gradients are more predictable and larger
    learning rates become usable. It also makes the model
    invariant to the SCALE of the weights, which decouples
    the effective learning rate from the weight magnitude.

    THE HONEST POSITION: IT WORKS RELIABLY AND THE THEORY IS
    STILL DEBATED. That is true of several things in this
    chapter, and it is better to know it than to repeat a
    tidy explanation that is probably wrong.            */
```

The feed-forward network

```
/* THE SIMPLEST PART OF THE ARCHITECTURE AND TWO THIRDS OF
   THE PARAMETERS (chapter 20).                          */

    FFN(x) = W_2 @ activation(W_1 @ x + b_1) + b_2

        W_1: (d_model, 4*d_model)     EXPAND
        W_2: (4*d_model, d_model)     PROJECT BACK

    APPLIED INDEPENDENTLY AT EVERY POSITION. There is no
    mixing across the sequence here at all - that is
    attention's job. The FFN is a per-token transformation.

    THE DIVISION OF LABOUR IN A TRANSFORMER BLOCK:
        ATTENTION  moves information BETWEEN positions
        FFN        processes information AT a position

/* --- SWIGLU: what modern models use --- */
    SwiGLU(x) = (SiLU(x @ W_gate) * (x @ W_up)) @ W_down

    A GATED linear unit: one branch produces values, the
    other produces a multiplicative gate. Three matrices
    instead of two, so d_ff is reduced from 4d to
    (8/3)d to keep the parameter count equal.

    Consistently a small quality improvement over ReLU or
    GELU FFNs. Nobody has a fully satisfying explanation;
    the gating presumably lets the layer suppress its own
    output conditionally.

    class SwiGLU(nn.Module):
        def __init__(self, d, hidden):
            super().__init__()
            self.gate = nn.Linear(d, hidden, bias=False)
            self.up   = nn.Linear(d, hidden, bias=False)
            self.down = nn.Linear(hidden, d, bias=False)
        def forward(self, x):
            return self.down(F.silu(self.gate(x))
                             * self.up(x))

/* --- WHAT THE FFN IS BELIEVED TO DO --- */

    THE KEY-VALUE MEMORY VIEW, which has real evidence behind
    it:
      · each ROW of W_1 acts as a PATTERN DETECTOR - the
        dot product with x fires when a particular feature is
        present
      · the activation gates it
      · each COLUMN of W_2 is the VALUE written back into the
        residual stream when that pattern fires

      So the FFN is a large associative memory: "when you see
      this pattern, add this to the stream". FACTUAL RECALL
      HAS BEEN LOCALISED TO SPECIFIC FFN NEURONS in several
      studies - the ROME and MEMIT model-editing work
      modifies exactly these weights to change a stored fact.

    THE 4x EXPANSION gives room for many more patterns than
    d_model dimensions - superposition again (chapter 17).

/* --- MIXTURE OF EXPERTS, which is an FFN change --- */
```

```
   Replace the single FFN with N of them plus a router:

       gate   = softmax(x @ W_router)        # (N,)
       top_k  = argtopk(gate, k=2)
       out    = sum over the chosen experts of
                gate_i * Expert_i(x)

     · total parameters up, ACTIVE parameters per token
       unchanged
     · requires a LOAD-BALANCING AUXILIARY LOSS, or the
       router collapses onto a few favourite experts and
       the rest never train
     · all experts must be resident in memory even though
       only k run - so it saves COMPUTE, not MEMORY, which
       is exactly the wrong trade for an embedded device

   NOTE THAT MoE MODIFIES THE FFN, NOT ATTENTION. That is
   not a coincidence: the FFN is where the parameters are.
                                                        */
```

THE BLOCK, IN ONE SENTENCE EACH

```
RESIDUAL     gives the gradient an identity path, so
             depth is trainable.
LAYERNORM    keeps activations in a usable range and
             smooths the landscape.
PRE-NORM     keeps the residual path clean, so very
             deep models train.
ATTENTION    moves information between positions.
FFN          transforms information at each position,
             and stores most of what the model knows.
```

The cost picture

```
/* PER LAYER, per token, in FLOPs (roughly, ignoring
   constants):

     ATTENTION projections   8 * d^2      (Q,K,V,O)
     ATTENTION scores+AV     4 * n * d    (n = sequence
                                           length)
     FFN                    16 * d^2      (4d expansion,
                                           two matmuls)
     norms                   negligible

   SO FOR SHORT SEQUENCES THE FFN DOMINATES COMPUTE, and
   attention's quadratic term only takes over when
   n is comparable to d:

        4*n*d  >  24*d^2   when   n > 6d

   For d = 4096 that is n > 24,576 tokens. BELOW THAT, THE
   MODEL IS MOSTLY DOING FFN MATMULS, not attention. This
   surprises people who assume attention is always the
   bottleneck - it becomes one at long context, and at short
   context the FFN is the cost.

/* --- WHAT THIS MEANS FOR OPTIMISATION --- */
     SHORT CONTEXT   optimise the FFN: quantise it
                     (chapter 26), use MoE, prune it
     LONG CONTEXT    optimise attention: Flash Attention,
                     sliding windows, GQA (chapter 19)
     GENERATION      neither - you are memory-bandwidth
                     bound (chapters 04, 25)

/* --- AND FOR EMBEDDED (chapter 27) --- */
     · LayerNorm needs a mean, a variance and a reciprocal
       square root per token. On a device without an FPU
       that is expensive; RMSNorm halves it, and
       fixed-point implementations need care with the
       variance's dynamic range.
     · SwiGLU needs a sigmoid per hidden unit - 11k
       transcendental evaluations per token at d = 4096.
       ReLU is one comparison. On an MCU, choose ReLU.
     · the FFN's two large matmuls are where a small
       transformer spends its time, so an NPU that only
       accelerates dense matmul still gets you most of the
       win.                                              */
```

How it shows up

Symptom	Cause
Deep model diverges, shallow one trains	Post-norm — switch to pre-norm
Training needs very long warmup	Post-norm, or missing residual scaling at init
Activations grow steadily with depth	Normal for pre-norm — ensure a final LayerNorm exists
Removing the residual breaks training entirely	Expected — the gradient loses its identity path
`nan` in LayerNorm	Zero variance, or `eps` too small in fp16
MoE model uses only two experts	No load-balancing loss — router collapse

Symptom	Cause
MoE saves compute but not memory	By design — all experts must be resident
Parameter count doesn't match after switching to SwiGLU	`d_ff` must drop to 8/3·d for three matrices
Attention optimisation gives little speedup	Short context — the FFN dominates
LayerNorm is slow on an MCU	Two reductions plus rsqrt — use RMSNorm

Check yourself

- ✓ Give the gradient argument for residual connections.
- ✓ Explain the residual stream as a bus, and why its norm grows with depth.
- ✓ Write LayerNorm and RMSNorm, and say what RMSNorm drops.
- ✓ Explain pre-norm versus post-norm and which one enables depth.
- ✓ State the honest position on why normalisation helps.
- ✓ Write the FFN and state the division of labour with attention.
- ✓ Explain SwiGLU and why `d_ff` changes to 8/3·d.
- ✓ Give the key-value memory view of the FFN and the evidence for it.
- ✓ Explain mixture of experts and why it saves compute but not memory.
- ✓ Compute the crossover sequence length where attention overtakes the FFN.
- ✓ Say which component to optimise for short context, long context and generation.

Pretraining and scaling laws

Predict the next token on a very large amount of text. The objective is trivial; the engineering is not, and the empirical laws governing how performance improves with scale are the most practically useful result in the field.

The objective

```
TRAINING DATA:  raw text. No labels. No annotation.

  input   [The, cat, sat, on, the]
  target  [cat, sat, on, the, mat]

SHIFT BY ONE. Cross-entropy at every position
(chapter 10). With causal masking, one forward pass over
a sequence of length n yields n training examples
(chapter 19).

THAT IS THE ENTIRE PRETRAINING OBJECTIVE OF EVERY LARGE
LANGUAGE MODEL.

WHY IT WORKS AT ALL - and this is the genuinely
surprising part:

  "The capital of France is ___"      needs a FACT
  "2 + 2 = ___"                       needs ARITHMETIC
  "def fib(n): return ___"            needs CODE
  "Q: ...  A: ___"                    needs REASONING
  "Translate: le chat -> ___"         needs TRANSLATION
  "... therefore the answer is ___"   needs INFERENCE

PREDICTING THE NEXT TOKEN WELL ENOUGH, ACROSS ENOUGH
TEXT, REQUIRES MODELLING WHATEVER PRODUCED THE TEXT.
Nobody designed for translation or arithmetic; those
capabilities are means to an end for a compression
objective (chapter 10).

THE HONEST FRAMING: this is an EMPIRICAL result, not a
predicted one. In 2018 essentially nobody expected that
scaling this objective would produce in-context learning
or chain-of-thought reasoning. The theory is still
catching up.

AND THE ALTERNATIVE OBJECTIVES, for context:
  MASKED LM (BERT)   hide 15% of tokens, predict them.
                     Bidirectional context, better
                     representations - but you only train
                     on 15% of positions, and it does not
                     generate.
  SPAN CORRUPTION    (T5) mask contiguous spans.
  NEXT-TOKEN won because it trains on EVERY position, it
  generates natively, and it scales.
```

The data

```
/* A MODERN PRETRAINING CORPUS: 2-20 TRILLION TOKENS.
   Roughly the sources, in order of contribution:          */

    WEB CRAWL          Common Crawl, FineWeb, RefinedWeb.
                       The bulk, and the most in need of
                       filtering.
    CODE               GitHub, The Stack. Improves reasoning
                       measurably, even on non-code tasks.
    BOOKS              long-form coherence, narrative
                       structure
    WIKIPEDIA          dense, high-quality facts. Small but
                       heavily upweighted.
    ACADEMIC           arXiv, PubMed
    CURATED / SYNTHETIC increasingly significant: textbook-
                       style generated data, filtered by
                       quality models

/* --- THE PIPELINE, and it matters more than the
       architecture --- */

  1. EXTRACT text from HTML. Boilerplate removal is
     surprisingly hard and surprisingly important.

  2. LANGUAGE IDENTIFICATION and filtering.

  3. QUALITY FILTERING
       · heuristics: mean word length, punctuation ratio,
         proportion of stopwords, lines ending in "..."
       · a CLASSIFIER trained to recognise "reference-like"
         text
       · perplexity filtering against a small reference
         model

  4. DEDUPLICATION - THE HIGHEST-VALUE STEP.
       exact-match, then FUZZY (MinHash / LSH) at document
       and paragraph level.
       Duplicated data causes memorisation without
       generalisation, and it wastes compute. Removing
       duplicates reliably improves models at fixed
       compute - one of the few interventions that is
       almost always positive.

  5. DECONTAMINATION - remove anything matching benchmark
     test sets (chapter 12). Frequently done badly, which
     is why published benchmark numbers should be read
     sceptically.

  6. PII AND TOXICITY FILTERING.

  7. MIXING AND UPWEIGHTING. Wikipedia might be repeated
     several times; low-quality web crawl seen once. The
     mixture weights are a real hyperparameter and are
     usually not published.

/* --- HOW MUCH DATA IS THERE, HONESTLY --- */
    High-quality English text on the public internet is
    estimated at a few tens of trillions of tokens. Frontier
    models already train on a meaningful fraction of it.

    THE RESPONSES: multilingual data, code, multiple epochs
```

```
    (up to ~4 epochs costs little quality), synthetic data,
    and non-public licensed corpora. "Running out of data"
    is a real constraint on the current recipe, and it is
    part of why attention has shifted toward post-training
    (chapter 24) and inference-time compute.               */
```

Scaling laws

```
THE CENTRAL EMPIRICAL RESULT (Kaplan 2020, Hoffmann
2022):

  LOSS FALLS AS A POWER LAW IN MODEL SIZE, DATA AND
  COMPUTE, SMOOTHLY, OVER MANY ORDERS OF MAGNITUDE.

     L(N) = (Nc / N)^alpha        N = parameters
     L(D) = (Dc / D)^beta         D = tokens
     L(C) = (Cc / C)^gamma        C = compute

On a log-log plot these are STRAIGHT LINES:

  log
  loss
    |  \
    |    \
    |      \
    |        \
    |          \
    +------------------ log compute

THE PRACTICAL CONSEQUENCE, and it is why these laws
matter: YOU CAN TRAIN SMALL MODELS AND PREDICT THE LOSS
OF A LARGE ONE BEFORE SPENDING THE MONEY. Frontier runs
are planned this way - a series of small runs fits the
curve, and the big run's loss is forecast in advance and
usually lands close.

THE CHINCHILLA RESULT (2022), which corrected the field:

  For a COMPUTE BUDGET C, the optimal split is
  approximately

     20 TOKENS PER PARAMETER

  GPT-3: 175B parameters, 300B tokens
         -> 1.7 tokens/parameter. SEVERELY
            UNDERTRAINED.
  Chinchilla: 70B parameters, 1.4T tokens
         -> a 70B model BEAT the 175B one, at the same
            compute.

THE LESSON WAS THAT EVERYONE HAD BEEN BUILDING MODELS
TOO BIG AND TRAINING THEM TOO LITTLE.

AND THE MODERN CORRECTION TO THE CORRECTION:

  Chinchilla optimises TRAINING compute. But a deployed
  model is trained ONCE and run BILLIONS of times, so
  INFERENCE cost dominates total cost.

  So current practice deliberately OVERTRAINS SMALL
  MODELS far past Chinchilla-optimal:
    Llama 3 8B: ~15T tokens -> ~1,875 tokens/parameter,
    nearly 100x Chinchilla.

  A smaller model trained much longer costs more to
  train and far less to serve. FOR ANYTHING THAT WILL
  RUN ON A DEVICE (chapter 27), THIS IS THE RIGHT TRADE
  AND IT IS WHY GOOD SMALL MODELS EXIST NOW.
```

```
THE COMPUTE FORMULA (chapter 04):

     C  ~=  6 * N * D     FLOPs

  Llama-3-8B: 6 * 8e9 * 15e12 = 7.2e23 FLOPs.
  On 16,000 H100s at ~400 TFLOP/s effective:
     7.2e23 / (16000 * 4e14) = ~112,000 seconds of pure
     compute, and in practice weeks of wall-clock once
     efficiency, restarts and data loading are counted.
```

The engineering

```
/* NO SINGLE ACCELERATOR HOLDS A LARGE MODEL. Training is a
   distributed systems problem.                              */

/* --- THE PARALLELISM AXES --- */
    DATA PARALLEL       every device holds a FULL COPY of
                        the model, processes a different
                        batch slice, and gradients are
                        ALL-REDUCED. Simple; limited by
                        model memory.

    ZeRO / FSDP         SHARD the optimiser state, then the
                        gradients, then the parameters
                        across devices, gathering each layer
                        only when needed. Removes the
                        Adam-state memory wall (chapter 11)
                        at the cost of extra communication.

    TENSOR PARALLEL     SPLIT INDIVIDUAL MATRICES across
                        devices - each holds part of a
                        weight matrix. Needs very fast
                        interconnect (NVLink), so it stays
                        WITHIN a node.

    PIPELINE PARALLEL   different LAYERS on different
                        devices. Creates a "bubble" of idle
                        time, mitigated by splitting the
                        batch into micro-batches.

    EXPERT PARALLEL     MoE experts on different devices
                        (chapter 22).

    IN PRACTICE, ALL AT ONCE: tensor parallel inside a node,
    pipeline parallel across nodes, data parallel across
    replicas. "3-D parallelism".

/* --- MIXED PRECISION --- */
    bf16 for the forward and backward passes; fp32 for the
    master weights and the optimiser state.

    BF16, NOT FP16. Same exponent range as fp32, fewer
    mantissa bits. It cannot overflow where fp16 does, so
    NO LOSS SCALING IS NEEDED. This alone removed a whole
    class of training instability, and it is why every
    modern accelerator supports it.

/* --- GRADIENT CHECKPOINTING (chapter 07) --- */
    Recompute activations in the backward pass instead of
    storing them. ~30% more compute, a large memory saving.
    Standard.

/* --- WHAT THE OPERATIONS ACTUALLY LOOK LIKE --- */
    · CHECKPOINT FREQUENTLY. Hardware fails; at 16,000 GPUs
      something fails every few hours. Meta reported a
      failure roughly every 3 hours during Llama 3 training.
    · MONITOR THE LOSS CURVE CONTINUOUSLY. LOSS SPIKES ARE
      NORMAL. The standard response is to roll back to a
      checkpoint and skip the offending data batch
      (chapter 11).
    · MFU (model FLOPs utilisation) is the efficiency
      metric: achieved FLOPs / peak FLOPs. 40-55% is good.
```

```
      Below 30% means something is wrong - usually
      communication or data loading.
    · DATA LOADING MUST KEEP UP. Feeding thousands of
      accelerators is itself a serious I/O problem.

/* --- THE SEQUENCE OF A REAL RUN --- */
    1. tokenise and shard the corpus into fixed blocks
       (chapter 16) - no padding, documents concatenated
       with separators
    2. warmup over ~2000 steps (chapter 11)
    3. cosine decay to ~10% of peak
    4. AdamW, beta2 = 0.95, weight decay 0.1, grad clip 1.0
    5. batch size ramped up over training - small batches
       early are more sample-efficient
    6. evaluate on held-out perplexity and a benchmark suite
       every few thousand steps
    7. a final "cooldown" or annealing phase on
       high-quality data, which reliably improves the final
       model                                              */
```

EMERGENCE, AND THE ARGUMENT ABOUT IT

Some capabilities appear abruptly with scale — multi-digit arithmetic, chain-of-thought benefit, in-context learning — showing near-zero performance below a threshold and useful performance above it. **But a well-supported critique** argues much of this is an artefact of *discontinuous metrics*: exact-match accuracy on a 5-digit sum is all-or-nothing, so a smooth improvement in per-token probability looks like a sudden jump. Measured with a continuous metric, many "emergent" curves become smooth. Some genuine phase changes remain — induction-head formation (chapter 19) is a real, abrupt structural transition. Treat "emergence" claims as needing a look at the metric first.

What it costs, and what it produces

```
/* --- ROUGH TRAINING COSTS --- */
    GPT-2 (1.5B, 2019)         ~$50k
    GPT-3 (175B, 2020)         ~$5M
    Llama 3 70B (2024)         ~$30-60M
    Frontier models (2025-26)  hundreds of millions

    NOT INCLUDING: failed runs, data pipeline work,
    salaries, or the evaluation infrastructure - which
    collectively often exceed the compute bill.

/* --- WHAT YOU GET: A BASE MODEL --- */
    A base model COMPLETES TEXT. It does not follow
    instructions, answer questions, or refuse anything.

        prompt: "What is the capital of France?"
        base model: "What is the capital of Germany?
                     What is the capital of Italy?
                     ..."

    It continued the pattern - a list of questions - which
    is exactly what the objective asked for. IT IS NOT
    BROKEN; it is doing precisely what it was trained to do.

    TURNING IT INTO AN ASSISTANT IS A SEPARATE STAGE
    (chapter 24), and that stage costs a tiny fraction of
    pretraining while changing the user-visible behaviour
    almost entirely.

/* --- AND WHAT THIS MEANS IF YOU ARE NOT OPENAI --- */

    YOU WILL NOT PRETRAIN A FRONTIER MODEL. What you will
    do:

      · FINE-TUNE an open base model (chapter 24) -
        hundreds to thousands of dollars
      · PRETRAIN A SMALL DOMAIN MODEL - a 10-100M parameter
        model on your own corpus (sensor logs, protocol
        traces, domain text) is genuinely feasible on one
        GPU in days, and for a narrow embedded task it may
        beat anything general-purpose
      · DISTIL a large model into a small one (chapter 26)
      · or simply USE an existing model well

    THE SCALING LAWS ARE STILL USEFUL AT YOUR SCALE: they
    tell you how to split a fixed budget between model size
    and data, and 20 tokens per parameter remains a sound
    starting point for a from-scratch run. Chapter 28's
    project is exactly this, at the smallest possible size.
                                                          */
```

How it shows up

Symptom	Cause
Base model does not answer questions	Working as designed — it completes text; it needs post-training
Model memorises passages verbatim	Duplicated data — deduplicate
Benchmark scores far above real quality	Test-set contamination — decontaminate

Symptom	Cause
Large model underperforms a smaller one	Undertrained — check tokens per parameter
MFU below 30%	Communication overhead or a starved data loader
Loss spikes mid-run	Normal at scale — roll back and skip the batch
Training unstable in fp16	Use bf16 — no loss scaling needed
Out of memory with a model that should fit	Optimiser state — use ZeRO/FSDP and checkpointing
Serving cost dominates the budget	Chinchilla-optimal sizing — overtrain a smaller model instead
An "emergent" capability vanishes under a different metric	The metric was discontinuous, not the capability

Check yourself

- ✓ State the pretraining objective and why one pass gives n examples.
- ✓ Explain why next-token prediction produces translation and arithmetic.
- ✓ Contrast next-token, masked-LM and span-corruption objectives.
- ✓ List the seven data pipeline stages and say which has the highest value.
- ✓ State the scaling laws and their single most useful practical consequence.
- ✓ State the Chinchilla ratio and why GPT-3 was undertrained.
- ✓ Explain why current practice deliberately overtrains small models.
- ✓ Use `C ≈ 6ND` to estimate a training run.
- ✓ Name five parallelism axes and say which stays within a node.
- ✓ Explain why bf16 is preferred over fp16.
- ✓ Give the critique of emergence and the one clear counterexample.
- ✓ Describe what a base model does with a question, and why.

Fine-tuning, instruction tuning and RLHF

Turning a text completer into something useful. Post-training costs a tiny fraction of pretraining and accounts for almost everything a user perceives about a model's character and usefulness.

The stages

```
1. PRETRAINING          (chapter 23)
     trillions of tokens, months, millions of dollars
     -> a BASE MODEL that completes text

2. SUPERVISED FINE-TUNING (SFT) / INSTRUCTION TUNING
     10k-1M curated (instruction, response) pairs
     hours to days
     -> a model that FOLLOWS INSTRUCTIONS

3. PREFERENCE OPTIMISATION (RLHF, DPO, and relatives)
     10k-1M human preference comparisons
     -> a model that is HELPFUL, HONEST AND HARMLESS
        according to whoever wrote the guidelines

4. (optional) CONTINUED PRETRAINING on domain data,
     inserted between 1 and 2 when you need domain
     knowledge rather than domain style

THE PROPORTIONS ARE STRIKING:
     pretraining      >99% of the compute
     post-training     <1% of the compute
     but post-training is responsible for essentially
     ALL of the difference between "a strange text
     completer" and "a useful assistant".

THE STANDARD INTERPRETATION - the SUPERFICIAL ALIGNMENT
HYPOTHESIS: post-training does not teach new knowledge.
It teaches the model WHICH OF ITS EXISTING CAPABILITIES
TO SURFACE, and in what format. Evidence: a few thousand
high-quality examples get most of the benefit, and
fine-tuning rarely adds facts the base model did not
already contain.

THE PRACTICAL COROLLARY, and it is the most useful thing
in this chapter:

  IF THE BASE MODEL DOES NOT KNOW SOMETHING,
  FINE-TUNING WILL NOT TEACH IT RELIABLY.
  IT WILL TEACH IT TO SOUND CONFIDENT ABOUT IT.

For new facts, use RETRIEVAL (chapter 17) or continued
pretraining on a lot of domain text - not a few thousand
Q&A pairs.
```

Supervised fine-tuning

```
/* MECHANICALLY IDENTICAL TO PRETRAINING - same
   cross-entropy, same optimiser. Only the data changes. */

    TRAINING EXAMPLE:
      <|im_start|>user
      Explain what a mutex is.<|im_end|>
      <|im_start|>assistant
      A mutex is a synchronisation primitive that...<|im_end|>

    AND THE ONE IMPORTANT DETAIL:

      MASK THE LOSS ON THE PROMPT TOKENS.

    You want the model to learn to PRODUCE the response, not
    to predict the user's question. Set the prompt positions
    to ignore_index (chapter 16).

        labels = input_ids.clone()
        labels[:prompt_len] = -100     # ignored by
                                       # cross_entropy

    Omitting this still "works" and produces a measurably
    worse model that sometimes continues by inventing the
    next user turn.

/* --- WHAT MAKES GOOD SFT DATA --- */
    QUALITY BEATS QUANTITY, decisively. The LIMA result:
    1,000 carefully curated examples produced a model
    competitive with one trained on 50,000 mediocre ones.

    WHAT TO CURATE FOR:
      · DIVERSITY of task types, lengths and formats
      · CONSISTENT STYLE - the model learns the average, so
        inconsistent formatting produces inconsistent output
      · CORRECTNESS. A wrong answer in the data teaches the
        model to be wrong confidently.
      · REFUSALS where appropriate, or the model will
        never decline anything
      · and MULTI-TURN conversations, or it will handle only
        single turns well

    SOURCES: human-written (expensive, best), model-generated
    and filtered (Self-Instruct, Evol-Instruct), converted
    from existing datasets, or DISTILLED from a stronger
    model (check the licence).

/* --- LoRA: the technique that made this accessible --- */
    Freeze W. Learn a LOW-RANK UPDATE (chapters 03, 05):

        W_new = W + (alpha/r) * B @ A

        A: (r, d_in)   initialised randomly
        B: (d_out, r)  INITIALISED TO ZERO, so the model
                       starts unchanged

    For d = 4096 and r = 16:
        full fine-tune  16.8M parameters per matrix
        LoRA             131k parameters
        -> 128x fewer trainable parameters
```

```
    WHY IT WORKS: the weight UPDATE during fine-tuning has
    low intrinsic rank. Adaptation lives in a small
    subspace, so representing it compactly loses little.

    THE PRACTICAL BENEFITS:
      · fine-tune a 7B model on one consumer GPU
      · the adapter is a few megabytes - ship many task
        adapters for one base model, swap at runtime
      · NO INFERENCE COST if you merge B@A into W afterwards
      · and QLoRA: quantise the frozen base to 4 bits
        (chapter 26) and train the adapter in bf16. A 70B
        model fine-tunes on a single 48 GB card.

    HYPERPARAMETERS THAT MATTER: r (8-64), alpha (usually
    2r), and WHICH MODULES to adapt - attention projections
    only is the classic recipe, but including the FFN
    generally works better.

    from peft import LoraConfig, get_peft_model
    cfg = LoraConfig(r=16, lora_alpha=32, lora_dropout=0.05,
                     target_modules=["q_proj","k_proj",
                                     "v_proj","o_proj",
                                     "gate_proj","up_proj",
                                     "down_proj"])
    model = get_peft_model(base_model, cfg)
    model.print_trainable_parameters()
    # trainable: 0.24% of all parameters

/* --- CATASTROPHIC FORGETTING --- */
    Fine-tuning hard on a narrow task degrades everything
    else. A model tuned only on SQL forgets how to write
    prose.

    MITIGATIONS: a LOW learning rate (1e-5 to 5e-5, an order
    of magnitude below pretraining), FEW epochs (1-3), MIX
    IN general data, or use LoRA - which by constraining the
    update to a low-rank subspace forgets substantially
    less.                                                  */
```

Learning from preferences

```
/* THE PROBLEM SFT CANNOT SOLVE: for most requests there is
   no single correct answer, only better and worse ones. And
   it is far easier for a human to say "B is better than A"
   than to write the ideal A.

/* --- CLASSIC RLHF, THREE STEPS --- */

  1. COLLECT PREFERENCES
       Sample two responses to the same prompt. A human
       picks the better one. Repeat 10k-1M times, against
       written guidelines.

  2. TRAIN A REWARD MODEL
       A copy of the model with a scalar head, trained so
       that preferred responses score higher:

         L = -log sigmoid( r(chosen) - r(rejected) )

       (The Bradley-Terry model - the same logistic form as
       chapter 13.)

  3. OPTIMISE THE POLICY AGAINST THE REWARD, with PPO,
     subject to a KL PENALTY:

         objective = E[ r(x, y) ]
                     - beta * KL(policy || reference)

       THE KL TERM IS ESSENTIAL. Without it the policy
       finds adversarial inputs that the reward model scores
       highly and humans find worthless - REWARD HACKING.
       Classic failure modes: extreme verbosity, excessive
       hedging, opening every response with flattery,
       compulsive list-making. IF YOU HAVE NOTICED MODELS
       DOING THESE THINGS, THIS IS WHERE THEY COME FROM.

       It is the REVERSE KL of chapter 10 - mode-seeking,
       keeping the policy near the reference.

/* --- DPO: what most people use now --- */
    Direct Preference Optimisation removes the reward model
    and the RL loop entirely. The insight: the optimal
    policy under a KL-constrained reward objective has a
    closed form, so the reward can be expressed in terms of
    the policy itself. Substituting gives a plain
    supervised loss over preference pairs:

      L = -log sigmoid( beta * [
              log pi(y_w|x) - log pi_ref(y_w|x)
            - log pi(y_l|x) + log pi_ref(y_l|x) ] )

    NO REWARD MODEL. NO SAMPLING LOOP. NO PPO. Just a loss
    function over (prompt, chosen, rejected) triples, run
    like any other fine-tune.

    · far simpler and more stable
    · usually comparable results
    · the main loss is that you cannot do online exploration
      against a learned reward

    VARIANTS: IPO, KTO (needs only binary good/bad labels,
```

```
    not pairs), ORPO (merges SFT and preference learning
    into one stage), SimPO (reference-free).

/* --- RLAIF AND CONSTITUTIONAL AI --- */
    Replace the human labeller with a model, guided by an
    explicit written set of principles. The model critiques
    and revises its own outputs against the constitution,
    and those revisions become training data.

    · dramatically cheaper and faster to iterate
    · the principles are WRITTEN DOWN and inspectable, which
      is a genuine transparency advantage over implicit
      preferences in a labelling pool
    · and the obvious concern: the judging model's biases
      become the training signal

/* --- RLVR: verifiable rewards --- */
    For maths, code and other checkable domains, skip
    preferences entirely: RUN THE TESTS. Reward = did the
    unit test pass, did the proof check, is the answer
    correct.

    An objective, unhackable reward signal, and the basis of
    the recent reasoning-model results. It only works where
    correctness is mechanically checkable - which is a real
    limit, and also exactly the situation in a great deal of
    engineering work.                                    */
```

CHOOSING YOUR APPROACH

```
NEED A FORMAT OR STYLE          -> SFT, or just prompting
NEED DOMAIN KNOWLEDGE           -> RETRIEVAL first;
                                   continued pretraining
                                   if you have a lot of
                                   text
NEED BETTER JUDGEMENT/TONE      -> DPO on preference pairs
NEED CHECKABLE CORRECTNESS      -> RLVR against tests
LIMITED COMPUTE                 -> LoRA or QLoRA
JUST TRYING SOMETHING           -> PROMPT FIRST
```

Try prompting before fine-tuning. A good system prompt plus a few in-context examples solves a surprising fraction of what people reach for fine-tuning to do, costs nothing, and can be changed in a minute rather than a day.

Doing it

```
from transformers import (AutoModelForCausalLM,
                          AutoTokenizer, TrainingArguments)
from peft import LoraConfig
from trl import SFTTrainer, DPOTrainer

# --- SFT ---
model = AutoModelForCausalLM.from_pretrained(
            "meta-llama/Llama-3.1-8B", torch_dtype="bfloat16",
            device_map="auto")
tok = AutoTokenizer.from_pretrained("meta-llama/Llama-3.1-8B")

args = TrainingArguments(
    output_dir="out",
    num_train_epochs=2,            # 1-3. MORE OVERFITS.
    per_device_train_batch_size=4,
    gradient_accumulation_steps=8, # effective batch 32
    learning_rate=2e-5,            # LOW (chapter 11)
    lr_scheduler_type="cosine",
    warmup_ratio=0.03,
    bf16=True,
    gradient_checkpointing=True,
    logging_steps=10,
    eval_strategy="steps", eval_steps=100,
)

trainer = SFTTrainer(
    model=model, args=args,
    train_dataset=train_ds, eval_dataset=eval_ds,
    peft_config=LoraConfig(r=16, lora_alpha=32),
    max_seq_length=2048,
)
trainer.train()

# --- DPO, on a dataset of {prompt, chosen, rejected} ---
dpo = DPOTrainer(
    model=sft_model,
    ref_model=None,        # LoRA: the base with adapters
                           # disabled IS the reference
    args=dpo_args,
    beta=0.1,              # the KL strength
    train_dataset=pref_ds,
)
dpo.train()

# --- MERGE AND EXPORT ---
merged = model.merge_and_unload()   # folds B@A into W
merged.save_pretrained("final")     # zero inference
                                    # overhead

/* --- EVALUATION: THE PART PEOPLE SKIP --- */
    · HOLD OUT a test set BEFORE you start (chapter 12)
    · CHECK FOR REGRESSION on general benchmarks, not only
      your task - catastrophic forgetting is invisible if
      you only measure what you tuned for
    · LLM-AS-JUDGE for open-ended quality, with the known
      biases accounted for: judges prefer LONGER answers,
      prefer their own family's style, and are sensitive to
      option ORDER (so randomise it)
    · AND READ THE OUTPUTS. A hundred generations, by hand.
      Every automated metric misses things that are obvious
```

```
      on inspection (chapter 12).

/* --- WHAT GOES WRONG --- */
    OVERFITTING       loss near zero, outputs degenerate and
                      repetitive. Fewer epochs.
    FORGETTING        general ability drops. Lower lr, mix
                      in general data, use LoRA.
    FORMAT COLLAPSE   every answer takes the same shape.
                      Diversify the data.
    SYCOPHANCY        preference training rewards agreement,
                      so the model agrees with incorrect
                      user claims. A known and actively
                      studied side effect of RLHF.
    VERBOSITY         reward models like long answers. A
                      length penalty helps.
    OVER-REFUSAL      too many refusal examples, or too
                      broad. The model declines benign
                      requests. Balance deliberately.     */
```

How it shows up

Symptom	Cause
Model invents the next user turn	Loss not masked on prompt tokens
Confidently wrong on domain facts	Fine-tuning taught style, not knowledge — use retrieval
General ability drops after tuning	Catastrophic forgetting — lower LR, fewer epochs, LoRA
Outputs repetitive and degenerate	Too many epochs on too little data
Answers grow steadily longer	Reward hacking on length
Model agrees with incorrect user claims	Sycophancy from preference training
Benign requests refused	Refusal data too broad
Policy diverges into nonsense during RL	KL penalty too weak or absent
LLM-judge scores disagree with human reading	Length and position bias — randomise and read outputs
LoRA has no effect	Wrong `target_modules`, or `alpha` too small
Fine-tuned model is slower	Adapters not merged

Check yourself

- ✓ Name the post-training stages and their relative compute cost.
- ✓ State the superficial alignment hypothesis and its practical corollary.
- ✓ Explain prompt-token loss masking and what happens without it.
- ✓ Give four properties of good SFT data.
- ✓ Write the LoRA update, say why B starts at zero, and compute the parameter saving.
- ✓ Explain QLoRA and what it makes possible.
- ✓ Describe the three RLHF steps and the reward-model loss.
- ✓ Explain the KL penalty and name four reward-hacking behaviours it prevents.
- ✓ Explain what DPO removes and why it is simpler.
- ✓ Describe RLAIF and RLVR, and the limit of each.
- ✓ Choose an approach for six different needs.

✓ List three known biases of LLM-as-judge evaluation.

Inference: sampling, the KV cache and context

Training happens once; inference happens billions of times. This is where the systems engineering lives, and where an embedded engineer's instincts about memory bandwidth turn out to be exactly the right ones.

The generation loop

```
A MODEL PRODUCES ONE DISTRIBUTION OVER THE VOCABULARY,
FOR THE NEXT TOKEN. Generating text means running it
repeatedly, feeding each choice back in.

  tokens = tokenise(prompt)
  loop:
     logits = model(tokens)[-1]      # last position only
     probs  = softmax(logits / T)
     next   = sample(probs)
     tokens.append(next)
     if next == EOS or len(tokens) >= max: break

THIS IS AUTOREGRESSIVE DECODING, and it has two distinct
phases with completely different performance characters:

PREFILL - process the whole prompt at once
  · one forward pass over n tokens, fully parallel
  · MATRIX-MATRIX products -> COMPUTE BOUND (chapter 04)
  · fast per token: thousands of tokens/second
  · determines TIME TO FIRST TOKEN

DECODE - generate one token at a time
  · one forward pass per token, inherently sequential
  · MATRIX-VECTOR products -> MEMORY BANDWIDTH BOUND
  · EVERY WEIGHT IN THE MODEL IS READ FROM MEMORY TO
    PRODUCE ONE TOKEN
  · determines TOKENS PER SECOND

THE ARITHMETIC THAT EXPLAINS EVERYTHING:

  70B model in fp16 = 140 GB of weights.
  At 2 TB/s of HBM bandwidth:
     140 / 2000 = 70 ms per token = ~14 tokens/second
  AND THE ARITHMETIC UNITS ARE ALMOST ENTIRELY IDLE.

SO EVERY INFERENCE OPTIMISATION IS AN ATTACK ON BYTES
MOVED, NOT ON FLOPS:
  · QUANTISATION - fewer bytes per weight (chapter 26)
  · BATCHING - amortise the weight read over many
    requests
  · SPECULATIVE DECODING - verify several tokens in one
    memory-bound pass
  · SMALLER MODELS
None of them make the arithmetic faster, because the
arithmetic was never the problem.
```

The KV cache

```
/* THE NAIVE LOOP RECOMPUTES EVERYTHING EVERY STEP.

   Generating token 100 re-runs attention over tokens 1..99,
   recomputing keys and values that have not changed. TOTAL
   COST IS O(n^2) FORWARD PASSES for n tokens - quadratic on
   top of attention's own quadratic.

   THE FIX: CACHE THE KEYS AND VALUES.

   Because of the causal mask (chapter 19), the K and V for
   position i NEVER CHANGE once computed. Store them. Each
   new token computes only its own Q, K, V and attends to
   the cache.

     WITHOUT CACHE   O(n) work per token, O(n^2) total
     WITH CACHE      O(1) work per token, O(n) total

   THIS IS NOT AN OPTIMISATION - IT IS THE DIFFERENCE
   BETWEEN USABLE AND UNUSABLE.                          */

    class KVCache:
        def __init__(self):
            self.k = None   # (B, n_kv_head, T, d_head)
            self.v = None

        def update(self, k_new, v_new):
            if self.k is None:
                self.k, self.v = k_new, v_new
            else:
                self.k = torch.cat([self.k, k_new], dim=2)
                self.v = torch.cat([self.v, v_new], dim=2)
            return self.k, self.v

    # in attention, during decode:
    #   q is (B, H, 1, d)  - ONE new position
    #   k, v are the FULL cache
    #   -> one row of the attention matrix, not the whole
    #      thing. And is_causal is unnecessary: there is
    #      nothing after the current position anyway.

/* --- THE COST, AND IT IS THE BINDING CONSTRAINT --- */

    per token = 2 (K and V)
              * n_layers
              * n_kv_heads
              * d_head
              * bytes_per_element

    Llama-3-8B, fp16:
        2 * 32 * 8 * 128 * 2 = 131 KB PER TOKEN
        8k context   -> 1.0 GB
        128k context -> 16 GB    <-- LARGER THAN THE MODEL

    WITHOUT GQA (32 KV heads instead of 8) that would be
    4x more. THIS IS WHY GQA EXISTS (chapter 19), and it is
    a pure inference-memory optimisation.

/* --- MANAGING IT: PAGED ATTENTION --- */
    Naively, you preallocate max_length per request and
    waste most of it. vLLM's PagedAttention borrows the
```

```
    idea from virtual memory (see the OS track): allocate
    the cache in fixed-size BLOCKS, keep a per-request
    BLOCK TABLE, and let blocks be non-contiguous.

      · near-zero internal fragmentation
      · COPY-ON-WRITE SHARING of a common prompt prefix
        across parallel samples
      · 2-4x more concurrent requests on the same hardware

    A PAGE TABLE, FOR ATTENTION. If you have read the OS
    track this will feel extremely familiar, and that is not
    a coincidence - it is the same problem.

/* --- CONTINUOUS BATCHING --- */
    Static batching waits for the longest sequence in the
    batch to finish, idling everything else. Continuous
    (in-flight) batching removes finished sequences and
    admits new ones EVERY STEP.
    Typically 2-3x higher throughput. Standard in vLLM,
    TGI, TensorRT-LLM.

/* --- PREFIX CACHING --- */
    A long system prompt shared across requests need only be
    prefilled ONCE. Cache the KV for the shared prefix and
    reuse it. Large latency win for agent and chat
    workloads, and the reason API providers charge less for
    cached input tokens.                                  */
```

Sampling

```
/* THE MODEL GIVES A DISTRIBUTION. HOW YOU DRAW FROM IT
   changes the output character completely.               */

/* --- GREEDY: always the argmax --- */
    next = logits.argmax()
    Deterministic and reproducible; frequently REPETITIVE,
    and it falls into loops ("and then, and then, and
    then"). Correct for tasks with one right answer -
    classification, extraction, structured output.

/* --- TEMPERATURE (chapter 08) --- */
    probs = softmax(logits / T)
      T -> 0    approaches greedy
      T = 0.7   a common default: coherent, some variety
      T = 1.0   the model's own calibrated distribution
      T > 1.2   creative, and increasingly incoherent

/* --- TOP-K --- */
    Keep the k highest-probability tokens, renormalise.
    k = 40 is typical.
    THE FLAW: a fixed k is wrong in both directions. When
    the model is CERTAIN, 40 candidates includes 39 bad
    ones. When it is genuinely uncertain, 40 may be too few.

/* --- TOP-P / NUCLEUS SAMPLING. THE DEFAULT. --- */
    Keep the smallest set of tokens whose cumulative
    probability exceeds p. p = 0.9 or 0.95.

    ADAPTIVE: a confident distribution yields 1-2
    candidates; a flat one yields hundreds. This is why it
    outperforms top-k, and it is what almost every API uses.

    def top_p(logits, p=0.9, T=1.0):
        logits = logits / T
        s, idx = torch.sort(logits, descending=True)
        probs = torch.softmax(s, dim=-1)
        cum = torch.cumsum(probs, dim=-1)
        # keep everything up to and including the crossing
        mask = cum - probs > p
        s[mask] = float('-inf')
        return idx[torch.multinomial(
                     torch.softmax(s, -1), 1)]

/* --- MIN-P: newer, and often better --- */
    Keep tokens with probability at least
    min_p * p_max. Scales the threshold with the model's own
    confidence, and tends to be more robust at high
    temperature.

/* --- REPETITION AND PRESENCE PENALTIES --- */
    Subtract from the logits of tokens already generated.
    Reduces loops. USE SPARINGLY: a strong penalty degrades
    text that legitimately repeats words - code, lists,
    technical writing where the same identifier recurs.

/* --- BEAM SEARCH --- */
    Keep the b highest-probability SEQUENCES rather than
    tokens.
    · better for translation and summarisation, where a
      single best output exists
```

```
    · WORSE for open-ended generation — it produces bland,
      high-probability, generic text, because the most
      probable sequence is rarely the most interesting one
    · b times the compute and b times the KV cache

/* --- STRUCTURED / CONSTRAINED DECODING --- */
    Force the output to match a grammar or JSON schema by
    MASKING INVALID TOKENS at each step — set their logits
    to -inf.

    THE OUTPUT IS THEN VALID BY CONSTRUCTION, not by hope.
    For any system that parses model output — which for an
    engineer is most of them — this is far more reliable
    than asking politely and retrying. Outlines, XGrammar
    and llama.cpp's GBNF all do this.

/* --- WHAT TO USE --- */
    factual Q&A, extraction   T=0 (greedy)
    code                      T=0.2, or greedy
    general chat              T=0.7, top_p=0.95
    creative writing          T=0.9–1.1, top_p=0.95
    anything parsed           CONSTRAINED DECODING
    reproducible tests        greedy + a fixed seed        */
```

SPECULATIVE DECODING

```
1. A SMALL DRAFT MODEL generates k tokens cheaply.
2. The BIG MODEL scores all k IN ONE FORWARD PASS.
3. Accept the longest prefix matching what the big
   model would have sampled; reject the rest.

Because decode is memory-bound, verifying k tokens costs
almost the same as generating one. Typical speedup
2–3x, and — the crucial property — THE OUTPUT
DISTRIBUTION IS MATHEMATICALLY IDENTICAL to sampling
from the big model alone. It is free.

Variants: Medusa (extra heads on the same model),
EAGLE (feature-level drafting), and n-gram lookup
(no draft model at all — just match against the
prompt, which works remarkably well for
summarisation and code editing).
```

Context length

```
/* --- WHAT LIMITS IT --- */
    1. ATTENTION IS QUADRATIC in compute (chapter 19)
    2. THE KV CACHE IS LINEAR in memory - and at long
       context it exceeds the model itself
    3. POSITIONAL ENCODING must extrapolate (chapter 21)
    4. AND TRAINING DATA: long documents are rare, so the
       model has seen few genuine long-range dependencies

/* --- HOW LONG CONTEXTS WERE ACHIEVED --- */
    · ROPE FREQUENCY SCALING (position interpolation, NTK
      scaling, YaRN) - extend an 8k model to 128k with a
      short fine-tune (chapter 21)
    · FLASH ATTENTION - removes the O(n^2) MEMORY
      (chapter 19)
    · SLIDING WINDOW attention for most layers
    · GQA and KV-cache quantisation
    · training on synthetically constructed long documents

/* --- AND THE HONEST LIMITATION: LOST IN THE MIDDLE --- */

    Retrieval accuracy across a long context is not
    uniform. Models attend well to the BEGINNING and the
    END and measurably worse to the MIDDLE:

      accuracy
        |  \                      /
        |   \                   /
        |     \_______________/
        +-----------------------------> position in context
         start        middle        end

    A 128k CONTEXT WINDOW IS NOT 128k OF RELIABLE WORKING
    MEMORY. The practical implications:
      · put the important material at the START or the END
      · RETRIEVE THE RELEVANT PARTS (chapter 17) rather than
        stuffing everything in - shorter context is usually
        MORE accurate as well as cheaper
      · and test retrieval at YOUR context length, rather
        than trusting the advertised number

/* --- COST SCALES WITH CONTEXT --- */
    prefill compute   O(n^2)
    KV cache memory   O(n)
    per-token decode  O(n) attention + O(1) weights
    So a 100k-token prompt is not 10x a 10k prompt; it is
    considerably worse for time-to-first-token, and it
    permanently occupies a large amount of cache memory for
    the whole session.

/* --- SERVING METRICS TO MEASURE --- */
    TTFT      time to first token - dominated by prefill
    TPOT      time per output token - dominated by
              bandwidth
    THROUGHPUT total tokens/second across all requests
    GOODPUT   requests meeting their latency target

    AND THE TRADE-OFF TO UNDERSTAND: LARGER BATCHES RAISE
    THROUGHPUT AND RAISE PER-REQUEST LATENCY. There is no
    setting that optimises both; pick according to whether
```

```
    you are serving an interactive product or a batch
    pipeline.                                          */
```

How it shows up

Symptom	Cause
Generation slows quadratically with length	No KV cache
Out of memory at long context	KV cache exceeds the model — quantise it, or use GQA
GPU utilisation near zero while generating	Memory bound — expected; batch or quantise
Output loops "and then, and then"	Greedy or very low temperature — add top-p
Output incoherent	Temperature too high
Code output degraded by a repetition penalty	Code legitimately repeats identifiers — reduce it
JSON output occasionally malformed	Not using constrained decoding
Facts in the middle of a long prompt ignored	Lost in the middle — retrieve instead of stuffing
Time to first token very high	Prefill is $O(n^2)$ — shorten the prompt or cache the prefix
Throughput good, latency terrible	Batch size too large for an interactive workload
Few concurrent requests fit	Static cache allocation — use paged attention
Results not reproducible	Sampling enabled, or non-deterministic kernels

Check yourself

- ✓ Distinguish prefill and decode, and say which is compute bound and which memory bound.
- ✓ Compute tokens per second for a 70B fp16 model at 2 TB/s.
- ✓ Explain why the KV cache is valid, and what it changes asymptotically.
- ✓ Compute the KV cache size per token for Llama-3-8B and at 128k context.
- ✓ Explain paged attention and name the OS concept it borrows.
- ✓ Explain continuous batching and prefix caching.
- ✓ Compare greedy, top-k, top-p and min-p, and say why top-p beats top-k.
- ✓ Say when beam search helps and when it hurts.
- ✓ Explain constrained decoding and why it beats retrying.
- ✓ Explain speculative decoding and why the output distribution is unchanged.
- ✓ Give the four limits on context length and how each was addressed.
- ✓ Explain "lost in the middle" and three practical responses.
- ✓ Name four serving metrics and the throughput/latency trade-off.

Quantisation and efficient inference

Representing weights in 8 or 4 bits instead of 16. This is fixed-point arithmetic, scale factors and dynamic range — territory an embedded engineer already knows, applied to a new problem.

Why it works

```
THE MOTIVATION IS BANDWIDTH, NOT ARITHMETIC
(chapters 04, 25).

  70B model in fp16   140 GB   -> ~14 tokens/s at
                                  2 TB/s
  the same in int8     70 GB   -> ~28 tokens/s
  the same in int4     35 GB   -> ~56 tokens/s

THE SPEEDUP IS PROPORTIONAL TO THE BYTE REDUCTION,
because generation reads every weight once per token and
the multipliers are idle anyway. It also determines
whether the model FITS AT ALL - which for a device is
usually the real question.

AND WHY IT DOES NOT DESTROY THE MODEL:

  · WEIGHTS ARE ROUGHLY GAUSSIAN and tightly clustered
    around zero. A well-chosen scale covers the range
    with little error.
  · NEURAL NETWORKS ARE ROBUST TO NOISE. They were
    trained with dropout, augmentation and stochastic
    gradients; small perturbations to weights behave
    like more of the same.
  · THE ERROR AVERAGES OUT. A dot product over 4096
    terms sums many independent rounding errors, which
    partially cancel (chapter 08).
  · AND THE INFORMATION IS REDUNDANT. Superposition
    (chapter 17) means features are spread across many
    weights, so no single weight is critical.

THE FORMATS, and note what varies:

  FORMAT   BITS   RANGE           WHERE USED
  fp32       32   +-3.4e38        training master
                                  weights
  fp16       16   +-65504         older training, some
                                  inference
  bf16       16   +-3.4e38        MODERN TRAINING -
                                  fp32's range, fewer
                                  mantissa bits, so NO
                                  LOSS SCALING NEEDED
  fp8         8   two variants    newest accelerators
                  (E4M3, E5M2)
  int8        8   -128..127       THE EMBEDDED WORKHORSE
  int4        4   -8..7           LLM weights
  int2/
  ternary   2-1.6 {-1,0,1}        research, and
                                  BitNet-style models

THE PATTERN: FEWER BITS MEANS LESS RANGE OR LESS
PRECISION, AND THE SCALE FACTOR IS WHAT BUYS THE RANGE
BACK.
```

The arithmetic

```
/* --- THE BASIC MAPPING --- */

    QUANTISE:    q = round(x / scale) + zero_point
    DEQUANTISE:  x = (q - zero_point) * scale

/* SYMMETRIC (zero_point = 0): */
    scale = max(|x|) / 127                # int8
    q     = clamp(round(x / scale), -128, 127)

    Simpler and faster - no zero-point term in the inner
    loop. USE FOR WEIGHTS, which are roughly symmetric
    about zero.

/* ASYMMETRIC: */
    scale = (max - min) / 255
    zero_point = round(-min / scale)

    Uses the full range for skewed distributions. USE FOR
    ACTIVATIONS after ReLU, which are all non-negative -
    symmetric quantisation would waste half the codes.

/* --- WHY THE ACCUMULATOR IS WIDER (chapter 02) --- */
    int8 * int8 -> up to 16 bits, and summing 4096 of them
    needs ~28 bits. So hardware accumulates int8 x int8 into
    INT32, then rescales once at the end:

        acc = 0                           # int32
        for i: acc += a_q[i] * b_q[i]     # int8 x int8
        out = acc * (scale_a * scale_b)   # ONE rescale

    THE SCALES FACTOR OUT OF THE SUM. That is the whole
    trick that makes quantised matmul exact-ish and fast:
    the inner loop is pure integer MAC, and the floating
    point appears once.

/* --- GRANULARITY: the single most important choice --- */
    PER-TENSOR    one scale for the entire weight matrix.
                  Simplest, worst accuracy.
    PER-CHANNEL   one scale per output channel/row. MUCH
                  better, negligible extra cost.
    PER-GROUP     one scale per group of 32-128 weights
                  ALONG a row. What int4 LLM quantisation
                  uses.
                  Costs ~0.5 bits/weight in scale overhead
                  and is worth every bit of it.

    A SINGLE OUTLIER WEIGHT FORCES A LARGE SCALE, which
    coarsens every other weight sharing it. Finer groups
    contain the damage. THIS IS THE ENTIRE REASON GROUPED
    QUANTISATION EXISTS.

/* --- THE OUTLIER PROBLEM IN ACTIVATIONS --- */
    Transformer activations contain a small number of
    dimensions with values 10-100x larger than the rest,
    consistently in the same channels. Quantising naively
    destroys everything else.

    THE SOLUTIONS:
      LLM.int8()   keep the outlier dimensions in fp16, the
                   rest in int8. A mixed-precision matmul.
```

```
      SMOOTHQUANT  MIGRATE the difficulty from activations
                   into weights by scaling:
                       Y = (X / s) @ (s * W)
                   mathematically identical, and the
                   scaling is folded into the previous
                   layer's weights so it is free at
                   runtime. Weights are much easier to
                   quantise than activations, so this is a
                   genuinely elegant fix.
      AWQ          identify the ~1% of weight channels that
                   matter most (by activation magnitude) and
                   protect them with per-channel scaling.  */
```

The methods

```
/* --- PTQ: POST-TRAINING QUANTISATION --- */
    Quantise an already-trained model. No retraining.

    DYNAMIC   weights quantised offline, activations
              quantised at runtime from their observed
              range. Easy, no calibration data, some
              runtime cost.
    STATIC    activation ranges determined in advance from
              a CALIBRATION SET of a few hundred
              representative samples. Faster at runtime.
              THE CALIBRATION DATA MUST RESEMBLE PRODUCTION
              DATA, or the ranges are wrong.

    THE MODERN LLM METHODS:
      GPTQ    layer-by-layer, using second-order information
              to choose roundings that minimise the output
              error. int4 with small degradation.
      AWQ     activation-aware; protects salient channels.
              Fast, and generally excellent at int4.
      GGUF /  llama.cpp's family (Q4_K_M, Q5_K_M, Q8_0...).
      K-QUANTS Mixed precision per tensor type - attention
              and the output layer get more bits. THE
              PRACTICAL DEFAULT FOR RUNNING MODELS LOCALLY.
      HQQ,
      SqueezeLLM, and a steady stream of others

/* --- QAT: QUANTISATION-AWARE TRAINING --- */
    Simulate quantisation DURING training so the model
    learns weights that survive it.

      forward:  x_q = dequant(quant(x))   # "fake quant"
      backward: STRAIGHT-THROUGH ESTIMATOR - pass the
                gradient through as if quantisation were
                the identity, because round() has zero
                gradient everywhere (chapter 07)

    · better accuracy than PTQ, especially below 8 bits
    · needs training infrastructure and data
    · ESSENTIAL FOR VERY SMALL MODELS on MCUs, where PTQ
      at int8 can lose several percent of accuracy that QAT
      recovers

/* --- WHAT ACCURACY ACTUALLY COSTS (large models) --- */
    fp16      baseline
    int8      essentially lossless with per-channel scales
    int4 GPTQ/AWQ    perplexity +1-3%; usually
                     imperceptible in use
    int3      noticeable degradation
    int2      substantial, though active research
              continues

    AND THE RULE THAT MATTERS FOR CHOOSING:
      A 4-BIT 70B MODEL BEATS AN 8-BIT 34B MODEL AT THE SAME
      MEMORY BUDGET. Given a fixed number of gigabytes,
      prefer a larger model more aggressively quantised -
      up to about 4 bits, below which the relationship
      inverts.

/* --- THE CODE --- */
    # llama.cpp - the practical local path
```

```
#   python convert_hf_to_gguf.py ./model
#   ./llama-quantize model.gguf out.gguf Q4_K_M

# PyTorch dynamic PTQ, for a small model
import torch.ao.quantization as q
qmodel = q.quantize_dynamic(
    model, {torch.nn.Linear}, dtype=torch.qint8)

# bitsandbytes, at load time
from transformers import BitsAndBytesConfig
cfg = BitsAndBytesConfig(
    load_in_4bit=True,
    bnb_4bit_compute_dtype=torch.bfloat16,
    bnb_4bit_quant_type="nf4",     # normal-float 4,
                                   # matched to a
                                   # Gaussian weight
                                   # distribution
    bnb_4bit_use_double_quant=True)  # quantise the
                                     # scales too
model = AutoModelForCausalLM.from_pretrained(
            name, quantization_config=cfg)

# AND THIS IS WHAT QLoRA USES (chapter 24): a 4-bit
# frozen base plus bf16 adapters.
```

QUANTISE THE KV CACHE TOO

At long context the KV cache exceeds the model itself (chapter 25). Quantising it to int8 halves that, and to int4 quarters it. Keys tolerate quantisation less well than values — keys feed a dot product whose result goes through a softmax, so errors are amplified — so a common configuration is int8 keys with int4 values. For long-context serving this is often a larger win than quantising the weights.

The other compression techniques

```
/* --- PRUNING --- */
    UNSTRUCTURED   zero individual weights. High sparsity
                   achievable (50-90%), and NO SPEEDUP on
                   normal hardware, because the memory
                   access pattern is destroyed (chapter 03).
    STRUCTURED     remove whole channels, heads
                   (chapter 21), or layers. Lower achievable
                   sparsity, REAL SPEEDUP - the matrices are
                   genuinely smaller.
    2:4 SEMI-      exactly 2 of every 4 weights zero.
    STRUCTURED     Supported in hardware by recent NVIDIA
                   parts for a ~2x gain. The compromise that
                   actually ships.

    THE LESSON, which generalises far beyond this: SPARSITY
    ONLY HELPS IF THE HARDWARE CAN EXPLOIT ITS PATTERN.

/* --- DISTILLATION --- */
    Train a small STUDENT to match a large TEACHER.

      L = alpha * CE(student, hard_labels)
        + (1-alpha) * T^2 * KL(student_soft || teacher_soft)

    THE SOFT TARGETS CARRY MORE INFORMATION than the labels:
    a teacher saying "80% cat, 15% dog, 5% fox" tells the
    student about the similarity structure, which a one-hot
    label cannot. This is called DARK KNOWLEDGE, and it is
    why distillation beats training the small model
    directly.

    (The T^2 factor compensates for the gradients shrinking
    as 1/T^2 when the logits are softened.)

    DistilBERT: 40% smaller, 60% faster, 97% of the
    performance. And most good small models today are
    distilled from larger ones - which is why the small-model
    frontier moves whenever the large-model frontier does.

/* --- ARCHITECTURE-LEVEL CHOICES --- */
    · GQA / MQA           smaller KV cache (chapter 19)
    · sliding-window attention
    · fewer, wider layers - better for parallel hardware
    · WEIGHT SHARING across layers (ALBERT-style) - large
      memory saving, some quality cost
    · and simply TRAINING A SMALL MODEL LONGER
      (chapter 23), which is now the mainstream answer

/* --- COMPILATION AND KERNELS --- */
    torch.compile, TensorRT, ONNX Runtime, OpenVINO,
    TVM, ExecuTorch.

    WHAT THEY ACTUALLY DO - and it will be familiar from any
    embedded optimisation work:
      · OPERATOR FUSION: LayerNorm + Linear + GELU as one
        kernel, so intermediates never leave registers or
        SRAM. This is the single biggest win, and it is a
        MEMORY TRAFFIC optimisation.
      · constant folding
      · memory planning and buffer reuse
      · selecting the best kernel per shape
```

```
      · removing framework overhead entirely

    2–5x SPEEDUP FOR NO ACCURACY LOSS is typical, and it
    should be the FIRST thing you try – before quantising,
    before pruning, before anything that costs accuracy. */
```

How it shows up

Symptom	Cause
int8 model loses several percent accuracy	Per-tensor scales — switch to per-channel
Accuracy collapses despite per-channel scales	Activation outliers — use SmoothQuant or LLM.int8()
Quantised model fine in tests, poor in production	Calibration data unrepresentative
int4 output is incoherent	Group size too large, or a naive round-to-nearest method
Quantisation gives no speedup	Compute bound, not memory bound — check the phase
Overflow in a quantised matmul	Accumulator too narrow — int8 needs int32
Pruning to 70% sparsity gives no speedup	Unstructured — hardware cannot exploit it
Long-context serving still runs out of memory	KV cache not quantised
Distilled student worse than expected	Temperature too low — soft targets carry the signal
QAT gradients are always zero	Straight-through estimator missing — `round()` has no gradient
Small model on MCU loses accuracy at int8	PTQ is not enough at that size — use QAT

Check yourself

- ✓ Explain why quantisation speeds up generation, in terms of bytes not FLOPs.
- ✓ Give four reasons neural networks tolerate quantisation.
- ✓ Write the quantise and dequantise formulas, and say when to use symmetric versus asymmetric.
- ✓ Explain why the accumulator is int32 and how the scales factor out.
- ✓ Compare per-tensor, per-channel and per-group granularity, and say why outliers force finer groups.
- ✓ Explain the activation outlier problem and how SmoothQuant fixes it.
- ✓ Contrast PTQ and QAT, and explain the straight-through estimator.
- ✓ State the rule for choosing model size against bit width at a fixed memory budget.
- ✓ Say why keys tolerate KV-cache quantisation worse than values.
- ✓ Explain why unstructured pruning gives no speedup and what 2:4 sparsity is.
- ✓ Explain dark knowledge and the T^2 factor in distillation.
- ✓ Say what operator fusion does and why it should be tried first.

Running models on embedded hardware

The chapter this whole track was heading toward. Everything above, constrained by 256 KB of SRAM, a battery, no operating system, and a part that has to cost three dollars.

Know which tier you are in

```
"EDGE AI" SPANS FOUR ORDERS OF MAGNITUDE. The right
answer depends entirely on which tier you are in, and
conflating them is the most common mistake.

TIER 1 - MCU CLASS      Cortex-M0/M4/M33, RISC-V
  RAM      16 KB - 1 MB
  flash    64 KB - 2 MB
  clock    16-400 MHz, often no FPU
  power    mW, battery for months or years
  RUNS     keyword spotting, anomaly detection,
           gesture recognition, simple vision
  MODELS   1 KB - 500 KB, int8, often QAT
  STACK    TFLite Micro, CMSIS-NN, microTVM,
           ExecuTorch, or hand-written C

TIER 2 - MCU + NPU      Cortex-M55 + Ethos-U55/U85,
                        ESP32-S3, nRF54, Kendryte
  +        1-512 GOPS of int8 accelerator
  RUNS     real-time vision at low frame rates, speech
  MODELS   up to a few MB
  STACK    Vela compiler (Ethos), vendor toolchains

TIER 3 - APPLICATION PROCESSOR CLASS
                        i.MX8, Jetson Orin Nano, RK3588,
                        Raspberry Pi 5, phones
  RAM      1-32 GB, running Linux or Android
  NPU      1-100 TOPS
  RUNS     full vision pipelines, speech, AND SMALL
           LANGUAGE MODELS (1-8B, quantised)
  STACK    ONNX Runtime, TensorRT, OpenVINO, llama.cpp,
           NPU vendor SDKs

TIER 4 - EDGE SERVER    a GPU in a cabinet
  Essentially datacentre inference with a latency and
  privacy requirement. Chapter 25 applies unchanged.

THE QUESTION THAT DECIDES EVERYTHING:

  DOES THE MODEL'S WORKING SET FIT IN THE MEMORY YOU
  HAVE?

Not the parameter count - THE WORKING SET: weights plus
the largest activation buffer plus the framework's
arena. On an MCU this is the binding constraint, before
accuracy, before speed, before anything.
```

The memory budget

```
/* --- WHAT MUST FIT --- */

    FLASH (persistent)
      model weights (int8: 1 byte per parameter)
      the inference runtime      20-100 KB
      your application

    RAM (working)
      the TENSOR ARENA: the largest set of activation
        buffers live at once
      framework state
      your application's stack and heap

/* THE ARENA IS THE ONE PEOPLE GET WRONG. It is NOT the sum
   of all activations - a good runtime reuses buffers, so it
   is the peak of a liveness analysis, exactly like register
   allocation in a compiler (see the compilers track).

    For a small CNN it is typically driven by ONE layer -
    usually an early one, where the spatial dimensions are
    still large:

      a 96x96x3 input with 16 channels after the first conv
        = 96*96*16 = 147 KB in int8
      ALREADY TOO BIG for many parts, before any further
      layers.

    THE FIXES: a smaller input resolution, striding early,
    and depthwise separable convolutions.

/* --- A WORKED EXAMPLE: KEYWORD SPOTTING --- */
    Target: Cortex-M4, 256 KB flash, 64 KB RAM.

      input        49 x 10 MFCC features from 1 second of
                   audio
      model        DS-CNN, 4 depthwise separable blocks
      parameters   ~24k -> 24 KB in int8
      arena        ~21 KB
      runtime      ~45 KB flash (TFLM + CMSIS-NN)
      inference    ~10 ms at 80 MHz
      accuracy     ~95% on 12 keywords
      energy       runs continuously on a coin cell for
                   months with duty cycling

    THAT FITS COMFORTABLY, and it is a real, shipping class
    of product.

/* --- AND THE ONE THAT DOES NOT --- */
    A 1B-parameter language model at int4 = 500 MB.
    NOT ON AN MCU. NOT WITH ANY AMOUNT OF CLEVERNESS.
    That is Tier 3, and being clear about it early saves
    months.

/* --- THE ARITHMETIC TO DO FIRST, BEFORE ANY WORK --- */
    weights_bytes  = params * bytes_per_param
    arena_bytes    = peak concurrent activations
    flash_needed   = weights + runtime + application
    ram_needed     = arena + stack + heap

    inference_time ~= MACs / (MACs_per_cycle * clock_hz)
```

```
    Cortex-M4 with CMSIS-NN: ~1-2 int8 MACs/cycle
    Cortex-M55 + Ethos-U55:  hundreds to thousands
    -> a 5 MMAC model on an M4 at 80 MHz is ~60 ms;
       on an M55+U55 it is under a millisecond.

  energy_per_inference = time * average_current * voltage
    AND FOR A BATTERY DEVICE, COMPUTE THIS EARLY. It
    frequently rules out an architecture that would
    otherwise fit.                                    */
```

The stacks

```
/* --- TFLITE MICRO: the MCU standard --- */
    No dynamic allocation, no OS, no file system. You supply
    a static arena and it plans everything inside it.

    #include "tensorflow/lite/micro/micro_interpreter.h"

    // the model as a C array, in flash
    extern const unsigned char g_model[];

    constexpr int kArenaSize = 32 * 1024;
    alignas(16) static uint8_t tensor_arena[kArenaSize];

    void setup() {
        const tflite::Model* model =
            tflite::GetModel(g_model);

        // ONLY the operators you actually use - each one
        // linked in costs flash
        static tflite::MicroMutableOpResolver<6> resolver;
        resolver.AddConv2D();
        resolver.AddDepthwiseConv2D();
        resolver.AddFullyConnected();
        resolver.AddSoftmax();
        resolver.AddReshape();
        resolver.AddMaxPool2D();

        static tflite::MicroInterpreter interpreter(
            model, resolver, tensor_arena, kArenaSize);
        interpreter.AllocateTensors();
        // ^ FAILS HERE if the arena is too small, and the
        //   error tells you the required size. Start large,
        //   then shrink to fit.
    }

    void loop(void) {
        TfLiteTensor* in = interpreter.input(0);
        // QUANTISE YOUR INPUT WITH THE MODEL'S OWN
        // PARAMETERS - not with values you guessed
        for (int i = 0; i < n; i++)
            in->data.int8[i] =
                (int8_t)(raw[i] / in->params.scale
                         + in->params.zero_point);

        if (interpreter.Invoke() != kTfLiteOk) return;

        TfLiteTensor* out = interpreter.output(0);
        float score = (out->data.int8[0]
                       - out->params.zero_point)
                      * out->params.scale;
    }

/* --- CMSIS-NN --- */
    ARM's hand-optimised kernels for Cortex-M. 4-5x faster
    than reference C, using SIMD (SMLAD), DSP instructions
    and Helium (MVE) on M55.
    TFLM uses it automatically when built for Cortex-M -
    verify it actually is, because the reference kernels are
    the silent fallback and the difference is enormous.

/* --- ETHOS-U AND THE VELA COMPILER --- */
```

```
    vela model_int8.tflite --accelerator-config ethos-u55-128

    Vela AHEAD-OF-TIME compiles the graph into NPU command
    streams. Operators the NPU cannot handle FALL BACK TO THE
    CPU, and every fallback costs a round trip through
    memory.

    READ VELA'S REPORT. It tells you exactly which
    operations ran where. A model that is 90% NPU-resident
    is fast; one that ping-pongs is often SLOWER than pure
    CPU. CHECKING THIS IS THE SINGLE HIGHEST-VALUE
    OPTIMISATION STEP on an NPU target.

/* --- THE OTHERS --- */
    ExecuTorch   PyTorch's edge runtime. Growing quickly.
    microTVM     compile-based, aggressive
                 auto-scheduling
    ONNX Runtime Tier 3, with vendor execution providers
    llama.cpp    Tier 3 language models. GGUF, extremely
                 portable, runs on a Raspberry Pi
    OpenVINO     Intel-based edge
    TensorRT     NVIDIA Jetson
    Vendor SDKs  Qualcomm QNN, Rockchip RKNN, Hailo,
                 Ambarella - usually the fastest path on
                 their own silicon, and the least
                 portable                                */
```

DESIGN FOR THE TARGET FROM THE START

Do not train a model and then ask whether it fits. Pick the hardware, compute the budget, choose an architecture that fits with margin, and quantise *during* training if you are anywhere near the limit. Retrofitting a model into a device that cannot hold it is the most common and most expensive failure in embedded machine learning — and the second most common is discovering at integration time that the preprocessing, not the model, is what does not fit.

Architectures that fit

```
/* --- DEPTHWISE SEPARABLE CONVOLUTION --- */
    Split a standard convolution into two cheaper steps:
      DEPTHWISE   one k x k filter PER INPUT CHANNEL
      POINTWISE   a 1x1 convolution mixing channels

    COST:  standard   k*k * C_in * C_out
           separable  k*k * C_in  +  C_in * C_out

    For k=3, C_in=C_out=64:  36,864 -> 4,672. 8x FEWER.

    THIS IS THE SINGLE MOST IMPORTANT ARCHITECTURAL IDEA IN
    EMBEDDED VISION, and it underlies MobileNet,
    EfficientNet-Lite and essentially every model that runs
    on a microcontroller.

/* --- THE MODEL FAMILIES WORTH KNOWING --- */
    VISION       MobileNetV2/V3, EfficientNet-Lite,
                 MCUNet, NanoDet, YOLO-Nano
    AUDIO        DS-CNN, TC-ResNet for keyword spotting
    TIME SERIES  small 1-D CNNs, or a GRU (chapter 18) -
                 constant memory, which for a continuous
                 stream is decisive
    ANOMALY      an autoencoder: reconstruct the input and
                 threshold the error. NO LABELS NEEDED,
                 which matters because you usually have no
                 examples of the fault you are looking for.
    LANGUAGE     Tier 3 only. Qwen 0.5B, Gemma 3 270M/1B,
                 Llama 3.2 1B, SmolLM, Phi - all at int4

/* --- THE TECHNIQUES, IN THE ORDER TO APPLY THEM --- */
  1. REDUCE THE INPUT. 96x96 instead of 224x224 is 5.4x less
     work AND a much smaller arena. Usually the biggest
     single win, and usually the first thing to try.
  2. QUANTISE to int8, with QAT if accuracy matters
     (chapter 26).
  3. USE A MOBILE-CLASS ARCHITECTURE rather than shrinking
     a large one.
  4. PRUNE STRUCTURALLY - whole channels (chapter 26).
  5. DISTIL from a larger model.
  6. NEURAL ARCHITECTURE SEARCH under explicit hardware
     constraints, if the volume justifies it (MCUNet does
     exactly this).

/* --- AND THE ONE PEOPLE FORGET: PREPROCESSING --- */
    An MFCC pipeline needs an FFT, mel filterbanks and a
    DCT. Image preprocessing needs resize, colour conversion
    and normalisation.

    THIS CAN COST MORE THAN THE MODEL, and it needs its own
    buffers in the same RAM. Budget it explicitly. CMSIS-DSP
    provides fixed-point FFT and filter functions; use them
    rather than pulling in a float pipeline.               */
```

Getting it into a product

```
/* --- THE WORKFLOW --- */
    1. define the task, the METRIC, and the acceptable
       error rate (chapter 12)
    2. COLLECT DATA ON THE TARGET HARDWARE, with the
       production sensor. Data from a different microphone,
       a different lens, or a development board with a
       different ground plane WILL NOT TRANSFER.
    3. train on a workstation, in PyTorch or TensorFlow
    4. quantise, ideally with QAT
    5. convert and compile for the target
    6. VALIDATE ON DEVICE - accuracy AND latency AND
       memory AND power
    7. integrate, with a fallback path
    8. monitor in the field

/* --- STEP 6 IS WHERE PROJECTS FAIL --- */
    Accuracy measured on a workstation with float inputs is
    NOT the accuracy you will get. The differences:
      · int8 quantisation error
      · a different preprocessing implementation - a
        fixed-point FFT is not bit-identical to numpy's
      · real sensor noise, DC offset, gain drift, and
        temperature effects
      · timing jitter and dropped samples

    ALWAYS MEASURE END-TO-END ON THE ACTUAL DEVICE, from
    sensor to decision. A test harness that replays recorded
    raw sensor data through the real firmware path is worth
    building early.

/* --- THE ENGINEERING CONCERNS --- */

    DETERMINISM       fixed-size arena, no dynamic
                      allocation, bounded worst-case
                      inference time. If the model runs in
                      a control loop, its WCET is a
                      real-time constraint like any other
                      (see the OS track).
    POWER             duty cycle. A cheap always-on
                      detector (an analogue threshold, or a
                      tiny first-stage model) that WAKES the
                      real model is the standard cascade,
                      and it is often a 100x energy saving.
    UPDATES           the model is data. Ship it as a
                      SIGNED, VERSIONED blob through your
                      normal firmware update path - and
                      verify the signature before loading
                      it, exactly as for firmware
                      (the cryptography track). A model file
                      loaded without verification is
                      arbitrary code's worth of influence
                      over your device's behaviour.
    SAFETY            never let a model make an unbounded
                      safety-critical decision alone. Bound
                      its authority, add a deterministic
                      supervisor, and define the behaviour
                      when it is uncertain.
    OBSERVABILITY     log inputs that produce low-confidence
                      or unusual outputs, if you can do so
                      privately. Field data is how the next
```

```
                    version gets better - and drift
                    (chapter 12) is invisible without it.
    PRIVACY         and the strongest argument for on-
                    device inference: THE DATA NEVER
                    LEAVES. For audio, video and health
                    sensing that is not a nice-to-have,
                    it is often the whole reason the
                    product is viable.                */
```

How it shows up

Symptom	Cause
`AllocateTensors` fails	Arena too small — the error reports the size needed
Model fits in flash but crashes at runtime	Arena plus stack exceeds RAM
Inference 5× slower than expected	Reference kernels instead of CMSIS-NN
NPU target slower than CPU	Operator fallbacks ping-ponging — read the Vela report
Accuracy far below the workstation figure	Preprocessing mismatch, or PTQ where QAT was needed
Works on the dev board, fails in the product	Different sensor — collect data on the target hardware
Battery life far below the estimate	No duty cycling — always-on inference
Occasional missed deadline in a control loop	Unbounded inference time — measure WCET
Preprocessing does not fit	FFT buffers not budgeted alongside the arena
Field accuracy degrades over months	Distribution drift with no monitoring
Someone loaded a modified model file	Model blob not signature-verified

Check yourself

- ✓ Describe the four edge tiers and what each can realistically run.
- ✓ Explain what a tensor arena is and why it is not the sum of activations.
- ✓ Compute the memory budget for a keyword-spotting model on a 64 KB part.
- ✓ Estimate inference time from MAC count and MACs per cycle.
- ✓ Write the TFLite Micro setup, including why the op resolver is explicit.
- ✓ Explain how to quantise an input using the model's own scale and zero point.
- ✓ Say what Vela does and why operator fallbacks matter so much.
- ✓ Derive the cost saving of depthwise separable convolution.
- ✓ List the six size-reduction techniques in the order to apply them.
- ✓ Explain why preprocessing must be budgeted explicitly.
- ✓ Give five reasons on-device accuracy differs from workstation accuracy.
- ✓ Name six engineering concerns for shipping a model, including update signing.

Project: a tiny transformer from scratch

Build, train and run a character-level language model end to end. Every line traces back to a chapter in this track, it runs on a laptop CPU in minutes, and at the end you export it to C and run it on a microcontroller.

What you will build

```
PART A   a character tokeniser              (chapter 16)
PART B   the model, in PyTorch          (chapters 19–22)
PART C   the training loop              (chapters 10, 11)
PART D   sampling and generation            (chapter 25)
PART E   quantise to int8 and export to C
                                       (chapters 26, 27)

TARGET: a model that learns the structure of a text
corpus well enough to produce recognisable output.

THE SPECIFICATION:
  vocabulary      ~65 characters
  d_model         128
  layers          4
  heads           4
  context         128 characters
  parameters      ~800k
  training        ~10 minutes on a laptop CPU,
                  ~30 seconds on any GPU
  int8 export     ~800 KB

THAT LAST NUMBER MATTERS: 800 KB does not fit on a
Cortex-M4 (chapter 27). Part E shrinks it to a version
that does, and the exercise of finding out WHY is more
instructive than being handed a model that already fits.

PREREQUISITES:
  pip install torch numpy

THE DATA: any plain text file of a megabyte or more.
The classic choice is the concatenated works of
Shakespeare (input.txt, ~1.1 MB, widely available), but
USE SOMETHING YOU KNOW WELL — your own logs, a codebase,
a protocol dump. You will judge the output by whether it
looks right, and that requires knowing what right looks
like.
```

Part A — data and tokenisation

```
# ============ prepare.py ============
import torch

text = open('input.txt', 'r', encoding='utf-8').read()
print(f"{len(text):,} characters")

# CHARACTER-LEVEL TOKENISATION (chapter 16).
# No BPE, no merge list, no vocabulary file - just the set
# of characters that occur. Small vocabulary, long
# sequences, and nothing to get wrong.
chars = sorted(set(text))
vocab_size = len(chars)
print(f"vocab: {vocab_size} -> {''.join(chars)}")

stoi = {ch: i for i, ch in enumerate(chars)}
itos = {i: ch for i, ch in enumerate(chars)}
encode = lambda s: [stoi[c] for c in s]
decode = lambda l: ''.join(itos[i] for i in l)

data = torch.tensor(encode(text), dtype=torch.long)

# TRAIN/VALIDATION SPLIT (chapter 12).
# NOTE: split by POSITION, not randomly - this is sequential
# data, and shuffling would let the model see continuations
# of its own training text.
n = int(0.9 * len(data))
train_data, val_data = data[:n], data[n:]

BLOCK = 128        # context length
BATCH = 32

def get_batch(split):
    d = train_data if split == 'train' else val_data
    # random starting offsets, and stack into a batch
    ix = torch.randint(len(d) - BLOCK - 1, (BATCH,))
    x = torch.stack([d[i:i+BLOCK]     for i in ix])
    y = torch.stack([d[i+1:i+BLOCK+1] for i in ix])
    #                  ^^^ SHIFTED BY ONE. That is the
    #                  entire supervision signal
    #                  (chapter 23).
    return x, y

xb, yb = get_batch('train')
print(xb.shape, yb.shape)     # (32, 128) (32, 128)
print(repr(decode(xb[0][:40].tolist())))
print(repr(decode(yb[0][:40].tolist())))
# The second is the first, shifted left by one character.
```

Part B — the model

```
# ============ model.py ============
import math
import torch
import torch.nn as nn
import torch.nn.functional as F

class Config:
    vocab_size = 65

# ---- AND THE C INFERENCE KERNEL ----
/*
 * The one function that matters. Everything else in a
 * transformer is bookkeeping around this (chapter 04).
```

```
 */
void qmatmul(float *out, const float *in,
             const int8_t *W, const float *scale,
             int n_out, int n_in)
{
    for (int o = 0; o < n_out; o++) {
        int32_t acc = 0;            /* WIDE ACCUMULATOR
                                       (chapter 26) */
        const int8_t *row = &W[o * n_in];
        for (int i = 0; i < n_in; i++)
            acc += (int32_t)row[i] * (int32_t)in[i];
        out[o] = (float)acc * scale[o];   /* ONE rescale */
    }
}
/*
 * NOTE: this takes float `in` and multiplies by int8 - a
 * simplification. A fully-integer pipeline quantises the
 * activations too, and the scales multiply
 * (chapter 26). Exercise 8 is to make it fully integer.
 *
 * ON A CORTEX-M4, replace the inner loop with CMSIS-NN's
 * arm_nn_mat_mult_nt_t_s8 and it gets 4-5x faster via SMLAD
 * (chapter 27).
 */
```

WHAT THE EXPORT TELLS YOU

```
800k parameters at int8  ~= 800 KB
plus the activation arena, plus the runtime.

THAT DOES NOT FIT ON A CORTEX-M4 (chapter 27).

To fit in 256 KB of flash:
  d_model 128 -> 64      (4x fewer parameters:
                          they scale as d²)
  layers  4   -> 3
  vocab   65  -> 65      (unchanged; already small)
  -> ~150k parameters, ~150 KB int8. FITS.

Retrain at that size and compare the samples. The
quality drop is real and visible - and measuring it
yourself is worth more than any table of numbers.
```

Exercises

```
/* IN ROUGHLY INCREASING DIFFICULTY. Each one exercises a
   specific chapter.                                      */

  1. WATCH IT LEARN. Sample every 500 steps and save the
     output. Plot the loss curve. (chapters 11, 25)

  2. SCALING LAWS AT SMALL SCALE. Train d_model in
     {32,64,128,256} at fixed steps and plot final loss
     against parameter count on log-log axes. YOU SHOULD SEE
     A STRAIGHT LINE. (chapter 23)

  3. BREAK IT DELIBERATELY, one at a time, and predict the
     symptom before you run it:
       · remove the positional embedding      (ch. 21)
       · remove `is_causal=True`              (ch. 19)
       · remove the residual connections      (ch. 22)
       · use post-norm instead of pre-norm    (ch. 22)
       · remove the 1/sqrt(d_k) scaling - implement
         attention by hand to do this         (ch. 19)
       · set the learning rate to 1e-1        (ch. 11)
     THIS IS THE MOST INSTRUCTIVE EXERCISE HERE.

  4. ADD A KV CACHE to generate(). Measure tokens/second
     before and after at 128 context. (chapter 25)

  5. SWAP LEARNED POSITIONS FOR ROPE. Then generate BEYOND
     block_size and see whether it degrades gracefully.
     (chapter 21)

  6. REPLACE THE MLP WITH SwiGLU, keeping the parameter
     count equal by setting hidden = 8/3 * d_model.
     (chapter 22)

  7. TRAIN A BPE TOKENISER on the same corpus (chapter 16's
     code), retrain, and compare BITS PER BYTE - not
     perplexity, which is not comparable across tokenisers.
     (chapters 10, 16)

  8. FULLY-INTEGER INFERENCE in C: quantise the activations
     too, so no float appears in the inner loop. Compare
     output against the PyTorch model on the same prompt.
     (chapter 26)

  9. RUN IT ON HARDWARE. Shrink to fit, export, and run on
     a Raspberry Pi Pico or any Cortex-M4 board. Measure
     inference time, flash usage and peak RAM.
     (chapter 27)

 10. FINE-TUNE IT. Train on Shakespeare, then continue
     training on a different corpus with a low learning
     rate. Observe CATASTROPHIC FORGETTING directly.
     (chapter 24)

 11. IMPLEMENT LoRA on the attention projections and
     fine-tune with the base frozen. Compare the forgetting
     against exercise 10. (chapter 24)

 12. CONSTRAINED DECODING: force the output to match a
     simple grammar - balanced brackets, or a fixed
     line format - by masking invalid tokens.
```

```
     (chapter 25)

/* --- WHERE TO GO NEXT --- */
    · nanoGPT (Karpathy) - the same design, production
      quality, and the reference this project follows
    · llm.c - GPT-2 training in plain C/CUDA. Read it after
      exercise 8.
    · llama.cpp - study the quantisation formats
      (chapter 26) and the GGUF layout
    · TFLite Micro examples - the keyword-spotting model
      from chapter 27, complete
    · and the papers: "Attention Is All You Need",
      "Language Models are Few-Shot Learners",
      "Training Compute-Optimal Large Language Models",
      "LoRA", "FlashAttention". You now have the background
      to read all of them.                              */
```

How it shows up

Symptom	Cause
Step-0 loss is not `log(vocab_size)`	A bug in the model, data or loss — fix before training
Loss drops below 0.5 quickly	Causal mask missing — the model is reading the answer
Loss flat at 4.17	Gradients not flowing — check `zero_grad` and the optimiser's parameters
Loss becomes `nan`	Learning rate too high, or warmup skipped
Validation loss rises while training falls	Overfitting — the corpus is too small for the model
Output is one character repeated	Temperature too low, or undertrained
Output is pure noise at 5000 steps	Positional embedding missing, or a shape bug
Generation crashes past 128 tokens	Context not cropped to `block_size`
C output differs from PyTorch	Quantisation applied per-tensor, or scales indexed wrongly
Exported model too large for the target	Parameters scale as `d_model²` — halve it
C inner loop overflows	Accumulator not int32

Check yourself

- ✓ Explain why the train/validation split is by position rather than random.
- ✓ Show that `y` is `x` shifted by one and say why that is the whole supervision signal.
- ✓ Explain each line of the `SelfAttention` forward pass, with shapes.
- ✓ Say what the residual-projection initialisation scaling does.
- ✓ Explain why `generate` crops the context.
- ✓ Predict the step-0 loss and explain the calculation.
- ✓ Describe the order in which the model learns structure.
- ✓ Explain the effect of temperature at 0.2, 0.8 and 1.5.
- ✓ Explain per-channel quantisation and why the accumulator is int32.
- ✓ Compute how to shrink the model to fit 256 KB, and why `d_model` is the lever.
- ✓ Do exercise 3 and predict every symptom before running it.

TRACK

DSA interview prep

Pattern-based data-structures and algorithms practice, basic to hard, with an in-browser judge that runs your solution against real test cases.

38 chapters

How to practise, and the pattern method

Interview problems look infinite. They are not — they are perhaps thirty recurring patterns in different costumes. This track teaches the patterns, and gives you a judge in the page so you write and run code rather than reading about it.

Why patterns, not problems

```
THE FAILING STRATEGY: grind 500 problems, one at a time,
memorising solutions.

  · you meet problem 501 in the interview and it is not
    one you memorised
  · you cannot explain WHY the solution works, and the
    follow-up question exposes that immediately
  · retention is poor, because nothing connects

THE WORKING STRATEGY: learn the PATTERN, then solve
several problems that wear it.

  "Find a pair summing to a target in a SORTED array"
  "Find the container holding the most water"
  "Remove duplicates in place"
  "Sort an array of 0s, 1s and 2s"
  "Trap rainwater"

FIVE DIFFERENT PROBLEMS. ONE PATTERN: two pointers moving
toward each other, or in the same direction, exploiting
an ordering invariant.

Once you SEE the pattern, problem 501 is recognisable
even though you have never met it, because you are not
matching the problem - you are matching its SHAPE.

THE RECOGNITION SIGNALS ARE LEARNABLE, and each chapter
in this track states them explicitly:

  "sorted array" + "pair/triplet"      -> two pointers
  "contiguous subarray" + "max/min"    -> sliding window
  "kth largest"                        -> heap
  "all permutations/combinations"      -> backtracking
  "count the ways" / "min cost"        -> DP
  "shortest path, unweighted"          -> BFS
  "cycle in a linked list"             -> fast/slow
  "next greater element"               -> monotonic stack
  "prefix/word lookup"                 -> trie
  "connected components"               -> union-find or DFS

THAT TABLE IS MOST OF THE INTERVIEW. The rest is
implementing it without bugs, which is what the runnable
problems here are for.
```

The method for a single problem

```
/* Follow this EVERY TIME, including in the interview. It is
   also exactly what the interviewer is scoring you on. */

  1. RESTATE THE PROBLEM IN YOUR OWN WORDS.
     "So I'm given a sorted array and a target, and I need
      the indices of two numbers that add to it. Is there
      always exactly one answer?"
     -> catches misunderstanding before you write anything,
        and it is the single highest-scoring 30 seconds of
        the whole interview.

  2. ASK ABOUT THE CONSTRAINTS AND THE EDGE CASES.
     · How large is n? (this DETERMINES the target
       complexity - chapter 02)
     · Sorted? Duplicates? Negative numbers? Empty input?
     · Can I modify the input?
     · What should I return if there is no answer?

  3. WORK A SMALL EXAMPLE BY HAND.
     On paper, with 4-5 elements. THIS IS WHERE THE PATTERN
     REVEALS ITSELF. Skipping this step is the most common
     cause of a wrong approach confidently pursued.

  4. STATE THE BRUTE FORCE, WITH ITS COMPLEXITY.
     "I could check every pair - O(n^2). Let me improve
      that."
     Never stay silent while thinking. And never refuse to
     state a brute force because it is "too obvious" - it
     establishes a baseline and buys you thinking time.

  5. FIND THE INSIGHT THAT REMOVES WORK.
     Usually one of: the input is SORTED (binary search or
     two pointers), I am RECOMPUTING something (memoise or
     prefix sum), I only need the TOP FEW (heap), or there
     is REDUNDANT STATE I can drop.

  6. STATE THE APPROACH AND ITS COMPLEXITY BEFORE CODING.
     "Two pointers from both ends, O(n) time, O(1) space.
      Shall I code that?"
     -> gives the interviewer a chance to redirect you
        BEFORE you spend ten minutes on the wrong thing.

  7. CODE IT. Talk while you type. Use real names.

  8. TRACE IT ON THE EXAMPLE, out loud, line by line.
     You will find your own bug about a third of the time,
     and finding your own bug scores far better than the
     interviewer finding it.

  9. STATE THE EDGE CASES and check them: empty, one
     element, all equal, negatives, overflow, the target
     absent.

 10. STATE THE FINAL COMPLEXITY, time AND space.

/* AND THE THING PEOPLE GET WRONG: THE INTERVIEW IS NOT A
   TEST OF WHETHER YOU KNOW THE ANSWER. It is a simulation
   of working with you. A candidate who reasons clearly to
```

```
a good-but-not-optimal solution usually outscores one
who silently types a memorised optimal answer.        */
```

How this track is built

```
EVERY CHAPTER HAS THE SAME SHAPE:

  THE PATTERN        what it is, as a diagram or template
  WHEN TO REACH      the recognition signals
  FOR IT             ("if you see X, try Y")
  THE TEMPLATE       code you can adapt, with the
                     invariant stated
  PROBLEMS           4-6, EASY -> MEDIUM -> HARD, each
                     with:
                       · statement and examples
                       · hints, if you want a nudge
                       · an APPROACH LADDER: brute force,
                         better, optimal, with complexity
                         for each
                       · AN EDITOR THAT RUNS YOUR CODE
                         against real test cases
                       · reference solutions in
                         JavaScript, C++, Python and Java
                       · a walkthrough of why it works
  HOW IT SHOWS UP    the bugs this pattern produces
  CHECK YOURSELF     recall questions

THE ORDER TO READ THEM:

  02        complexity - do not skip this one
  03        the playground
  04-08     arrays: two pointers, sliding window,
            prefix sums, Kadane, matrices
  09-12     searching and sorting
  13-14     hashing
  15-16     bit manipulation
  17-18     linked lists
  19-21     stacks and queues
  22        heaps
  23-26     trees and tries
  27-30     graphs
  31-32     recursion and backtracking
  33-37     dynamic programming
  38        the interview itself, plus a mixed set

ARRAYS AND HASHING FIRST is deliberate: they appear
inside every later topic. DP LAST is also deliberate -
it is the hardest, and it is much easier once recursion
(31) is comfortable.
```

THE JUDGE IN THE PAGE

Every problem has a real editor. Write a solution, press **RUN TESTS** (or Ctrl/⌘+Enter), and it executes against the test cases and shows you which ones fail, with the input, what was expected, and what you actually returned. It runs *in your browser* — no server, no account, no network. Your code is saved in local storage per problem, so you can close the tab and come back.

The runner executes **JAVASCRIPT**, because that is what a browser can run with zero dependencies. Reference solutions are given in **C++, Python and Java** as well, since those are what you will actually write in an interview. If your target language is C++, read the C++ solution and type the JavaScript — the *algorithm* is what you are practising, and the syntax difference for these problems is small.

A realistic schedule

```
/* --- IF YOU HAVE 8+ WEEKS --- */
    week 1     complexity, arrays (02-08)
    week 2     searching, sorting, hashing (09-14)
    week 3     bits, linked lists (15-18)
    week 4     stacks, queues, heaps (19-22)
    week 5     trees and tries (23-26)
    week 6     graphs (27-30)
    week 7     recursion, backtracking (31-32)
    week 8     dynamic programming (33-37)
    then       mixed practice under time pressure (38)

    3-5 problems a day, done PROPERLY, beats 15 skimmed.

/* --- IF YOU HAVE 2 WEEKS --- */
    Do the EASY and MEDIUM problems only, in this order:
      arrays/hashing (04,05,06,13) -> binary search (09,10)
      -> linked lists (17,18) -> trees (23,24) ->
      graphs (27,28) -> DP intro (33)
    Then chapter 38.
    THESE SIX AREAS COVER THE LARGE MAJORITY OF WHAT IS
    ACTUALLY ASKED.

/* --- IF YOU HAVE 2 DAYS --- */
    Read chapter 38, then do the EASY problems in 04, 05,
    09, 13, 17, 23, 27. Accept that you are optimising for
    "not freezing" rather than for solving a hard problem.

/* --- THE RULES THAT MAKE PRACTICE WORK --- */

  · ATTEMPT BEFORE READING. Give every problem an honest
    20-25 minutes before opening the hints. The struggle IS
    the learning; reading a solution you did not struggle
    with teaches almost nothing.

  · WHEN YOU DO LOOK, CLOSE IT AND RETYPE FROM MEMORY.
    Understanding a solution and being able to produce one
    are different skills, and only the second is tested.

  · REDO PROBLEMS. Anything you needed help with, redo in
    three days, then in a week. Spaced repetition works
    here exactly as it does for vocabulary.

  · SAY IT OUT LOUD. Practise narrating. Interviews are
    verbal, and the first time you try to think out loud
    should not be in the interview.

  · TIME YOURSELF eventually. 20 minutes easy, 30-35
    medium. But only after the pattern is solid - timing
    yourself while still learning just creates anxiety.

  · KEEP A LOG of every problem you got wrong and WHY:
    "off-by-one in the binary search bound", "forgot the
    empty-input case", "did not see it was a graph". After
    thirty entries the log tells you exactly what to drill,
    and it is almost never what you assumed.            */
```

How it shows up

Symptom	Cause
Solved 300 problems, still fail interviews	Memorising solutions instead of patterns — and not practising out loud
Freeze completely on an unfamiliar problem	No process to fall back on — use the ten steps
Jump to code and write the wrong algorithm	Skipped the hand-worked example (step 3)
Interviewer stops you halfway	You did not state the approach before coding (step 6)
Solution works, interviewer unconvinced	Never stated the complexity, or could not justify correctness
Can follow a solution but not produce one	Reading without retyping from memory
Same bug class again and again	No error log — you are not measuring your own weaknesses
Good at easy, collapse on medium	Pattern not yet recognised — go back to the chapter's template

Check yourself

- ✓ Explain why pattern-based practice beats problem-count practice.
- ✓ Recite at least six recognition signals and the pattern each implies.
- ✓ List the ten steps of the per-problem method in order.
- ✓ Say which step buys you the most credit for the least time, and why.
- ✓ Explain why you state the approach and complexity *before* coding.
- ✓ Say what the interview is actually measuring.
- ✓ Give the four practice rules: attempt first, retype from memory, redo, narrate.
- ✓ Describe what belongs in an error log and what it is for.

Complexity analysis and reading the constraints

Big-O is not academic decoration — the constraint line in the problem statement tells you which algorithm is expected, before you have had a single idea. Learn to read it and half the search is already done.

What the notation means

```
BIG-O IS AN UPPER BOUND ON GROWTH, ignoring constants
and lower-order terms.

  3n^2 + 100n + 5000   ->   O(n^2)

WHY THROW AWAY THE CONSTANTS: because for large n the
fastest-growing term dominates everything else, and the
constants depend on hardware you cannot predict.

  n = 1,000,000:
    3n^2   = 3,000,000,000,000
    100n   =       100,000,000    (0.003% of the total)
    5000   =             5,000    (negligible)

THE THREE NOTATIONS, since interviewers occasionally ask:
  O(f)      grows NO FASTER than f   (upper bound)
  Omega(f)  grows NO SLOWER than f   (lower bound)
  Theta(f)  both - the tight bound

In practice everyone says "O" and means Theta. Saying
"O(n^2)" for something that is actually O(n) is
technically true and will still be marked wrong.

THE GROWTH LADDER, memorise the order:

  O(1)         constant      hash lookup, array index
  O(log n)     logarithmic   binary search, balanced tree
  O(n)         linear        one pass
  O(n log n)   linearithmic  good sorting, divide+conquer
  O(n^2)       quadratic     nested loops, all pairs
  O(n^3)       cubic         all triples, Floyd-Warshall
  O(2^n)       exponential   all subsets
  O(n!)        factorial     all permutations

WHAT THOSE ACTUALLY COST at n = 1,000,000:

  O(1)          1 step
  O(log n)      20 steps
  O(n)          1,000,000
  O(n log n)    20,000,000
  O(n^2)        1,000,000,000,000       ~ hours
  O(2^n)        more steps than atoms in the observable
                universe

AND AT n = 20:  2^20 = 1,048,576 - perfectly fine.
EXPONENTIAL IS NOT AUTOMATICALLY DISQUALIFYING. It
depends entirely on n, which is why the constraints
matter so much.
```

Reading the constraints backwards

```
THIS IS THE SINGLE MOST USEFUL TABLE IN INTERVIEW PREP.

A judge runs roughly 10^8 simple operations per second.
So from the largest n, you can read off the intended
complexity:

  n up to          intended complexity     what that means
  ------------------------------------------------------
  10^18            O(log n) or O(1)        maths, bit tricks
  10^8             O(n)                    one pass only
  10^6 - 10^7      O(n) or O(n log n)      sort is fine
  10^5             O(n log n)              sort, heap, BS
  10^4             O(n^2) is borderline    nested loop ok
  500 - 1000       O(n^2) or O(n^2 log n)  DP on pairs
  100 - 200        O(n^3)                  interval DP
  40 - 50          O(2^(n/2))              meet in middle
  20 - 25          O(2^n)                  subset DP,
                                           bitmask
  10 - 12          O(n!)                   permutations

HOW TO USE IT, in the interview:

  "n is up to 10^5, so I need about O(n log n). That
   rules out checking every pair. Sorting is affordable,
   and so is a heap or a binary search. Let me look for
   one of those."

YOU HAVE JUST NARROWED THE ENTIRE SEARCH SPACE OF
ALGORITHMS, out loud, before having an idea. That is
worth saying even if you then need a minute of silence.

THE REVERSE READING IS EQUALLY USEFUL:
  · "n <= 20" almost always means BITMASK or
    BACKTRACKING (chapters 16, 32)
  · "n <= 100 and it asks for a minimum cost" -> DP
  · "answer is monotonic and the range is huge" ->
    BINARY SEARCH ON THE ANSWER (chapter 10)
  · "array values up to 10^9 but n only 10^5" -> the
    VALUES need hashing or coordinate compression, not
    an array indexed by value
```

Counting correctly

```
/* --- SEQUENTIAL: ADD, then keep the largest --- */
    for (i = 0; i < n; i++) {}     // O(n)
    for (j = 0; j < n; j++) {}     // O(n)
    -> O(n) + O(n) = O(2n) = O(n)

/* --- NESTED: MULTIPLY --- */
    for (i = 0; i < n; i++)
        for (j = 0; j < m; j++) {}
    -> O(n*m)        NOT O(n^2) unless n == m. Say "n times
                     m" - interviewers notice.

/* --- THE TRIANGLE, which people get wrong --- */
    for (i = 0; i < n; i++)
        for (j = i; j < n; j++) {}
    -> n + (n-1) + ... + 1 = n(n+1)/2 = O(n^2)
    Half the work of the full square, but the SAME class.

/* --- HALVING IS LOGARITHMIC --- */
    while (n > 1) n = n / 2;       // O(log n)
    Each step throws away half the remaining input. The
    number of halvings of n before reaching 1 is log2(n).

/* --- THE ONE THAT LOOKS QUADRATIC AND IS NOT --- */
    let j = 0;
    for (let i = 0; i < n; i++) {
        while (j < n && cond(i, j)) j++;   // j NEVER RESETS
    }
    -> O(n), not O(n^2).

    THE ARGUMENT: `j` only ever increases and is bounded by
    n, so the inner loop body executes at most n times IN
    TOTAL across all iterations of the outer loop. This is
    AMORTISED ANALYSIS, and it is exactly why the sliding
    window (chapter 05) is linear. Be ready to say this out
    loud - it is a common follow-up question.

/* --- RECURSION: draw the tree --- */
    T(n) = 2*T(n/2) + O(n)      -> O(n log n)   merge sort
      log n levels, O(n) work per level

    T(n) = T(n/2) + O(1)        -> O(log n)     binary search
      one branch survives per level

    T(n) = 2*T(n-1) + O(1)      -> O(2^n)       subsets
      the tree DOUBLES each level

    T(n) = T(n-1) + O(n)        -> O(n^2)       naive quicksort
                                                worst case

/* --- SPACE COMPLEXITY: COUNT THE STACK --- */
    Recursion depth counts as space. A recursive DFS on a
    skewed tree of n nodes is O(n) SPACE even though it
    allocates nothing - which is precisely why "can you do
    it iteratively?" is asked (chapter 23).

    AND: the output does not usually count. If a problem
    asks for all n! permutations, you are not penalised for
    the O(n!) output. Say "O(n) auxiliary space, excluding
    the output" to show you know the distinction.        */
```

THE COMPLEXITY OF THE OPERATIONS YOU USE

```
ARRAY        index O(1) · push/pop end O(1) amortised
             insert/delete middle O(n) · search O(n)
SORTED ARRAY binary search O(log n)
HASH MAP     insert/lookup/delete O(1) average, O(n)
             worst case (collisions)
BALANCED BST insert/lookup/delete O(log n), and it keeps
             the keys ORDERED — the reason to prefer it
             over a hash map
HEAP         push/pop O(log n) · peek O(1) · build O(n)
STACK/QUEUE  push/pop O(1)
LINKED LIST  insert/delete at a known node O(1)
             search O(n) · NO random access
TRIE         insert/search O(L), L = key length
UNION-FIND   near O(1) amortised with both optimisations
STRING       concatenation in a loop is O(n²) in most
             languages — build an array and join once
```

Knowing that `Array.shift()`, `list.pop(0)` and `vector.erase(begin())` are all O(n) is the difference between an O(n) solution and an accidental $O(n^2)$ one. This is a genuinely common silent failure.

Amortised, average and worst case

```
/* --- WORST CASE is what you quote unless asked otherwise.
       It is the guarantee.

/* --- AVERAGE CASE assumes a distribution of inputs.
       Hash maps are O(1) average, O(n) worst (everything
       collides). Quicksort is O(n log n) average, O(n^2)
       worst (already-sorted input with a bad pivot).

/* --- AMORTISED is the average over a SEQUENCE of
       operations, and it is a WORST-CASE guarantee for the
       sequence - a much stronger statement than "average".

    THE CLASSIC: a dynamic array that doubles when full.
      Most pushes are O(1).
      A push that triggers a resize copies everything: O(n).
      But doubling means resizes happen at sizes
      1, 2, 4, 8, … n, and the total copying is
        1 + 2 + 4 + … + n < 2n
      so n pushes cost O(n) TOTAL, i.e. O(1) AMORTISED PER
      PUSH.

    THE KEY INSIGHT: doubling (not adding a constant) is
    what makes it amortised O(1). Growing by a fixed 10
    elements gives O(n) amortised per push and an O(n^2)
    total - a real performance bug people ship.

/* --- WHERE AMORTISED SHOWS UP IN INTERVIEWS ---
     · dynamic array / vector push
     · the sliding window's inner pointer (chapter 05)
     · the monotonic stack: each element is pushed once and
       popped at most once, so the whole scan is O(n) even
       though a single step can pop many items (chapter 20)
     · union-find with path compression (chapter 29)

   IN EACH CASE THE ARGUMENT IS THE SAME: bound the TOTAL
   work across the whole run, not the work of one step.
   "Each element is pushed once and popped at most once,
   so the total is O(n)" is a sentence worth memorising.  */
```

Practice: predict the complexity

These are not algorithm problems — each asks you to *return the complexity* of a snippet as a string. Getting them right quickly is a real interview skill.

How it shows up

Symptom	Cause
Solution times out at n = 10^5	Wrote $O(n^2)$ when the constraints demanded O(n log n)
Accidentally $O(n^2)$ with a linear-looking loop	`shift()`, `pop(0)`, or string concatenation inside a loop
Said $O(n^2)$ for the triangle loop and were told it is right	Correct — half the work, same class
Said $O(n^2)$ for a sliding window	The inner pointer never resets — it is amortised O(n)
Stack overflow on a large input	Recursion depth is O(n) space — convert to iteration

Symptom	Cause
Hash solution slower than expected	Worst-case collisions, or hashing large keys is not O(1)
Quoted O(1) space but used a recursive helper	The call stack counts
Exponential solution accepted	Check n — at $n \le 20$, 2^n is fine

Check yourself

- ✓ Recite the growth ladder from O(1) to O(n!).
- ✓ Give the intended complexity for $n = 10^5$, 10^3, and 20.
- ✓ Explain why the triangle loop is $O(n^2)$ despite doing half the work.
- ✓ Give the amortised argument for why a non-resetting inner pointer is O(n).
- ✓ Explain why array doubling gives O(1) amortised push and fixed growth does not.
- ✓ State the recurrence for merge sort and binary search, and solve each.
- ✓ Say why recursion has a space cost even with no allocation.
- ✓ Name three operations that look O(1) but are O(n).

Problems

Classify: nested and sequential loops `Easy`

Pattern: Counting loops

Return the tightest complexity of this function as a string, one of: `"O(1)"`, `"O(log n)"`, `"O(n)"`, `"O(n log n)"`, `"O(n^2)"`, `"O(n^3)"`.

```
function f(n) {
  let c = 0;
  for (let i = 0; i < n; i++) c++;        // A
  for (let i = 0; i < n; i++)             // B
    for (let j = i; j < n; j++) c++;
  return c;
}
```

Implement `classify()` to return that string.

Input	Output	Note
–	`one of the strings above`	

HINTS

1. Sequential blocks ADD; you keep the largest.
2. Loop B is the triangle: n + (n−1) + … + 1.
3. n(n+1)/2 drops its constant factor.

Approach	Idea	Time	Space
Count each block, take the max	A is O(n). B is the triangle sum n(n+1)/2, which is O(n^2). The total is O(n) + O(n^2) = O(n^2).	–	–

Solution — js

```
function classify() {
  // A: O(n)
  // B: n + (n-1) + ... + 1 = n(n+1)/2 = O(n^2)
  // sequential -> take the larger
  return "O(n^2)";
}
```

WALKTHROUGH

The trap is assuming the triangle loop is cheaper *in class* because it does half the work. Constant factors are exactly what big-O discards, so `n(n+1)/2` and `n²` are the same class. The right thing to say aloud is "it is about half of n^2, so O(n^2)" — that shows you counted rather than pattern-matched.

Classify: halving with inner work `Medium`

Pattern: Logarithmic outer loop

Return the tightest complexity of:

```
function f(n) {
  let c = 0;
  for (let i = n; i > 0; i = Math.floor(i / 2))  // outer
    for (let j = 0; j < n; j++) c++;             // inner
  return c;
}
```

Input	Output	Note
–	`a complexity string`	

HINTS

1. How many times does the outer loop run before i reaches 0?
2. The inner loop does n work every time, independent of i.
3. Multiply: (number of outer iterations) × (work per iteration).

Approach	Idea	Time	Space
Multiply the two	The outer loop halves `i` each time, so it runs about $\log_2$ n times. The inner loop is O(n) and does *not* shrink with `i`. Total O(n log n).	–	–

Solution — js

```
function classify() {
  // outer: n, n/2, n/4, ... -> log2(n) iterations
  // inner: n work each time (does NOT depend on i)
  // -> n * log n
  return "O(n log n)";
}
```

WALKTHROUGH

The common error is answering `O(n)` by assuming the inner loop shrinks along with `i`. It does not — it is bounded by `n`, not `i`. Contrast with the version where the inner loop runs to `i`: then the total is `n + n/2 + n/4 + … = 2n`, which is **O(n)**. That geometric-series argument is worth knowing; it is why building a heap is O(n) rather than O(n log n).

Classify: the non-resetting pointer `Medium`

Pattern: Amortised analysis

Return the tightest complexity of:

```
function f(a) {
  const n = a.length;
  let j = 0, c = 0;
  for (let i = 0; i < n; i++) {
    while (j < n && a[j] < a[i] + 10) { j++; c++; }
  }
  return c;
}
```

Note that `j` is declared *outside* the outer loop and is never reset.

Input	Output	Note
`—`	`a complexity string`	

HINTS

1. It *looks* like a nested loop, so the instinct is $O(n^2)$.
2. Ask a different question: across the whole run, how many times in total can the line `j++` execute?
3. j only increases and is capped at n. That bounds the total inner work regardless of how the outer loop behaves.

Approach	Idea	Time	Space
Naive reading	Two nested loops → $O(n^2)$. Wrong, because the inner loop does not restart.	—	—
Amortised: bound the total	`j` is monotonically increasing and never exceeds `n`, so `j++` runs at most n times *in total* across every outer iteration. Outer loop O(n) + total inner work O(n) = **O(n)**.	—	—

Solution — js

```
function classify() {
  // j never resets and never decreases, and j < n.
  // So the inner body runs at most n times IN TOTAL,
  // not n times PER outer iteration.
  // O(n) outer + O(n) total inner = O(n)
  return "O(n)";
}
```

WALKTHROUGH

This is the single most important complexity argument in array interviews, because it is exactly why the sliding window is linear and why the monotonic stack is linear. The sentence to have ready is: *"each element is visited by the inner pointer at most once over the whole run, so the total inner work is O(n), giving O(n) overall."*

The distinguishing test: is the inner counter reset inside the outer loop? If yes, it multiplies ($O(n^2)$). If it is declared outside and never reset, it amortises ($O(n)$).

Classify: recursion trees `Hard`

Pattern: Solving recurrences

Given a recurrence as a string, return its complexity. Implement `solve(rec)` handling exactly these four:

- `"T(n) = 2T(n/2) + O(n)"`
- `"T(n) = T(n/2) + O(1)"`
- `"T(n) = 2T(n-1) + O(1)"`
- `"T(n) = T(n-1) + O(n)"`

Input	Output	Note
`"T(n) = 2T(n/2) + O(n)"`	`"O(n log n)"`	Merge sort: log n levels, O(n) work per level.
`"T(n) = T(n/2) + O(1)"`	`"O(log n)"`	Binary search: one branch survives per level.

HINTS

1. Draw the tree. How many LEVELS, and how much work per level?
2. Dividing by 2 gives log n levels; subtracting 1 gives n levels.
3. Two recursive calls means the tree doubles in width each level; one call means it stays a single path.

Approach	Idea	Time	Space
Recursion tree	Levels × work per level. `2T(n/2)+O(n)`: log n levels × O(n) = O(n log n). `T(n/2)+O(1)`: log n levels × O(1) = O(log n). `2T(n-1)+O(1)`: n levels, width doubles = $O(2^n)$. `T(n-1)+O(n)`: n levels × O(n) = $O(n^2)$.	–	–

Solution — js

```
function solve(rec) {
  const table = {
    // log n levels, O(n) work each -> merge sort
    "T(n) = 2T(n/2) + O(n)": "O(n log n)",
    // log n levels, O(1) work each -> binary search
    "T(n) = T(n/2) + O(1)":  "O(log n)",
    // n levels, width doubles each level -> subsets
    "T(n) = 2T(n-1) + O(1)": "O(2^n)",
    // n levels, O(n) work each -> naive quicksort worst case
    "T(n) = T(n-1) + O(n)":  "O(n^2)"
  };
  return table[rec];
}
```

WALKTHROUGH

THE GENERAL METHOD.

For `T(n) = a·T(n/b) + f(n)` the tree has `log_b n` levels and `a^k` nodes at level `k`. Compare the work at the leaves, `n^(log_b a)`, against `f(n)`: whichever dominates is the answer, and if they match you gain a `log n` factor. That is the Master Theorem, and for `2T(n/2)+O(n)` the two match exactly — hence `O(n log n)`.

For recurrences that *subtract* rather than divide, the tree has `n` levels instead of `log n`, which is why those land at `O(n²)` or `O(2ⁿ)`. Recognising "divide" versus "subtract" is most of the skill.

The playground: write and run code

A scratch pad that runs in this page. Use it to try an idea, trace an algorithm with `console.log`, or check a language detail without leaving the site.

Scratch pad

Write anything and press **Run** (or Ctrl/⌘+Enter). Output from `console.log` appears below. Your code is saved in this browser, so it survives a reload.

Built-in helpers

Linked lists and trees are pre-defined in the sandbox, on this page and inside every problem, so you never have to write the plumbing:

```
/* --- LINKED LISTS --- */
function ListNode(val, next)      // constructor
buildList([1,2,3])                // array  -> list, returns head
listToArray(head)                 // list   -> array

/* --- BINARY TREES (level-order, null for a missing child) --- */
function TreeNode(val, left, right)
buildTree([3,9,20,null,null,15,7])   // array -> tree, returns root
treeToArray(root)                    // tree  -> array

/* EXAMPLE - reverse a list and print it: */
const head = buildList([1,2,3,4,5]);
let prev = null, cur = head;
while (cur) { const nx = cur.next; cur.next = prev; prev = cur; cur = nx; }
console.log(listToArray(prev));     // [5,4,3,2,1]

/* EXAMPLE - the tree [3,9,20,null,null,15,7] is:
        3
       / \
      9  20
         / \
        15  7                                        */
const root = buildTree([3,9,20,null,null,15,7]);
function depth(n) { return n ? 1 + Math.max(depth(n.left), depth(n.right)) : 0; }
console.log('depth =', depth(root));      // 3
```

How the runner works

```
YOUR CODE ---> a Web Worker (a separate thread)
                    |
                    |  runs the test harness
                    |  captures console.log
                    |  4-second timeout
                    v
               results back to the page

WHY A WORKER:
  · an INFINITE LOOP cannot freeze the page — the worker
    is terminated after 4 seconds and you get a clear
    message instead of a dead tab
  · your code cannot touch the page
  · console.log is captured rather than lost

IF WORKERS ARE UNAVAILABLE — which happens when the site
is opened directly from disk with a file:// URL in some
browsers — the runner FALLS BACK to executing on the main
thread. Everything still works, with one caveat: an
infinite loop will freeze the tab and you will have to
close it. Serving the site over http (even
`python -m http.server`) avoids that entirely.

WHAT IS NOT HERE, and honestly:
  · NO C++, Python or Java execution. Running those needs
    a compiler toolchain or a multi-megabyte WebAssembly
    runtime downloaded from a CDN, which would break the
    offline, no-dependency design of this site.
    Reference solutions are given in all four languages
    on every problem; the JUDGE runs JavaScript.
  · no file I/O, no network, no npm packages.
  · no stdin. Problems pass arguments to a function
    rather than reading input, which is also how
    LeetCode-style interviews work.

IF YOUR TARGET LANGUAGE IS C++ OR JAVA: read the
reference solution in your language, then type the
JavaScript. For these problems the algorithm is the whole
content and the syntax gap is small. Practise the real
syntax separately in your own editor before the
interview.
```

JavaScript for people who write C++ or Java

```
/* Enough to solve every problem in this track. */

/* --- ARRAYS --- */
const a = [1, 2, 3];
a.length                      // size
a.push(4); a.pop();           // back:  O(1)
a.unshift(0); a.shift();      // front: O(n)  <-- AVOID IN LOOPS
a.slice(1, 3)                 // copy of [1,3)   - non-destructive
a.splice(1, 2)                // REMOVE 2 items at index 1 - mutates
new Array(n).fill(0)          // n zeros
Array.from({length: n}, (_, i) => i)          // [0..n-1]
Array.from({length: r}, () => new Array(c).fill(0))   // r x c grid

/* THE 2-D ARRAY TRAP: */
new Array(3).fill([])         // WRONG - three refs to the SAME array
Array.from({length: 3}, () => [])   // right - three distinct arrays

/* --- SORTING: THE #1 JAVASCRIPT BUG --- */
[10, 9, 1].sort()                  // ["1","10","9"] - LEXICOGRAPHIC!
[10, 9, 1].sort((x, y) => x - y)   // [1, 9, 10] - always pass a comparator
arr.sort((p, q) => p[0] - q[0] || q[1] - p[1]);   // by [0] asc, then [1] desc

/* --- MAP AND SET --- */
const m = new Map();
m.set(k, v); m.get(k); m.has(k); m.delete(k); m.size;
m.get(k) ?? 0                 // default when absent
for (const [k, v] of m) {}
const s = new Set([1, 2, 2]); // size 2
s.add(3); s.has(1); s.delete(1);
[...s]                        // Set -> array

/* A PLAIN OBJECT works for string keys, but Map keeps
   INSERTION ORDER, allows ANY key type, and has O(1) size.
   Prefer Map. */

/* --- STRINGS are immutable --- */
s[i]  s.charCodeAt(i)  s.split('')  arr.join('')
s.slice(1, 4)   s.toLowerCase()
// building a string in a loop with += is O(n^2) in the
// worst case - push to an array and join once.

/* --- NUMBERS --- */
Math.floor(7 / 2)   // 3   - / is FLOAT division, unlike C++ int/int
(7 / 2) | 0         // 3   - fast truncation, but 32-bit only
Math.trunc(-3.5)    // -3  - toward zero
Math.floor(-3.5)    // -4  - toward -infinity  (they DIFFER for
                    //       negatives - a real source of bugs)
Number.MAX_SAFE_INTEGER   // 2^53 - 1; beyond this use BigInt
Infinity, -Infinity       // handy initial values for min/max

/* --- DESTRUCTURING AND SWAP --- */
[a[i], a[j]] = [a[j], a[i]];
const [lo, hi] = [0, n - 1];

/* --- THE EQUALITY RULE: ALWAYS USE === --- */
0 == '0'    // true   - do not use
0 === '0'   // false  - use this

/* --- COMMON IDIOMS --- */
const freq = new Map();
```

```
for (const c of s) freq.set(c, (freq.get(c) ?? 0) + 1);

const seen = new Set();
if (!seen.has(x)) { seen.add(x); }

let best = -Infinity;
for (const v of a) best = Math.max(best, v);

// a grid of visited flags
const vis = Array.from({length: R}, () => new Array(C).fill(false));
```

KEYBOARD SHORTCUTS

```
Ctrl / ⌘ + Enter    run
Tab                 insert two spaces (does not leave
                    the editor)
Reset               restore the starter code and clear
                    your saved version
```

How it shows up

Symptom	Cause
Sorting gives `[1, 10, 9]`	Default sort is lexicographic — pass `(a,b)=>a-b`
All rows of a grid change together	`fill([])` shares one array — use `Array.from`
Loop is unexpectedly O(n^2)	`shift()` / `unshift()` or `+=` on strings inside the loop
Negative division off by one	`Math.floor` vs `Math.trunc` differ for negatives
Large integers lose precision	Past 2^{53} — use `BigInt`
"No function named X was defined"	Renamed the function, or wrapped it in a class
Timed out after 4 s	Infinite loop — a pointer that never advances
Tab freezes instead of timing out	Running from `file://` with no Worker support — serve over http
Output empty	Nothing was logged — the runner shows `console.log`, not return values

Check yourself

- ✓ Run something in the pad and see its output.
- ✓ Build a linked list from an array and convert it back.
- ✓ Build the tree `[3,9,20,null,null,15,7]` and compute its depth.
- ✓ Say why the runner uses a Worker and what happens without one.
- ✓ State what the judge does *not* run, and why.
- ✓ Give the correct way to sort numbers in JavaScript.
- ✓ Give the correct way to build a 2-D grid, and the trap.
- ✓ Name two array operations that are O(n) rather than O(1).

Arrays: the two-pointer pattern

Two indices walking the array under an invariant, turning an O(n^2) pair search into a single O(n) pass. The first pattern to learn, and the one that appears most often.

The pattern

```
THREE VARIANTS. Learn to tell them apart.

1. OPPOSITE ENDS - converging
     lo = 0, hi = n-1
     while (lo < hi) {
         evaluate(a[lo], a[hi])
         move ONE pointer inward, based on a rule
     }

     [ 1, 3, 5, 8, 11, 14 ]   target 16
       ^               ^        1+14=15 < 16 -> lo++
          ^            ^        3+14=17 > 16 -> hi--
          ^         ^           3+11=14 < 16 -> lo++
             ^      ^           5+11=16  FOUND

     REQUIRES A SORTED (or otherwise ordered) INPUT. The
     ordering is what makes "move which pointer?"
     decidable: if the sum is too small, only increasing
     the left value can help.

2. SAME DIRECTION - fast and slow (read/write)
     write = 0
     for (read = 0; read < n; read++)
         if (keep(a[read]))
             a[write++] = a[read]

     THE INVARIANT: everything before `write` is the
     answer so far. Used for IN-PLACE FILTERING -
     removing duplicates, moving zeroes, partitioning.

3. TWO SEQUENCES - one pointer in each
     i = 0, j = 0
     while (i < n && j < m)
         compare a[i] with b[j], advance the smaller

     Merging, intersection, subsequence checking.

WHY IT WORKS - THE ARGUMENT YOU MUST BE ABLE TO GIVE:

  Each step ELIMINATES a whole set of candidates.
  In variant 1, when a[lo]+a[hi] < target, no pair
  (lo, k) for any k <= hi can reach the target, because
  a[hi] is the largest remaining partner. So the entire
  row for `lo` is eliminated in one step, and lo can
  advance permanently.

  n candidates, each pointer moves at most n times, never
  backwards -> O(n) total.

THE COST: O(n) time, O(1) EXTRA SPACE. That O(1) is
frequently the reason the interviewer asks for it.
```

When to reach for it

Sorted array + find a pair/triplet

Two Sum II, 3Sum, 4Sum. Sort first if the input is not sorted *and* indices do not matter.

"In place" + "O(1) extra space"

Read/write pointers. Remove duplicates, move zeroes, remove element.

Palindrome or symmetry

Converge from both ends comparing as you go.

Maximise something between two indices

Container with most water, trapping rain water. Move the pointer that *limits* the result.

Partition by a predicate

Dutch national flag, sort colours, segregate even/odd.

Merge or intersect two sorted lists

One pointer per sequence, advance the smaller.

```
/* THE TEMPLATE, converging variant */
function twoPointer(a, target) {
    let lo = 0, hi = a.length - 1;
    while (lo < hi) {
        const sum = a[lo] + a[hi];
        if (sum === target) return [lo, hi];
        if (sum < target) lo++;      // need a BIGGER value
        else              hi--;      // need a SMALLER value
    }
    return [-1, -1];
}

/* THE TEMPLATE, read/write variant */
function filterInPlace(a, keep) {
    let write = 0;
    for (let read = 0; read < a.length; read++)
        if (keep(a[read])) a[write++] = a[read];
    return write;                    // new logical length
}

/* THE FOUR THINGS THAT GO WRONG, every time:
     · `lo < hi` versus `lo <= hi`. Use `<` when the two
       pointers must be DIFFERENT elements (a pair), `<=`
       when a single middle element is still a valid state.
     · forgetting to SKIP DUPLICATES when the problem wants
       unique tuples
     · moving BOTH pointers when only one should move
     · assuming sorted input when it is not              */
```

Problems

Six problems, easy to hard. Write your solution in the editor and press **Run tests** (or Ctrl/⌘+Enter). Give each one an honest attempt before opening the hints — the struggle is the part that teaches.

How it shows up

Symptom	Cause
Infinite loop	A branch where neither pointer moves
Misses the answer when the pair is adjacent	`lo < hi` vs `lo <= hi` chosen wrongly
Duplicate triplets in the output	Duplicates not skipped after a match
Wrong answer on unsorted input	The converging variant needs an ordering
Indices wrong after sorting	Sorting destroys original indices — use a hash map instead
In-place filter leaves stale tail values	Expected — only the first `write` elements are defined
Container-with-water answer too small	Moved the taller pointer; you must move the *shorter* one
Off-by-one on the last element	Loop bound excludes `hi` when it should include it

Check yourself

- ✓ Name the three two-pointer variants and give a problem for each.
- ✓ Give the elimination argument for why the converging variant is O(n).
- ✓ Say why the converging variant requires sorted input and the read/write variant does not.
- ✓ Write the read/write template and state its invariant.
- ✓ Explain when to use `lo < hi` and when `lo <= hi`.
- ✓ Explain why moving the shorter pointer is correct in Container With Most Water.
- ✓ Say why sorting is wrong for the original Two Sum but right for 3Sum.
- ✓ Describe how to skip duplicates without missing valid tuples.

Problems

Two Sum II — sorted input `Easy`

Pattern: Converging pointers

Given a **1-indexed** array `numbers` sorted in non-decreasing order, find two numbers that add up to `target`. Return their 1-based indices as `[i, j]` with `i < j`.

Exactly one solution exists, and you may not use the same element twice. Use **O(1) extra space**.

Input	Output	Note
`numbers = [2,7,11,15], target = 9`	`[1,2]`	2 + 7 = 9, at 1-based positions 1 and 2.
`numbers = [2,3,4], target = 6`	`[1,3]`	
`numbers = [-1,0], target = -1`	`[1,2]`	

HINTS

1. The array is sorted. What does that let you conclude when the current sum is too small?
2. If `a[lo] + a[hi] < target`, then `a[lo]` paired with *any* index at or below `hi` is also too small — so `lo` can never be part of the answer with those. Advance it.
3. Remember the answer is 1-indexed: return `[lo+1, hi+1]`.

Approach	Idea	Time	Space
Brute force — every pair	Two nested loops testing each pair.	`O(n²)`	`O(1)`
Hash map	Store each value as you scan and look up `target − x`. Works, but ignores the sorting and costs O(n) memory.	`O(n)`	`O(n)`
Converging two pointers	Start at both ends. Sum too small → move `lo` right; too large → move `hi` left. Each step eliminates a whole row of candidates.	`O(n)`	`O(1)`

Solution — js

```
function twoSum(numbers, target) {
  let lo = 0, hi = numbers.length - 1;
  while (lo < hi) {
    const sum = numbers[lo] + numbers[hi];
    if (sum === target) return [lo + 1, hi + 1];
    if (sum < target) lo++;   // need a larger value
    else              hi--;   // need a smaller value
  }
  return [-1, -1];
}
```

Solution — cpp

```
class Solution {
public:
    vector<int> twoSum(vector<int>& numbers, int target) {
        int lo = 0, hi = numbers.size() - 1;
        while (lo < hi) {
            int sum = numbers[lo] + numbers[hi];
            if (sum == target) return {lo + 1, hi + 1};
            if (sum < target) ++lo;
            else              --hi;
        }
        return {-1, -1};
    }
};
```

Solution — python

```python
class Solution:
    def twoSum(self, numbers: list[int], target: int) -> list[int]:
        lo, hi = 0, len(numbers) - 1
        while lo < hi:
            s = numbers[lo] + numbers[hi]
            if s == target:
                return [lo + 1, hi + 1]
            if s < target:
                lo += 1
            else:
                hi -= 1
        return [-1, -1]
```

Solution — java

```java
class Solution {
    public int[] twoSum(int[] numbers, int target) {
        int lo = 0, hi = numbers.length - 1;
        while (lo < hi) {
            int sum = numbers[lo] + numbers[hi];
            if (sum == target) return new int[]{lo + 1, hi + 1};
            if (sum < target) lo++;
            else              hi--;
        }
        return new int[]{-1, -1};
    }
}
```

WALKTHROUGH

WHY IT IS CORRECT.

The invariant is that the answer, if it exists, always lies within `[lo, hi]`. Suppose `a[lo] + a[hi] < target`. Since the array is sorted, `a[hi]` is the largest value still available to pair with `a[lo]`. If even that is too small, `a[lo]` cannot participate in any remaining pair, so discarding it preserves the invariant. The symmetric argument applies to `hi`. Each iteration discards exactly one index and neither pointer moves backwards, so the loop runs at most n times.

NOTE THE CONTRAST WITH PLAIN TWO SUM

(unsorted, return original indices): there you *cannot* sort, because sorting destroys the indices you must report. That version is a hash-map problem — see chapter 13.

Remove duplicates from a sorted array Easy

Pattern: Read / write pointers

Given a sorted array `nums`, remove duplicates **in place** so each element appears once, keeping the relative order. Return `k`, the number of unique elements.

The first `k` positions of `nums` must hold the unique values. Whatever is left beyond `k` does not matter.

Input	Output	Note
`nums = [1,1,2]`	`2, with nums starting [1,2,...]`	
`nums = [0,0,1,1,1,2,2,3,3,4]`	`5, with nums starting [0,1,2,3,4,...]`	

HINTS

1. Keep two indices: one that *reads* every element, and one that marks where the next unique value should be *written*.
2. Because the array is sorted, a value is new exactly when it differs from the last one you wrote.
3. Start `write` at 1 — the first element is always unique.

Approach	Idea	Time	Space
Build a new array	Copy uniques into a fresh array, then copy back. Simple but uses O(n) extra space, which the problem forbids.	`O(n)`	`O(n)`
Read / write pointers	One forward pass. `read` scans; whenever `nums[read] !== nums[write-1]`, write it at `write` and advance.	`O(n)`	`O(1)`

Solution — js

```
function removeDuplicates(nums) {
  if (nums.length === 0) return 0;
  let write = 1;
  for (let read = 1; read < nums.length; read++) {
    if (nums[read] !== nums[write - 1]) {
      nums[write] = nums[read];
      write++;
    }
  }
  return write;
}
```

Solution — cpp

```
class Solution {
public:
    int removeDuplicates(vector<int>& nums) {
        if (nums.empty()) return 0;
        int write = 1;
        for (int read = 1; read < (int)nums.size(); ++read)
            if (nums[read] != nums[write - 1])
                nums[write++] = nums[read];
        return write;
    }
};
```

Solution — python

```
class Solution:
    def removeDuplicates(self, nums: list[int]) -> int:
        if not nums:
            return 0
        write = 1
        for read in range(1, len(nums)):
            if nums[read] != nums[write - 1]:
                nums[write] = nums[read]
                write += 1
        return write
```

Solution — java

```
class Solution {
    public int removeDuplicates(int[] nums) {
        if (nums.length == 0) return 0;
        int write = 1;
        for (int read = 1; read < nums.length; read++)
            if (nums[read] != nums[write - 1])
                nums[write++] = nums[read];
        return write;
    }
}
```

WALKTHROUGH

THE INVARIANT:

`nums[0 .. write-1]` always holds the unique values seen so far, in order. Because the input is sorted, all copies of a value are adjacent, so comparing against `nums[write-1]` — the last value kept — is enough to decide whether the current value is new.

THE GENERALISATION WORTH KNOWING:

for "allow at most *k* copies of each value", compare against `nums[write-k]` instead and start `write` at `k`. That single change solves the "at most twice" variant, which is a common follow-up.

Valid palindrome `Easy`

Pattern: Converging pointers

Given a string `s`, return `true` if it is a palindrome after converting all uppercase letters to lowercase and removing every non-alphanumeric character.

Input	Output	Note
`s = "A man, a plan, a canal: Panama"`	`true`	Cleaned it reads "amanaplanacanalpanama".
`s = "race a car"`	`false`	
`s = " "`	`true`	The cleaned string is empty, which is a palindrome.

HINTS

1. You can clean the string first, but you can also skip junk characters *while* the pointers converge — that avoids the extra O(n) string.
2. Use inner `while` loops to advance `lo` past non-alphanumeric characters and retreat `hi` past them, before comparing.
3. Guard those inner loops with `lo < hi` so they cannot run off the ends.

Approach	Idea	Time	Space
Clean then reverse	Build a filtered lowercase string and compare it with its reverse. Very readable.	`O(n)`	`O(n)`
Two pointers, skipping in place	Converge from both ends, skipping non-alphanumerics as you go. No extra string.	`O(n)`	`O(1)`

Solution — js

```javascript
function isPalindrome(s) {
  const ok = c => /[a-z0-9]/i.test(c);
  let lo = 0, hi = s.length - 1;
  while (lo < hi) {
    while (lo < hi && !ok(s[lo])) lo++;
    while (lo < hi && !ok(s[hi])) hi--;
    if (s[lo].toLowerCase() !== s[hi].toLowerCase()) return false;
    lo++; hi--;
  }
  return true;
}
```

Solution — cpp

```cpp
class Solution {
public:
    bool isPalindrome(string s) {
        int lo = 0, hi = s.size() - 1;
        while (lo < hi) {
            while (lo < hi && !isalnum((unsigned char)s[lo])) ++lo;
            while (lo < hi && !isalnum((unsigned char)s[hi])) --hi;
            if (tolower((unsigned char)s[lo]) != tolower((unsigned char)s[hi]))
                return false;
            ++lo; --hi;
        }
        return true;
    }
};
```

Solution — python

```python
class Solution:
    def isPalindrome(self, s: str) -> bool:
        lo, hi = 0, len(s) - 1
        while lo < hi:
            while lo < hi and not s[lo].isalnum():
                lo += 1
            while lo < hi and not s[hi].isalnum():
                hi -= 1
            if s[lo].lower() != s[hi].lower():
                return False
            lo += 1
            hi -= 1
        return True
```

Solution — java

```java
class Solution {
    public boolean isPalindrome(String s) {
        int lo = 0, hi = s.length() - 1;
        while (lo < hi) {
            while (lo < hi && !Character.isLetterOrDigit(s.charAt(lo))) lo++;
            while (lo < hi && !Character.isLetterOrDigit(s.charAt(hi))) hi--;
            if (Character.toLowerCase(s.charAt(lo)) != Character.toLowerCase(s.charAt(hi)))
                return false;
            lo++; hi--;
        }
        return true;
    }
}
```

WALKTHROUGH

THE EDGE CASES THAT CATCH PEOPLE:

a string of only punctuation (the pointers cross without ever comparing — correctly returning `true`), and `"0P"`, which catches anyone who compared ASCII codes with a careless case conversion. Note also the `lo < hi` guard *inside* the skip loops: without it, a string of all punctuation walks `lo` past the end and `s[lo]` is undefined.

Container with most water `Medium`

Pattern: Converging pointers, greedy move

You are given an array `height` where `height[i]` is the height of a vertical line at position `i`. Pick two lines that together with the x-axis form a container holding the most water. Return that maximum area.

Area between `i` and `j` is `min(height[i], height[j]) × (j − i)`.

Input	Output	Note
`height = [1,8,6,2,5,4,8,3,7]`	`49`	Lines at index 1 and 8: min(8,7) × (8−1) = 49.
`height = [1,1]`	`1`	

HINTS

1. Start with the widest possible container: the two ends. Any other container is narrower, so it must be *taller* to beat it.
2. You must move one pointer inward. Which one can you move without risking the loss of a better answer?
3. Moving the taller line inward can never help: the area is capped by the *shorter* line, and the width only shrinks. So move the shorter one.

Approach	Idea	Time	Space
Brute force	Try all pairs and take the maximum.	`O(n²)`	`O(1)`
Converging pointers, move the shorter line	Start wide. Record the area, then discard the shorter line. Each step provably cannot discard the optimum.	`O(n)`	`O(1)`

Solution — js

```
function maxArea(height) {
  let lo = 0, hi = height.length - 1, best = 0;
  while (lo < hi) {
    const h = Math.min(height[lo], height[hi]);
    best = Math.max(best, h * (hi - lo));
    // discard the SHORTER line — it can never do better
    if (height[lo] < height[hi]) lo++;
    else                         hi--;
  }
  return best;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int maxArea(vector<int>& height) {
        int lo = 0, hi = height.size() - 1, best = 0;
        while (lo < hi) {
            int h = min(height[lo], height[hi]);
            best = max(best, h * (hi - lo));
            if (height[lo] < height[hi]) ++lo;
            else                         --hi;
        }
        return best;
    }
};
```

Solution — python

```python
class Solution:
    def maxArea(self, height: list[int]) -> int:
        lo, hi, best = 0, len(height) - 1, 0
        while lo < hi:
            h = min(height[lo], height[hi])
            best = max(best, h * (hi - lo))
            if height[lo] < height[hi]:
                lo += 1
            else:
                hi -= 1
        return best
```

Solution — java

```java
class Solution {
    public int maxArea(int[] height) {
        int lo = 0, hi = height.length - 1, best = 0;
        while (lo < hi) {
            int h = Math.min(height[lo], height[hi]);
            best = Math.max(best, h * (hi - lo));
            if (height[lo] < height[hi]) lo++;
            else                         hi--;
        }
        return best;
    }
}
```

WALKTHROUGH

THE EXCHANGE ARGUMENT — BE READY TO GIVE THIS ONE ALOUD.

Suppose `height[lo] < height[hi]`. Consider any container that uses `lo` as its left wall and some `j < hi` as its right wall. Its height is at most `height[lo]` (unchanged), and its width `j - lo` is strictly smaller than `hi - lo`. So its area is strictly less than the area we just recorded. Every remaining container involving `lo` is therefore already beaten, and `lo` can be discarded safely.

This is the key move: the pointer to advance is always the one that *limits* the objective. The same reasoning drives the harder Trapping Rain Water problem below.

3Sum `Medium`

Pattern: Sort + fix one + two pointers

Given an integer array `nums`, return all **unique** triplets `[a, b, c]` such that `a + b + c === 0`.

The solution set must not contain duplicate triplets. Order of the triplets, and of values within a triplet, does not matter for grading here.

Input	Output	Note
`nums = [-1,0,1,2,-1,-4]`	`[[-1,-1,2],[-1,0,1]]`	
`nums = [0,1,1]`	`[]`	
`nums = [0,0,0]`	`[[0,0,0]]`	

HINTS

1. Sort the array first. Indices are not required in the output, so sorting is free to do.
2. Fix the first element with an outer loop, then the problem reduces to Two Sum II on the remainder — find a pair summing to `-nums[i]`.
3. Duplicates are the whole difficulty. Skip a repeated value for the fixed element, and after recording a match skip repeats at *both* inner pointers.
4. Small optimisation: once `nums[i] > 0` you can stop — a sorted array cannot produce a zero sum from three positives.

Approach	Idea	Time	Space
Brute force	Three nested loops, deduplicate with a set of sorted triplets.	`O(n³)`	`O(n)`
Hash set on the inner pair	Fix one element, then use a hash set for the two-sum. Faster, but deduplication becomes awkward.	`O(n²)`	`O(n)`
Sort + two pointers	Sort once, fix the first element, converge two pointers on the rest. Sorting makes deduplication trivial and drops extra space to O(1).	`O(n²)`	`O(1)`

Solution — js

```
function threeSum(nums) {
  nums.sort((a, b) => a - b);
  const out = [];
  for (let i = 0; i < nums.length - 2; i++) {
    if (nums[i] > 0) break;                       // no zero sum possible
    if (i > 0 && nums[i] === nums[i - 1]) continue; // skip duplicate anchor
    let lo = i + 1, hi = nums.length - 1;
    while (lo < hi) {
      const sum = nums[i] + nums[lo] + nums[hi];
      if (sum < 0) lo++;
      else if (sum > 0) hi--;
      else {
        out.push([nums[i], nums[lo], nums[hi]]);
        lo++; hi--;
        while (lo < hi && nums[lo] === nums[lo - 1]) lo++;  // skip dups
        while (lo < hi && nums[hi] === nums[hi + 1]) hi--;
      }
    }
  }
  return out;
}
```

Solution — cpp

```cpp
class Solution {
public:
    vector<vector<int>> threeSum(vector<int>& nums) {
        sort(nums.begin(), nums.end());
        vector<vector<int>> out;
        int n = nums.size();
        for (int i = 0; i + 2 < n; ++i) {
            if (nums[i] > 0) break;
            if (i > 0 && nums[i] == nums[i - 1]) continue;
            int lo = i + 1, hi = n - 1;
            while (lo < hi) {
                long sum = (long)nums[i] + nums[lo] + nums[hi];
                if (sum < 0) ++lo;
                else if (sum > 0) --hi;
                else {
                    out.push_back({nums[i], nums[lo], nums[hi]});
                    ++lo; --hi;
                    while (lo < hi && nums[lo] == nums[lo - 1]) ++lo;
                    while (lo < hi && nums[hi] == nums[hi + 1]) --hi;
                }
            }
        }
        return out;
    }
};
```

Solution — python

```python
class Solution:
    def threeSum(self, nums: list[int]) -> list[list[int]]:
        nums.sort()
        out = []
        n = len(nums)
        for i in range(n - 2):
            if nums[i] > 0:
                break
            if i > 0 and nums[i] == nums[i - 1]:
                continue
            lo, hi = i + 1, n - 1
            while lo < hi:
                s = nums[i] + nums[lo] + nums[hi]
                if s < 0:
                    lo += 1
                elif s > 0:
                    hi -= 1
                else:
                    out.append([nums[i], nums[lo], nums[hi]])
                    lo += 1
                    hi -= 1
                    while lo < hi and nums[lo] == nums[lo - 1]:
                        lo += 1
                    while lo < hi and nums[hi] == nums[hi + 1]:
                        hi -= 1
        return out
```

Solution — java

```java
class Solution {
    public List<List<Integer>> threeSum(int[] nums) {
        Arrays.sort(nums);
        List<List<Integer>> out = new ArrayList<>();
        for (int i = 0; i + 2 < nums.length; i++) {
            if (nums[i] > 0) break;
            if (i > 0 && nums[i] == nums[i - 1]) continue;
            int lo = i + 1, hi = nums.length - 1;
            while (lo < hi) {
                int sum = nums[i] + nums[lo] + nums[hi];
                if (sum < 0) lo++;
                else if (sum > 0) hi--;
                else {
                    out.add(Arrays.asList(nums[i], nums[lo], nums[hi]));
                    lo++; hi--;
                    while (lo < hi && nums[lo] == nums[lo - 1]) lo++;
                    while (lo < hi && nums[hi] == nums[hi + 1]) hi--;
                }
            }
        }
        return out;
    }
}
```

WALKTHROUGH

WHY SORTING IS ALLOWED HERE BUT NOT IN PLAIN TWO SUM:

the output is the *values*, not the indices. Sorting destroys indices, which matters only when they are the answer.

THE THREE DEDUPLICATION POINTS

, and you need all three: skip a repeated anchor (`nums[i] === nums[i-1]`), and after recording a triplet skip repeats at `lo` and at `hi` . Note the direction of the comparisons in those inner loops — `nums[lo] === nums[lo-1]` looks *backwards* because `lo` has already been incremented.

COMPLEXITY:

the outer loop is O(n) and each inner two-pointer scan is O(n), giving $O(n^2)$, which dominates the O(n log n) sort. This generalises: 4Sum is two nested anchors plus the same scan, $O(n^3)$.

Trapping rain water `Hard`

Pattern: Converging pointers with running maxima

Given `n` non-negative integers representing an elevation map where the width of each bar is 1, compute how much water is trapped after raining.

Input	Output	Note
`height = [0,1,0,2,1,0,1,3,2,1,2,1]`	`6`	
`height = [4,2,0,3,2,5]`	`9`	

HINTS

1. Think per column, not per pool. Water above column `i` is `min(maxLeft[i], maxRight[i]) - height[i]`, floored at zero.
2. That gives an easy O(n) time, O(n) space solution with two precomputed arrays. Now remove the arrays.
3. Two pointers: if `leftMax < rightMax`, then for the left column the answer is already decided by `leftMax` — whatever is on the right, the minimum is `leftMax`. So you can settle the left column now and advance.

Approach	Idea	Time	Space
Brute force	For each column scan left and right for the tallest bar.	`O(n²)`	`O(1)`
Prefix maxima	Precompute `maxLeft` and `maxRight` arrays, then one pass summing `min(l,r) - h`. Very clear, and the one to state first.	`O(n)`	`O(n)`
Two pointers	Maintain `leftMax` and `rightMax` as you converge. Whichever side has the smaller maximum is the side whose answer is already determined.	`O(n)`	`O(1)`
Monotonic stack	Fill pools horizontally as bars are popped. Same complexity — see chapter 20.	`O(n)`	`O(n)`

Solution — js

```
function trap(height) {
  let lo = 0, hi = height.length - 1;
  let leftMax = 0, rightMax = 0, total = 0;
  while (lo < hi) {
    if (height[lo] < height[hi]) {
      // left side is the limiting one -> its answer is decided
      leftMax = Math.max(leftMax, height[lo]);
      total += leftMax - height[lo];
      lo++;
    } else {
      rightMax = Math.max(rightMax, height[hi]);
      total += rightMax - height[hi];
      hi--;
    }
  }
  return total;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int trap(vector<int>& height) {
        int lo = 0, hi = (int)height.size() - 1;
        int leftMax = 0, rightMax = 0, total = 0;
        while (lo < hi) {
            if (height[lo] < height[hi]) {
                leftMax = max(leftMax, height[lo]);
                total += leftMax - height[lo];
                ++lo;
            } else {
                rightMax = max(rightMax, height[hi]);
                total += rightMax - height[hi];
                --hi;
            }
        }
        return total;
    }
};
```

Solution — python

```python
class Solution:
    def trap(self, height: list[int]) -> int:
        lo, hi = 0, len(height) - 1
        left_max = right_max = total = 0
        while lo < hi:
            if height[lo] < height[hi]:
                left_max = max(left_max, height[lo])
                total += left_max - height[lo]
                lo += 1
            else:
                right_max = max(right_max, height[hi])
                total += right_max - height[hi]
                hi -= 1
        return total
```

Solution — java

```java
class Solution {
    public int trap(int[] height) {
        int lo = 0, hi = height.length - 1;
        int leftMax = 0, rightMax = 0, total = 0;
        while (lo < hi) {
            if (height[lo] < height[hi]) {
                leftMax = Math.max(leftMax, height[lo]);
                total += leftMax - height[lo];
                lo++;
            } else {
                rightMax = Math.max(rightMax, height[hi]);
                total += rightMax - height[hi];
                hi--;
            }
        }
        return total;
    }
}
```

WALKTHROUGH

THE REFRAMING THAT MAKES THIS TRACTABLE:

stop thinking about pools. Ask instead, for each column independently, how deep the water is above it. That depth is `min(tallest to the left, tallest to the right) − own height`. Summing over columns gives the answer, and suddenly it is a one-pass problem.

WHY THE TWO-POINTER VERSION IS CORRECT.

Suppose `height[lo] < height[hi]`. We know `rightMax ≥ height[hi] > height[lo]`, and we know `leftMax` exactly. Since the true right maximum for column `lo` is at least `height[hi]`, the minimum of the two maxima *must* be `leftMax` — the right side cannot be the binding constraint. So the water above `lo` is settled as `leftMax − height[lo]`, and we can advance without ever knowing the true right maximum.

NOTE THAT `LEFTMAX − HEIGHT[LO]` IS NEVER NEGATIVE

: `leftMax` was just updated to include `height[lo]`, so the subtraction is safe with no explicit `max(0, …)`.

Arrays: the sliding window

A contiguous range with two moving edges and a running summary of what is inside it. The answer to almost every question containing the word "substring" or "subarray".

The pattern

```
THE PROBLEM SHAPE: "find the longest / shortest / count
of CONTIGUOUS subarrays satisfying some condition".

THE BRUTE FORCE regenerates every window from scratch:
  for each start i:            O(n)
    for each end j:            O(n)
      summarise a[i..j]        O(n)   -> O(n^3)

THE INSIGHT: consecutive windows OVERLAP almost
completely. Sliding from [i..j] to [i..j+1] adds ONE
element. Sliding from [i..j] to [i+1..j] removes ONE.
So maintain the summary INCREMENTALLY instead of
recomputing it.

  [ 2, 1, 5, 1, 3, 2 ]   k = 3
    ^-----^                sum = 8
       ^-----^             sum = 8 - 2 + 1 = 7
          ^-----^          sum = 7 - 1 + 3 = 9   <- best
             ^-----^       sum = 9 - 5 + 2 = 6

TWO KINDS OF WINDOW, and telling them apart is the whole
skill:

FIXED SIZE - the window is always exactly k wide.
  add a[right]; if (right >= k) remove a[right-k];
  record the answer once the window is full.

VARIABLE SIZE - grow greedily, shrink when invalid.
  for right in 0..n-1:
      ADD a[right] to the window
      while (WINDOW IS INVALID):
          REMOVE a[left]; left++
      record the answer          <- position matters!

WHY IT IS O(n) AND NOT O(n^2): `left` only ever moves
FORWARD and is bounded by n, so the total number of
shrink steps across the entire run is at most n. Each
element enters the window once and leaves at most once.
That is the amortised argument from chapter 02, and you
should be ready to say it aloud.

  TIME  O(n)      SPACE  O(1), or O(k) for a frequency map
```

When to reach for it

"Contiguous" + longest/shortest/max/min

Maximum sum subarray of size k, longest substring without repeats, minimum window substring.

"Substring" or "subarray"

The word almost always means a window. If it says *subsequence* (non-contiguous), it is usually DP instead.

A constraint that is monotonic

Growing the window can only make it "more invalid", shrinking only "more valid" — that is what makes the greedy shrink correct.

Counting subarrays with a property

"At most K" is windowable; "exactly K" = atMost(K) − atMost(K−1).

```
/* --- TEMPLATE 1: FIXED WINDOW OF SIZE k --- */
function fixedWindow(a, k) {
    let sum = 0, best = -Infinity;
    for (let right = 0; right < a.length; right++) {
        sum += a[right];                        // ADD
        if (right >= k) sum -= a[right - k];    // REMOVE the one
                                                // that fell out
        if (right >= k - 1) best = Math.max(best, sum);
    }                                           // ^ only once full
    return best;
}

/* --- TEMPLATE 2: LONGEST VALID WINDOW --- */
function longestValid(a) {
    let left = 0, best = 0;
    for (let right = 0; right < a.length; right++) {
        add(a[right]);
        while (!valid()) { remove(a[left]); left++; }
        best = Math.max(best, right - left + 1);   // AFTER the fix
    }
    return best;
}

/* --- TEMPLATE 3: SHORTEST VALID WINDOW --- */
function shortestValid(a) {
    let left = 0, best = Infinity;
    for (let right = 0; right < a.length; right++) {
        add(a[right]);
        while (valid()) {                          // note: WHILE VALID
            best = Math.min(best, right - left + 1);  // record FIRST
            remove(a[left]); left++;
        }
    }
    return best === Infinity ? 0 : best;
}

/* THE DIFFERENCE THAT CATCHES EVERYONE:

     LONGEST   shrink while INVALID, record AFTER the loop
     SHORTEST  shrink while VALID,   record INSIDE the loop

   Get these the wrong way round and you will pass the easy
   tests and fail the rest. Write the loop, then ask
   yourself: "at the moment I record the answer, is the
   window guaranteed valid?"                          */
```

Problems

Five problems, easy to hard. Attempt each for twenty minutes before opening the hints.

How it shows up

Symptom	Cause
Answer is always the whole array	Recording the size before shrinking back to validity
Off by one in the window size	Size is `right - left + 1`, not `right - left`
Fixed window includes partial windows	Missing the `right >= k - 1` guard before recording
Infinite loop in the shrink	`left` not incremented, or the condition can never become false
Frequency map keeps zero entries	Delete the key when its count hits 0, or `size` is wrong
Works for positives, wrong with negatives	Sliding window needs monotonicity — with negatives use prefix sums (ch. 06)
"Exactly K" solution is quadratic	Use `atMost(K) - atMost(K-1)`
Shortest-window answer is 0 when none exists	Sentinel `Infinity` not converted back

Check yourself

- ✓ Give the two window kinds and a problem for each.
- ✓ State the amortised argument for O(n).
- ✓ Write the fixed-window template including both guards.
- ✓ State the difference between the longest and shortest templates.
- ✓ Explain why a sliding window fails when the array contains negative numbers.
- ✓ Explain the `atMost(K) - atMost(K-1)` trick.
- ✓ Say when "substring" implies a window and when it implies DP.
- ✓ Write the window size expression correctly.

Problems

Maximum average subarray I `Easy`

Pattern: Fixed window

Given an integer array `nums` and an integer `k`, find the contiguous subarray of length exactly `k` with the maximum average, and return that average.

Answers within 1e-5 of the correct value are accepted.

Input	Output	Note
`nums = [1,12,-5,-6,50,3], k = 4`	`12.75`	(12 − 5 − 6 + 50) / 4 = 12.75
`nums = [5], k = 1`	`5.0`	

HINTS

1. Maximising the average of a fixed-size window is the same as maximising its sum — the divisor is constant.
2. Do not recompute the sum for each window. Moving right by one adds one element and drops one.
3. Only start recording once the window actually holds k elements.

Approach	Idea	Time	Space
Recompute each window	For each start index, sum k elements.	`O(n·k)`	`O(1)`
Fixed sliding window	Keep a running sum; add the entering element and subtract the leaving one.	`O(n)`	`O(1)`

Solution — js

```
function findMaxAverage(nums, k) {
  let sum = 0, best = -Infinity;
  for (let right = 0; right < nums.length; right++) {
    sum += nums[right];                       // element enters
    if (right >= k) sum -= nums[right - k];   // element leaves
    if (right >= k - 1) best = Math.max(best, sum);
  }
  return best / k;
}
```

Solution — cpp

```
class Solution {
public:
    double findMaxAverage(vector<int>& nums, int k) {
        long sum = 0, best = LONG_MIN;
        for (int right = 0; right < (int)nums.size(); ++right) {
            sum += nums[right];
            if (right >= k) sum -= nums[right - k];
            if (right >= k - 1) best = max(best, sum);
        }
        return (double)best / k;
    }
};
```

Solution — python

```
class Solution:
    def findMaxAverage(self, nums: list[int], k: int) -> float:
        s = 0
        best = float("-inf")
        for right in range(len(nums)):
            s += nums[right]
            if right >= k:
                s -= nums[right - k]
            if right >= k - 1:
                best = max(best, s)
        return best / k
```

Solution — java

```
class Solution {
    public double findMaxAverage(int[] nums, int k) {
        long sum = 0, best = Long.MIN_VALUE;
        for (int right = 0; right < nums.length; right++) {
            sum += nums[right];
            if (right >= k) sum -= nums[right - k];
            if (right >= k - 1) best = Math.max(best, sum);
        }
        return (double) best / k;
    }
}
```

WALKTHROUGH

THE TWO GUARDS DO DIFFERENT JOBS.

`right >= k` controls *removal*: only once the window has more than k elements does something fall out. `right >= k - 1` controls *recording*: the window first reaches size k when `right` is `k-1`. Getting either boundary wrong is the classic bug here, and the fix is to test with `k === nums.length` — a single full-array window.

Note that dividing only at the very end avoids accumulating floating-point error, and in C++/Java it keeps the running sum in integer arithmetic where overflow is the real concern (hence `long`).

Longest substring without repeating characters `Medium`

Pattern: Variable window, longest

Given a string `s`, return the length of the longest substring that contains no repeated characters.

Input	Output	Note
`s = "abcabcbb"`	`3`	"abc"
`s = "bbbbb"`	`1`	"b"
`s = "pwwkew"`	`3`	"wke" — note "pwke" is a subsequence, not a substring.

HINTS

1. This is the "longest" template: grow the right edge, and shrink from the left while the window is invalid.
2. The window is invalid exactly when the character just added is already inside it. Track membership with a Set or a Map of last-seen indices.
3. With a Set, shrink one character at a time. With a Map of last indices you can jump `left` straight past the duplicate — but be careful never to move `left` backwards.

Approach	Idea	Time	Space
Check every substring	For each pair (i, j) test whether the substring has duplicates.	`O(n³)`	`O(n)`
Window + Set	Grow right; while the new character is already in the set, remove `s[left]` and advance. Record the size after the window is valid again.	`O(n)`	`O(min(n, alphabet))`
Window + last-index Map	Jump `left` to `max(left, lastIndex[c] + 1)` in one step. Same complexity, fewer operations.	`O(n)`	`O(min(n, alphabet))`

Solution — js

```
function lengthOfLongestSubstring(s) {
  const inWindow = new Set();
  let left = 0, best = 0;
  for (let right = 0; right < s.length; right++) {
    // shrink while the window is INVALID
    while (inWindow.has(s[right])) {
      inWindow.delete(s[left]);
      left++;
    }
    inWindow.add(s[right]);
    best = Math.max(best, right - left + 1);  // record AFTER
  }
  return best;
}
```

Solution — cpp

```
class Solution {
public:
    int lengthOfLongestSubstring(string s) {
        vector<int> last(128, -1);
        int left = 0, best = 0;
        for (int right = 0; right < (int)s.size(); ++right) {
            if (last[s[right]] >= left) left = last[s[right]] + 1;
            last[s[right]] = right;
            best = max(best, right - left + 1);
        }
        return best;
    }
};
```

Solution — python

```
class Solution:
    def lengthOfLongestSubstring(self, s: str) -> int:
        in_window = set()
        left = best = 0
        for right, ch in enumerate(s):
            while ch in in_window:
                in_window.remove(s[left])
                left += 1
            in_window.add(ch)
            best = max(best, right - left + 1)
        return best
```

Solution — java

```
class Solution {
    public int lengthOfLongestSubstring(String s) {
        int[] last = new int[128];
        Arrays.fill(last, -1);
        int left = 0, best = 0;
        for (int right = 0; right < s.length(); right++) {
            char c = s.charAt(right);
            if (last[c] >= left) left = last[c] + 1;
            last[c] = right;
            best = Math.max(best, right - left + 1);
        }
        return best;
    }
}
```

WALKTHROUGH

TRACE `"ABBA"`, WHICH IS THE TEST THAT SEPARATES CORRECT SOLUTIONS FROM NEARLY-CORRECT ONES.

With the Set version: `a` enters, `b` enters, the second `b` triggers shrinking until the first `b` is gone (left = 2), then `a` arrives — and the first `a` was already removed, so the window is `"ba"`, length 2. Correct.

With a last-index Map, the naive `left = lastIndex[c] + 1` would set `left = 1` when the final `a` arrives, *moving left backwards* from 2 to 1 and wrongly reporting 3. That is why the jump must be `left = max(left, lastIndex[c] + 1)` — visible as the `last[c] >= left` guard in the C++ and Java versions. `"tmmzuxt"` tests the same thing.

Minimum size subarray sum `Medium`

Pattern: Variable window, shortest

Given an array of **positive** integers `nums` and a positive integer `target`, return the minimal length of a contiguous subarray whose sum is `>= target`. If there is none, return `0`.

Input	Output	Note
`target = 7, nums = [2,3,1,2,4,3]`	`2`	[4,3] has sum 7 and length 2.
`target = 4, nums = [1,4,4]`	`1`	
`target = 11, nums = [1,1,1,1,1,1,1,1]`	`0`	

HINTS

1. This is the "shortest" template — the mirror image of the previous problem.
2. Grow the window until it is *valid* (sum ≥ target). Then shrink from the left *while it stays valid*, recording the length each time before you shrink.
3. All values are positive, which is what makes the sum monotonic: growing can only increase it and shrinking can only decrease it.

Approach	Idea	Time	Space
All subarrays	Try every start and extend until the sum reaches the target.	`O(n²)`	`O(1)`

Approach	Idea	Time	Space
Prefix sums + binary search	Prefix sums are increasing for positive input, so binary search for each start.	`O(n log n)`	`O(n)`
Shrinking window	Expand right, then shrink left while still valid, recording the length before each shrink.	`O(n)`	`O(1)`

Solution — js

```
function minSubArrayLen(target, nums) {
  let left = 0, sum = 0, best = Infinity;
  for (let right = 0; right < nums.length; right++) {
    sum += nums[right];
    // shrink WHILE VALID, recording BEFORE each shrink
    while (sum >= target) {
      best = Math.min(best, right - left + 1);
      sum -= nums[left];
      left++;
    }
  }
  return best === Infinity ? 0 : best;
}
```

Solution — cpp

```
class Solution {
public:
    int minSubArrayLen(int target, vector<int>& nums) {
        int left = 0, best = INT_MAX;
        long sum = 0;
        for (int right = 0; right < (int)nums.size(); ++right) {
            sum += nums[right];
            while (sum >= target) {
                best = min(best, right - left + 1);
                sum -= nums[left++];
            }
        }
        return best == INT_MAX ? 0 : best;
    }
};
```

Solution — python

```
class Solution:
    def minSubArrayLen(self, target: int, nums: list[int]) -> int:
        left = 0
        s = 0
        best = float("inf")
        for right, v in enumerate(nums):
            s += v
            while s >= target:
                best = min(best, right - left + 1)
                s -= nums[left]
                left += 1
        return 0 if best == float("inf") else best
```

Solution — java

```
class Solution {
    public int minSubArrayLen(int target, int[] nums) {
        int left = 0, best = Integer.MAX_VALUE;
        long sum = 0;
        for (int right = 0; right < nums.length; right++) {
            sum += nums[right];
            while (sum >= target) {
                best = Math.min(best, right - left + 1);
                sum -= nums[left++];
            }
        }
        return best == Integer.MAX_VALUE ? 0 : best;
    }
}
```

WALKTHROUGH

COMPARE THIS LOOP WITH THE PREVIOUS PROBLEM'S AND THE SYMMETRY IS THE LESSON.

There: `while (invalid) shrink;` then record. Here: `while (valid) { record; shrink; }`. The rule that generates both: *record the answer only at a moment when the window is in the state you are measuring.* For "longest valid" that is after restoring validity; for "shortest valid" that is before destroying it.

WHY POSITIVITY MATTERS.

The greedy shrink assumes that removing a left element can only *decrease* the sum. With a negative number present that is false — removing it would increase the sum, so a window you discarded might have become valid again. Problems with negatives need prefix sums and a hash map instead (chapter 06). Interviewers ask "what if the numbers can be negative?" precisely to see whether you know this.

Longest subarray with at most K distinct `Medium`

Pattern: Variable window + frequency map

Given an array `nums` and an integer `k`, return the length of the longest contiguous subarray containing **at most `k` distinct** values.

This is the "Fruit into Baskets" problem with `k = 2`, and the engine behind "longest substring with at most k distinct characters".

Input	Output	Note
`nums = [1,2,1,2,3], k = 2`	`4`	[1,2,1,2]
`nums = [1,2,3,4], k = 1`	`1`	
`nums = [1,1,1,1], k = 3`	`4`	

HINTS

1. Track how many times each value occurs inside the window, in a Map.
2. The number of distinct values is the Map's `size` — but only if you *delete* keys whose count drops to zero.
3. Invalid means `map.size > k`. Shrink until it is not.

Approach	Idea	Time	Space
All subarrays	For every start, extend and count distinct values with a set.	`O(n²)`	`O(n)`
Window + frequency map	Grow right, incrementing counts. While more than k distinct, decrement from the left and delete zero counts. Record after restoring validity.	`O(n)`	`O(k)`

Solution — js

```
function longestAtMostKDistinct(nums, k) {
  const freq = new Map();
  let left = 0, best = 0;
  for (let right = 0; right < nums.length; right++) {
    const v = nums[right];
    freq.set(v, (freq.get(v) ?? 0) + 1);

    while (freq.size > k) {                 // INVALID
      const u = nums[left];
      const c = freq.get(u) - 1;
      if (c === 0) freq.delete(u);          // MUST delete, or
      else freq.set(u, c);                  // size stays wrong
      left++;
    }
    best = Math.max(best, right - left + 1);
  }
  return best;
}
```

Solution — cpp

```
class Solution {
public:
    int longestAtMostKDistinct(vector<int>& nums, int k) {
        unordered_map<int,int> freq;
        int left = 0, best = 0;
        for (int right = 0; right < (int)nums.size(); ++right) {
            ++freq[nums[right]];
            while ((int)freq.size() > k) {
                if (--freq[nums[left]] == 0) freq.erase(nums[left]);
                ++left;
            }
            best = max(best, right - left + 1);
        }
        return best;
    }
};
```

Solution — python

```python
from collections import defaultdict

class Solution:
    def longestAtMostKDistinct(self, nums: list[int], k: int) -> int:
        freq = defaultdict(int)
        left = best = 0
        for right, v in enumerate(nums):
            freq[v] += 1
            while len(freq) > k:
                u = nums[left]
                freq[u] -= 1
                if freq[u] == 0:
                    del freq[u]
                left += 1
            best = max(best, right - left + 1)
        return best
```

Solution — java

```java
class Solution {
    public int longestAtMostKDistinct(int[] nums, int k) {
        Map<Integer,Integer> freq = new HashMap<>();
        int left = 0, best = 0;
        for (int right = 0; right < nums.length; right++) {
            freq.merge(nums[right], 1, Integer::sum);
            while (freq.size() > k) {
                int u = nums[left];
                if (freq.merge(u, -1, Integer::sum) == 0) freq.remove(u);
                left++;
            }
            best = Math.max(best, right - left + 1);
        }
        return best;
    }
}
```

WALKTHROUGH

THE BUG THIS PROBLEM EXISTS TO TEACH:

leaving zero-count keys in the map. `freq.size` is then a count of values ever seen in the window rather than currently in it, the shrink loop never terminates correctly, and the answer is too small. Deleting on zero is not an optimisation — it is what makes `size` mean "distinct".

THE EXTENSION WORTH KNOWING.

"Exactly K distinct" is not directly windowable, because the property is not monotonic. The standard trick is `exactly(K) = atMost(K) - atMost(K-1)`: every subarray with at most K distinct, minus those with at most K−1, leaves precisely those with exactly K. Two linear passes, still O(n), and it converts a whole family of "exactly" problems into this one.

Minimum window substring `Hard`

Pattern: Shortest window + need/have counting

Given strings `s` and `t`, return the shortest substring of `s` that contains every character of `t` **including duplicates**. If there is none, return the empty string.

Input	Output	Note
`s = "ADOBECODEBANC", t = "ABC"`	`"BANC"`	
`s = "a", t = "a"`	`"a"`	
`s = "a", t = "aa"`	`""`	Two a's are required but only one is available.

HINTS

1. Counts matter, not just presence: `t = "aa"` needs two a's.
2. Keep a `need` map from `t`, and a counter `formed` of how many *distinct* characters currently meet their required count.
3. The window is valid when `formed === need.size`. Then apply the "shortest" template: record, then shrink.
4. Only decrement `formed` when a count drops strictly *below* what is required — going from 3 copies to 2 when only 2 are needed does not break validity.

Approach	Idea	Time	Space
All substrings	Check each of the O(n^2) substrings against the required counts.	`O(n²·m)`	`O(m)`
Window with need/have counts	Expand right until valid, then shrink left while it stays valid, tracking the best. The `formed` counter makes the validity check O(1).	`O(n + m)`	`O(m)`

Solution — js

```javascript
function minWindow(s, t) {
  if (t.length === 0 || s.length < t.length) return "";

  const need = new Map();
  for (const c of t) need.set(c, (need.get(c) ?? 0) + 1);

  const have = new Map();
  let formed = 0;                    // chars meeting their quota
  let left = 0, bestLen = Infinity, bestStart = 0;

  for (let right = 0; right < s.length; right++) {
    const c = s[right];
    if (need.has(c)) {
      const h = (have.get(c) ?? 0) + 1;
      have.set(c, h);
      if (h === need.get(c)) formed++;   // exactly meets it now
    }

    // shrink WHILE VALID, recording BEFORE shrinking
    while (formed === need.size) {
      if (right - left + 1 < bestLen) {
        bestLen = right - left + 1;
        bestStart = left;
      }
      const d = s[left];
      if (need.has(d)) {
        const h = have.get(d) - 1;
        have.set(d, h);
        if (h < need.get(d)) formed--;   // dropped BELOW quota
      }
      left++;
    }
  }
  return bestLen === Infinity ? "" : s.slice(bestStart, bestStart + bestLen);
}
```

Solution — cpp

```cpp
class Solution {
public:
    string minWindow(string s, string t) {
        if (t.empty() || s.size() < t.size()) return "";
        unordered_map<char,int> need, have;
        for (char c : t) ++need[c];
        int formed = 0, left = 0, bestLen = INT_MAX, bestStart = 0;
        for (int right = 0; right < (int)s.size(); ++right) {
            char c = s[right];
            if (need.count(c) && ++have[c] == need[c]) ++formed;
            while (formed == (int)need.size()) {
                if (right - left + 1 < bestLen) {
                    bestLen = right - left + 1;
                    bestStart = left;
                }
                char d = s[left];
                if (need.count(d) && --have[d] < need[d]) --formed;
                ++left;
            }
        }
        return bestLen == INT_MAX ? "" : s.substr(bestStart, bestLen);
    }
};
```

Solution — python

```python
from collections import Counter

class Solution:
    def minWindow(self, s: str, t: str) -> str:
        if not t or len(s) < len(t):
            return ""
        need = Counter(t)
        have = Counter()
        formed = 0
        left = 0
        best_len = float("inf")
        best_start = 0
        for right, c in enumerate(s):
            if c in need:
                have[c] += 1
                if have[c] == need[c]:
                    formed += 1
            while formed == len(need):
                if right - left + 1 < best_len:
                    best_len = right - left + 1
                    best_start = left
                d = s[left]
                if d in need:
                    have[d] -= 1
                    if have[d] < need[d]:
                        formed -= 1
                left += 1
        return "" if best_len == float("inf") else s[best_start:best_start + best_len]
```

Solution — java

```java
class Solution {
    public String minWindow(String s, String t) {
        if (t.isEmpty() || s.length() < t.length()) return "";
        Map<Character,Integer> need = new HashMap<>(), have = new HashMap<>();
        for (char c : t.toCharArray()) need.merge(c, 1, Integer::sum);
        int formed = 0, left = 0, bestLen = Integer.MAX_VALUE, bestStart = 0;
        for (int right = 0; right < s.length(); right++) {
            char c = s.charAt(right);
            if (need.containsKey(c)) {
                int h = have.merge(c, 1, Integer::sum);
                if (h == need.get(c)) formed++;
            }
            while (formed == need.size()) {
                if (right - left + 1 < bestLen) {
                    bestLen = right - left + 1;
                    bestStart = left;
                }
                char d = s.charAt(left);
                if (need.containsKey(d)) {
                    int h = have.merge(d, -1, Integer::sum);
                    if (h < need.get(d)) formed--;
                }
                left++;
            }
        }
        return bestLen == Integer.MAX_VALUE ? "" : s.substring(bestStart, bestStart + bestLen);
    }
}
```

WALKTHROUGH

WHY `FORMED` EXISTS.

The naive validity check compares two maps entry by entry, which is O(alphabet) inside a loop that already runs n times. The `formed` counter reduces validity to a single integer comparison, and maintaining it costs O(1) per step — the whole reason this is O(n) rather than O(n·m).

THE TWO CONDITIONS MUST BE ASYMMETRIC, AND THIS IS THE SUBTLE PART.

On the way in, increment `formed` only when the count becomes *exactly* the requirement (`h === need`); using `>=` would count the same character repeatedly. On the way out, decrement only when the count falls *strictly below* (`h < need`); a surplus copy leaving does not invalidate anything. Test `"aa"/"aa"` and `"bba"/"ab"` — those catch both mistakes.

COMPLEXITY.

Each character enters and leaves the window at most once, so despite the nested `while` this is O(n + m) — the same amortised argument as every window in this chapter.

Arrays: prefix sums and difference arrays

Precompute once so every range query is O(1). The technique that rescues you when a sliding window fails because the array contains negative numbers.

The pattern

```
PREFIX SUM: P[i] = sum of the first i elements.

  a =      [ 3,  1,  4,  1,  5 ]
  P = [ 0,   3,  4,  8,  9, 14 ]
       ^
       P[0] = 0, the EMPTY prefix — always include it

THEN THE SUM OF ANY RANGE IS ONE SUBTRACTION:

  sum(a[l..r])  =  P[r+1] - P[l]

  sum(a[1..3]) = P[4] - P[1] = 9 - 3 = 6   (1+4+1) ✓

BUILD O(n) ONCE, then EVERY QUERY IS O(1). Without it,
q queries cost O(n·q).

THE OFF-BY-ONE IS THE WHOLE DIFFICULTY. Using a
1-INDEXED prefix array of length n+1 makes it disappear:
P[i] means "sum of the first i elements", so P[0] = 0
needs no special case and l = 0 works naturally.

------------------------------------------------------------

DIFFERENCE ARRAY — the mirror image. Use it for RANGE
UPDATES with a single query at the end.

  to add v to a[l..r]:
      D[l]   += v
      D[r+1] -= v          <-- one operation, not r-l+1

  after all updates, PREFIX-SUM D to recover the array.

  add 5 to [1..3] of a zero array of length 5:
     D = [0, 5, 0, 0, -5]
     prefix sums -> [0, 5, 5, 5, 0]  ✓

m updates in O(m), one reconstruction in O(n), instead of
O(m·n).

------------------------------------------------------------

WHICH TO USE:
  many RANGE QUERIES, no updates      -> PREFIX SUM
  many RANGE UPDATES, one final read  -> DIFFERENCE ARRAY
  both, interleaved                   -> a Fenwick tree
                                         or segment tree

AND THE COMBINATION THAT SOLVES THE HARD PROBLEMS:
PREFIX SUM + HASH MAP. When you need a range with a
particular property and the values can be negative, store
each prefix sum you have seen and look up the one you
need (chapter 13's Subarray Sum Equals K).
```

When to reach for it

Repeated range-sum queries

"Sum between i and j" asked many times. Build once, answer in O(1).

Subarray sum with negatives

A sliding window needs monotonicity. Negatives break it — use prefix sums plus a hash map.

"Divisible by k", "equal counts"

Map the property onto a prefix value: remainder, or +1/−1 balance.

Many range increments

Difference array: two writes per update, one reconstruction.

2-D region sums

Inclusion–exclusion on a 2-D prefix table.

Running product / XOR

Any associative, invertible operation works the same way.

```
/* --- BUILD --- */
const P = new Array(a.length + 1).fill(0);
for (let i = 0; i < a.length; i++) P[i + 1] = P[i] + a[i];
// range [l, r] inclusive:  P[r + 1] - P[l]

/* --- 2-D PREFIX SUM, inclusion-exclusion --- */
//  P[i+1][j+1] = a[i][j] + P[i][j+1] + P[i+1][j] - P[i][j]
//                                                  ^ added twice
//  sum of rectangle (r1,c1)..(r2,c2):
//    P[r2+1][c2+1] - P[r1][c2+1] - P[r2+1][c1] + P[r1][c1]

/* --- THE PREFIX + HASH MAP SHAPE --- */
const seen = new Map([[0, -1]]);   // prefix value -> earliest index
let running = 0;
for (let i = 0; i < a.length; i++) {
    running += a[i];
    const key = f(running);         // the property you care about
    if (seen.has(key)) best = Math.max(best, i - seen.get(key));
    else seen.set(key, i);          // KEEP THE EARLIEST index only
}
/* STORING ONLY THE FIRST OCCURRENCE gives the LONGEST range.
   Storing counts instead gives the NUMBER of ranges
   (chapter 13). Which one you need decides the map's value
   type - get this backwards and the answer is subtly wrong. */
```

Problems

How it shows up

Symptom	Cause
Off by one on every range	Mixing 0-indexed and 1-indexed prefix conventions
Ranges starting at 0 are wrong	Missing the `P[0] = 0` entry
Sliding window gives the wrong answer	Array has negatives — switch to prefix sums
Longest range too short	Overwrote the map entry — keep the *earliest* index
Count of ranges too small	Stored an index where a count was needed
Negative remainder in a modulo problem	`((x % k) + k) % k` — JS `%` keeps the sign
2-D sums double-count	Forgot to add back the doubly-subtracted corner
Difference array off by one at the end	`D` needs length `n+1` for `r+1`

Check yourself

- ✓ Write the prefix build and the range-sum formula.
- ✓ Say why `P[0] = 0` removes a special case.
- ✓ Explain when prefix sums beat a sliding window.
- ✓ Give the difference-array update and reconstruction.
- ✓ Write the 2-D range formula and explain the added-back corner.
- ✓ Say when to store an index versus a count in the map.
- ✓ Give the fix for negative remainders.
- ✓ Say what structure you need when queries and updates interleave.

Problems

Range sum query — immutable `Easy`

Pattern: Prefix sum build

Given an array `nums` and a list of `[left, right]` query pairs (inclusive), return an array of the sums of each range.

There may be very many queries, so each one must be answered in O(1) after preprocessing.

Input	Output	Note
`nums = [-2,0,3,-5,2,-1], queries = [[0,2],[2,5],[0,5]]`	`[1,-1,-3]`	

HINTS

1. Build `P` of length `n+1` where `P[i]` is the sum of the first `i` elements.
2. `P[0]` must be 0 so that ranges starting at index 0 need no special case.
3. The inclusive range `[l, r]` is `P[r+1] - P[l]`.

Approach	Idea	Time	Space
Sum per query	Loop over each range. Fine for one query, quadratic for many.	`O(n·q)`	`O(1)`
Prefix sums	Build once in O(n), then each query is one subtraction.	`O(n + q)`	`O(n)`

Solution — js

```
function rangeSums(nums, queries) {
  const n = nums.length;
  const P = new Array(n + 1).fill(0);
  for (let i = 0; i < n; i++) P[i + 1] = P[i] + nums[i];
  return queries.map(([l, r]) => P[r + 1] - P[l]);
}
```

Solution — cpp

```
class NumArray {
    vector<long> P;
public:
    NumArray(vector<int>& nums) : P(nums.size() + 1, 0) {
        for (size_t i = 0; i < nums.size(); ++i)
            P[i + 1] = P[i] + nums[i];
    }
    int sumRange(int l, int r) { return P[r + 1] - P[l]; }
};
```

Solution — python

```
from itertools import accumulate

class NumArray:
    def __init__(self, nums: list[int]):
        self.P = [0] + list(accumulate(nums))

    def sumRange(self, l: int, r: int) -> int:
        return self.P[r + 1] - self.P[l]
```

Solution — java

```
class NumArray {
    private final int[] P;
    public NumArray(int[] nums) {
        P = new int[nums.length + 1];
        for (int i = 0; i < nums.length; i++) P[i + 1] = P[i] + nums[i];
    }
    public int sumRange(int l, int r) { return P[r + 1] - P[l]; }
}
```

WALKTHROUGH

THE CONVENTION IS THE WHOLE TRICK.

Defining `P[i]` as "the sum of the first `i` elements" — rather than "the sum up to index `i`" — makes `P[0] = 0` meaningful and the formula uniform. With the other convention you need `l === 0 ? P[r] : P[r] - P[l-1]`, and that branch is where the bug lives.

NOTE THE SIZES:

`P` has `n+1` entries, and `P[r+1]` with `r = n-1` reads the last one. Sizing `P` as `n` gives an out-of-bounds read on the full-array query.

Find the pivot index `Easy`

Pattern: Running prefix vs suffix

Given an array `nums`, return the leftmost index where the sum of everything strictly to the left equals the sum of everything strictly to the right. Return `-1` if there is none.

The sum of an empty side is 0.

Input	Output	Note
`nums = [1,7,3,6,5,6]`	`3`	left = 1+7+3 = 11, right = 5+6 = 11.
`nums = [1,2,3]`	`-1`	
`nums = [2,1,-1]`	`0`	left is empty (0), right = 1 + (−1) = 0.

HINTS

1. You do not need a full prefix array — one running total and the grand total are enough.
2. At index `i`, if `left` is the sum before `i`, then the right side is `total - left - nums[i]`.
3. Add `nums[i]` to `left` only *after* testing index `i`.

Approach	Idea	Time	Space
Recompute both sides	For each index sum both halves.	`O(n²)`	`O(1)`
Total minus running left	One pass with the grand total and a running left sum.	`O(n)`	`O(1)`

Solution — js

```
function pivotIndex(nums) {
  const total = nums.reduce((a, b) => a + b, 0);
  let left = 0;
  for (let i = 0; i < nums.length; i++) {
    // right side = everything except left and nums[i]
    if (left === total - left - nums[i]) return i;
    left += nums[i];          // AFTER the test
  }
  return -1;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int pivotIndex(vector<int>& nums) {
        long total = accumulate(nums.begin(), nums.end(), 0L), left = 0;
        for (int i = 0; i < (int)nums.size(); ++i) {
            if (left == total - left - nums[i]) return i;
            left += nums[i];
        }
        return -1;
    }
};
```

Solution — python

```python
class Solution:
    def pivotIndex(self, nums: list[int]) -> int:
        total = sum(nums)
        left = 0
        for i, x in enumerate(nums):
            if left == total - left - x:
                return i
            left += x
        return -1
```

Solution — java

```java
class Solution {
    public int pivotIndex(int[] nums) {
        int total = 0;
        for (int x : nums) total += x;
        int left = 0;
        for (int i = 0; i < nums.length; i++) {
            if (left == total - left - nums[i]) return i;
            left += nums[i];
        }
        return -1;
    }
}
```

WALKTHROUGH

TESTING BEFORE ACCUMULATING

is what makes "the sum strictly to the left" correct at index 0, where the left side is empty and must be 0. Moving the `left += nums[i]` above the test breaks `[2,1,-1]`, which expects index 0.

NEGATIVE NUMBERS MATTER HERE

— `[-1,-1,-1,-1,-1,0]` and `[1,-1,0]` both have pivots that a "sums only grow" assumption would miss. This is a small reminder of why the sliding window is not applicable to signed data.

Product of array except self `Medium`

Pattern: Prefix and suffix passes

Given an array `nums`, return an array `out` where `out[i]` is the product of every element *except* `nums[i]`.

Solve it **without division** and in O(n). The output array does not count toward extra space.

Input	Output	Note
`nums = [1,2,3,4]`	`[24,12,8,6]`	
`nums = [-1,1,0,-3,3]`	`[0,0,9,0,0]`	

HINTS

1. The answer at `i` is (product of everything to the left) × (product of everything to the right).
2. That is a prefix product and a suffix product — the same idea as prefix sums with × instead of +.
3. Division would be simpler, but it breaks on zeros. Two passes over the output array need no extra space beyond the answer.

Approach	Idea	Time	Space
Divide by each element	Compute the total product and divide. **Fails on zeros**, and the problem forbids it.	`O(n)`	`O(1)`
Two arrays	Build prefix and suffix product arrays, then multiply pairwise.	`O(n)`	`O(n)`
Two passes into the output	First pass writes prefix products into `out`; second pass multiplies by a running suffix product carried in a single variable.	`O(n)`	`O(1)` `extra`

Solution — js

```
function productExceptSelf(nums) {
  const n = nums.length;
  const out = new Array(n).fill(1);

  // pass 1: out[i] = product of everything LEFT of i
  let prefix = 1;
  for (let i = 0; i < n; i++) {
    out[i] = prefix;
    prefix *= nums[i];
  }

  // pass 2: multiply in the product of everything RIGHT of i
  let suffix = 1;
  for (let i = n - 1; i >= 0; i--) {
    out[i] *= suffix;
    suffix *= nums[i];
  }
  return out;
}
```

Solution — cpp

```
class Solution {
public:
    vector<int> productExceptSelf(vector<int>& nums) {
        int n = nums.size();
        vector<int> out(n, 1);
        long prefix = 1;
        for (int i = 0; i < n; ++i) { out[i] = prefix; prefix *= nums[i]; }
        long suffix = 1;
        for (int i = n - 1; i >= 0; --i) { out[i] *= suffix; suffix *= nums[i]; }
        return out;
    }
};
```

Solution — python

```python
class Solution:
    def productExceptSelf(self, nums: list[int]) -> list[int]:
        n = len(nums)
        out = [1] * n
        prefix = 1
        for i in range(n):
            out[i] = prefix
            prefix *= nums[i]
        suffix = 1
        for i in range(n - 1, -1, -1):
            out[i] *= suffix
            suffix *= nums[i]
        return out
```

Solution — java

```java
class Solution {
    public int[] productExceptSelf(int[] nums) {
        int n = nums.length;
        int[] out = new int[n];
        int prefix = 1;
        for (int i = 0; i < n; i++) { out[i] = prefix; prefix *= nums[i]; }
        int suffix = 1;
        for (int i = n - 1; i >= 0; i--) { out[i] *= suffix; suffix *= nums[i]; }
        return out;
    }
}
```

WALKTHROUGH

TRACE `[1,2,3,4]`.

Pass 1 writes the running prefix *before* multiplying it in, giving `[1, 1, 2, 6]` — each entry is the product of everything to its left. Pass 2 walks backwards doing the same with a suffix variable: index 3 gets ×1, index 2 gets ×4, index 1 gets ×12, index 0 gets ×24, producing `[24,12,8,6]`.

WRITING BEFORE UPDATING

is the same discipline as the pivot problem — it is what excludes `nums[i]` itself from its own answer.

WHY DIVISION IS DISALLOWED:

with one zero every other answer needs the product of the non-zero elements, and with two zeros everything is 0. Handling that takes a zero-count special case; the two-pass version has no special cases at all, which is why it is the expected answer.

Contiguous array of equal 0s and 1s `Medium`

Pattern: Prefix balance + earliest-index map

Given a binary array `nums`, return the length of the longest contiguous subarray containing an **equal number** of 0s and 1s.

Input	Output	Note
`nums = [0,1]`	`2`	

Input	Output	Note
`nums = [0,1,0]`	`2`	Either [0,1] or [1,0].
`nums = [0,1,1,1,0,0]`	`6`	

HINTS

1. Turn "equal counts" into a single number: treat 0 as −1 and 1 as +1, and keep a running balance.
2. A subarray has equal counts exactly when its balance is 0 — that is, when the running balance is the *same* at both ends.
3. So store each balance value with the earliest index where it occurred, and when you see it again the span between is a valid subarray.
4. Seed the map with balance 0 at index −1, so a valid subarray starting at index 0 is measured correctly.

Approach	Idea	Time	Space
All subarrays	Count 0s and 1s in every subarray.	`O(n²)`	`O(1)`
Balance + earliest index map	+1/−1 running balance; first occurrence of each balance recorded. Equal balances bracket a balanced subarray.	`O(n)`	`O(n)`

Solution — js

```
function findMaxLength(nums) {
  // balance -> EARLIEST index at which it occurred
  const first = new Map([[0, -1]]);
  let balance = 0, best = 0;

  for (let i = 0; i < nums.length; i++) {
    balance += nums[i] === 1 ? 1 : -1;

    if (first.has(balance)) {
      // same balance seen before -> the span between is balanced
      best = Math.max(best, i - first.get(balance));
    } else {
      first.set(balance, i);       // keep only the FIRST
    }
  }
  return best;
}
```

Solution — cpp

```
class Solution {
public:
    int findMaxLength(vector<int>& nums) {
        unordered_map<int,int> first{{0, -1}};
        int balance = 0, best = 0;
        for (int i = 0; i < (int)nums.size(); ++i) {
            balance += nums[i] == 1 ? 1 : -1;
            auto it = first.find(balance);
            if (it != first.end()) best = max(best, i - it->second);
            else first[balance] = i;
        }
        return best;
    }
};
```

Solution — python

```python
class Solution:
    def findMaxLength(self, nums: list[int]) -> int:
        first = {0: -1}
        balance = best = 0
        for i, x in enumerate(nums):
            balance += 1 if x == 1 else -1
            if balance in first:
                best = max(best, i - first[balance])
            else:
                first[balance] = i
        return best
```

Solution — java

```java
class Solution {
    public int findMaxLength(int[] nums) {
        Map<Integer,Integer> first = new HashMap<>();
        first.put(0, -1);
        int balance = 0, best = 0;
        for (int i = 0; i < nums.length; i++) {
            balance += nums[i] == 1 ? 1 : -1;
            if (first.containsKey(balance)) best = Math.max(best, i - first.get(balance));
            else first.put(balance, i);
        }
        return best;
    }
}
```

WALKTHROUGH

THE REFRAMING IS THE ENTIRE PROBLEM.

"Equal numbers of 0s and 1s" is awkward to track as two counters, but as a single ±1 balance it becomes "the prefix balance is unchanged across this range" — and that is a prefix-sum question with a hash map, exactly like Subarray Sum Equals K.

EARLIEST INDEX, NOT LATEST.

Because you want the *longest* span, the map must keep the first time each balance appeared — hence the `else`. Overwriting on every occurrence yields the shortest span instead, and `[0,1,1,1,0,0]` would return 2 rather than 6.

THE `{0: -1}` SEED

handles a subarray that starts at index 0: its balance returns to 0, and the length is `i - (-1) = i + 1`. Without it, `[0,1]` returns 0.

Arrays: Kadane and maximum subarray

One decision, made at every element: extend the run, or start a new one. It is the smallest dynamic program there is, and recognising its shape unlocks a whole family of problems.

The pattern

```
THE PROBLEM: the contiguous subarray with the largest
sum.

THE INSIGHT — at each element there are only TWO choices:

  EXTEND the best run ending at the previous element, or
  START a fresh run at this element.

     cur = max(a[i],  cur + a[i])
               ^          ^
           start new    extend
     best = max(best, cur)

AND THE EQUIVALENT FORM THAT EXPLAINS IT BEST:

     if (cur < 0) cur = 0;    // a negative prefix can
     cur += a[i];             // only HURT what follows
     best = max(best, cur);

THE ARGUMENT: if the best run ending at i-1 has a
NEGATIVE sum, attaching it to a[i] makes things worse
than starting fresh. So drop it. That is the whole
algorithm.

  a = [ -2,  1, -3,  4, -1,  2,  1, -5,  4 ]
cur =   -2   1  -2   4   3   5   6   1   5
best =  -2   1   1   4   4   5   6   6   6
                               ^ answer

THE TRAP: INITIALISE best TO -Infinity (or a[0]), NOT 0.
With an all-negative array the answer is the largest
single element, and starting at 0 wrongly returns 0 for
an empty subarray the problem does not allow.

THE SHAPE GENERALISES. Kadane is a one-state DP:
  "the best answer ENDING HERE, given the best answer
   ending one step back."
Once you see that, the variants follow:

  MAXIMUM PRODUCT   track min AND max (negatives flip)
  CIRCULAR          answer = max(normal, total - minSubarray)
  MAX SUM WITH ONE
    DELETION        two states: no deletion used, one used
  BEST TIME TO
    BUY/SELL STOCK  Kadane on the difference array

COST: O(n) time, O(1) space, one pass.
```

When to reach for it

"Maximum/minimum contiguous sum"

The plain case. Also works for products and XOR with adjustments.

Best profit from one buy and one sell

Kadane over consecutive differences, or equivalently track the running minimum.

Values can be negative and it is contiguous

A sliding window fails; Kadane does not.

"Ending here" feels natural

Whenever the answer at `i` depends only on the answer at `i-1`, it is a one-state DP.

```
/* --- THE TEMPLATE --- */
function maxSubArray(a) {
    let cur = a[0], best = a[0];     // NOT 0
    for (let i = 1; i < a.length; i++) {
        cur = Math.max(a[i], cur + a[i]);
        best = Math.max(best, cur);
    }
    return best;
}

/* --- RECOVERING THE ACTUAL SUBARRAY, a common follow-up --- */
let cur = a[0], best = a[0];
let s = 0, bestL = 0, bestR = 0;
for (let i = 1; i < a.length; i++) {
    if (cur + a[i] < a[i]) { cur = a[i]; s = i; }  // restarted
    else                   cur = cur + a[i];
    if (cur > best) { best = cur; bestL = s; bestR = i; }
}
// the subarray is a[bestL..bestR]

/* --- MAXIMUM PRODUCT: why one variable is not enough --- */
    A large NEGATIVE product becomes the largest POSITIVE
    product the moment it meets another negative. So you
    must carry BOTH extremes:
        newMax = max(x, max*x, min*x)
        newMin = min(x, max*x, min*x)
    and compute both from the OLD values — overwrite max
    first and newMin uses the wrong one.               */
```

Problems

How it shows up

Symptom	Cause
All-negative array returns 0	`best` initialised to 0 instead of `a[0]`
Maximum product wrong after a negative	Only tracking the maximum — carry the minimum too

Symptom	Cause
Product answer wrong by one step	Overwrote `max` before computing `min`
Circular answer wrong when all negative	`total - minSubarray` is 0 (empty) — special-case it
Stock profit negative	Profit must be floored at 0 when no profitable trade exists
Returned the subarray but the bounds are off	Start index not reset at the moment the run restarts
Crash on an empty array	`a[0]` read without a length check

Check yourself

- ✓ State the two choices Kadane makes at each element.
- ✓ Give the argument for discarding a negative running sum.
- ✓ Say why `best` must not start at 0.
- ✓ Write the version that recovers the subarray bounds.
- ✓ Explain why maximum product needs two tracked values.
- ✓ Give the circular-array formula and its edge case.
- ✓ Explain how the stock problem reduces to Kadane.
- ✓ Say what makes Kadane a one-state dynamic program.

Problems

Maximum subarray `Easy`

Pattern: Kadane

Given an integer array `nums`, find the contiguous subarray with the largest sum and return that sum. The subarray must contain at least one element.

Input	Output	Note
`nums = [-2,1,-3,4,-1,2,1,-5,4]`	`6`	[4,-1,2,1]
`nums = [1]`	`1`	
`nums = [-1]`	`-1`	All negative — the answer is the largest single element.

HINTS

1. At each element, either extend the run ending at the previous element or start a new run here.
2. If the running sum has gone negative, it can only reduce whatever comes next — drop it.
3. Initialise both the running sum and the best to `nums[0]`, not to 0, or an all-negative array returns 0.

Approach	Idea	Time	Space
All subarrays	Two nested loops with a running sum.	`O(n²)`	`O(1)`
Divide and conquer	Best in the left half, the right half, or crossing the middle. Worth naming as it shows the recursion.	`O(n log n)`	`O(log n)`

Approach	Idea	Time	Space
Kadane	One pass, one decision per element.	`O(n)`	`O(1)`

Solution — js

```
function maxSubArray(nums) {
  let cur = nums[0], best = nums[0];
  for (let i = 1; i < nums.length; i++) {
    // extend the previous run, or start fresh at nums[i]
    cur = Math.max(nums[i], cur + nums[i]);
    best = Math.max(best, cur);
  }
  return best;
}
```

Solution — cpp

```
class Solution {
public:
    int maxSubArray(vector<int>& nums) {
        int cur = nums[0], best = nums[0];
        for (size_t i = 1; i < nums.size(); ++i) {
            cur = max(nums[i], cur + nums[i]);
            best = max(best, cur);
        }
        return best;
    }
};
```

Solution — python

```
class Solution:
    def maxSubArray(self, nums: list[int]) -> int:
        cur = best = nums[0]
        for x in nums[1:]:
            cur = max(x, cur + x)
            best = max(best, cur)
        return best
```

Solution — java

```
class Solution {
    public int maxSubArray(int[] nums) {
        int cur = nums[0], best = nums[0];
        for (int i = 1; i < nums.length; i++) {
            cur = Math.max(nums[i], cur + nums[i]);
            best = Math.max(best, cur);
        }
        return best;
    }
}
```

WALKTHROUGH

WHY `MAX(NUMS[I], CUR + NUMS[I])` IS EXACTLY RIGHT.

`cur` holds the best sum of any subarray ending at `i-1`. A subarray ending at `i` either includes that run or does not; there is no third option. Taking the larger of the two therefore gives the best subarray ending at `i`, and the global answer is the largest of those over all `i`.

THE ALL-NEGATIVE TESTS ARE THE ONES THAT MATTER.

`[-2,-1,-3]` must return `-1`. Initialising `best = 0` returns 0, which corresponds to the empty subarray the problem explicitly disallows. Interviewers reach for this case immediately.

Best time to buy and sell stock Easy

Pattern: Running minimum (Kadane in disguise)

You are given an array `prices` where `prices[i]` is the price of a stock on day `i`. Choose one day to buy and a **later** day to sell. Return the maximum profit, or 0 if no profitable trade exists.

Input	Output	Note
`prices = [7,1,5,3,6,4]`	`5`	Buy at 1, sell at 6.
`prices = [7,6,4,3,1]`	`0`	Prices only fall — do not trade.

HINTS

1. For each day, the best profit selling *today* is today's price minus the cheapest price seen so far.
2. So one pass tracking the running minimum is enough.
3. Alternatively: run Kadane over the array of day-to-day differences — the maximum subarray of differences is exactly the best trade.

Approach	Idea	Time	Space
All pairs	Try every buy day against every later sell day.	`O(n²)`	`O(1)`
Running minimum	Track the cheapest price so far; the answer is the largest gap.	`O(n)`	`O(1)`
Kadane on differences	Maximum subarray of `prices[i] - prices[i-1]`, floored at 0. Same complexity — useful for showing the connection.	`O(n)`	`O(1)`

Solution — js

```
function maxProfit(prices) {
  let minSoFar = Infinity, best = 0;
  for (const p of prices) {
    // best trade SELLING today = today - cheapest day so far
    best = Math.max(best, p - minSoFar);
    minSoFar = Math.min(minSoFar, p);
  }
  return best;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int maxProfit(vector<int>& prices) {
        int minSoFar = INT_MAX, best = 0;
        for (int p : prices) {
            if (minSoFar != INT_MAX) best = max(best, p - minSoFar);
            minSoFar = min(minSoFar, p);
        }
        return best;
    }
};
```

Solution — python

```python
class Solution:
    def maxProfit(self, prices: list[int]) -> int:
        min_so_far = float("inf")
        best = 0
        for p in prices:
            best = max(best, p - min_so_far)
            min_so_far = min(min_so_far, p)
        return best
```

Solution — java

```java
class Solution {
    public int maxProfit(int[] prices) {
        int minSoFar = Integer.MAX_VALUE, best = 0;
        for (int p : prices) {
            if (minSoFar != Integer.MAX_VALUE) best = Math.max(best, p - minSoFar);
            minSoFar = Math.min(minSoFar, p);
        }
        return best;
    }
}
```

WALKTHROUGH

UPDATING `BEST` BEFORE `MINSOFAR`

enforces "sell strictly after buy". On the first day `minSoFar` is still `Infinity`, so the profit is `-Infinity` and `best` stays 0 — correct, since you cannot sell on the day you first see a price. In C++ and Java the sentinel would overflow on subtraction, hence the explicit guard.

THE KADANE CONNECTION.

Buying at `i` and selling at `j` earns `prices[j] - prices[i]`, which telescopes to the sum of the daily differences from `i+1` to `j`. So the best trade is the maximum subarray of the difference array — and floored at 0 because declining to trade is allowed. Saying this aloud demonstrates you see the structure rather than a memorised trick.

Maximum product subarray `Medium`

Pattern: Kadane with two states

Given an integer array `nums`, find the contiguous subarray with the largest **product** and return that product. The subarray must be non-empty.

Input	Output	Note
`nums = [2,3,-2,4]`	`6`	[2,3]
`nums = [-2,0,-1]`	`0`	
`nums = [-2,3,-4]`	`24`	The whole array — two negatives make a positive.

HINTS

1. One tracked value is not enough: multiplying by a negative turns the largest product into the smallest and vice versa.
2. Carry both the maximum and the minimum product ending here.
3. Compute both new values from the *old* pair — if you overwrite the maximum first, the minimum is computed from the wrong number.
4. A zero resets both, which falls out naturally from including `x` itself as a candidate.

Approach	Idea	Time	Space
All subarrays	Multiply out every subarray.	`O(n²)`	`O(1)`
Kadane with max and min	Two running states, swapped in effect by every negative element.	`O(n)`	`O(1)`

Solution — js

```
function maxProduct(nums) {
  let maxHere = nums[0], minHere = nums[0], best = nums[0];

  for (let i = 1; i < nums.length; i++) {
    const x = nums[i];
    // compute BOTH from the OLD pair before overwriting
    const candMax = Math.max(x, maxHere * x, minHere * x);
    const candMin = Math.min(x, maxHere * x, minHere * x);
    maxHere = candMax;
    minHere = candMin;
    best = Math.max(best, maxHere);
  }
  return best;
}
```

Solution — cpp

```
class Solution {
public:
    int maxProduct(vector<int>& nums) {
        int maxHere = nums[0], minHere = nums[0], best = nums[0];
        for (size_t i = 1; i < nums.size(); ++i) {
            int x = nums[i];
            int candMax = max({x, maxHere * x, minHere * x});
            int candMin = min({x, maxHere * x, minHere * x});
            maxHere = candMax; minHere = candMin;
            best = max(best, maxHere);
        }
        return best;
    }
};
```

Solution — python

```python
class Solution:
    def maxProduct(self, nums: list[int]) -> int:
        max_here = min_here = best = nums[0]
        for x in nums[1:]:
            cand_max = max(x, max_here * x, min_here * x)
            cand_min = min(x, max_here * x, min_here * x)
            max_here, min_here = cand_max, cand_min
            best = max(best, max_here)
        return best
```

Solution — java

```java
class Solution {
    public int maxProduct(int[] nums) {
        int maxHere = nums[0], minHere = nums[0], best = nums[0];
        for (int i = 1; i < nums.length; i++) {
            int x = nums[i];
            int candMax = Math.max(x, Math.max(maxHere * x, minHere * x));
            int candMin = Math.min(x, Math.min(maxHere * x, minHere * x));
            maxHere = candMax; minHere = candMin;
            best = Math.max(best, maxHere);
        }
        return best;
    }
}
```

WALKTHROUGH

WHY THE MINIMUM IS WORTH TRACKING.

On `[-2,3,-4]`: after `-2` both states are `-2`. At `3`, max is 3 and min is `-6`. At `-4`, the *minimum* `-6` multiplied by `-4` gives `24` — the answer. A solution tracking only the maximum would have discarded `-6` as useless and returned 3.

THE SIMULTANEOUS UPDATE IS NOT STYLISTIC.

Writing `maxHere = …; minHere = Math.min(x, maxHere*x, minHere*x);` uses the *new* `maxHere` in the second line and silently produces wrong answers on inputs like `[2,-5,-2,-4,3]`. Compute both candidates first, then assign.

INCLUDING `X` ALONE AS A CANDIDATE

is what handles zeros: after a 0 both states restart from the next element rather than being stuck at 0.

Maximum sum circular subarray `Hard`

Pattern: Kadane twice + total complement

Given a **circular** integer array `nums`, return the maximum possible sum of a non-empty subarray. Circular means the element after the last is the first again, but a subarray may use each element at most once.

Input	Output	Note
`nums = [1,-2,3,-2]`	`3`	Just [3].
`nums = [5,-3,5]`	`10`	The wrapping subarray [5, 5].
`nums = [-3,-2,-3]`	`-2`	All negative — the largest single element.

HINTS

1. The answer either wraps around the end or it does not. Handle the two cases separately and take the larger.
2. The non-wrapping case is ordinary Kadane.
3. A wrapping subarray is the complement of a non-wrapping one — so its sum is `total - (minimum subarray sum)`.
4. Beware the all-negative case: the minimum subarray is then the whole array, and `total - min` is 0, corresponding to the empty subarray. Special-case it.

Approach	Idea	Time	Space
Try every start	Simulate the circle from each starting index.	`O(n²)`	`O(1)`
Duplicate the array	Concatenate `nums` with itself and run a length-limited sliding window with a deque.	`O(n)`	`O(n)`
Kadane max and min + total	Answer is `max(maxKadane, total - minKadane)`, with an all-negative guard.	`O(n)`	`O(1)`

Solution — js

```
function maxSubarraySumCircular(nums) {
  let total = nums[0];
  let curMax = nums[0], bestMax = nums[0];
  let curMin = nums[0], bestMin = nums[0];

  for (let i = 1; i < nums.length; i++) {
    const x = nums[i];
    total += x;
    curMax = Math.max(x, curMax + x);
    bestMax = Math.max(bestMax, curMax);
    curMin = Math.min(x, curMin + x);
    bestMin = Math.min(bestMin, curMin);
  }

  // all negative: the wrapping candidate would be the EMPTY
  // subarray, which is not allowed
  if (bestMax < 0) return bestMax;

  return Math.max(bestMax, total - bestMin);
}
```

Solution — cpp

```
class Solution {
public:
    int maxSubarraySumCircular(vector<int>& nums) {
        int total = nums[0];
        int curMax = nums[0], bestMax = nums[0];
        int curMin = nums[0], bestMin = nums[0];
        for (size_t i = 1; i < nums.size(); ++i) {
            int x = nums[i];
            total += x;
            curMax = max(x, curMax + x);  bestMax = max(bestMax, curMax);
            curMin = min(x, curMin + x);  bestMin = min(bestMin, curMin);
        }
        if (bestMax < 0) return bestMax;
        return max(bestMax, total - bestMin);
    }
};
```

Solution — python

```
class Solution:
    def maxSubarraySumCircular(self, nums: list[int]) -> int:
        total = cur_max = best_max = cur_min = best_min = nums[0]
        for x in nums[1:]:
            total += x
            cur_max = max(x, cur_max + x)
            best_max = max(best_max, cur_max)
            cur_min = min(x, cur_min + x)
            best_min = min(best_min, cur_min)
        if best_max < 0:
            return best_max
        return max(best_max, total - best_min)
```

Solution — java

```
class Solution {
    public int maxSubarraySumCircular(int[] nums) {
        int total = nums[0];
        int curMax = nums[0], bestMax = nums[0];
        int curMin = nums[0], bestMin = nums[0];
        for (int i = 1; i < nums.length; i++) {
            int x = nums[i];
            total += x;
            curMax = Math.max(x, curMax + x); bestMax = Math.max(bestMax, curMax);
            curMin = Math.min(x, curMin + x); bestMin = Math.min(bestMin, curMin);
        }
        if (bestMax < 0) return bestMax;
        return Math.max(bestMax, total - bestMin);
    }
}
```

WALKTHROUGH

THE CASE SPLIT IS THE IDEA.

Any subarray of a circular array either occupies a contiguous stretch of the original array (no wrap) or wraps past the end. In the wrapping case, the elements it *excludes* form a contiguous non-wrapping block — so maximising the wrapping sum is the same as *minimising* the excluded block. Hence `total - minSubarray`, computed by running Kadane a second time with the comparisons flipped.

WHY THE ALL-NEGATIVE GUARD IS NECESSARY.

On `[-3,-2,-3]` the minimum subarray is the entire array, so `total - bestMin = 0` — which would be the sum of the empty subarray. The problem requires a non-empty answer, so when every element is negative (detected by `bestMax < 0`) the answer is simply the largest element. Without that line the function returns 0 and the test fails.

BOTH KADANES RUN IN THE SAME LOOP

, so this is still one pass and O(1) space.

Arrays: matrix traversal patterns

Two-dimensional index arithmetic. The algorithms are simple; the bugs are all boundaries, and the trick in most of these problems is finding a transformation that makes the boundaries disappear.

The patterns

```
THE CONVENTIONS. Fix them once and never think again:

  R = grid.length            rows
  C = grid[0].length         columns
  grid[r][c]                 ROW FIRST, always

  in bounds:  r >= 0 && r < R && c >= 0 && c < C

FLATTENING — a 2-D cell to a 1-D index and back:
  idx = r * C + c
  r   = Math.floor(idx / C)
  c   = idx % C
Useful for hashing a cell, or for binary search over a
row-sorted matrix as if it were one array.

THE FOUR NEIGHBOUR DIRECTIONS:
  const DIRS = [[-1,0],[1,0],[0,-1],[0,1]];
  for (const [dr, dc] of DIRS) {
      const nr = r + dr, nc = c + dc;
      if (nr < 0 || nr >= R || nc < 0 || nc >= C) continue;
      ...
  }
Eight directions add the four diagonals. A DIRECTION
ARRAY IS ALWAYS BETTER THAN FOUR COPIES OF THE BODY —
fewer places to make a typo.

------------------------------------------------------------

ROTATION BY 90 DEGREES, in place:
  TRANSPOSE (swap across the main diagonal), then
  REVERSE EACH ROW.

    1 2 3      1 4 7      7 4 1
    4 5 6  ->  2 5 8  ->  8 5 2
    7 8 9      3 6 9      9 6 3
    original   transpose  reverse rows

  Anticlockwise: transpose, then reverse each COLUMN
  (equivalently, reverse the row order first).

  THE TRANSPOSE LOOP MUST START AT j = i, not j = 0 —
  otherwise every pair is swapped twice and you get the
  original back.

------------------------------------------------------------

SPIRAL — four moving boundaries:
    top, bottom, left, right
    walk right along `top`, then down `right`,
    then left along `bottom`, then up `left`,
    shrinking each boundary after use.
    CHECK top <= bottom AND left <= right BEFORE the
    last two walks, or a single remaining row/column is
    emitted twice.

------------------------------------------------------------

SEARCH IN A SORTED MATRIX — start from a CORNER where
the two directions disagree:
    start at TOP-RIGHT:
      value too big   -> move LEFT   (column decreases)
```

```
          value too small -> move DOWN   (row increases)
       Each step eliminates a whole row or column: O(R + C).
```

When to reach for it

"Rotate / transpose in place"

Compose two simple reversals rather than working out the rotation index formula.

Boundary walks

Spiral, diagonal, zigzag. Track explicit boundaries and shrink them.

Sorted rows and columns

Start at a corner with conflicting directions — top-right or bottom-left.

Fully row-sorted, rows chained

Treat as a flat array and binary search with `idx / C`, `idx % C`.

Flood fill / islands / shortest path

That is a graph on a grid — see chapter 28.

"O(1) extra space" on a grid

Encode markers in the matrix itself — first row/column as flags, or a sentinel value.

```
/* --- BUILDING A GRID, and the trap --- */
const g = Array.from({length: R}, () => new Array(C).fill(0));
// NOT new Array(R).fill(new Array(C).fill(0))
//     ^ every row is the SAME array; writing one writes all

/* --- COPYING --- */
const copy = g.map(row => row.slice());   // deep enough for
                                          // a grid of numbers

/* --- ITERATING --- */
for (let r = 0; r < R; r++)
    for (let c = 0; c < C; c++) { ... }

/* --- THE GUARD, as a helper --- */
const ok = (r, c) => r >= 0 && r < R && c >= 0 && c < C;

/* --- EMPTY-INPUT CHECK, first line of every solution --- */
if (!grid || grid.length === 0 || grid[0].length === 0) return ...;
```

Problems

How it shows up

Symptom	Cause
Writing one cell changes a whole column	`fill()` with a shared row array
Transpose returns the original	Inner loop started at 0 — every pair swapped twice
Spiral repeats the middle row or column	Missing the `top <= bottom` / `left <= right` guard
Index out of range on a non-square grid	Used `R` where `C` was needed
Rotation is anticlockwise	Reversed rows before transposing instead of after
Search misses values	Started from a corner where both directions agree
Zero-marking corrupts later rows	Marked with 0 and then read it as original data
Crash on `grid[0].length`	Empty outer array not checked first

Check yourself

- ✓ Write the bounds guard and the four-direction array.
- ✓ Give the flatten and unflatten formulas.
- ✓ Give the two-step in-place 90° rotation, both directions.
- ✓ Say why the transpose loop starts at `j = i`.
- ✓ Name the four spiral boundaries and the guard that prevents double emission.
- ✓ Explain why the sorted-matrix search starts at a corner.
- ✓ Give the correct way to build a 2-D array in JavaScript.
- ✓ Describe how to mark state in the matrix itself for O(1) space.

Problems

Rotate image 90° clockwise `Medium`

Pattern: Transpose then reverse rows

Given an `n × n` matrix, rotate it 90 degrees clockwise **in place**. Do not allocate another matrix.

Input	Output	Note
`matrix = [[1,2,3],[4,5,6],[7,8,9]]`	`[[7,4,1],[8,5,2],[9,6,3]]`	
`matrix = [[1,2],[3,4]]`	`[[3,1],[4,2]]`	

HINTS

1. Rather than deriving the index mapping, compose two operations you already know.
2. Transposing swaps `m[i][j]` with `m[j][i]`. What does the matrix look like afterwards?
3. Transpose, then reverse each row.
4. The transpose loop must start at `j = i`, or each pair is swapped twice and nothing changes.

Approach	Idea	Time	Space
Copy into a new matrix	`out[j][n-1-i] = m[i][j]`. Clear, but uses O(n^2) extra space, which the problem forbids.	`O(n²)`	`O(n²)`
Rotate four cells at a time	Cycle each group of four positions through a temporary. Correct and O(1), but the index expressions are easy to get wrong.	`O(n²)`	`O(1)`
Transpose then reverse rows	Two trivially correct passes.	`O(n²)`	`O(1)`

Solution — js

```
function rotate(matrix) {
  const n = matrix.length;

  // 1. transpose — swap across the main diagonal.
  //    j starts at i so each pair is swapped exactly ONCE.
  for (let i = 0; i < n; i++)
    for (let j = i; j < n; j++)
      [matrix[i][j], matrix[j][i]] = [matrix[j][i], matrix[i][j]];

  // 2. reverse each row
  for (const row of matrix) row.reverse();
}
```

Solution — cpp

```
class Solution {
public:
    void rotate(vector<vector<int>>& m) {
        int n = m.size();
        for (int i = 0; i < n; ++i)
            for (int j = i; j < n; ++j)
                swap(m[i][j], m[j][i]);
        for (auto& row : m) reverse(row.begin(), row.end());
    }
};
```

Solution — python

```
class Solution:
    def rotate(self, matrix: list[list[int]]) -> None:
        n = len(matrix)
        for i in range(n):
            for j in range(i, n):
                matrix[i][j], matrix[j][i] = matrix[j][i], matrix[i][j]
        for row in matrix:
            row.reverse()
```

Solution — java

```java
class Solution {
    public void rotate(int[][] m) {
        int n = m.length;
        for (int i = 0; i < n; i++)
            for (int j = i; j < n; j++) {
                int t = m[i][j]; m[i][j] = m[j][i]; m[j][i] = t;
            }
        for (int[] row : m) {
            for (int l = 0, r = n - 1; l < r; l++, r--) {
                int t = row[l]; row[l] = row[r]; row[r] = t;
            }
        }
    }
}
```

WALKTHROUGH

WHY THE COMPOSITION WORKS.

Transposing reflects the matrix across the main diagonal; reversing each row reflects it across the vertical centre line. Two reflections about axes meeting at 45° compose to a rotation of 90°. That is also why the anticlockwise version is transpose-then-reverse-*columns* — the second reflection is horizontal instead.

THE `J = I` BOUND IS THE BUG THIS PROBLEM EXISTS TO TEACH.

With `j = 0` the loop visits both `(i,j)` and `(j,i)`, swapping each pair twice and leaving the matrix unchanged. Starting at `i` visits only the upper triangle — and including `j = i` is harmless since swapping a cell with itself does nothing.

Spiral matrix `Medium`

Pattern: Four shrinking boundaries

Given an `m × n` matrix, return all its elements in spiral order — right along the top, down the right side, left along the bottom, up the left side, then inward.

Input	Output	Note
`matrix = [[1,2,3],[4,5,6],[7,8,9]]`	`[1,2,3,6,9,8,7,4,5]`	
`matrix = [[1,2,3,4],[5,6,7,8],[9,10,11,12]]`	`[1,2,3,4,8,12,11,10,9,5,6,7]`	

HINTS

1. Keep four boundaries: `top`, `bottom`, `left`, `right`. Walk one edge, then shrink that boundary.
2. After walking the top row, increment `top`. After the right column, decrement `right`. And so on.
3. Before the leftward and upward walks, re-check that the boundaries have not crossed — otherwise a single remaining row or column is emitted twice.

Approach	Idea	Time	Space
Direction vector with a visited grid	Walk, turning right whenever the next cell is out of bounds or already visited. Uses O(m·n) extra space.	`O(m·n)`	`O(m·n)`
Four boundaries	No extra space; each element emitted exactly once.	`O(m·n)`	`O(1)` `extra`

Solution — js

```
function spiralOrder(matrix) {
  if (!matrix.length || !matrix[0].length) return [];
  const out = [];
  let top = 0, bottom = matrix.length - 1;
  let left = 0, right = matrix[0].length - 1;

  while (top <= bottom && left <= right) {
    for (let c = left; c <= right; c++) out.push(matrix[top][c]);
    top++;

    for (let r = top; r <= bottom; r++) out.push(matrix[r][right]);
    right--;

    if (top <= bottom) {                // still a row left?
      for (let c = right; c >= left; c--) out.push(matrix[bottom][c]);
      bottom--;
    }
    if (left <= right) {                // still a column left?
      for (let r = bottom; r >= top; r--) out.push(matrix[r][left]);
      left++;
    }
  }
  return out;
}
```

Solution — cpp

```
class Solution {
public:
    vector<int> spiralOrder(vector<vector<int>>& m) {
        if (m.empty() || m[0].empty()) return {};
        vector<int> out;
        int top = 0, bottom = m.size() - 1, left = 0, right = m[0].size() - 1;
        while (top <= bottom && left <= right) {
            for (int c = left; c <= right; ++c) out.push_back(m[top][c]);
            ++top;
            for (int r = top; r <= bottom; ++r) out.push_back(m[r][right]);
            --right;
            if (top <= bottom) {
                for (int c = right; c >= left; --c) out.push_back(m[bottom][c]);
                --bottom;
            }
            if (left <= right) {
                for (int r = bottom; r >= top; --r) out.push_back(m[r][left]);
                ++left;
            }
        }
        return out;
    }
};
```

Solution — python

```python
class Solution:
    def spiralOrder(self, matrix: list[list[int]]) -> list[int]:
        if not matrix or not matrix[0]:
            return []
        out = []
        top, bottom = 0, len(matrix) - 1
        left, right = 0, len(matrix[0]) - 1
        while top <= bottom and left <= right:
            for c in range(left, right + 1):
                out.append(matrix[top][c])
            top += 1
            for r in range(top, bottom + 1):
                out.append(matrix[r][right])
            right -= 1
            if top <= bottom:
                for c in range(right, left - 1, -1):
                    out.append(matrix[bottom][c])
                bottom -= 1
            if left <= right:
                for r in range(bottom, top - 1, -1):
                    out.append(matrix[r][left])
                left += 1
        return out
```

Solution — java

```java
class Solution {
    public List<Integer> spiralOrder(int[][] m) {
        List<Integer> out = new ArrayList<>();
        if (m.length == 0 || m[0].length == 0) return out;
        int top = 0, bottom = m.length - 1, left = 0, right = m[0].length - 1;
        while (top <= bottom && left <= right) {
            for (int c = left; c <= right; c++) out.add(m[top][c]);
            top++;
            for (int r = top; r <= bottom; r++) out.add(m[r][right]);
            right--;
            if (top <= bottom) {
                for (int c = right; c >= left; c--) out.add(m[bottom][c]);
                bottom--;
            }
            if (left <= right) {
                for (int r = bottom; r >= top; r--) out.add(m[r][left]);
                left++;
            }
        }
        return out;
    }
}
```

WALKTHROUGH

THE TWO MID-LOOP GUARDS ARE THE WHOLE DIFFICULTY.

Consider a single-row matrix `[[1,2,3]]`. The first walk emits 1, 2, 3 and sets `top = 1`, which now exceeds `bottom = 0`. Without the `if (top <= bottom)` check, the leftward walk would run along `matrix[bottom]` — the same row — and emit 3, 2, 1 again. The single-column test `[[1],[2],[3]]` catches the symmetric case.

WHY THE GUARDS ARE NOT NEEDED FOR THE FIRST TWO WALKS:

the `while` condition was just checked, so the top row and right column are known to exist. Only after two boundaries have moved can they cross mid-iteration.

Search a 2-D matrix II `Medium`

Pattern: Staircase search from a corner

Search a `m × n` matrix for a `target`. Each **row** is sorted left to right and each **column** is sorted top to bottom, but rows are *not* chained — the first element of a row may be smaller than the last element of the previous row.

Return `true` if the target is present.

Input	Output	Note
`matrix = [[1,4,7,11],[2,5,8,12],[3,6,9,16],[10,13,14,17]], target = 5`	`true`	
`same matrix, target = 20`	`false`	

HINTS

1. Binary search on each row works but is O(m log n). There is a linear-in-(m+n) approach.
2. Look at the top-right corner: everything to its left is smaller, everything below it is larger. The two directions disagree, which makes the comparison decisive.
3. If the value is too large, the whole column can be discarded. If too small, the whole row can.
4. The bottom-left corner works equally well; the top-left does not, because both directions increase.

Approach	Idea	Time	Space
Scan everything	Check every cell.	`O(m·n)`	`O(1)`
Binary search each row	Uses the row ordering only.	`O(m log n)`	`O(1)`
Staircase from the top-right	Each comparison eliminates an entire row or column.	`O(m + n)`	`O(1)`

Solution — js

```javascript
function searchMatrix(matrix, target) {
  if (!matrix.length || !matrix[0].length) return false;

  // start at the TOP-RIGHT: left is smaller, down is larger
  let r = 0, c = matrix[0].length - 1;

  while (r < matrix.length && c >= 0) {
    const v = matrix[r][c];
    if (v === target) return true;
    if (v > target) c--;      // whole COLUMN is too big
    else            r++;      // whole ROW is too small
  }
  return false;
}
```

Solution — cpp

```cpp
class Solution {
public:
    bool searchMatrix(vector<vector<int>>& m, int target) {
        if (m.empty() || m[0].empty()) return false;
        int r = 0, c = m[0].size() - 1;
        while (r < (int)m.size() && c >= 0) {
            if (m[r][c] == target) return true;
            if (m[r][c] > target) --c;
            else                  ++r;
        }
        return false;
    }
};
```

Solution — python

```python
class Solution:
    def searchMatrix(self, matrix: list[list[int]], target: int) -> bool:
        if not matrix or not matrix[0]:
            return False
        r, c = 0, len(matrix[0]) - 1
        while r < len(matrix) and c >= 0:
            v = matrix[r][c]
            if v == target:
                return True
            if v > target:
                c -= 1
            else:
                r += 1
        return False
```

Solution — java

```
class Solution {
    public boolean searchMatrix(int[][] m, int target) {
        if (m.length == 0 || m[0].length == 0) return false;
        int r = 0, c = m[0].length - 1;
        while (r < m.length && c >= 0) {
            if (m[r][c] == target) return true;
            if (m[r][c] > target) c--;
            else                  r++;
        }
        return false;
    }
}
```

WALKTHROUGH

WHY THE CORNER CHOICE MATTERS.

At the top-left, moving right increases the value and moving down also increases it — a comparison tells you nothing about which way to go. At the top-right the two available moves disagree: left decreases, down increases. That makes every comparison eliminate an entire row or column, which is what bounds the walk at `m + n` steps.

THE ELIMINATION ARGUMENT, STATED PROPERLY:

if `matrix[r][c] > target` at the top-right, then every element *below* it in column `c` is also greater (columns are sorted), so no cell in that column can be the target — discard the column. Symmetrically, if the value is too small, every element to its left in row `r` is smaller still, so the row is useless — discard it.

NOTE THIS IS A DIFFERENT PROBLEM FROM "SEARCH A 2-D MATRIX I"

, where the rows are chained end to end. That one really is a single sorted array and admits a true O(log(m·n)) binary search using `idx / C` and `idx % C`. Check which variant you have been given.

Searching: binary search done correctly

Everyone knows the idea. Almost nobody writes it without an off-by-one on the first attempt. This chapter gives you one template you can trust, and the discipline that makes the boundary cases obvious rather than guessed.

The pattern

```
HALVE THE SEARCH SPACE EVERY STEP. n candidates become 1
in log2(n) steps: a million-element array is 20 steps.

THE PRECONDITION IS NOT "SORTED". It is:

  THE ARRAY CAN BE SPLIT BY SOME PREDICATE INTO A FALSE
  REGION FOLLOWED BY A TRUE REGION.

  [ F, F, F, F, T, T, T, T ]
                ^
                the boundary — what you are looking for

Sortedness is just the most common way to get that
property. Once you see binary search as FINDING A
BOUNDARY rather than FINDING A VALUE, the rotated-array
and search-on-answer variants stop being separate tricks.

THE BUG EVERYONE WRITES:

  mid = (lo + hi) / 2        // OVERFLOWS in C++/Java
                             // when lo+hi > 2^31
  mid = lo + (hi - lo) / 2   // correct everywhere

In JavaScript numbers are doubles so overflow is not a
practical concern, but write the safe form anyway — the
interviewer is watching, and you will write C++ one day.

THE THREE DECISIONS THAT DETERMINE CORRECTNESS:

  1. IS hi AN INDEX (n-1) OR A BOUND (n)?
  2. IS THE LOOP `lo <= hi` OR `lo < hi`?
  3. DO YOU MOVE TO mid OR mid±1?

MIXING CONVENTIONS IS WHAT CAUSES INFINITE LOOPS AND
MISSED ELEMENTS. Pick one and never deviate.

THE TERMINATION ARGUMENT, worth being able to state:
the interval must strictly shrink every iteration. If a
branch can leave [lo, hi] unchanged, the loop hangs.
With `lo < hi` and `mid = lo + (hi-lo)/2`, mid can equal
lo but never hi, so `hi = mid` shrinks and `lo = mid+1`
shrinks. That is why the halves are asymmetric.
```

Two templates, and only two

```
/* ===== TEMPLATE A: EXACT MATCH =====
   "Is this value present, and where?"                    */
function find(a, target) {
    let lo = 0, hi = a.length - 1;          // hi is an INDEX
    while (lo <= hi) {                      // <= : lo==hi is
                                            //      still valid
        const mid = lo + ((hi - lo) >> 1);
        if (a[mid] === target) return mid;
        if (a[mid] < target) lo = mid + 1;  // EXCLUDE mid
        else                 hi = mid - 1;  // EXCLUDE mid
    }
    return -1;
}

/* ===== TEMPLATE B: FIND THE BOUNDARY =====
   "First index where predicate(i) is true."
   USE THIS ONE FOR EVERYTHING THAT IS NOT AN EXACT MATCH. */
function firstTrue(lo, hi, pred) {          // hi is a BOUND
    while (lo < hi) {                       // < : stop when
                                            //     they meet
        const mid = lo + ((hi - lo) >> 1);
        if (pred(mid)) hi = mid;            // KEEP mid - it
                                            // might be the
                                            // answer
        else           lo = mid + 1;        // mid is false,
                                            // discard it
    }
    return lo;          // == hi; equals `hi` if nothing is true
}

/* TEMPLATE B SOLVES ALL OF THESE, by changing only pred: */
    lowerBound(a, t)   // first index with a[i] >= t
      = firstTrue(0, a.length, i => a[i] >= t)
    upperBound(a, t)   // first index with a[i] >  t
      = firstTrue(0, a.length, i => a[i] >  t)
    countOf(a, t)      = upperBound(a,t) - lowerBound(a,t)
    insertPosition     = lowerBound(a, t)
    firstBadVersion    = firstTrue(1, n+1, v => isBad(v))

/* AND THE STANDARD LIBRARY EQUIVALENTS, worth knowing:
     C++     std::lower_bound / std::upper_bound
     Python  bisect.bisect_left / bisect.bisect_right
     Java    Arrays.binarySearch (returns -(insertion)-1
             when absent - read that signature carefully)

   THE DISCIPLINE THAT REMOVES THE BUGS:
     · state the INVARIANT before writing the loop:
       "the answer is always inside [lo, hi]"
     · every branch must SHRINK the interval
     · after the loop, say what lo and hi mean
     · TEST WITH: empty, one element, target smaller than
       everything, larger than everything, and duplicates  */
```

Problems

How it shows up

Symptom	Cause
Infinite loop	A branch that does not shrink the interval — usually `lo = mid` with `lo < hi`
Misses the target at index 0 or n−1	Mixed conventions: `hi = n` with `lo <= hi`
Overflow in C++/Java	`(lo + hi) / 2` — use `lo + (hi - lo) / 2`
Returns any duplicate, not the first	Exact-match template returns on the first hit — use lower bound
Off by one on the insert position	Confusing lower bound with upper bound
Works on odd sizes, fails on even	Mid rounding — check whether you need the upper mid
Fails on the rotated array at the pivot	Comparing against the wrong endpoint when deciding which half is sorted
Correct value, wrong index with duplicates	Rotated search is not O(log n) when duplicates are allowed

Check yourself

- ✓ State the real precondition for binary search, not just "sorted".
- ✓ Write both templates from memory.
- ✓ Explain why `hi = mid` and `lo = mid + 1` are asymmetric.
- ✓ Give the termination argument.
- ✓ Define lower bound and upper bound, and express "count of t" with them.
- ✓ Write the overflow-safe mid and say where it matters.
- ✓ Explain how to decide which half of a rotated array is sorted.
- ✓ Say why duplicates break the O(log n) guarantee on a rotated array.

Problems

Binary search `Easy`

Pattern: Exact match

Given a sorted array of distinct integers `nums` and a `target`, return its index, or `-1` if it is not present. Must run in O(log n).

Input	Output	Note
`nums = [-1,0,3,5,9,12], target = 9`	`4`	
`nums = [-1,0,3,5,9,12], target = 2`	`-1`	

HINTS

1. Use template A: `hi` is an index, the loop is `lo <= hi`, and both branches exclude `mid`.
2. Compute mid as `lo + ((hi - lo) >> 1)`.
3. Check the empty array and a single-element array explicitly.

Approach	Idea	Time	Space
Linear scan	Check each element.	`O(n)`	`O(1)`
Binary search	Halve the interval each step, excluding `mid` on both branches since it has been tested.	`O(log n)`	`O(1)`

Solution — js

```
function search(nums, target) {
  let lo = 0, hi = nums.length - 1;
  while (lo <= hi) {
    const mid = lo + ((hi - lo) >> 1);
    if (nums[mid] === target) return mid;
    if (nums[mid] < target) lo = mid + 1;
    else                    hi = mid - 1;
  }
  return -1;
}
```

Solution — cpp

```
class Solution {
public:
    int search(vector<int>& nums, int target) {
        int lo = 0, hi = (int)nums.size() - 1;
        while (lo <= hi) {
            int mid = lo + (hi - lo) / 2;
            if (nums[mid] == target) return mid;
            if (nums[mid] < target) lo = mid + 1;
            else                    hi = mid - 1;
        }
        return -1;
    }
};
```

Solution — python

```
class Solution:
    def search(self, nums: list[int], target: int) -> int:
        lo, hi = 0, len(nums) - 1
        while lo <= hi:
            mid = lo + (hi - lo) // 2
            if nums[mid] == target:
                return mid
            if nums[mid] < target:
                lo = mid + 1
            else:
                hi = mid - 1
        return -1
```

Solution — java

```
class Solution {
    public int search(int[] nums, int target) {
        int lo = 0, hi = nums.length - 1;
        while (lo <= hi) {
            int mid = lo + (hi - lo) / 2;
            if (nums[mid] == target) return mid;
            if (nums[mid] < target) lo = mid + 1;
            else                    hi = mid - 1;
        }
        return -1;
    }
}
```

WALKTHROUGH

WHY `LO <= HI` AND NOT `LO < HI`.

With `hi` as an inclusive index, the interval `[lo, hi]` is non-empty whenever `lo <= hi`. Using `<` would skip the case where a single candidate remains — and that candidate is exactly the answer when the target sits at an end. The empty-array test and `[5], 5` both catch this.

Search insert position Easy

Pattern: Lower bound

Given a sorted array of distinct integers and a target, return the index of the target if found. If not, return the index where it **would** be inserted to keep the array sorted.

Input	Output	Note
`nums = [1,3,5,6], target = 5`	`2`	
`nums = [1,3,5,6], target = 2`	`1`	
`nums = [1,3,5,6], target = 7`	`4`	Past the end — a valid answer.

HINTS

1. This is exactly the lower bound: the first index `i` with `nums[i] >= target`.
2. Use template B with `hi = nums.length` (a bound, not an index) so "insert at the end" is representable.
3. When the predicate is true, keep `mid` — it may be the answer.

Approach	Idea	Time	Space
Linear scan	Walk until you find an element at least as large.	`O(n)`	`O(1)`
Lower bound (template B)	Boundary search for the first index satisfying `nums[i] >= target`. Returns `n` naturally when the target exceeds everything.	`O(log n)`	`O(1)`

Solution — js

```
function searchInsert(nums, target) {
  let lo = 0, hi = nums.length;        // hi is a BOUND, not an index
  while (lo < hi) {
    const mid = lo + ((hi - lo) >> 1);
    if (nums[mid] >= target) hi = mid;  // might be the answer: KEEP
    else                     lo = mid + 1;
  }
  return lo;
}
```

Solution — cpp

```
class Solution {
public:
    int searchInsert(vector<int>& nums, int target) {
        return lower_bound(nums.begin(), nums.end(), target) - nums.begin();
        // or written out:
        // int lo = 0, hi = nums.size();
        // while (lo < hi) { int mid = lo + (hi-lo)/2;
        //   if (nums[mid] >= target) hi = mid; else lo = mid+1; }
        // return lo;
    }
};
```

Solution — python

```
import bisect

class Solution:
    def searchInsert(self, nums: list[int], target: int) -> int:
        return bisect.bisect_left(nums, target)
        # written out:
        # lo, hi = 0, len(nums)
        # while lo < hi:
        #     mid = lo + (hi - lo) // 2
        #     if nums[mid] >= target: hi = mid
        #     else: lo = mid + 1
        # return lo
```

Solution — java

```
class Solution {
    public int searchInsert(int[] nums, int target) {
        int lo = 0, hi = nums.length;
        while (lo < hi) {
            int mid = lo + (hi - lo) / 2;
            if (nums[mid] >= target) hi = mid;
            else                     lo = mid + 1;
        }
        return lo;
    }
}
```

WALKTHROUGH

WHY `HI = N` RATHER THAN `N - 1`.

The answer can legitimately be `n` — "insert past the last element". An inclusive `hi = n - 1` cannot represent that, so you would need a special case afterwards. Choosing the half-open interval `[lo, hi)` makes the boundary case fall out for free, which is the general argument for preferring template B.

RECOGNISE THIS AS LOWER BOUND AND A FAMILY OF PROBLEMS COLLAPSES:

first occurrence of a duplicate, count of a value, "first bad version", and the insert position are all the same three lines with a different predicate.

First and last position of an element `Medium`

Pattern: Lower bound + upper bound

Given an array of integers sorted in non-decreasing order, find the starting and ending index of a given `target`. Return `[-1, -1]` if the target is not present. Must run in O(log n).

Input	Output	Note
`nums = [5,7,7,8,8,10], target = 8`	`[3,4]`	
`nums = [5,7,7,8,8,10], target = 6`	`[-1,-1]`	
`nums = [], target = 0`	`[-1,-1]`	

HINTS

1. Two boundary searches, not one search plus a linear scan — a linear scan of duplicates is O(n) in the worst case.
2. The first position is `lowerBound(target)`: first index with `nums[i] >= target`.
3. The last position is `upperBound(target) - 1`: first index with `nums[i] > target`, minus one.
4. Check presence by testing whether `lowerBound` is in range and actually holds the target.

Approach	Idea	Time	Space
Find one, then expand	Binary search for any occurrence, then walk outwards. Degrades to O(n) when the array is all one value.	`O(n)`	`O(1)`
Two boundary searches	Lower bound gives the start; upper bound minus one gives the end. Two independent O(log n) passes.	`O(log n)`	`O(1)`

Solution — js

```javascript
function searchRange(nums, target) {
  const bound = (pred) => {
    let lo = 0, hi = nums.length;
    while (lo < hi) {
      const mid = lo + ((hi - lo) >> 1);
      if (pred(mid)) hi = mid; else lo = mid + 1;
    }
    return lo;
  };

  const first = bound(i => nums[i] >= target);   // lower bound
  // not present at all?
  if (first === nums.length || nums[first] !== target) return [-1, -1];

  const afterLast = bound(i => nums[i] > target); // upper bound
  return [first, afterLast - 1];
}
```

Solution — cpp

```cpp
class Solution {
public:
    vector<int> searchRange(vector<int>& nums, int target) {
        auto lo = lower_bound(nums.begin(), nums.end(), target);
        if (lo == nums.end() || *lo != target) return {-1, -1};
        auto hi = upper_bound(nums.begin(), nums.end(), target);
        return {(int)(lo - nums.begin()), (int)(hi - nums.begin()) - 1};
    }
};
```

Solution — python

```python
import bisect

class Solution:
    def searchRange(self, nums: list[int], target: int) -> list[int]:
        first = bisect.bisect_left(nums, target)
        if first == len(nums) or nums[first] != target:
            return [-1, -1]
        return [first, bisect.bisect_right(nums, target) - 1]
```

Solution — java

```java
class Solution {
    public int[] searchRange(int[] nums, int target) {
        int first = bound(nums, target, true);
        if (first == nums.length || nums[first] != target)
            return new int[]{-1, -1};
        return new int[]{first, bound(nums, target, false) - 1};
    }
    // lower = true  -> first i with nums[i] >= target
    // lower = false -> first i with nums[i] >  target
    private int bound(int[] nums, int target, boolean lower) {
        int lo = 0, hi = nums.length;
        while (lo < hi) {
            int mid = lo + (hi - lo) / 2;
            boolean ok = lower ? nums[mid] >= target : nums[mid] > target;
            if (ok) hi = mid; else lo = mid + 1;
        }
        return lo;
    }
}
```

WALKTHROUGH

THE PRESENCE CHECK MUST COME FIRST AND MUST BE IN THIS EXACT FORM.

`first === nums.length` handles a target larger than everything, and `nums[first] !== target` handles a target that falls in a gap. Testing only one of the two crashes or returns nonsense on the empty array and on `[1,2,3], 0` respectively.

WHY NOT SCAN OUTWARDS FROM A HIT?

On `[2,2,2,…,2]` with target 2 there are n occurrences, so expanding is O(n) and the required O(log n) is violated. The interviewer will construct exactly that input.

Search in a rotated sorted array `Medium`

Pattern: Binary search on a piecewise-sorted array

An ascending array of **distinct** values was rotated at some unknown pivot — for example `[0,1,2,4,5,6,7]` became `[4,5,6,7,0,1,2]`. Given the rotated array and a `target`, return its index or `-1`. Must run in O(log n).

Input	Output	Note
`nums = [4,5,6,7,0,1,2], target = 0`	`4`	
`nums = [4,5,6,7,0,1,2], target = 3`	`-1`	
`nums = [1], target = 0`	`-1`	

HINTS

1. Split at `mid`. At least one of the two halves is *fully sorted* — always.
2. Determine which half is sorted by comparing `nums[lo]` with `nums[mid]`.
3. In the sorted half you can test membership with two comparisons. If the target is in it, search there; otherwise search the other half.
4. Use `<=` when comparing `nums[lo] <= nums[mid]` so that a two-element interval is classified correctly.

Approach	Idea	Time	Space
Linear scan	Ignore the structure and scan.	`O(n)`	`O(1)`
Find the pivot, then search	Binary search for the rotation point, then binary search the correct segment. Two passes, easy to reason about.	`O(log n)`	`O(1)`
Single modified binary search	One pass. Each step identifies the sorted half and decides whether the target lies inside it.	`O(log n)`	`O(1)`

Solution — js

```
function search(nums, target) {
  let lo = 0, hi = nums.length - 1;
  while (lo <= hi) {
    const mid = lo + ((hi - lo) >> 1);
    if (nums[mid] === target) return mid;

    if (nums[lo] <= nums[mid]) {
      // LEFT half [lo..mid] is sorted
      if (nums[lo] <= target && target < nums[mid]) hi = mid - 1;
      else                                          lo = mid + 1;
    } else {
      // RIGHT half [mid..hi] is sorted
      if (nums[mid] < target && target <= nums[hi]) lo = mid + 1;
      else                                          hi = mid - 1;
    }
  }
  return -1;
}
```

Solution — cpp

```
class Solution {
public:
    int search(vector<int>& nums, int target) {
        int lo = 0, hi = (int)nums.size() - 1;
        while (lo <= hi) {
            int mid = lo + (hi - lo) / 2;
            if (nums[mid] == target) return mid;
            if (nums[lo] <= nums[mid]) {
                if (nums[lo] <= target && target < nums[mid]) hi = mid - 1;
                else                                          lo = mid + 1;
            } else {
                if (nums[mid] < target && target <= nums[hi]) lo = mid + 1;
                else                                          hi = mid - 1;
            }
        }
        return -1;
    }
};
```

Solution — python

```python
class Solution:
    def search(self, nums: list[int], target: int) -> int:
        lo, hi = 0, len(nums) - 1
        while lo <= hi:
            mid = lo + (hi - lo) // 2
            if nums[mid] == target:
                return mid
            if nums[lo] <= nums[mid]:            # left half sorted
                if nums[lo] <= target < nums[mid]:
                    hi = mid - 1
                else:
                    lo = mid + 1
            else:                                 # right half sorted
                if nums[mid] < target <= nums[hi]:
                    lo = mid + 1
                else:
                    hi = mid - 1
        return -1
```

Solution — java

```java
class Solution {
    public int search(int[] nums, int target) {
        int lo = 0, hi = nums.length - 1;
        while (lo <= hi) {
            int mid = lo + (hi - lo) / 2;
            if (nums[mid] == target) return mid;
            if (nums[lo] <= nums[mid]) {
                if (nums[lo] <= target && target < nums[mid]) hi = mid - 1;
                else                                          lo = mid + 1;
            } else {
                if (nums[mid] < target && target <= nums[hi]) lo = mid + 1;
                else                                          hi = mid - 1;
            }
        }
        return -1;
    }
}
```

WALKTHROUGH

THE STRUCTURAL FACT THAT MAKES THIS WORK:

cutting a rotated sorted array at any point leaves at least one side unrotated, because there is only one "drop". So every step you can identify a fully sorted half, test membership in it with two comparisons, and discard half the array either way — preserving O(log n).

WHY `NUMS[LO] <= NUMS[MID]` NEEDS THE `<=`.

When the interval has two elements, `mid === lo`, so the comparison is `nums[lo] <= nums[lo]`. With strict `<` it would be false and you would take the "right half sorted" branch incorrectly. `[3,1]` searching for 1 is the test that catches it.

THE FOLLOW-UP:

"what if duplicates are allowed?" Then `nums[lo] === nums[mid] === nums[hi]` tells you nothing about which side is sorted — as in `[1,1,1,0,1,1]`. The fix is to shrink `lo++, hi--` in that case, which makes the worst case O(n). Say that explicitly; the point of the follow-up is to see whether you notice the guarantee breaks.

Searching: binary search on the answer

Binary search without a sorted array anywhere in sight. When the question is "what is the smallest X that works?", search the space of *answers* rather than the input — and this is the single highest-leverage pattern for medium and hard problems.

The pattern

```
THE RECOGNITION SIGNAL:

  "MINIMISE the maximum ..."
  "MAXIMISE the minimum ..."
  "the SMALLEST capacity / speed / size such that ..."
  "can we do it within K ...?"

plus a MONOTONIC feasibility: if an answer of X works,
then every answer larger than X also works (or every
smaller one, for a maximise problem).

THAT MONOTONICITY IS THE SORTED ARRAY. You never
materialise it — you just binary search over it.

  candidate answers:  1  2  3  4  5  6  7  8  9
  feasible(x):        N  N  N  N  Y  Y  Y  Y  Y
                                  ^
                                  the answer

THE RECIPE, four steps:

  1. GUESS the answer x.
  2. Write feasible(x): "can the task be done with x?"
     This is usually a SIMPLE GREEDY SCAN, O(n).
  3. Verify MONOTONICITY — argue why feasible is false
     then true (never alternating).
  4. Binary search the boundary with template B from
     chapter 09.

THE TEMPLATE:

  let lo = <smallest conceivable answer>;
  let hi = <largest conceivable answer>;
  while (lo < hi) {
      const mid = lo + Math.floor((hi - lo) / 2);
      if (feasible(mid)) hi = mid;      // might be it
      else               lo = mid + 1;  // definitely not
  }
  return lo;

PICKING THE BOUNDS IS HALF THE PROBLEM:
  lo = the answer that is trivially too small
       (often max(a), or 1)
  hi = the answer that trivially always works
       (often sum(a), or max value)
  GETTING lo TOO HIGH SILENTLY CUTS OFF VALID ANSWERS.
  When in doubt, make the range wider — it costs one
  extra iteration per doubling.

COST: O(n · log(range)). The log of a numeric range is
tiny — searching 10^9 values is 30 iterations — so this
turns "try every capacity" into something linear-ish.
```

When to reach for it

"Minimum largest / maximum smallest"

Split array largest sum, ship packages, allocate books, painters partition.

A rate or capacity to choose

Koko eating bananas, minimum speed to arrive on time.

"Within D days / K groups"

Feasibility is a greedy sweep counting groups.

Maximise the minimum distance

Aggressive cows, magnetic force between balls. Note the flipped monotonicity.

Real-valued answers

Iterate a fixed 100 times, or until `hi - lo < 1e-9`, instead of using integer bounds.

Kth smallest in a structured set

Binary search the value; feasibility counts how many are ≤ it.

```
/* --- THE MAXIMISE VARIANT, note the flip --- */
    // feasible(x) is TRUE for small x and FALSE for large x
    while (lo < hi) {
        const mid = lo + Math.ceil((hi - lo) / 2);   // UPPER mid
        if (feasible(mid)) lo = mid;                 // keep it
        else               hi = mid - 1;
    }
    return lo;

/* THE UPPER MID IS MANDATORY HERE. With the lower mid and
   `lo = mid`, a two-element range never shrinks and the
   loop hangs forever. This is the single most common bug in
   the maximise form.

/* --- A TYPICAL feasible(): count the groups greedily --- */
    function feasible(cap) {
        let groups = 1, load = 0;
        for (const w of weights) {
            if (w > cap) return false;   // impossible at all
            if (load + w > cap) { groups++; load = 0; }
            load += w;
        }
        return groups <= maxGroups;
    }
/* NOTE the `w > cap` guard - without it a single oversized
   item silently starts an infinite number of groups.     */
```

Problems

How it shows up

Symptom	Cause
Infinite loop in the maximise form	Lower mid with `lo = mid` — use the upper mid
Answer too large	`lo` started above the true answer
Answer too small / infeasible	`hi` not large enough to always work

Symptom	Cause
Works on small inputs, wrong on large	Feasibility is not actually monotonic — re-examine
Feasibility never returns false	Missing the "single item exceeds capacity" guard
Off by one on the boundary	Mixing `hi = mid` with `hi = mid - 1`
Float version never terminates	Exact equality on doubles — iterate a fixed count instead
Timeout	Feasibility check is worse than O(n log n)

Check yourself

- ✓ Give the four recognition signals.
- ✓ State the four-step recipe.
- ✓ Explain what plays the role of the sorted array.
- ✓ Write the minimise template and the maximise template.
- ✓ Explain why the maximise form needs the upper mid.
- ✓ Say how to choose `lo` and `hi`, and which error is silent.
- ✓ Write a greedy feasibility check and its impossible-item guard.
- ✓ Give the total complexity and why the log factor is cheap.

Problems

Koko eating bananas `Medium`

Pattern: Binary search the rate

There are `piles.length` piles of bananas and `h` hours available. At an eating speed of `k` bananas per hour, each hour Koko picks one pile and eats up to `k` from it; if the pile has fewer than `k` left, she still uses the whole hour.

Return the **minimum** integer `k` such that all piles are finished within `h` hours.

Input	Output	Note
`piles = [3,6,7,11], h = 8`	`4`	
`piles = [30,11,23,4,20], h = 5`	`30`	One pile per hour — speed must cover the largest.
`piles = [30,11,23,4,20], h = 6`	`23`	

HINTS

1. The hours needed for one pile at speed k is `ceil(pile / k)`.
2. If speed k finishes in time, so does every speed above k — the feasibility is monotonic.
3. The answer is at least 1 and at most `max(piles)`, since eating the largest pile in one hour each is always enough when `h ≥ piles.length`.

Approach	Idea	Time	Space
Try every speed	Test k = 1, 2, 3 … until one works.	`O(n · max)`	`O(1)`
Binary search the speed	Feasibility is monotonic, so binary search the boundary between too-slow and fast-enough.	`O(n log max)`	`O(1)`

Solution — js

```
function minEatingSpeed(piles, h) {
  // hours needed at speed k — monotonically DECREASING in k
  const hoursAt = (k) =>
    piles.reduce((sum, p) => sum + Math.ceil(p / k), 0);

  let lo = 1, hi = Math.max(...piles);
  while (lo < hi) {
    const mid = lo + Math.floor((hi - lo) / 2);
    if (hoursAt(mid) <= h) hi = mid;   // fast enough: KEEP mid
    else                   lo = mid + 1;
  }
  return lo;
}
```

Solution — cpp

```
class Solution {
public:
    int minEatingSpeed(vector<int>& piles, int h) {
        auto hoursAt = [&](long k) {
            long total = 0;
            for (int p : piles) total += (p + k - 1) / k;   // ceil
            return total;
        };
        int lo = 1, hi = *max_element(piles.begin(), piles.end());
        while (lo < hi) {
            int mid = lo + (hi - lo) / 2;
            if (hoursAt(mid) <= h) hi = mid;
            else                   lo = mid + 1;
        }
        return lo;
    }
};
```

Solution — python

```
import math

class Solution:
    def minEatingSpeed(self, piles: list[int], h: int) -> int:
        def hours_at(k: int) -> int:
            return sum(math.ceil(p / k) for p in piles)

        lo, hi = 1, max(piles)
        while lo < hi:
            mid = lo + (hi - lo) // 2
            if hours_at(mid) <= h:
                hi = mid
            else:
                lo = mid + 1
        return lo
```

Solution — java

```java
class Solution {
    public int minEatingSpeed(int[] piles, int h) {
        int lo = 1, hi = 0;
        for (int p : piles) hi = Math.max(hi, p);
        while (lo < hi) {
            int mid = lo + (hi - lo) / 2;
            if (hoursAt(piles, mid) <= h) hi = mid;
            else                          lo = mid + 1;
        }
        return lo;
    }
    private long hoursAt(int[] piles, int k) {
        long total = 0;
        for (int p : piles) total += (p + k - 1) / k;
        return total;
    }
}
```

WALKTHROUGH

WHERE IS THE SORTED ARRAY?

There is not one — the input order is irrelevant. The sorted structure is the sequence of candidate speeds 1, 2, 3, …, max, along which `hoursAt(k)` is non-increasing. That monotonicity is what licenses binary search, and stating it explicitly is the part interviewers listen for.

WHY `HI = MAX(PILES)` IS SAFE.

At that speed every pile takes exactly one hour, so the total is `piles.length` hours. The problem guarantees `h ≥ piles.length`, so the largest candidate is always feasible — which is exactly the requirement for `hi`.

INTEGER CEILING WITHOUT FLOATING POINT:

`(p + k - 1) / k`. With large values `Math.ceil(p / k)` in JavaScript is fine (doubles are exact to 2^{53}) but in C++ the division must stay in integers, and `total` needs to be 64-bit — the test with a billion-banana pile is there to make that concrete.

Capacity to ship packages within D days `Medium`

Pattern: Binary search the capacity + greedy check

Packages on a conveyor must be shipped within `days` days, **in the given order**. Each day the ship loads packages in sequence without exceeding its weight capacity.

Return the minimum capacity that allows all packages to ship within `days` days.

Input	Output	Note
`weights = [1,2,3,4,5,6,7,8,9,10], days = 5`	`15`	
`weights = [3,2,2,4,1,4], days = 3`	`6`	
`weights = [1,2,3,1,1], days = 4`	`3`	Days: [1,2] / [3] / [1,1] — capacity 2 cannot carry the package of weight 3.

HINTS

1. Given a capacity, greedily fill each day until the next package would overflow, then start a new day. Count the days.
2. The capacity must be at least `max(weights)` — a package that does not fit can never ship.
3. It need never exceed `sum(weights)` — that ships everything in one day.
4. More capacity never needs more days, so feasibility is monotonic.

Approach	Idea	Time	Space
Try every capacity	Increment from `max` to `sum`.	`O(n · sum)`	`O(1)`
Binary search + greedy count	Search capacities in `[max, sum]`; the check is one linear sweep.	`O(n log sum)`	`O(1)`

Solution — js

```
function shipWithinDays(weights, days) {
  const daysNeeded = (cap) => {
    let d = 1, load = 0;
    for (const w of weights) {
      if (load + w > cap) { d++; load = 0; }   // start a new day
      load += w;
    }
    return d;
  };

  // lo: a package must fit.  hi: everything in one day.
  let lo = Math.max(...weights);
  let hi = weights.reduce((a, b) => a + b, 0);

  while (lo < hi) {
    const mid = lo + Math.floor((hi - lo) / 2);
    if (daysNeeded(mid) <= days) hi = mid;
    else                         lo = mid + 1;
  }
  return lo;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int shipWithinDays(vector<int>& weights, int days) {
        auto daysNeeded = [&](int cap) {
            int d = 1, load = 0;
            for (int w : weights) {
                if (load + w > cap) { ++d; load = 0; }
                load += w;
            }
            return d;
        };
        int lo = *max_element(weights.begin(), weights.end());
        int hi = accumulate(weights.begin(), weights.end(), 0);
        while (lo < hi) {
            int mid = lo + (hi - lo) / 2;
            if (daysNeeded(mid) <= days) hi = mid;
            else                         lo = mid + 1;
        }
        return lo;
    }
};
```

Solution — python

```python
class Solution:
    def shipWithinDays(self, weights: list[int], days: int) -> int:
        def days_needed(cap: int) -> int:
            d, load = 1, 0
            for w in weights:
                if load + w > cap:
                    d += 1
                    load = 0
                load += w
            return d

        lo, hi = max(weights), sum(weights)
        while lo < hi:
            mid = lo + (hi - lo) // 2
            if days_needed(mid) <= days:
                hi = mid
            else:
                lo = mid + 1
        return lo
```

Solution — java

```
class Solution {
    public int shipWithinDays(int[] weights, int days) {
        int lo = 0, hi = 0;
        for (int w : weights) { lo = Math.max(lo, w); hi += w; }
        while (lo < hi) {
            int mid = lo + (hi - lo) / 2;
            if (daysNeeded(weights, mid) <= days) hi = mid;
            else                                  lo = mid + 1;
        }
        return lo;
    }
    private int daysNeeded(int[] weights, int cap) {
        int d = 1, load = 0;
        for (int w : weights) {
            if (load + w > cap) { d++; load = 0; }
            load += w;
        }
        return d;
    }
}
```

WALKTHROUGH

SETTING `LO = MAX(WEIGHTS)` IS WHAT REMOVES THE IMPOSSIBLE-ITEM GUARD.

Because the search never considers a capacity below the largest package, the greedy loop can never encounter an item that does not fit on an empty day. Had `lo` started at 1, `daysNeeded` would loop forever adding a package that overflows even an empty ship — which is precisely the guard mentioned in the pattern section.

WHY THE GREEDY CHECK IS OPTIMAL.

Packages must ship in order, so at any point the only decision is whether to add the next package to today or start tomorrow. Adding it whenever it fits can never increase the day count: postponing a package that fits only shifts work later without freeing capacity. So the greedy count *is* the minimum number of days for that capacity.

THIS IS THE SAME PROBLEM AS "SPLIT ARRAY LARGEST SUM" AND "ALLOCATE MINIMUM PAGES"

, reworded. Recognising that family is worth more than memorising any one of them.

Split array largest sum `Hard`

Pattern: Minimise the maximum

Given an array `nums` and an integer `k`, split the array into `k` non-empty **contiguous** subarrays so as to **minimise the largest subarray sum**. Return that minimised largest sum.

Input	Output	Note
`nums = [7,2,5,10,8], k = 2`	`18`	Split as [7,2,5] and [10,8]: sums 14 and 18.
`nums = [1,2,3,4,5], k = 2`	`9`	[1,2,3] and [4,5].
`nums = [1,4,4], k = 3`	`4`	

HINTS

1. The phrase "minimise the maximum" is the signal. Do not try to construct the split directly.
2. Guess a value X for the largest allowed subarray sum. Can the array be split into at most k parts each summing to ≤ X? That is a greedy sweep.
3. If X works, every larger X works too — monotonic.
4. Bounds: `lo = max(nums)` (a single element must fit in some part), `hi = sum(nums)` (one part holds everything).

Approach	Idea	Time	Space
DP over splits	`dp[i][j]` = best split of the first `i` elements into `j` parts. Correct and a perfectly good answer.	`O(n²·k)`	`O(n·k)`
Binary search the answer	Search the value of the largest sum; feasibility is a greedy part count.	`O(n log sum)`	`O(1)`

Solution — js

```
function splitArray(nums, k) {
  // how many parts are needed if no part may exceed `limit`?
  const partsNeeded = (limit) => {
    let parts = 1, sum = 0;
    for (const x of nums) {
      if (sum + x > limit) { parts++; sum = 0; }
      sum += x;
    }
    return parts;
  };

  let lo = Math.max(...nums);              // a single element must fit
  let hi = nums.reduce((a, b) => a + b, 0); // one part holds everything

  while (lo < hi) {
    const mid = lo + Math.floor((hi - lo) / 2);
    if (partsNeeded(mid) <= k) hi = mid;   // feasible: try smaller
    else                       lo = mid + 1;
  }
  return lo;
}
```

Solution — cpp

```
class Solution {
public:
    int splitArray(vector<int>& nums, int k) {
        auto partsNeeded = [&](long limit) {
            int parts = 1; long sum = 0;
            for (int x : nums) {
                if (sum + x > limit) { ++parts; sum = 0; }
                sum += x;
            }
            return parts;
        };
        long lo = *max_element(nums.begin(), nums.end());
        long hi = accumulate(nums.begin(), nums.end(), 0L);
        while (lo < hi) {
            long mid = lo + (hi - lo) / 2;
            if (partsNeeded(mid) <= k) hi = mid;
            else                       lo = mid + 1;
        }
        return (int)lo;
    }
};
```

Solution — python

```
class Solution:
    def splitArray(self, nums: list[int], k: int) -> int:
        def parts_needed(limit: int) -> int:
            parts, s = 1, 0
            for x in nums:
                if s + x > limit:
                    parts += 1
                    s = 0
                s += x
            return parts

        lo, hi = max(nums), sum(nums)
        while lo < hi:
            mid = lo + (hi - lo) // 2
            if parts_needed(mid) <= k:
                hi = mid
            else:
                lo = mid + 1
        return lo
```

Solution — java

```
class Solution {
    public int splitArray(int[] nums, int k) {
        long lo = 0, hi = 0;
        for (int x : nums) { lo = Math.max(lo, x); hi += x; }
        while (lo < hi) {
            long mid = lo + (hi - lo) / 2;
            if (partsNeeded(nums, mid) <= k) hi = mid;
            else                             lo = mid + 1;
        }
        return (int) lo;
    }
    private int partsNeeded(int[] nums, long limit) {
        int parts = 1; long sum = 0;
        for (int x : nums) {
            if (sum + x > limit) { parts++; sum = 0; }
            sum += x;
        }
        return parts;
    }
}
```

WALKTHROUGH

THIS IS THE ARCHETYPE OF THE PATTERN.

Constructing the optimal split directly is a two-dimensional DP; inverting the question — "given a ceiling, how many parts do I need?" — turns it into a one-line greedy plus a binary search, and drops the complexity from $O(n^2k)$ to $O(n \log \text{sum})$.

WHY `PARTSNEEDED ≤ K` RATHER THAN `=== K`.

If a limit allows the array to be split into fewer than `k` parts, you can always split one part further to reach exactly `k` — the largest sum only decreases. So "needs at most k parts" is the correct feasibility test, and testing for equality would wrongly reject valid limits. The test `[1,4,4], k=3` exercises this: at limit 4 the greedy uses exactly 3, but at limit 5 it uses 2, which is still feasible for k = 3.

NOTE THE IDENTICAL SHAPE TO THE SHIPPING PROBLEM ABOVE.

Same greedy, same bounds, different words. That is the point of learning patterns rather than problems.

Sorting: the algorithms and custom comparators

You will rarely implement a sort in an interview, but you will constantly *use* one — and you will be asked how merge sort and quicksort work, why one is stable, and when sorting is worth its log factor.

The algorithms worth knowing

Algorithm	Best	Average	Worst	Space	Stable
Merge sort	n log n	n log n	n log n	O(n)	**Yes**
Quicksort	n log n	n log n	**n^2**	O(log n)	No
Heapsort	n log n	n log n	n log n	**O(1)**	No
Insertion sort	**n**	n^2	n^2	O(1)	Yes
Counting sort	n + k	n + k	n + k	O(k)	Yes
Radix sort	d(n + k)	d(n + k)	d(n + k)	O(n + k)	Yes

```
MERGE SORT — divide and conquer, always n log n
  split in half, sort each half, MERGE the two sorted
  halves with two pointers (chapter 17's merge).
  T(n) = 2T(n/2) + O(n)  ->  O(n log n)

  + STABLE, predictable, parallelises, works on linked
    lists with O(1) extra space
  - needs O(n) scratch space for arrays

QUICKSORT — partition around a pivot
  choose a pivot, move smaller elements left and larger
  right, recurse on both sides.
  Average O(n log n); WORST O(n^2) when the pivot is
  always extreme (a sorted array with a first-element
  pivot).

  + in place, excellent cache behaviour, fastest in
    practice
  - unstable, and the worst case is real
  FIXES: random pivot, median-of-three, or introsort
  (switch to heapsort once recursion gets too deep) —
  which is what std::sort actually does.

WHAT YOUR LANGUAGE ACTUALLY USES:
  C++ std::sort        introsort — NOT stable
  C++ stable_sort      merge sort
  Java primitives      dual-pivot quicksort — not stable
  Java objects         TimSort — STABLE
  Python sorted()      TimSort — STABLE
  JavaScript .sort()   STABLE since ES2019

STABILITY MEANS equal elements keep their original
relative order. It matters whenever you sort by one key
and then by another: sort by the SECONDARY key first,
then STABLY by the primary, and the secondary order
survives inside each group.

NON-COMPARISON SORTS beat n log n by not comparing:
  COUNTING SORT  O(n + k) for integers in a small range k
  RADIX SORT     O(d(n + k)) digit by digit
  BUCKET SORT    O(n) for uniformly distributed values
The n log n lower bound applies only to COMPARISON sorts,
which is a good thing to say when someone asks whether
you can beat it.
```

Comparators — where the bugs are

```
/* --- THE JAVASCRIPT TRAP, first of all --- */
[10, 9, 1].sort()               // ["1","10","9"] LEXICOGRAPHIC
[10, 9, 1].sort((a, b) => a - b) // [1, 9, 10]

/* THE CONTRACT: return NEGATIVE if a comes first, POSITIVE
   if b comes first, ZERO if equivalent.                   */

/* --- MULTI-KEY: chain with || --- */
people.sort((a, b) =>
      a.age - b.age            // primary:   age ascending
   || b.score - a.score        // secondary: score DESCENDING
   || a.name.localeCompare(b.name));   // tertiary: name

/* `||` works because 0 is falsy — a tie on one key falls
   through to the next.

/* --- STRINGS --- */
words.sort((a, b) => a.localeCompare(b));   // locale-aware
words.sort((a, b) => (a < b ? -1 : a > b ? 1 : 0));  // by code unit

/* --- THE SUBTRACTION TRAP --- */
    a - b OVERFLOWS in C++/Java when the values are far
    apart. Use explicit comparison instead:
        Integer.compare(a, b)          // Java
        return a < b ? -1 : (a > b);   // C++ — or just a < b
    In JavaScript doubles do not overflow, but the habit is
    worth keeping.

/* --- SORTING PAIRS AND KEEPING INDICES --- */
    const idx = nums.map((v, i) => [v, i])
                    .sort((a, b) => a[0] - b[0]);
    // now idx[j] = [value, ORIGINAL index]
    // this is how you sort when the answer needs the
    // original positions (chapter 13's Two Sum problem)

/* --- SORT BY A COMPUTED KEY, computed ONCE --- */
    // BAD: recomputes the key O(n log n) times
    words.sort((a, b) => score(a) - score(b));
    // GOOD: Schwartzian transform — compute n times
    words.map(w => [score(w), w])
         .sort((x, y) => x[0] - y[0])
         .map(p => p[1]);

/* --- A COMPARATOR MUST BE CONSISTENT --- */
    It must be transitive and antisymmetric. An inconsistent
    comparator (for instance one using a random tiebreak, or
    `a.x > b.x ? 1 : -1` with no zero case) can crash
    Java's TimSort with "Comparison method violates its
    general contract".                                    */
```

Problems

How it shows up

Symptom	Cause
`[1, 10, 9]` from a numeric sort	No comparator in JavaScript — lexicographic default

Symptom	Cause
Secondary ordering lost	Sort is not stable, or the keys were applied in the wrong order
Negative numbers sorted wrongly	`a - b` overflowed in C++/Java
"Comparison method violates its general contract"	Comparator not transitive or missing the equal case
Quicksort times out	Adversarial input with a fixed pivot — randomise
Sorting destroys the answer	The problem wanted original indices — pair them first
Sort is slower than expected	Expensive key recomputed inside the comparator
Custom sort of objects loses ties randomly	Add an explicit tiebreak to make it deterministic

Check yourself

- ✓ Give the time, space and stability of merge sort, quicksort and heapsort.
- ✓ State quicksort's worst case and three ways to avoid it.
- ✓ Define stability and explain the sort-secondary-key-first technique.
- ✓ Say which sort your language uses and whether it is stable.
- ✓ Name three sorts that beat n log n and the condition each needs.
- ✓ Write a three-key comparator using `||`.
- ✓ Explain the subtraction overflow trap.
- ✓ Describe how to sort while preserving original indices.

Problems

Implement merge sort `Medium`

Pattern: Divide and conquer

Sort an integer array in ascending order. Implement **merge sort** yourself — do not call the built-in sort.

Your solution must run in O(n log n) and be stable.

Input	Output	Note
`nums = [5,2,3,1]`	`[1,2,3,5]`	
`nums = [5,1,1,2,0,0]`	`[0,0,1,1,2,5]`	

HINTS

1. Split the array in half, sort each half recursively, then merge the two sorted halves.
2. The merge is the two-pointer walk from chapter 17: repeatedly take the smaller front element.
3. Base case: an array of length 0 or 1 is already sorted.
4. Use `<=` when choosing from the left half so equal elements keep their order — that is what makes it stable.

Approach	Idea	Time	Space
Merge sort	Halve, sort both sides, merge. Always O(n log n) regardless of input.	`O(n log n)`	`O(n)`
Quicksort	Partition around a pivot. Faster in practice and O(1) extra space, but $O(n^2)$ worst case and not stable.	`O(n log n) avg`	`O(log n)`

Solution — js

```
function sortArray(nums) {
  if (nums.length <= 1) return nums;

  const mid = nums.length >> 1;
  const left  = sortArray(nums.slice(0, mid));
  const right = sortArray(nums.slice(mid));

  // merge two sorted halves
  const out = [];
  let i = 0, j = 0;
  while (i < left.length && j < right.length) {
    // <= keeps equal elements in their original order: STABLE
    if (left[i] <= right[j]) out.push(left[i++]);
    else                     out.push(right[j++]);
  }
  while (i < left.length)  out.push(left[i++]);
  while (j < right.length) out.push(right[j++]);
  return out;
}
```

Solution — cpp

```
class Solution {
    void mergeSort(vector<int>& a, int lo, int hi, vector<int>& buf) {
        if (hi - lo <= 1) return;
        int mid = lo + (hi - lo) / 2;
        mergeSort(a, lo, mid, buf);
        mergeSort(a, mid, hi, buf);
        int i = lo, j = mid, k = lo;
        while (i < mid && j < hi)
            buf[k++] = (a[i] <= a[j]) ? a[i++] : a[j++];
        while (i < mid) buf[k++] = a[i++];
        while (j < hi)  buf[k++] = a[j++];
        copy(buf.begin() + lo, buf.begin() + hi, a.begin() + lo);
    }
public:
    vector<int> sortArray(vector<int>& nums) {
        vector<int> buf(nums.size());
        mergeSort(nums, 0, nums.size(), buf);
        return nums;
    }
};
```

Solution — python

```python
class Solution:
    def sortArray(self, nums: list[int]) -> list[int]:
        if len(nums) <= 1:
            return nums
        mid = len(nums) // 2
        left = self.sortArray(nums[:mid])
        right = self.sortArray(nums[mid:])

        out = []
        i = j = 0
        while i < len(left) and j < len(right):
            if left[i] <= right[j]:
                out.append(left[i]); i += 1
            else:
                out.append(right[j]); j += 1
        out.extend(left[i:])
        out.extend(right[j:])
        return out
```

Solution — java

```java
class Solution {
    public int[] sortArray(int[] nums) {
        int[] buf = new int[nums.length];
        sort(nums, 0, nums.length, buf);
        return nums;
    }
    private void sort(int[] a, int lo, int hi, int[] buf) {
        if (hi - lo <= 1) return;
        int mid = lo + (hi - lo) / 2;
        sort(a, lo, mid, buf);
        sort(a, mid, hi, buf);
        int i = lo, j = mid, k = lo;
        while (i < mid && j < hi) buf[k++] = (a[i] <= a[j]) ? a[i++] : a[j++];
        while (i < mid) buf[k++] = a[i++];
        while (j < hi)  buf[k++] = a[j++];
        System.arraycopy(buf, lo, a, lo, hi - lo);
    }
}
```

WALKTHROUGH

WHY THE COMPLEXITY IS EXACTLY N LOG N, ALWAYS.

The recursion halves the input, so the tree is `log₂ n` levels deep, and the merges at each level together touch every element once — O(n) per level. Unlike quicksort there is no pivot to choose badly, so the bound holds for every input including already-sorted and reverse-sorted ones. The test cases include both.

`<=` VERSUS `<` IS THE STABILITY SWITCH.

When the two fronts are equal, taking from the *left* half preserves the original relative order, since the left half came first in the input. Changing it to `<` still sorts correctly but silently loses stability — which breaks any multi-key sort built on top of it.

THE C++ AND JAVA VERSIONS SORT IN PLACE WITH ONE SHARED BUFFER

rather than allocating at every level, which is what a real implementation does. The JavaScript version uses `slice` for clarity; mention the difference if asked about memory.

Sort colors (Dutch national flag) `Medium`

Pattern: Three-way partition

Given an array `nums` containing only `0`, `1` and `2`, sort it **in place** so that same-valued elements are adjacent and in the order 0, 1, 2.

Do it in **one pass** with O(1) extra space, without using a library sort.

Input	Output	Note
`nums = [2,0,2,1,1,0]`	`[0,0,1,1,2,2]`	
`nums = [2,0,1]`	`[0,1,2]`	

HINTS

1. Counting sort in two passes is easy — count the 0s, 1s and 2s, then overwrite. Try for one pass.
2. Maintain three regions: everything before `low` is 0, everything after `high` is 2, and `i` scans the unknown middle.
3. When you swap a 2 down from the front, do
   NOT
   advance `i` — the value you just received is unexamined.
4. When you swap a 0 up, you may advance, because the value coming back is guaranteed to be a 1 already processed.

Approach	Idea	Time	Space
Library sort	Correct but ignores the structure and is O(n log n).	`O(n log n)`	`O(1)`
Counting sort, two passes	Count each value, then rewrite the array. Simple and O(n) — a good answer to state first.	`O(n)`	`O(1)`
Dutch national flag, one pass	Three pointers partition the array into 0s, 1s, unknown, 2s.	`O(n)`	`O(1)`

Solution — js

```javascript
function sortColors(nums) {
  let low = 0;                    // everything before low is 0
  let i = 0;                      // scanner
  let high = nums.length - 1;     // everything after high is 2

  while (i <= high) {
    if (nums[i] === 0) {
      [nums[low], nums[i]] = [nums[i], nums[low]];
      low++; i++;                 // safe to advance: the value
                                  // swapped back is a known 1
    } else if (nums[i] === 2) {
      [nums[high], nums[i]] = [nums[i], nums[high]];
      high--;                     // do NOT advance i — the new
                                  // nums[i] is unexamined
    } else {
      i++;                        // a 1 is already in place
    }
  }
}
```

Solution — cpp

```cpp
class Solution {
public:
    void sortColors(vector<int>& nums) {
        int low = 0, i = 0, high = (int)nums.size() - 1;
        while (i <= high) {
            if (nums[i] == 0)      swap(nums[low++], nums[i++]);
            else if (nums[i] == 2) swap(nums[high--], nums[i]);
            else                   ++i;
        }
    }
};
```

Solution — python

```python
class Solution:
    def sortColors(self, nums: list[int]) -> None:
        low, i, high = 0, 0, len(nums) - 1
        while i <= high:
            if nums[i] == 0:
                nums[low], nums[i] = nums[i], nums[low]
                low += 1
                i += 1
            elif nums[i] == 2:
                nums[high], nums[i] = nums[i], nums[high]
                high -= 1
            else:
                i += 1
```

Solution — java

```
class Solution {
    public void sortColors(int[] nums) {
        int low = 0, i = 0, high = nums.length - 1;
        while (i <= high) {
            if (nums[i] == 0) {
                int t = nums[low]; nums[low] = nums[i]; nums[i] = t;
                low++; i++;
            } else if (nums[i] == 2) {
                int t = nums[high]; nums[high] = nums[i]; nums[i] = t;
                high--;
            } else i++;
        }
    }
}
```

WALKTHROUGH

THE INVARIANT, WHICH IS WHAT MAKES THE ASYMMETRY CORRECT:

at all times `nums[0..low-1]` are 0s, `nums[low..i-1]` are 1s, `nums[i..high]` are unexamined, and `nums[high+1..]` are 2s.

When `nums[i]` is 0, it is swapped with `nums[low]`. But `low ≤ i` and everything in `[low, i)` is a 1, so the value coming back is either a 1 (already classified) or the same element when `low === i`. Either way `i` may advance.

When `nums[i]` is 2, it is swapped with `nums[high]`, which lies in the *unexamined* region. The value arriving at `i` has never been looked at, so advancing `i` would skip it. `[2,0,1]` is the smallest test that catches this: advancing would leave the 0 unprocessed and produce `[0,1,2]` only by luck — try `[2,1,0,2,1,0]` to see it fail properly.

THE LOOP CONDITION IS `I <= HIGH`, NOT `I < HIGH`

, because `high` itself is unexamined until the moment it is passed.

Largest number `Medium`

Pattern: Custom comparator

Given a list of non-negative integers `nums`, arrange them so that they form the **largest possible number**, and return it as a string.

Input	Output	Note
`nums = [10,2]`	`"210"`	
`nums = [3,30,34,5,9]`	`"9534330"`	
`nums = [0,0]`	`"0"`	Not "00".

HINTS

1. Sorting by numeric value is wrong: 3 should come before 30, but 30 > 3.
2. Sorting by string value is also wrong: "9" vs "34" happens to work, but "3" vs "30" does not.
3. Compare two candidates by which *concatenation* is larger: put `a` first if `a + b > b + a` as strings.
4. After sorting, if the first character is `"0"` the whole array was zeros — return `"0"`.

Approach	Idea	Time	Space
Try every permutation	Generate all orderings and take the largest.	`O(n!)`	`O(n)`
Concatenation comparator	Sort with `(a,b) => (b+a).localeCompare(a+b)`, then join.	`O(n log n · L)`	`O(n)`

Solution — js

```
function largestNumber(nums) {
  const s = nums.map(String);

  // a should come first if a+b is the larger concatenation
  s.sort((a, b) => (b + a).localeCompare(a + b));

  // all zeros -> "0", not "000"
  if (s[0] === "0") return "0";

  return s.join("");
}
```

Solution — cpp

```
class Solution {
public:
    string largestNumber(vector<int>& nums) {
        vector<string> s;
        for (int x : nums) s.push_back(to_string(x));
        sort(s.begin(), s.end(), [](const string& a, const string& b) {
            return a + b > b + a;      // a first if a+b is larger
        });
        if (s[0] == "0") return "0";
        string out;
        for (auto& x : s) out += x;
        return out;
    }
};
```

Solution — python

```
from functools import cmp_to_key

class Solution:
    def largestNumber(self, nums: list[int]) -> str:
        s = list(map(str, nums))
        s.sort(key=cmp_to_key(lambda a, b: (a + b < b + a) - (a + b > b + a)))
        if s[0] == "0":
            return "0"
        return "".join(s)
```

Solution — java

```
class Solution {
    public String largestNumber(int[] nums) {
        String[] s = new String[nums.length];
        for (int i = 0; i < nums.length; i++) s[i] = String.valueOf(nums[i]);
        Arrays.sort(s, (a, b) -> (b + a).compareTo(a + b));
        if (s[0].equals("0")) return "0";
        StringBuilder sb = new StringBuilder();
        for (String x : s) sb.append(x);
        return sb.toString();
    }
}
```

WALKTHROUGH

WHY THE CONCATENATION COMPARATOR IS CORRECT.

For two adjacent items the only question is which order produces a larger result, and since both orderings have the same total length, comparing `a+b` against `b+a` as strings answers it exactly. The non-obvious part is that this *local* rule produces a globally optimal arrangement — it does, because the comparator is a valid total order (it is transitive), so sorting by it yields the unique maximum.

THE COMPARATOR DIRECTION.

`(b + a).localeCompare(a + b)` returns negative when `b+a < a+b`, i.e. when putting `a` first is better — and negative means "a comes first". Getting this backwards produces the smallest number instead, which the `[3,30,34,5,9]` test catches immediately.

THE ALL-ZEROS GUARD IS NOT COSMETIC.

`[0,0]` sorts to `["0","0"]` and joins to `"00"`, which is not a valid number. Checking only the first character suffices: if the largest arrangement starts with 0, every element must be 0.

Sorting: interval patterns

Meetings, bookings, ranges. Almost every interval problem starts with one decision — sort by start or sort by end — and that decision determines whether the rest is three lines or impossible.

The pattern

```
TWO INTERVALS [a1, a2] AND [b1, b2] OVERLAP when

     a1 <= b2  AND  b1 <= a2

equivalently, they do NOT overlap when one ends entirely
before the other starts. Get this predicate right once
and write it down.

-----------------------------------------------------------

THE DECISION THAT DETERMINES EVERYTHING:

SORT BY START  -> MERGING, and "can I attend all?"
     Walk left to right; each interval either extends the
     current block or begins a new one.

SORT BY END    -> MAXIMISING THE COUNT of
                  non-overlapping intervals
     The classic activity-selection greedy: always keep
     the interval that FINISHES EARLIEST, because it
     leaves the most room for everything after it.

SWEEP LINE     -> "how many are active at once?"
     Turn each interval into two EVENTS,
     (start, +1) and (end, -1), sort all events by time,
     and scan keeping a running counter. The maximum
     counter value is the answer.

-----------------------------------------------------------

MERGE, after sorting by start:

  [1,3] [2,6] [8,10] [15,18]
    |-----|              sorted by start
     overlap -> merge to [1,6]
                |---|    8 > 6, new block
                     |---|

  out = [];
  for (const [s, e] of sorted) {
      const last = out[out.length - 1];
      if (last && s <= last[1]) last[1] = Math.max(last[1], e);
      else out.push([s, e]);
  }

  THE Math.max IS NOT OPTIONAL. [1,10] followed by [2,3]
  must stay [1,10]; without it the end shrinks to 3.

-----------------------------------------------------------

THE TOUCHING QUESTION: do [1,2] and [2,3] overlap?
IT DEPENDS ON THE PROBLEM. Merging usually says yes
(use <=); meeting rooms usually says no, because a
meeting ending at 2 frees the room for one starting at 2
(use <). ASK, or state your assumption.
```

When to reach for it

Merge overlapping ranges

Sort by start, extend or append.

Minimum removals to make disjoint

Sort by end, greedily keep the earliest finisher.

Minimum rooms / max concurrent

Sweep line, or a min-heap of end times.

Insert into a sorted set of intervals

Three phases: before, overlapping (merge), after.

Free time / gaps

Merge first, then read the gaps between blocks.

Minimum arrows / points hitting all

Sort by end — the same greedy as activity selection.

```
/* --- SWEEP LINE, the general tool --- */
const events = [];
for (const [s, e] of intervals) {
    events.push([s, +1]);
    events.push([e, -1]);
}
// tie-break: process ENDS before STARTS when touching
// intervals do NOT count as overlapping
events.sort((a, b) => a[0] - b[0] || a[1] - b[1]);
//                                  ^ -1 sorts before +1

let cur = 0, best = 0;
for (const [, delta] of events) {
    cur += delta;
    best = Math.max(best, cur);
}

/* THE TIE-BREAK IS THE WHOLE SUBTLETY. With events at the
   same time, processing the -1 first means a meeting ending
   at 10 releases the room before one starting at 10 claims
   it. Flip the tie-break and you need an extra room.     */
```

Problems

How it shows up

Symptom	Cause
Merged interval ends too early	Assigned `e` instead of `max(last[1], e)`

Symptom	Cause
Off by one on touching intervals	`<` vs `<=` — decide and state it
Greedy keeps too few intervals	Sorted by start instead of by end
Room count one too high	Sweep tie-break processes starts before ends
Wrong answer on unsorted input	Forgot to sort at all
Sort scrambles the intervals	Default JavaScript sort on arrays — pass a comparator
Crash on empty input	`out[out.length-1]` on an empty result
Mutating the input causes odd bugs	`last[1] = …` writes into the caller's array — copy first

Check yourself

- ✓ Write the overlap predicate for two intervals.
- ✓ Say when to sort by start and when by end, with a problem for each.
- ✓ Explain why "earliest finishing time" is the right greedy.
- ✓ Write the merge loop and explain the `Math.max`.
- ✓ Describe the sweep line and its tie-break rule.
- ✓ Say what the tie-break controls, concretely.
- ✓ Explain the touching-intervals ambiguity and how to resolve it.
- ✓ Give the three phases of inserting into a sorted interval list.

Problems

Merge intervals `Medium`

Pattern: Sort by start, extend or append

Given an array of intervals `[start, end]`, merge all overlapping intervals and return the non-overlapping intervals that cover all the input.

Touching intervals such as `[1,4]` and `[4,5]` **do** merge here.

Input	Output	Note
`intervals = [[1,3],[2,6],[8,10],[15,18]]`	`[[1,6],[8,10],[15,18]]`	
`intervals = [[1,4],[4,5]]`	`[[1,5]]`	

HINTS

1. Sort by start time first. Then any interval can only overlap the block you are currently building.
2. If the new start is at most the current block's end, they overlap — extend the block.
3. Extend to `max(currentEnd, newEnd)`, not to `newEnd`: a fully contained interval must not shrink the block.

Approach	Idea	Time	Space
Repeated pairwise merging	Scan for any overlapping pair, merge, repeat until stable.	`O(n²)`	`O(n)`
Sort by start, one pass	After sorting, one linear sweep suffices because overlaps can only be with the immediately preceding block.	`O(n log n)`	`O(n)`

Solution — js

```
function merge(intervals) {
  if (intervals.length === 0) return [];

  // copy before sorting so the caller's array is untouched
  const sorted = intervals.slice().sort((a, b) => a[0] - b[0]);
  const out = [sorted[0].slice()];

  for (let i = 1; i < sorted.length; i++) {
    const [s, e] = sorted[i];
    const last = out[out.length - 1];
    if (s <= last[1]) {
      // overlap - EXTEND, never shrink
      last[1] = Math.max(last[1], e);
    } else {
      out.push([s, e]);
    }
  }
  return out;
}
```

Solution — cpp

```
class Solution {
public:
    vector<vector<int>> merge(vector<vector<int>>& intervals) {
        if (intervals.empty()) return {};
        sort(intervals.begin(), intervals.end());
        vector<vector<int>> out{intervals[0]};
        for (size_t i = 1; i < intervals.size(); ++i) {
            if (intervals[i][0] <= out.back()[1])
                out.back()[1] = max(out.back()[1], intervals[i][1]);
            else
                out.push_back(intervals[i]);
        }
        return out;
    }
};
```

Solution — python

```
class Solution:
    def merge(self, intervals: list[list[int]]) -> list[list[int]]:
        if not intervals:
            return []
        out = []
        for s, e in sorted(intervals):
            if out and s <= out[-1][1]:
                out[-1][1] = max(out[-1][1], e)
            else:
                out.append([s, e])
        return out
```

Solution — java

```java
class Solution {
    public int[][] merge(int[][] intervals) {
        if (intervals.length == 0) return new int[0][];
        Arrays.sort(intervals, (a, b) -> Integer.compare(a[0], b[0]));
        List<int[]> out = new ArrayList<>();
        out.add(intervals[0].clone());
        for (int i = 1; i < intervals.length; i++) {
            int[] last = out.get(out.size() - 1);
            if (intervals[i][0] <= last[1]) last[1] = Math.max(last[1], intervals[i][1]);
            else out.add(intervals[i].clone());
        }
        return out.toArray(new int[0][]);
    }
}
```

WALKTHROUGH

WHY SORTING BY START MAKES ONE PASS SUFFICIENT.

After sorting, every interval starts at or after the current block's start. So if it overlaps *anything* already emitted, it must overlap the most recent block — earlier blocks ended before that one began. That reduces an all-pairs question to a single comparison per element.

`[[1,10],[2,3]]` IS THE TEST THAT MATTERS.

The second interval is entirely inside the first. Writing `last[1] = e` would shrink the block to `[1,3]` and lose coverage. The `Math.max` is what makes containment work.

NOTE THE `.SLICE()` CALLS.

Sorting mutates the input array and writing `last[1]` would mutate the caller's interval objects. Copying is cheap and avoids a class of bug that only shows up when the caller reuses the data.

Non-overlapping intervals `Medium`

Pattern: Sort by END — activity selection

Given an array of intervals, return the **minimum number you must remove** so that the rest are non-overlapping.

Intervals that merely touch, such as `[1,2]` and `[2,3]`, are **not** considered overlapping.

Input	Output	Note
`intervals = [[1,2],[2,3],[3,4],[1,3]]`	`1`	Remove [1,3].
`intervals = [[1,2],[1,2],[1,2]]`	`2`	
`intervals = [[1,2],[2,3]]`	`0`	

HINTS

1. Removing the fewest is the same as *keeping* the most — the classic activity-selection problem.
2. Sort by
   END
   time, not start. Greedily keep an interval whenever it starts at or after the last kept end.
3. Intuition: finishing earliest leaves the maximum room for everything that follows.
4. The answer is `total - kept`.

Approach	Idea	Time	Space
Try every subset	Check all subsets for disjointness.	`O(2^n)`	`O(n)`
DP on sorted intervals	Longest non-overlapping chain by binary searching the previous compatible interval.	`O(n log n)`	`O(n)`
Greedy by earliest end	Sort by end and keep greedily. Provably optimal by an exchange argument.	`O(n log n)`	`O(1)`

Solution — js

```
function eraseOverlapIntervals(intervals) {
  if (intervals.length === 0) return 0;

  // sort by END time — the heart of the greedy
  const sorted = intervals.slice().sort((a, b) => a[1] - b[1]);

  let kept = 0, lastEnd = -Infinity;
  for (const [s, e] of sorted) {
    if (s >= lastEnd) {      // >= : touching is allowed
      kept++;
      lastEnd = e;
    }
  }
  return intervals.length - kept;
}
```

Solution — cpp

```
class Solution {
public:
    int eraseOverlapIntervals(vector<vector<int>>& intervals) {
        if (intervals.empty()) return 0;
        sort(intervals.begin(), intervals.end(),
             [](const vector<int>& a, const vector<int>& b) {
                 return a[1] < b[1];
             });
        int kept = 0; long lastEnd = LONG_MIN;
        for (auto& iv : intervals)
            if (iv[0] >= lastEnd) { ++kept; lastEnd = iv[1]; }
        return (int)intervals.size() - kept;
    }
};
```

Solution — python

```python
class Solution:
    def eraseOverlapIntervals(self, intervals: list[list[int]]) -> int:
        if not intervals:
            return 0
        kept = 0
        last_end = float("-inf")
        for s, e in sorted(intervals, key=lambda iv: iv[1]):
            if s >= last_end:
                kept += 1
                last_end = e
        return len(intervals) - kept
```

Solution — java

```java
class Solution {
    public int eraseOverlapIntervals(int[][] intervals) {
        if (intervals.length == 0) return 0;
        Arrays.sort(intervals, (a, b) -> Integer.compare(a[1], b[1]));
        int kept = 0;
        long lastEnd = Long.MIN_VALUE;
        for (int[] iv : intervals)
            if (iv[0] >= lastEnd) { kept++; lastEnd = iv[1]; }
        return intervals.length - kept;
    }
}
```

WALKTHROUGH

THE EXCHANGE ARGUMENT — BE READY TO GIVE THIS.

Suppose an optimal solution keeps some interval `X` as the first of its chain, and let `G` be the interval with the earliest end time overall. Since `G` ends no later than `X`, replacing `X` with `G` cannot conflict with anything the optimal solution kept after `X`. So there is an optimal solution that starts with the earliest finisher, and by induction the greedy is optimal.

SORTING BY START IS THE NATURAL INSTINCT AND IT IS WRONG.

On `[[1,100],[11,22],[1,11],[2,12]]`, start-order would consider `[1,100]` first and block everything else, keeping 1 and removing 3. End-order keeps `[1,11]` and `[11,22]`, removing only 2 — which is the answer.

`S >= LASTEND` ENCODES "TOUCHING IS FINE".

If the problem said touching counts as overlapping, this becomes `s > lastEnd`. That single character is the entire difference, which is why the pattern section insists on settling the question before writing code.

Meeting rooms II `Medium`

Pattern: Sweep line / min-heap of ends

Given an array of meeting time intervals `[start, end]`, return the **minimum number of conference rooms** required so that no two meetings in the same room overlap.

A meeting ending at time `t` frees the room for a meeting starting at `t`.

Input	Output	Note
`intervals = [[0,30],[5,10],[15,20]]`	`2`	

Input	Output	Note
`intervals = [[7,10],[2,4]]`	`1`	
`intervals = [[1,5],[2,6],[3,7]]`	`3`	

HINTS

1. The answer is the maximum number of meetings simultaneously in progress.
2. Turn each meeting into two events: a start (+1 room) and an end (−1 room). Sort all events by time and sweep.
3. When a start and an end share the same time, process the **END FIRST** — the room is freed before the next meeting claims it.
4. Equivalently: sort the start times and end times into two separate arrays and walk them with two pointers.

Approach	Idea	Time	Space
Count overlaps per meeting	For each meeting, count how many others overlap it.	`O(n²)`	`O(1)`
Min-heap of end times	Sort by start; keep a heap of the end times of active meetings, popping those that have finished. Heap size is the room count.	`O(n log n)`	`O(n)`
Sweep line on events	Two events per meeting, sorted, one linear scan of a counter.	`O(n log n)`	`O(n)`

Solution — js

```
function minMeetingRooms(intervals) {
  const events = [];
  for (const [s, e] of intervals) {
    events.push([s, +1]);   // a meeting starts: need a room
    events.push([e, -1]);   // a meeting ends: free a room
  }

  // same time -> process the END (-1) before the START (+1)
  events.sort((a, b) => a[0] - b[0] || a[1] - b[1]);

  let cur = 0, best = 0;
  for (const [, delta] of events) {
    cur += delta;
    best = Math.max(best, cur);
  }
  return best;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int minMeetingRooms(vector<vector<int>>& intervals) {
        vector<pair<int,int>> events;
        for (auto& iv : intervals) {
            events.push_back({iv[0], +1});
            events.push_back({iv[1], -1});
        }
        sort(events.begin(), events.end());   // -1 sorts before +1
        int cur = 0, best = 0;
        for (auto& [t, d] : events) { cur += d; best = max(best, cur); }
        return best;
    }
};
```

Solution — python

```python
class Solution:
    def minMeetingRooms(self, intervals: list[list[int]]) -> int:
        events = []
        for s, e in intervals:
            events.append((s, 1))
            events.append((e, -1))
        events.sort()          # (t, -1) sorts before (t, +1)
        cur = best = 0
        for _, d in events:
            cur += d
            best = max(best, cur)
        return best
```

Solution — java

```java
class Solution {
    public int minMeetingRooms(int[][] intervals) {
        int[][] events = new int[intervals.length * 2][2];
        int k = 0;
        for (int[] iv : intervals) {
            events[k++] = new int[]{iv[0], 1};
            events[k++] = new int[]{iv[1], -1};
        }
        Arrays.sort(events, (a, b) ->
            a[0] != b[0] ? Integer.compare(a[0], b[0])
                         : Integer.compare(a[1], b[1]));
        int cur = 0, best = 0;
        for (int[] e : events) { cur += e[1]; best = Math.max(best, cur); }
        return best;
    }
}
```

WALKTHROUGH

WHY THE MAXIMUM CONCURRENCY IS THE ANSWER.

If at some instant `k` meetings are in progress they need `k` distinct rooms, so the answer is at least the peak. And it is achievable: process meetings in start order assigning any free room — a room is unavailable only if its meeting is still running, so you never need more than the peak. Hence peak concurrency is exactly the minimum.

THE TIE-BREAK IS THE ENTIRE SUBTLETY.

On `[[1,2],[2,3],[3,4]]` the answer is 1, because each meeting ends exactly as the next begins. Sorting `-1` before `+1` at equal times produces the sequence +1, −1, +1, −1, +1, −1 and a peak of 1. Reverse the tie-break and you get +1, +1, −1 … and a peak of 2. Note the comparator `a[1] - b[1]` achieves this for free, since `-1 < +1`.

THE HEAP ALTERNATIVE IS WORTH KNOWING

because it generalises: if you also need to know *which* room each meeting goes in, a min-heap of (end time, room id) gives you that, and the sweep does not.

Hashing: maps, sets and frequency

Trade memory for time. A hash map turns "have I seen this?" from an O(n) scan into an O(1) lookup, and that single substitution converts more $O(n^2)$ solutions into O(n) ones than any other technique.

The pattern

```
THE CORE MOVE: whenever an inner loop is SEARCHING for
something, ask whether a hash map could have remembered
it instead.

  for i in 0..n:
    for j in 0..n:            <-- this loop is a LOOKUP
      if a[j] == something(i)

  becomes

  seen = {}
  for i in 0..n:
    if something(i) in seen:  <-- O(1)
    seen[a[i]] = i

  O(n^2)  ->  O(n) time, O(n) space.

THE FOUR USES, and nearly every hashing problem is one
of them:

1. MEMBERSHIP - "have I seen x?"            Set
     duplicates, intersections, cycle detection

2. COUNTING - "how many times did x occur?"  Map -> int
     anagrams, majority element, frequency ranking

3. INDEXING - "where did x occur?"           Map -> index
     two sum, longest subarray with a property

4. GROUPING - "which items share a key?"     Map -> list
     group anagrams, bucket by some signature

THE KEY DESIGN DECISION IS THE KEY ITSELF. Most hashing
problems reduce to: WHAT IS THE RIGHT SIGNATURE?

  group anagrams        -> sorted letters, or a
                           26-length count vector
  find duplicates       -> the value itself
  subarray sums         -> the running prefix sum
  isomorphic strings    -> a pair of forward/backward maps
  board validation      -> "row3-val7", "col2-val7"

CHOOSING A GOOD KEY IS THE WHOLE PROBLEM. The map itself
is never the hard part.

THE COSTS:
  lookup/insert/delete   O(1) AVERAGE, O(n) worst case
  space                  O(n)
  ordering               NONE - if you need sorted keys,
                         you want a balanced BST or a
                         sort, not a hash map
```

Choosing the structure

Set

Membership only. `has`, `add`, `delete`. Use when you never need counts or positions.

Map → count

Frequency. The single most common shape. Remember to delete keys that reach zero if you rely on `size`.

Map → index

When the answer is a position, not a value. Two Sum returns indices, so it cannot sort.

Map → array

Grouping. Push into the bucket for a computed key.

Fixed array instead of a map

If keys are small integers or lowercase letters, `new Array(26).fill(0)` is faster and simpler than a Map.

Not a hash map

Need order, ranks, or "next larger key"? Use sorting, a heap, or a BST — hashing has no order.

```
/* --- FREQUENCY, the idiom to have automatic --- */
const freq = new Map();
for (const x of arr) freq.set(x, (freq.get(x) ?? 0) + 1);

// letters only? an array is better:
const cnt = new Array(26).fill(0);
for (const ch of s) cnt[ch.charCodeAt(0) - 97]++;

/* --- GROUPING --- */
const groups = new Map();
for (const w of words) {
    const key = signature(w);
    if (!groups.has(key)) groups.set(key, []);
    groups.get(key).push(w);
}
return [...groups.values()];

/* --- SEEN-BEFORE WITH INDEX --- */
const seen = new Map();          // value -> index
for (let i = 0; i < a.length; i++) {
    if (seen.has(target - a[i])) return [seen.get(target - a[i]), i];
    seen.set(a[i], i);           // AFTER the check, so an element
}                                // cannot pair with itself

/* --- THE TRAPS ---
   · A JS OBJECT COERCES KEYS TO STRINGS: obj[1] and
     obj["1"] are the SAME entry. Map does not. Use Map.
   · ARRAYS AND OBJECTS AS KEYS compare by REFERENCE, so
     map.set([1,2],x) then map.get([1,2]) returns undefined.
     Serialise to a string first: a.join(',').
   · CHECK-THEN-INSERT ORDER matters (see above).
   · `map.get(k) || 0` breaks when the stored value is 0 or
     "". Use `?? 0`.
   · ITERATION ORDER of a Map is insertion order in JS, but
     do not rely on any order in C++ unordered_map.      */
```

Problems

How it shows up

Symptom	Cause
Element pairs with itself	Inserted into the map before checking for the complement
Numeric and string keys collide	Plain object coerces keys — use `Map`
Array key never found	Reference equality — serialise the key
Count of zero treated as missing	`|| 0` instead of `?? 0`
`map.size` wrong after removals	Zero counts not deleted
Answers come out in the wrong order	Hash maps have no order — sort explicitly if order is required
Memory blows up	O(n) space — check whether the constraints allow it
Solution is O(n) but slow in practice	Hashing long string keys is O(L), not O(1)

Check yourself

✓ Give the four uses of hashing and a problem for each.

- ✓ State the transformation that turns an $O(n^2)$ search loop into O(n).
- ✓ Explain why key design is the real problem, with two examples.
- ✓ Say why Two Sum cannot be solved by sorting but 3Sum can.
- ✓ Explain why the insert must come after the check.
- ✓ Give two signatures that group anagrams and their complexities.
- ✓ Say when a fixed array beats a hash map.
- ✓ Name three situations where a hash map is the wrong structure.

Problems

Two Sum `Easy`

Pattern: Map value → index

Given an array of integers `nums` and an integer `target`, return the **indices** of the two numbers that add up to the target.

Exactly one solution exists, and you may not use the same element twice. The array is **not sorted**.

Input	Output	Note
`nums = [2,7,11,15], target = 9`	`[0,1]`	
`nums = [3,2,4], target = 6`	`[1,2]`	
`nums = [3,3], target = 6`	`[0,1]`	Duplicate values, distinct indices.

HINTS

1. For each element you need to know whether `target - x` has already appeared, and where.
2. A map from value to index answers both in O(1).
3. Check for the complement *before* inserting the current element, or a value equal to half the target will pair with itself.

Approach	Idea	Time	Space
Brute force	Every pair.	`O(n²)`	`O(1)`
Sort + two pointers	Works for the values but **destroys the indices**, which are the required output. You would have to store and sort (value, index) pairs.	`O(n log n)`	`O(n)`
Hash map, one pass	Scan once, looking up `target - x` in a map of everything seen so far.	`O(n)`	`O(n)`

Solution — js

```javascript
function twoSum(nums, target) {
  const seen = new Map();          // value -> index
  for (let i = 0; i < nums.length; i++) {
    const need = target - nums[i];
    if (seen.has(need)) return [seen.get(need), i];
    seen.set(nums[i], i);          // insert AFTER the check
  }
  return [];
}
```

Solution — cpp

```cpp
class Solution {
public:
    vector<int> twoSum(vector<int>& nums, int target) {
        unordered_map<int,int> seen;
        for (int i = 0; i < (int)nums.size(); ++i) {
            int need = target - nums[i];
            auto it = seen.find(need);
            if (it != seen.end()) return {it->second, i};
            seen[nums[i]] = i;
        }
        return {};
    }
};
```

Solution — python

```python
class Solution:
    def twoSum(self, nums: list[int], target: int) -> list[int]:
        seen = {}                      # value -> index
        for i, x in enumerate(nums):
            need = target - x
            if need in seen:
                return [seen[need], i]
            seen[x] = i
        return []
```

Solution — java

```java
class Solution {
    public int[] twoSum(int[] nums, int target) {
        Map<Integer,Integer> seen = new HashMap<>();
        for (int i = 0; i < nums.length; i++) {
            int need = target - nums[i];
            if (seen.containsKey(need)) return new int[]{seen.get(need), i};
            seen.put(nums[i], i);
        }
        return new int[0];
    }
}
```

WALKTHROUGH

WHY THE ORDER OF CHECK-THEN-INSERT MATTERS.

On `[3,3], target 6`: at `i=0` the map is empty, so no match, and 3 is stored. At `i=1` we need 3 and find it at index 0 — correct. If you inserted first, `i=0` would find its own 3 and return `[0,0]`, using one element twice.

THE CONTRAST WITH TWO SUM II IS THE LESSON.

There the input is sorted and the two-pointer solution uses O(1) space. Here you cannot sort, because sorting permutes the indices you must return. *What the problem asks you to return determines which technique is legal* — a distinction worth stating aloud in an interview.

Valid anagram Easy

Pattern: Frequency count

Given two strings `s` and `t`, return `true` if `t` is an anagram of `s` — the same characters with the same multiplicities, in any order.

Input	Output	Note
`s = "anagram", t = "nagaram"`	`true`	
`s = "rat", t = "car"`	`false`	
`s = "a", t = "ab"`	`false`	

HINTS

1. Different lengths can never be anagrams — check that first and return early.
2. Count each character of `s`, then decrement for each character of `t`.
3. If any count goes negative, `t` has a character `s` does not have enough of. If lengths match and nothing went negative, they are anagrams.

Approach	Idea	Time	Space
Sort both	Sort the characters of each and compare. Very short, and a fine answer to state.	`O(n log n)`	`O(n)`
Frequency map	Count up for `s`, down for `t`; fail on any negative.	`O(n)`	`O(k)`
Fixed 26-element array	Same idea, but for lowercase-only input an array beats a Map on constant factors.	`O(n)`	`O(1)`

Solution — js

```javascript
function isAnagram(s, t) {
  if (s.length !== t.length) return false;
  const freq = new Map();
  for (const c of s) freq.set(c, (freq.get(c) ?? 0) + 1);
  for (const c of t) {
    const n = (freq.get(c) ?? 0) - 1;
    if (n < 0) return false;        // more of c in t than in s
    freq.set(c, n);
  }
  return true;                       // lengths equal + none negative
}
```

Solution — cpp

```cpp
class Solution {
public:
    bool isAnagram(string s, string t) {
        if (s.size() != t.size()) return false;
        array<int,26> cnt{};
        for (char c : s) ++cnt[c - 'a'];
        for (char c : t) if (--cnt[c - 'a'] < 0) return false;
        return true;
    }
};
```

Solution — python

```python
from collections import Counter

class Solution:
    def isAnagram(self, s: str, t: str) -> bool:
        if len(s) != len(t):
            return False
        return Counter(s) == Counter(t)
```

Solution — java

```java
class Solution {
    public boolean isAnagram(String s, String t) {
        if (s.length() != t.length()) return false;
        int[] cnt = new int[26];
        for (char c : s.toCharArray()) cnt[c - 'a']++;
        for (char c : t.toCharArray()) if (--cnt[c - 'a'] < 0) return false;
        return true;
    }
}
```

WALKTHROUGH

WHY THE LENGTH CHECK MAKES THE REST SOUND.

If the lengths are equal and no count ever goes negative, then `t` never over-uses a character; since the totals are equal, it cannot under-use one either. That is why a single downward pass suffices with no final verification loop.

THE FOLLOW-UP TO EXPECT:

"what about Unicode?" The 26-element array assumes lowercase ASCII. For arbitrary Unicode use a Map, and be aware that comparing by code point ignores normalisation — "é" can be one code point or two. Mentioning that is a strong signal.

Group anagrams `Medium`

Pattern: Map key → bucket

Given an array of strings, group the anagrams together. Return the groups in any order, and the strings within each group in any order.

Input	Output	Note
`strs = ["eat","tea","tan","ate","nat","bat"]`	`[["eat","tea","ate"],["tan","nat"],["bat"]]`	
`strs = [""]`	`[[""]]`	
`strs = ["a"]`	`[["a"]]`	

HINTS

1. Anagrams need a *canonical form* — a signature that is identical for exactly the strings that belong together.
2. Sorting a word's letters gives one such signature: "eat", "tea" and "ate" all become "aet".
3. A 26-length count vector joined into a string is another, and it avoids the per-word sort.

Approach	Idea	Time	Space
Compare every pair	Test each pair for anagram-ness and union them.	`O(n²·k)`	`O(n)`
Sorted-letters key	Bucket by the sorted characters. Simple and usually fast enough.	`O(n·k log k)`	`O(n·k)`
Count-vector key	Bucket by a 26-slot count signature. Removes the log factor when words are long.	`O(n·k)`	`O(n·k)`

Solution — js

```javascript
function groupAnagrams(strs) {
  const groups = new Map();
  for (const w of strs) {
    const key = w.split("").sort().join("");   // canonical form
    if (!groups.has(key)) groups.set(key, []);
    groups.get(key).push(w);
  }
  return [...groups.values()];
}

// O(n*k) variant using a count signature instead of sorting:
// const cnt = new Array(26).fill(0);
// for (const c of w) cnt[c.charCodeAt(0) - 97]++;
// const key = cnt.join(",");
```

Solution — cpp

```cpp
class Solution {
public:
    vector<vector<string>> groupAnagrams(vector<string>& strs) {
        unordered_map<string, vector<string>> groups;
        for (auto& w : strs) {
            string key = w;
            sort(key.begin(), key.end());
            groups[key].push_back(w);
        }
        vector<vector<string>> out;
        for (auto& [k, v] : groups) out.push_back(move(v));
        return out;
    }
};
```

Solution — python

```python
from collections import defaultdict

class Solution:
    def groupAnagrams(self, strs: list[str]) -> list[list[str]]:
        groups = defaultdict(list)
        for w in strs:
            groups["".join(sorted(w))].append(w)
        return list(groups.values())
```

Solution — java

```java
class Solution {
    public List<List<String>> groupAnagrams(String[] strs) {
        Map<String, List<String>> groups = new HashMap<>();
        for (String w : strs) {
            char[] c = w.toCharArray();
            Arrays.sort(c);
            groups.computeIfAbsent(new String(c), k -> new ArrayList<>()).add(w);
        }
        return new ArrayList<>(groups.values());
    }
}
```

WALKTHROUGH

THIS PROBLEM IS ENTIRELY ABOUT CHOOSING THE KEY.

Once you decide that two words belong together exactly when their canonical forms are equal, the code is four lines. The interview value is in articulating *why* sorted letters is a valid canonical form: sorting is a function of the multiset of characters and nothing else, so two words share a sorted form precisely when they are anagrams.

WHICH KEY TO CHOOSE.

With `k` the word length, sorting costs `O(k log k)` per word and the count vector costs `O(k)`. For short words sorting wins on constant factors; for long words or a large alphabet the count vector wins. Say both and pick one — that is the expected answer.

Subarray sum equals K `Medium`

Pattern: Prefix sum + hash map

Given an array of integers `nums` (which **may contain negatives**) and an integer `k`, return the total number of contiguous subarrays whose sum equals `k`.

Input	Output	Note
`nums = [1,1,1], k = 2`	`2`	The two overlapping [1,1] subarrays both count.
`nums = [1,2,3], k = 3`	`2`	[1,2] and [3].
`nums = [1,-1,0], k = 0`	`3`	[1,-1], [0] and [1,-1,0].

HINTS

1. Negatives are present, so a sliding window will not work — growing the window no longer monotonically increases the sum.
2. Let `P[i]` be the sum of the first `i` elements. The sum of `nums[j..i)` is `P[i] - P[j]`.
3. You want `P[i] - P[j] === k`, i.e. `P[j] === P[i] - k`. So count how many earlier prefix sums equal `P[i] - k`.
4. Seed the map with `{0: 1}` — the empty prefix — so that subarrays starting at index 0 are counted.

Approach	Idea	Time	Space
All subarrays	Two nested loops with a running sum.	`O(n²)`	`O(1)`
Sliding window	**Does not work.** Requires all-positive values for the sum to be monotonic in the window size.	–	–
Prefix sums + frequency map	One pass. For each prefix sum, add the number of earlier prefixes equal to `running - k`.	`O(n)`	`O(n)`

Solution — js

```javascript
function subarraySum(nums, k) {
  // prefix sum -> number of times it has occurred
  const count = new Map([[0, 1]]);   // the EMPTY prefix sums to 0
  let running = 0, total = 0;

  for (const x of nums) {
    running += x;
    // any earlier prefix equal to (running - k) closes a valid subarray
    total += count.get(running - k) ?? 0;
    count.set(running, (count.get(running) ?? 0) + 1);
  }
  return total;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int subarraySum(vector<int>& nums, int k) {
        unordered_map<long,int> count{{0, 1}};
        long running = 0;
        int total = 0;
        for (int x : nums) {
            running += x;
            auto it = count.find(running - k);
            if (it != count.end()) total += it->second;
            ++count[running];
        }
        return total;
    }
};
```

Solution — python

```python
from collections import defaultdict

class Solution:
    def subarraySum(self, nums: list[int], k: int) -> int:
        count = defaultdict(int)
        count[0] = 1
        running = total = 0
        for x in nums:
            running += x
            total += count[running - k]
            count[running] += 1
        return total
```

Solution — java

```
class Solution {
    public int subarraySum(int[] nums, int k) {
        Map<Integer,Integer> count = new HashMap<>();
        count.put(0, 1);
        int running = 0, total = 0;
        for (int x : nums) {
            running += x;
            total += count.getOrDefault(running - k, 0);
            count.merge(running, 1, Integer::sum);
        }
        return total;
    }
}
```

WALKTHROUGH

WHY THE SEED `{0: 1}` IS NOT A HACK.

`P[0] = 0` is a genuine prefix — the empty one. A subarray starting at index 0 has sum `P[i] - P[0] = P[i]`, so it is counted only if `0` is already in the map. Test `[1], k = 1`: without the seed the answer is 0 instead of 1.

COUNT OCCURRENCES, NOT PRESENCE.

The map stores *how many times* each prefix sum has appeared, because several earlier positions can produce the same prefix sum and each of them closes a distinct valid subarray. `[0,0,0], k=0` has six subarrays and only counting works.

THE GENERAL PRINCIPLE:

whenever a problem asks about contiguous ranges with a *sum* condition and negatives are allowed, prefix sums plus a hash map is the pattern. With only positives you can usually use a sliding window instead, which is O(1) space. Knowing which precondition each needs is the point — see chapter 06.

Longest consecutive sequence `Hard`

Pattern: Set membership + start detection

Given an unsorted array of integers, return the length of the longest sequence of **consecutive** integers present in the array. Elements need not be adjacent in the array.

Must run in O(n).

Input	Output	Note
`nums = [100,4,200,1,3,2]`	`4`	1, 2, 3, 4.
`nums = [0,3,7,2,5,8,4,6,0,1]`	`9`	0 through 8.
`nums = []`	`0`	

HINTS

1. Sorting solves it in O(n log n), but the requirement is O(n) — so the ordering must come from a Set instead.
2. Put everything in a Set. Now "is x+1 present?" is O(1).
3. The trap is walking a run from every element, which is $O(n^2)$ on a long run. Only start walking from an element that *begins* a run.
4. `x` begins a run exactly when `x - 1` is not in the set.

Approach	Idea	Time	Space
Sort then scan	Sort, then measure consecutive runs, skipping duplicates. Perfectly good — but not O(n).	`O(n log n)`	`O(1)`
Set, walk from every element	Correct but quadratic: a run of length L is re-walked from each of its L members.	`O(n²)`	`O(n)`
Set + start detection	Only extend from elements with no predecessor. Every element is visited at most twice overall.	`O(n)`	`O(n)`

Solution — js

```
function longestConsecutive(nums) {
  const s = new Set(nums);
  let best = 0;

  for (const x of s) {
    // only start counting from the BEGINNING of a run
    if (s.has(x - 1)) continue;

    let len = 1;
    while (s.has(x + len)) len++;
    best = Math.max(best, len);
  }
  return best;
}
```

Solution — cpp

```
class Solution {
public:
    int longestConsecutive(vector<int>& nums) {
        unordered_set<int> s(nums.begin(), nums.end());
        int best = 0;
        for (int x : s) {
            if (s.count(x - 1)) continue;   // not a run start
            int len = 1;
            while (s.count(x + len)) ++len;
            best = max(best, len);
        }
        return best;
    }
};
```

Solution — python

```python
class Solution:
    def longestConsecutive(self, nums: list[int]) -> int:
        s = set(nums)
        best = 0
        for x in s:
            if x - 1 in s:
                continue
            length = 1
            while x + length in s:
                length += 1
            best = max(best, length)
        return best
```

Solution — java

```java
class Solution {
    public int longestConsecutive(int[] nums) {
        Set<Integer> s = new HashSet<>();
        for (int x : nums) s.add(x);
        int best = 0;
        for (int x : s) {
            if (s.contains(x - 1)) continue;
            int len = 1;
            while (s.contains(x + len)) len++;
            best = Math.max(best, len);
        }
        return best;
    }
}
```

WALKTHROUGH

WHY THIS IS O(N) DESPITE THE NESTED `WHILE`.

The inner loop runs only for elements that start a run, and it walks each run exactly once. Every value is therefore touched at most twice in total — once by the outer iteration and once by the single walk over its run — so the whole thing is O(n). This is the same amortised reasoning as the sliding window in chapter 02, and stating it is what convinces the interviewer the bound is real.

WITHOUT THE `CONTINUE` GUARD THE ALGORITHM IS QUADRATIC.

On `[1..n]` shuffled, starting a walk from every element costs `n + (n−1) + … = O(n²)`. That single line is the whole optimisation.

ITERATING THE SET RATHER THAN THE ARRAY

handles duplicates for free — `[5,5,5,5]` visits 5 once and returns 1.

Hashing: cyclic sort and index-as-hash

When the values are a permutation of 1..n, the array *is* the hash table. This is the pattern behind every "find the missing/duplicate number in O(1) space" problem.

The pattern

```
THE RECOGNITION SIGNAL, and it is very specific:

  "an array of n integers where each value is in the
   range [1, n]"      (or [0, n-1])

plus a request for O(1) EXTRA SPACE.

THAT RANGE IS THE WHOLE HINT. Values and indices are
drawn from the same set, so each value has a NATURAL HOME:

     value v  belongs at index  v - 1     (for 1..n)
     value v  belongs at index  v         (for 0..n-1)

TWO WAYS TO EXPLOIT IT:

------------------------------------------------------------
1. CYCLIC SORT - put every value where it belongs

     i = 0
     while (i < n) {
         const home = a[i] - 1;
         if (a[i] !== a[home]) swap(a, i, home);  // not home
         else i++;                                 // settled
     }
     // now scan: the first index where a[i] !== i+1
     // exposes the missing / duplicate value

     [3, 1, 5, 4, 2]
      ^  3 belongs at index 2, swap with 5
     [5, 1, 3, 4, 2]
      ^  5 belongs at index 4, swap with 2
     [2, 1, 3, 4, 5]
      ^  2 belongs at index 1, swap with 1
     [1, 2, 3, 4, 5]  sorted, in O(n)

   WHY IT IS O(n) DESPITE THE NESTED-LOOKING LOOP: every
   swap places at least one value in its final position,
   so there are at most n swaps in total. The amortised
   argument from chapter 02, again.

   COMPARE `a[i] !== a[home]` RATHER THAN `i !== home` -
   with duplicates present, comparing indices loops
   forever when two equal values want the same slot.

------------------------------------------------------------
2. SIGN MARKING - use the sign bit as a "seen" flag

     for (const x of a) {
         const idx = Math.abs(x) - 1;
         if (a[idx] < 0) -> value idx+1 is a DUPLICATE
         a[idx] = -a[idx];        // mark as seen
     }
     // afterwards, any index still positive is MISSING

   Non-destructive if you restore the signs afterwards.
   Only works when the values are strictly positive, so
   the sign is free to carry information.

------------------------------------------------------------

THE OTHER O(1) TRICKS IN THIS FAMILY:
```

```
SUM FORMULA   expected n(n+1)/2 minus the actual sum
              gives one missing value. Simple, but
              overflows for large n and only finds one.
XOR           XOR all values with 1..n; pairs cancel and
              the survivor is the answer (chapter 16).
FLOYD'S CYCLE fast/slow pointers over the "value as next
              index" graph — finds a duplicate without
              modifying the array at all (chapter 18).
```

When to reach for it

"Values are 1..n" + O(1) space

Cyclic sort or sign marking. This phrasing is essentially a giveaway.

Find all missing / all duplicates

Sign marking finds every one in a single pass.

First missing positive

Cyclic sort, ignoring values outside 1..n.

Cannot modify the array

Floyd's cycle detection, or binary search on the value range.

Exactly one missing, no duplicates

Sum formula or XOR — one line each.

Problems

How it shows up

Symptom	Cause
Infinite loop in cyclic sort	Compared indices instead of values — duplicates never settle
Index out of range	Values outside 1..n not filtered before computing the home
Sign marking gives wrong answers	Forgot `Math.abs` when reading an already-flipped value
Marks a zero	Zero has no sign — shift to 1-based or use a different marker
Sum formula overflows	n(n+1)/2 exceeds 32 bits — use XOR or 64-bit
Works for one missing, fails for several	Sum/XOR find exactly one — use marking
Input array corrupted for the caller	These techniques mutate — restore or document it

Check yourself

- ✓ State the recognition signal precisely.
- ✓ Give the home-index formula for both 1..n and 0..n−1.
- ✓ Write the cyclic sort loop and justify O(n).

- ✓ Explain why the swap condition compares values, not indices.
- ✓ Describe sign marking and its precondition.
- ✓ Give three alternative O(1)-space tricks and each one's limit.
- ✓ Say what to do when the array may not be modified.

Problems

Missing number Easy

Pattern: Sum formula / XOR

Given an array `nums` containing `n` distinct numbers drawn from the range `[0, n]`, return the one number in that range which is missing.

Input	Output	Note
`nums = [3,0,1]`	`2`	
`nums = [0,1]`	`2`	
`nums = [9,6,4,2,3,5,7,0,1]`	`8`	

HINTS

1. The numbers 0..n sum to `n(n+1)/2`. Compare with the actual sum.
2. Alternatively, XOR everything in the array together with every index 0..n — each present value cancels itself and only the missing one survives.
3. The XOR version cannot overflow, which is the reason to prefer it.

Approach	Idea	Time	Space
Sort then scan	Sort and find the first gap.	`O(n log n)`	`O(1)`
Hash set	Insert everything, then test 0..n.	`O(n)`	`O(n)`
Sum formula	Expected total minus actual total.	`O(n)`	`O(1)`
XOR	Pairs cancel; no overflow risk.	`O(n)`	`O(1)`

Solution — js

```
function missingNumber(nums) {
  const n = nums.length;
  let x = n;                        // start with n itself
  for (let i = 0; i < n; i++) {
    x ^= i ^ nums[i];               // cancel index against value
  }
  return x;
}

// sum-formula alternative:
// const expected = n * (n + 1) / 2;
// return expected - nums.reduce((a, b) => a + b, 0);
```

Solution — cpp

```cpp
class Solution {
public:
    int missingNumber(vector<int>& nums) {
        int n = nums.size(), x = n;
        for (int i = 0; i < n; ++i) x ^= i ^ nums[i];
        return x;
    }
};
```

Solution — python

```python
class Solution:
    def missingNumber(self, nums: list[int]) -> int:
        x = len(nums)
        for i, v in enumerate(nums):
            x ^= i ^ v
        return x
```

Solution — java

```java
class Solution {
    public int missingNumber(int[] nums) {
        int n = nums.length, x = n;
        for (int i = 0; i < n; i++) x ^= i ^ nums[i];
        return x;
    }
}
```

WALKTHROUGH

WHY THE XOR WORKS.

XOR is associative and commutative, `a ^ a === 0`, and `a ^ 0 === a`. Folding together every index `0..n` and every array value pairs up each present number with its index, leaving only the number that has no partner — the missing one. Seeding `x = n` supplies the index `n` that the loop over `0..n-1` does not reach.

WHY XOR BEATS THE SUM FORMULA.

For `n` near 2^{31} the expected sum overflows a 32-bit integer, and in C++ or Java that is undefined or wraps. XOR never grows. Mentioning that trade-off is exactly the kind of detail interviewers reward.

Find all duplicates in an array `Medium`

Pattern: Sign marking

Given an array `nums` of length `n` where every value is in the range `[1, n]` and each appears **once or twice**, return all values that appear twice.

Use O(1) extra space (the output does not count) and one pass.

Input	Output	Note
`nums = [4,3,2,7,8,2,3,1]`	`[2,3]`	
`nums = [1,1,2]`	`[1]`	
`nums = [1]`	`[]`	

HINTS

1. Every value is a valid index (after subtracting 1). The array can record its own "seen" flags.
2. Negate `nums[|v| - 1]` to mark that value `|v|` has been seen.
3. If that slot is already negative, you are seeing `|v|` for the second time — record it.
4. Always read values through `Math.abs`, since earlier marking may have flipped them.

Approach	Idea	Time	Space
Hash set	Track seen values in a set. Clear, but O(n) extra space.	`O(n)`	`O(n)`
Sort then scan	Adjacent equal values are duplicates.	`O(n log n)`	`O(1)`
Sign marking	Use the sign bit of each slot as a seen flag.	`O(n)`	`O(1)`

Solution — js

```
function findDuplicates(nums) {
  const out = [];
  for (const v of nums) {
    const idx = Math.abs(v) - 1;      // v may already be negated
    if (nums[idx] < 0) {
      out.push(idx + 1);              // second sighting
    } else {
      nums[idx] = -nums[idx];         // mark as seen
    }
  }
  // (optional) restore: for (let i=0;i<nums.length;i++) nums[i]=Math.abs(nums[i]);
  return out;
}
```

Solution — cpp

```
class Solution {
public:
    vector<int> findDuplicates(vector<int>& nums) {
        vector<int> out;
        for (int v : nums) {
            int idx = abs(v) - 1;
            if (nums[idx] < 0) out.push_back(idx + 1);
            else               nums[idx] = -nums[idx];
        }
        return out;
    }
};
```

Solution — python

```
class Solution:
    def findDuplicates(self, nums: list[int]) -> list[int]:
        out = []
        for v in nums:
            idx = abs(v) - 1
            if nums[idx] < 0:
                out.append(idx + 1)
            else:
                nums[idx] = -nums[idx]
        return out
```

Solution — java

```java
class Solution {
    public List<Integer> findDuplicates(int[] nums) {
        List<Integer> out = new ArrayList<>();
        for (int v : nums) {
            int idx = Math.abs(v) - 1;
            if (nums[idx] < 0) out.add(idx + 1);
            else               nums[idx] = -nums[idx];
        }
        return out;
    }
}
```

WALKTHROUGH

THE SIGN BIT IS FREE STORAGE.

Because every value is guaranteed positive and in range, the sign carries no information of its own — so it can be repurposed as one bit of scratch space per slot, giving n bits of working memory without allocating anything. That is the trick, and it generalises: whenever the data does not use the full range of its type, the spare bits are usable.

`MATH.ABS` ON THE READ IS NOT OPTIONAL.

By the time you reach index 5 in `[4,3,2,7,8,2,3,1]`, the value stored there may already have been negated by an earlier iteration. Reading it raw gives a negative index and either a crash or silent nonsense.

PUSH `IDX + 1`, NOT `V`.

`v` is the possibly-negated array value; `idx + 1` is the actual number being duplicated. They coincide only when `v` happens to still be positive.

THIS MUTATES THE INPUT.

Say so aloud, and offer the restore loop — some interviewers specifically ask whether you noticed.

First missing positive `Hard`

Pattern: Cyclic sort with filtering

Given an unsorted integer array `nums` — which may contain negatives, zeros and duplicates — return the smallest **positive** integer that is **not** present.

Must run in O(n) time and use O(1) extra space.

Input	Output	Note
`nums = [1,2,0]`	`3`	
`nums = [3,4,-1,1]`	`2`	
`nums = [7,8,9,11,12]`	`1`	

HINTS

1. The answer is always in the range `1 .. n+1`: with `n` slots you cannot hide all of 1..n+1.
2. So any value outside `1..n` is irrelevant and can be ignored.
3. Cyclic sort: repeatedly send each in-range value to index `v - 1`. Then the first index whose value is not `i + 1` gives the answer.
4. Guard the swap with `nums[i] !== nums[home]`, not `i !== home`, or duplicates spin forever.

Approach	Idea	Time	Space
Sort then scan	Sort and walk looking for the first gap. Violates the O(n) requirement.	`O(n log n)`	`O(1)`
Hash set	Insert everything, then test 1, 2, 3 … Violates the O(1) space requirement.	`O(n)`	`O(n)`
Cyclic sort in place	Place each in-range value at its home index, then scan for the first mismatch.	`O(n)`	`O(1)`

Solution — js

```
function firstMissingPositive(nums) {
  const n = nums.length;

  // 1. send every in-range value to its home index v-1
  for (let i = 0; i < n; i++) {
    while (nums[i] >= 1 && nums[i] <= n &&
           nums[nums[i] - 1] !== nums[i]) {
      const home = nums[i] - 1;
      [nums[i], nums[home]] = [nums[home], nums[i]];
    }
  }

  // 2. the first slot not holding i+1 reveals the answer
  for (let i = 0; i < n; i++) {
    if (nums[i] !== i + 1) return i + 1;
  }
  return n + 1;          // 1..n all present
}
```

Solution — cpp

```
class Solution {
public:
    int firstMissingPositive(vector<int>& nums) {
        int n = nums.size();
        for (int i = 0; i < n; ++i)
            while (nums[i] >= 1 && nums[i] <= n &&
                   nums[nums[i] - 1] != nums[i])
                swap(nums[i], nums[nums[i] - 1]);
        for (int i = 0; i < n; ++i)
            if (nums[i] != i + 1) return i + 1;
        return n + 1;
    }
};
```

Solution — python

```python
class Solution:
    def firstMissingPositive(self, nums: list[int]) -> int:
        n = len(nums)
        for i in range(n):
            while 1 <= nums[i] <= n and nums[nums[i] - 1] != nums[i]:
                home = nums[i] - 1
                nums[i], nums[home] = nums[home], nums[i]
        for i in range(n):
            if nums[i] != i + 1:
                return i + 1
        return n + 1
```

Solution — java

```java
class Solution {
    public int firstMissingPositive(int[] nums) {
        int n = nums.length;
        for (int i = 0; i < n; i++)
            while (nums[i] >= 1 && nums[i] <= n && nums[nums[i] - 1] != nums[i]) {
                int home = nums[i] - 1;
                int t = nums[i]; nums[i] = nums[home]; nums[home] = t;
            }
        for (int i = 0; i < n; i++)
            if (nums[i] != i + 1) return i + 1;
        return n + 1;
    }
}
```

WALKTHROUGH

THE BOUND ARGUMENT COMES FIRST AND IT IS WHAT MAKES O(1) SPACE POSSIBLE.

With `n` array slots, the values 1 through `n+1` are `n+1` distinct candidates, so at least one must be absent. The answer therefore lies in `[1, n+1]`, and every value outside `1..n` — negatives, zeros, huge numbers — can be ignored entirely. That is why no extra structure is needed: the array itself is exactly large enough to index the candidate space.

THE SWAP GUARD IS THE CRUX.

Writing `while (… && i !== home)` looks equivalent but is not: on `[2,2,2,2]`, index 0 holds 2 whose home is index 1, which also holds 2. Swapping changes nothing, `i !== home` stays true, and the loop spins forever. Comparing *values* — "is my home already occupied by my own value?" — terminates because it detects the duplicate. Test `[1,1]` and `[2,2,2,2]` to confirm.

WHY THE WHOLE THING IS O(N) DESPITE A `WHILE` INSIDE A `FOR`.

Each successful swap puts at least one value permanently into its correct home, and a value once home is never moved again. So there are at most `n` swaps across the entire run, and the outer loop contributes another `n` — linear overall.

Bit manipulation: the fundamentals

The operators, the idioms, and the two-line tricks worth memorising. Everything here is O(1) and appears constantly in embedded work as well as in interviews.

The operators

```
&   AND    1 only where BOTH are 1      1100 & 1010 = 1000
|   OR     1 where EITHER is 1          1100 | 1010 = 1110
^   XOR    1 where they DIFFER          1100 ^ 1010 = 0110
~   NOT    flip every bit               ~1100       = 0011
                                        (in two's
                                         complement,
                                         ~x === -x - 1)
<<  SHIFT LEFT    x << k  ==  x * 2^k
>>  SHIFT RIGHT   arithmetic — copies the SIGN bit
>>> SHIFT RIGHT   logical — fills with ZEROS (JavaScript;
                  Java uses >>> too, C++ depends on
                  signedness)

THE SIX IDIOMS TO KNOW COLD:

  TEST bit i        (x >> i) & 1
  SET bit i         x | (1 << i)
  CLEAR bit i       x & ~(1 << i)
  TOGGLE bit i      x ^ (1 << i)
  LOWEST SET BIT    x & -x        -> isolates it
  CLEAR LOWEST SET  x & (x - 1)   -> removes it

THE LAST TWO ARE THE ONES THAT WIN PROBLEMS.

  x       = 1011 0100
  x - 1   = 1011 0011      borrow flips the lowest 1 and
                           everything below it
  x&(x-1) = 1011 0000      lowest set bit REMOVED
  -x      = 0100 1100      two's complement = ~x + 1
  x & -x  = 0000 0100      lowest set bit ISOLATED

USEFUL CONSEQUENCES:
  x & (x - 1) === 0        ->  x is a POWER OF TWO
                               (or zero — check separately)
  counting with x &= x-1   ->  loops once per SET BIT,
                               not once per bit

THE XOR PROPERTIES, which power chapter 16:
  x ^ x = 0        a value cancels itself
  x ^ 0 = x        zero is the identity
  XOR is COMMUTATIVE and ASSOCIATIVE — order never matters
  a ^ b ^ b = a    XOR is its own inverse
```

JAVASCRIPT'S BITWISE OPERATORS ARE 32-BIT

All of `& | ^ ~ << >>` convert their operands to **signed 32-bit** integers, so `1 << 31` is negative and anything above 2^{31} loses its high bits. Use `>>> 0` to read a result as unsigned, and `BigInt` if you genuinely need more than 32 bits. In C++ and Java the same care applies: shifting by ≥ the width is *undefined* in C++, and in Java the shift count is taken modulo 32 (or 64 for `long`), so `1 << 32` is `1`, not 0.

```
/* --- COUNTING SET BITS (population count) --- */
function popcount(x) {
    let c = 0;
    while (x) { x &= x - 1; c++; }   // one iteration PER SET BIT
    return c;
}
// built-ins: __builtin_popcount (C++), Integer.bitCount (Java),
//            bin(x).count('1') (Python)

/* --- ITERATE THE SET BITS --- */
while (mask) {
    const bit = mask & -mask;        // isolate the lowest
    const i   = Math.log2(bit);      // its index
    mask ^= bit;                     // remove it
}

/* --- SWAP WITHOUT A TEMPORARY (a party trick, not
       production code - it breaks when a === b aliases) --- */
a ^= b; b ^= a; a ^= b;

/* --- USEFUL MASKS --- */
(1 << k) - 1        // k low bits set:  k=4 -> 0b1111
x & ((1 << k) - 1)  // keep the low k bits
x >> k & 1          // read bit k
~0                  // all ones (-1)

/* --- PARITY of the set-bit count --- */
x ^= x >> 16; x ^= x >> 8; x ^= x >> 4;
x ^= x >> 2;  x ^= x >> 1;  return x & 1;

/* --- MULTIPLY / DIVIDE BY POWERS OF TWO --- */
x << 3   // x * 8
x >> 3   // floor(x / 8) for NON-NEGATIVE x
// CAREFUL: -7 >> 1 === -4, but -7 / 2 truncates to -3.
// Arithmetic shift rounds toward NEGATIVE INFINITY.  */
```

Problems

How it shows up

Symptom	Cause
Result is negative unexpectedly	Bit 31 set — JavaScript bitwise ops are signed 32-bit; use `>>> 0`
Shift by 32 does nothing	Java/JS take the count mod 32; C++ it is undefined
Loop never terminates on a negative input	`>>` preserves the sign forever — use `>>>`
Zero reported as a power of two	`x & (x-1) === 0` is also true for 0 — add `x > 0`
Negative division off by one	Arithmetic shift rounds toward −∞, division truncates toward 0
Precedence bug	`&` and `|` bind looser than `==` — parenthesise
Wrong answer above 2^{31}	Exceeded 32 bits — use `BigInt` or 64-bit types

Check yourself

✓ Write test, set, clear and toggle for bit *i*.

- ✓ Explain what `x & (x-1)` and `x & -x` do, with a worked binary example.
- ✓ Give the power-of-two test including the zero case.
- ✓ Write popcount using `x &= x-1` and say why it is O(set bits).
- ✓ State the four XOR properties.
- ✓ Explain the difference between `>>` and `>>>`.
- ✓ Say why `-7 >> 1` is not the same as `-7 / 2` truncated.
- ✓ State JavaScript's 32-bit limitation and its workaround.

Problems

Number of 1 bits Easy

Pattern: Clear the lowest set bit

Given a non-negative integer `n`, return the number of `1` bits in its binary representation (its Hamming weight).

Input	Output	Note
`n = 11 (1011)`	`3`	
`n = 128 (10000000)`	`1`	
`n = 0`	`0`	

HINTS

1. The obvious loop shifts right 32 times checking the low bit. That works but always costs 32 iterations.
2. `n & (n - 1)` clears the lowest set bit. How many times can you do that before reaching zero?
3. Exactly once per set bit — so the loop runs only as many times as there are 1s.

Approach	Idea	Time	Space
Check all 32 bits	Shift and test each position.	`O(32)`	`O(1)`
Clear the lowest set bit	`n &= n - 1` until zero; count the iterations.	`O(set bits)`	`O(1)`
Built-in	`Integer.bitCount`, `__builtin_popcount`. Say you know it exists, then write the loop.	`O(1)`	`O(1)`

Solution — js

```
function hammingWeight(n) {
  let count = 0;
  while (n !== 0) {
    n &= n - 1;      // remove the LOWEST set bit
    count++;
  }
  return count;
}
```

Solution — cpp

```
class Solution {
public:
    int hammingWeight(uint32_t n) {
        int count = 0;
        while (n) { n &= n - 1; ++count; }
        return count;
    }
};
```

Solution — python

```
class Solution:
    def hammingWeight(self, n: int) -> int:
        count = 0
        while n:
            n &= n - 1
            count += 1
        return count
```

Solution — java

```
class Solution {
    public int hammingWeight(int n) {
        int count = 0;
        while (n != 0) { n &= n - 1; count++; }
        return count;
    }
}
```

WALKTHROUGH

WHY `N & (N - 1)` REMOVES EXACTLY THE LOWEST SET BIT.

Subtracting 1 flips the lowest 1 to 0 and turns every 0 below it into 1; all higher bits are untouched. ANDing with the original therefore keeps every higher bit unchanged, kills the lowest 1, and zeroes everything below it. Worked: `1011 0100 - 1 = 1011 0011`, and `1011 0100 & 1011 0011 = 1011 0000`.

THE COMPLEXITY CLAIM MATTERS IN THE INTERVIEW.

The naive version is always 32 iterations; this one is exactly `popcount(n)` iterations, so for sparse numbers it is dramatically faster. Saying "O(number of set bits) rather than O(word size)" is the answer they are listening for.

WATCH THE SIGN IN JAVASCRIPT AND JAVA.

For `n` with bit 31 set, `n` is negative and `n !== 0` still terminates correctly because the AND strictly reduces the set bits. But writing the shift-based version with `>>` instead of `>>>` would loop forever on a negative value.

Power of two Easy

Pattern: Single-bit test

Given an integer `n`, return `true` if it is a power of two — that is, if `n === 2^k` for some non-negative integer `k`.

Input	Output	Note
`n = 1`	`true`	2^0

Input	Output	Note
`n = 16`	`true`	
`n = 3`	`false`	
`n = 0`	`false`	
`n = -16`	`false`	

HINTS

1. A power of two has exactly one bit set in its binary representation.
2. `n & (n - 1)` clears the lowest set bit — so for a power of two the result is 0.
3. That test is *also* true for `n = 0`, so require `n > 0` as well. Negatives must be rejected too.

Approach	Idea	Time	Space
Repeated division	Divide by 2 while even; check whether you land on 1.	`O(log n)`	`O(1)`
Popcount	Count set bits and test for exactly one.	`O(1)`	`O(1)`
Single AND	`n > 0 && (n & (n-1)) === 0`.	`O(1)`	`O(1)`

Solution — js

```
function isPowerOfTwo(n) {
  // n > 0 rules out zero and negatives;
  // (n & (n-1)) === 0 means exactly one bit is set
  return n > 0 && (n & (n - 1)) === 0;
}
```

Solution — cpp

```
class Solution {
public:
    bool isPowerOfTwo(int n) {
        return n > 0 && (n & (n - 1)) == 0;
    }
};
```

Solution — python

```
class Solution:
    def isPowerOfTwo(self, n: int) -> bool:
        return n > 0 and (n & (n - 1)) == 0
```

Solution — java

```
class Solution {
    public boolean isPowerOfTwo(int n) {
        return n > 0 && (n & (n - 1)) == 0;
    }
}
```

WALKTHROUGH

BOTH GUARDS ARE LOAD-BEARING.

`(0 & -1) === 0`, so zero passes the AND test and must be excluded by `n > 0`. Negative powers of two are not powers of two by the definition here, and in two's complement `-16 = …11110000` whose AND with `-17` is not zero anyway — but relying on that is fragile, and `n > 0` makes the intent explicit.

THE RELATED ONE-LINERS WORTH KNOWING:

`n & (n-1)` being zero means "at most one bit set"; `n & -n` isolates the lowest set bit, so `(n & -n) === n` is an equivalent power-of-two test. And `(n - 1) & n` appearing in a codebase is almost always a power-of-two mask for a ring buffer — see the embedded tracks on this site.

Reverse bits Easy

Pattern: Shift out, shift in

Reverse the bits of a given **32-bit unsigned** integer and return the result as an unsigned value.

For example, `43261596` (binary `00000010100101000001111010011100`) reverses to `964176192` (`00111001011110000010100101000000`).

Input	Output	Note
`n = 43261596`	`964176192`	
`n = 1`	`2147483648`	Bit 0 becomes bit 31.
`n = 0`	`0`	

HINTS

1. Process 32 bits. Each step: shift the answer left, pull the lowest bit off the input, and OR it in.
2. Shift the *input* right with `>>>` so the sign bit does not replicate.
3. The final result must be interpreted as unsigned — in JavaScript finish with `>>> 0`.

Approach	Idea	Time	Space
Build a binary string	Convert to a padded 32-character string, reverse it, parse back. Works, and is easy to explain.	`O(32)`	`O(32)`
Shift out, shift in	Thirty-two iterations of one shift each way.	`O(32)`	`O(1)`
Divide and conquer masks	Swap halves, then quarters, then bytes, then nibbles, then pairs — five masked steps, O(log 32).	`O(1)`	`O(1)`

Solution — js

```
function reverseBits(n) {
  let out = 0;
  for (let i = 0; i < 32; i++) {
    out = (out << 1) | (n & 1);   // make room, take the low bit
    n >>>= 1;                      // LOGICAL shift: no sign copy
  }
  return out >>> 0;                // read the result as unsigned
}
```

Solution — cpp

```cpp
class Solution {
public:
    uint32_t reverseBits(uint32_t n) {
        uint32_t out = 0;
        for (int i = 0; i < 32; ++i) {
            out = (out << 1) | (n & 1);
            n >>= 1;
        }
        return out;
    }
};
```

Solution — python

```python
class Solution:
    def reverseBits(self, n: int) -> int:
        out = 0
        for _ in range(32):
            out = (out << 1) | (n & 1)
            n >>= 1
        return out
```

Solution — java

```java
public class Solution {
    public int reverseBits(int n) {
        int out = 0;
        for (int i = 0; i < 32; i++) {
            out = (out << 1) | (n & 1);
            n >>>= 1;          // logical shift
        }
        return out;
    }
}
```

WALKTHROUGH

TWO PLACES THE SIGN BIT BITES.

First, `n >>= 1` in JavaScript or Java is an *arithmetic* shift: for a negative `n` it fills with 1s and the loop reads 1 bits forever. `>>>` fills with zeros, which is what "unsigned" requires. Second, `out` itself becomes negative once bit 31 is set, so the final `>>> 0` reinterprets the 32-bit pattern as an unsigned value — without it, `reverseBits(1)` returns `-2147483648` instead of `2147483648`.

THE MASK-BASED VERSION IS WORTH MENTIONING

as a follow-up: swap the two 16-bit halves, then the 8-bit groups within each, then 4, then 2, then 1 — five constant-masked steps instead of 32 iterations. It is the standard answer to "can you do better if this is called millions of times?", along with "cache results in a 256-entry byte lookup table".

Bit manipulation: XOR, subsets and tricks

The problem-solving half. XOR as a cancelling accumulator, integers as sets, and the handful of tricks that turn a hard-looking question into two lines.

XOR as a cancelling accumulator

```
THE FOUR PROPERTIES, and every XOR problem uses them:

  x ^ x = 0            a value CANCELS itself
  x ^ 0 = x            zero is the identity
  COMMUTATIVE          a ^ b = b ^ a
  ASSOCIATIVE          (a^b)^c = a^(b^c)

CONSEQUENCE: XOR-ing a whole collection together makes
every PAIR vanish, whatever the order. Whatever survives
is what appeared an ODD number of times.

  [4, 1, 2, 1, 2]  ->  4^1^2^1^2
                   =  4^(1^1)^(2^2)
                   =  4^0^0  =  4

THAT IS "SINGLE NUMBER" IN ONE LINE, in O(1) space, and
it is why the pattern is worth recognising instantly.

------------------------------------------------------------
TWO NUMBERS APPEARING ONCE — the two-pass trick

  xorAll = a ^ b            (everything else cancels)

  Any set bit in xorAll is a position where a and b
  DIFFER. Pick the lowest:

     diff = xorAll & -xorAll

  Now PARTITION the input by that bit. a and b land in
  different groups, and every duplicate pair lands in the
  SAME group (equal values have equal bits). XOR each
  group separately and you get a and b.

------------------------------------------------------------
EVERY NUMBER APPEARS THREE TIMES, one appears once

  XOR fails — three copies leave one behind. Instead,
  count each bit position modulo 3:

     ones = (ones ^ x) & ~twos;
     twos = (twos ^ x) & ~ones;

  `ones` holds bits seen 1 mod 3 times, `twos` bits seen
  2 mod 3. After the pass, `ones` is the answer.
  (The generic version: sum each of the 32 bit positions
   mod k. Easier to derive under pressure.)

------------------------------------------------------------
XOR PREFIX — the same idea as prefix sums (chapter 06)

  P[i] = a[0] ^ a[1] ^ ... ^ a[i-1]
  XOR of range [l, r]  =  P[r+1] ^ P[l]

  because the shared prefix cancels itself. Everything
  you know about prefix sums transfers, with ^ replacing
  + and its own inverse replacing subtraction.
```

Integers as sets

```
AN n-BIT INTEGER IS A SUBSET OF {0, 1, ..., n-1}.
Bit i set means element i is IN the subset.

  mask = 0b1011   ->   {0, 1, 3}

THE SET OPERATIONS:
  union            a | b
  intersection     a & b
  difference       a & ~b
  symmetric diff   a ^ b
  add element i    a | (1 << i)
  remove element i a & ~(1 << i)
  test element i   (a >> i) & 1
  size             popcount(a)
  is subset of b   (a & b) === a
  empty            a === 0
  full (n items)   a === (1 << n) - 1

ENUMERATE ALL 2^n SUBSETS:
  for (let mask = 0; mask < (1 << n); mask++) {
      for (let i = 0; i < n; i++)
          if (mask & (1 << i)) use(items[i]);
  }
  O(2^n · n). THIS IS WHY "n <= 20" IN A CONSTRAINT
  MEANS BITMASK (chapter 02).

ENUMERATE ALL SUBMASKS OF A MASK — a genuinely useful
idiom:
  for (let s = mask; s > 0; s = (s - 1) & mask) { ... }
  // then handle s = 0 separately
Total across all masks is 3^n, not 4^n.

THIS REPRESENTATION IS THE BASIS OF BITMASK DP
(chapter 37): the state "which items have I used?" is a
single integer, so the DP table is a flat array.
```

Problems

How it shows up

Symptom	Cause
XOR trick fails when values repeat 3×	XOR only cancels *pairs* — count bits mod 3
Two-single-numbers split puts both in one group	Partition bit not actually a differing bit
Subset loop misses the empty set	Submask loop stops at `s > 0` — handle 0 after
Subset enumeration overflows	`1 << n` with n ≥ 31 — JavaScript ints are 32-bit signed
Sum of two numbers loops forever	Carry not shifted, or negative handling in JS
Answer negative on the last bit	Bit 31 is the sign bit — finish with `>>> 0`
Gray code sequence has a jump	Formula must be `i ^ (i >> 1)`

Check yourself

- ✓ State the four XOR properties and derive "single number" from them.
- ✓ Explain the two-group partition for two unique numbers.
- ✓ Say why XOR fails when values repeat three times, and give the fix.
- ✓ Give the XOR-prefix range formula and why it works.
- ✓ Write the set operations on a bitmask: union, intersection, difference, subset test.
- ✓ Write the loop enumerating all 2^n subsets and give its complexity.
- ✓ Write the submask enumeration idiom and its total cost.
- ✓ Explain why "n ≤ 20" suggests a bitmask.

Problems

Single number Easy

Pattern: XOR cancellation

Every element in `nums` appears **twice** except for one, which appears once. Find that one.

Use O(1) extra space and linear time.

Input	Output	Note
`nums = [2,2,1]`	`1`	
`nums = [4,1,2,1,2]`	`4`	
`nums = [1]`	`1`	

HINTS

1. A hash set works but uses O(n) space, which the problem rules out.
2. What operation makes a value cancel itself?
3. XOR the whole array together — every pair vanishes and the loner survives.

Approach	Idea	Time	Space
Hash set	Add and remove; whatever remains is the answer.	`O(n)`	`O(n)`
Sort then scan	The loner breaks the pairing pattern.	`O(n log n)`	`O(1)`
XOR everything	One accumulator, one pass.	`O(n)`	`O(1)`

Solution — js

```
function singleNumber(nums) {
  let x = 0;
  for (const v of nums) x ^= v;   // pairs cancel to 0
  return x;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int singleNumber(vector<int>& nums) {
        int x = 0;
        for (int v : nums) x ^= v;
        return x;
    }
};
```

Solution — python

```python
from functools import reduce
import operator

class Solution:
    def singleNumber(self, nums: list[int]) -> int:
        return reduce(operator.xor, nums, 0)
```

Solution — java

```java
class Solution {
    public int singleNumber(int[] nums) {
        int x = 0;
        for (int v : nums) x ^= v;
        return x;
    }
}
```

WALKTHROUGH

ORDER DOES NOT MATTER

, which is the property doing the real work. Because XOR is commutative and associative, `4^1^2^1^2` can be regrouped as `4^(1^1)^(2^2) = 4^0^0 = 4` without touching the array. That is why no sorting or bookkeeping is needed.

IT WORKS FOR NEGATIVES TOO

, since XOR operates on the two's-complement bit pattern and identical patterns still cancel — the `[-1,-1,-2]` test confirms it.

Single number III — two loners `Medium`

Pattern: XOR then partition on a differing bit

Exactly **two** elements of `nums` appear once; every other element appears twice. Return the two singles in any order.

Linear time, constant extra space.

Input	Output	Note
`nums = [1,2,1,3,2,5]`	`[3,5]`	
`nums = [-1,0]`	`[-1,0]`	
`nums = [0,1]`	`[1,0]`	

HINTS

1. XOR everything: the pairs cancel and you are left with `a ^ b`, but mixed together.
2. Any set bit in `a ^ b` is a position where `a` and `b` differ. Isolate one with `x & -x`.
3. Split the array into two groups by that bit. Duplicates always land together; `a` and `b` land apart.
4. XOR each group separately — each collapses to one of the answers.

Approach	Idea	Time	Space
Hash map counts	Count occurrences and collect the ones. O(n) space.	`O(n)`	`O(n)`
XOR + partition bit	Two passes, one accumulator each, no extra memory.	`O(n)`	`O(1)`

Solution — js

```
function singleNumberIII(nums) {
  // pass 1: everything cancels except a ^ b
  let xorAll = 0;
  for (const v of nums) xorAll ^= v;

  // any set bit is a position where a and b DIFFER
  const diff = xorAll & -xorAll;   // isolate the lowest

  // pass 2: partition on that bit; each group holds one loner
  let a = 0, b = 0;
  for (const v of nums) {
    if (v & diff) a ^= v;
    else          b ^= v;
  }
  return [a, b];
}
```

Solution — cpp

```
class Solution {
public:
    vector<int> singleNumber(vector<int>& nums) {
        long xorAll = 0;
        for (int v : nums) xorAll ^= v;
        int diff = (int)(xorAll & -xorAll);
        int a = 0, b = 0;
        for (int v : nums) {
            if (v & diff) a ^= v;
            else          b ^= v;
        }
        return {a, b};
    }
};
```

Solution — python

```python
class Solution:
    def singleNumber(self, nums: list[int]) -> list[int]:
        xor_all = 0
        for v in nums:
            xor_all ^= v
        diff = xor_all & -xor_all
        a = b = 0
        for v in nums:
            if v & diff:
                a ^= v
            else:
                b ^= v
        return [a, b]
```

Solution — java

```java
class Solution {
    public int[] singleNumber(int[] nums) {
        int xorAll = 0;
        for (int v : nums) xorAll ^= v;
        int diff = xorAll & -xorAll;
        int a = 0, b = 0;
        for (int v : nums) {
            if ((v & diff) != 0) a ^= v;
            else                 b ^= v;
        }
        return new int[]{a, b};
    }
}
```

WALKTHROUGH

WHY THE PARTITION IS GUARANTEED TO SEPARATE THEM.

`a ≠ b`, so `a ^ b ≠ 0` and it has at least one set bit. At that bit position `a` and `b` disagree by definition of XOR, so exactly one of them has it set — they must land in different groups. Meanwhile any duplicated value has the same bits in both copies, so both copies land in the same group and cancel there. Each group therefore reduces to exactly one loner.

`XORALL & -XORALL` ISOLATES THE LOWEST SET BIT

(chapter 15). Any set bit would do; the lowest is simply the cheapest to extract. In C++ the intermediate is widened to `long` to avoid undefined behaviour when negating `INT_MIN`.

Counting bits Easy

Pattern: DP on bit structure

Given an integer `n`, return an array `ans` of length `n + 1` where `ans[i]` is the number of `1` bits in `i`.

Do it in a single pass, O(n) total — not O(n log n).

Input	Output	Note
`n = 2`	`[0,1,1]`	
`n = 5`	`[0,1,1,2,1,2]`	

HINTS

1. Calling popcount on each number independently is O(n log n). You want to reuse earlier answers.
2. Relate `i` to a smaller number whose answer you already have.
3. `i >> 1` is `i` with the last bit dropped — so `bits[i] = bits[i >> 1] + (i & 1)`.
4. Alternatively `bits[i] = bits[i & (i - 1)] + 1`, since `i & (i-1)` removes one set bit.

Approach	Idea	Time	Space
popcount each number	Independent counting per value.	`O(n log n)`	`O(1)`
DP on <code>i >> 1</code>	Each answer is one table lookup plus the last bit.	`O(n)`	`O(1) extra`

Solution — js

```
function countBits(n) {
  const bits = new Array(n + 1).fill(0);
  for (let i = 1; i <= n; i++) {
    // i >> 1 is i without its last bit — already computed
    bits[i] = bits[i >> 1] + (i & 1);
  }
  return bits;
}

// equivalent: bits[i] = bits[i & (i - 1)] + 1;
```

Solution — cpp

```
class Solution {
public:
    vector<int> countBits(int n) {
        vector<int> bits(n + 1, 0);
        for (int i = 1; i <= n; ++i)
            bits[i] = bits[i >> 1] + (i & 1);
        return bits;
    }
};
```

Solution — python

```
class Solution:
    def countBits(self, n: int) -> list[int]:
        bits = [0] * (n + 1)
        for i in range(1, n + 1):
            bits[i] = bits[i >> 1] + (i & 1)
        return bits
```

Solution — java

```
class Solution {
    public int[] countBits(int n) {
        int[] bits = new int[n + 1];
        for (int i = 1; i <= n; i++)
            bits[i] = bits[i >> 1] + (i & 1);
        return bits;
    }
}
```

WALKTHROUGH

THE RECURRENCE IS THE WHOLE SOLUTION.

Writing `i` in binary, dropping the last bit gives `i >> 1` — a strictly smaller number, so its answer is already in the table. The bit you dropped was `i & 1`. Hence `bits[i] = bits[i >> 1] + (i & 1)`, one lookup and one addition per value.

THIS IS DYNAMIC PROGRAMMING

, and a good one to recognise as such: an optimal-substructure relation on a smaller subproblem, with the table filled in increasing order so every dependency is ready. It is the smallest possible example of the technique in chapter 33.

THE ALTERNATIVE RECURRENCE

`bits[i] = bits[i & (i-1)] + 1` uses the lowest-set-bit clearing trick from chapter 15 instead, and is equally valid — mention both.

Sum of two integers without + `Medium`

Pattern: XOR as add, AND as carry

Given two integers `a` and `b`, return their sum **without using the `+` or `-` operators**.

Negative inputs must work correctly.

Input	Output	Note
`a = 1, b = 2`	`3`	
`a = 2, b = 3`	`5`	
`a = -1, b = 1`	`0`	

HINTS

1. Think about how binary addition works bit by bit: a sum bit and a carry bit.
2. The sum *ignoring carries* is exactly `a ^ b`. The carries are `(a & b) << 1`.
3. Repeat: add the carry into the sum, producing new carries, until there is no carry left.
4. Two's complement means the same loop handles negatives with no special cases.

Approach	Idea	Time	Space
Repeated increment	Add 1 `b` times. Correct only for tiny positive `b`.	`O(b)`	`O(1)`
XOR + carry loop	Simulate the ripple-carry adder. At most 32 iterations.	`O(1)`	`O(1)`

Solution — js

```javascript
function getSum(a, b) {
  while (b !== 0) {
    const carry = (a & b) << 1;   // where both bits are 1
    a = a ^ b;                    // sum ignoring carries
    b = carry;                    // fold the carry in next round
  }
  return a;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int getSum(int a, int b) {
        while (b != 0) {
            unsigned carry = (unsigned)(a & b) << 1;
            a = a ^ b;
            b = (int)carry;
        }
        return a;
    }
};
```

Solution — python

```python
class Solution:
    def getSum(self, a: int, b: int) -> int:
        MASK = 0xFFFFFFFF
        MAX = 0x7FFFFFFF
        while b != 0:
            carry = ((a & b) << 1) & MASK
            a = (a ^ b) & MASK
            b = carry
        # Python ints are unbounded — reinterpret as signed 32-bit
        return a if a <= MAX else ~(a ^ MASK)
```

Solution — java

```java
class Solution {
    public int getSum(int a, int b) {
        while (b != 0) {
            int carry = (a & b) << 1;
            a = a ^ b;
            b = carry;
        }
        return a;
    }
}
```

WALKTHROUGH

THE DECOMPOSITION OF BINARY ADDITION.

For each bit position, the result bit is the XOR of the inputs, and a carry is produced only where *both* inputs are 1 — that is the AND, shifted left one place to reach the next column. Adding the carry can itself produce new carries, so the process repeats; since each round pushes carries strictly leftwards, it terminates within the word width.

NEGATIVES WORK FOR FREE

because two's complement is designed so that the same bit-level addition is correct for signed values. `-1` is all ones, and `-1 + 1` ripples a carry off the top which is simply discarded — giving 0.

PYTHON NEEDS THE MASK

because its integers are arbitrary precision: the carry would keep growing left forever instead of falling off the end. Masking to 32 bits emulates a fixed-width register, and the final step reinterprets the pattern as signed. That contrast is a nice thing to be able to explain.

Linked lists: reversal and surgery

No random access, no length, only `next`. Every linked-list problem is pointer manipulation, and every linked-list bug is a pointer you overwrote before you had finished with it.

The pattern

```
THE THREE TECHNIQUES THAT SOLVE ALMOST EVERYTHING:

1. REVERSAL — three pointers, one pass
     prev = null, cur = head
     while (cur) {
         next = cur.next     <-- SAVE FIRST. Always.
         cur.next = prev     <-- rewire
         prev = cur          <-- advance
         cur = next
     }
     return prev             <-- the new head

     null <- 1    2 -> 3 -> null
             ^    ^
           prev  cur

2. DUMMY HEAD — removes every "what if it is the first
   node?" special case
     dummy = new ListNode(0, head)
     ... operate using `dummy` as a stable anchor ...
     return dummy.next

3. TWO POINTERS — fast/slow for the middle, cycles and
   "nth from the end" (chapter 18)

THE UNIVERSAL RULE:

  BEFORE YOU OVERWRITE A POINTER, SAVE WHAT YOU STILL
  NEED. Losing `cur.next` disconnects the rest of the
  list, and there is no way back — you cannot walk
  backwards.

THE FOUR-LINE REVERSAL IS WORTH MEMORISING COLD. It
appears inside palindrome checks, k-group reversal,
reordering, and addition problems. If you can write it
without thinking, a whole class of medium problems
becomes routine.

COSTS
  traverse / search      O(n)
  insert or delete at a KNOWN node   O(1)
  access the kth element O(n)     <-- no random access
  reverse                O(n) time, O(1) space
```

The helpers in this page

```
/* Pre-defined in the sandbox — you never write the
   plumbing (see chapter 03):                          */

function ListNode(val, next)     // the node constructor
buildList([1,2,3])               // array -> list, returns head
listToArray(head)                // list  -> array

/* Problems take and return ARRAYS; the judge converts to
   and from real lists for you. So you write real pointer
   code and get readable test output.                  */

/* --- THE DUMMY-HEAD IDIOM, in full --- */
function removeElements(head, val) {
    const dummy = new ListNode(0, head);
    let prev = dummy;                  // ALWAYS a valid node
    while (prev.next) {
        if (prev.next.val === val) prev.next = prev.next.next;
        else                       prev = prev.next;
    }
    return dummy.next;   // correct even if the head was removed
}
/* WITHOUT the dummy you need a separate branch for
   "the node to delete is the head", and that branch is
   where the bug lives. USE A DUMMY WHENEVER THE HEAD MIGHT
   CHANGE.

   NOTE the else: only advance when you did NOT delete.
   Advancing after a deletion skips the next node — the
   most common bug in this shape, caught by [7,7,7,7]
   removing 7.                                         */
```

Problems

How it shows up

Symptom	Cause
Only part of the list survives	Overwrote `cur.next` before saving it
Infinite loop when printing	Created a cycle — a node points back into the list
Consecutive duplicates survive	Advanced the pointer after a deletion — use `if/else`
Crash when the head is removed	No dummy node
Reversal returns the old head	Return `prev`, not `cur` (which is `null`)
Last node still points into the old list	Tail's `next` never set to `null`
Off by one on "nth from the end"	Gap between the pointers set to `n` instead of `n+1`
Works for odd lengths, fails for even	Middle definition — `slow` vs `slow.next`

Check yourself

- ✓ Write the three-pointer reversal from memory and say why `prev` is returned.
- ✓ State the universal rule about overwriting pointers.

- ✓ Explain what a dummy head removes, and when you need one.
- ✓ Explain why deletion uses `if/else` rather than always advancing.
- ✓ Give the complexity of access, search, and insert-at-known-node.
- ✓ Describe how to merge two sorted lists in O(1) extra space.
- ✓ Explain how to reverse only part of a list without breaking the joins.
- ✓ Say why recursion on a long list is a space risk.

Problems

Reverse a linked list `Easy`

Pattern: Three-pointer reversal

Given the `head` of a singly linked list, reverse it and return the new head.

The judge passes the list as an array and compares the returned list as an array.

Input	Output	Note
`head = [1,2,3,4,5]`	`[5,4,3,2,1]`	
`head = [1,2]`	`[2,1]`	
`head = []`	`[]`	

HINTS

1. You need three pointers: the node before, the current node, and the node after.
2. Save `cur.next` *before* you overwrite it — otherwise the rest of the list is lost.
3. When the loop ends `cur` is `null` and `prev` is the last node visited, which is the new head.

Approach	Idea	Time	Space
Copy to an array	Collect values, reverse, rebuild. Works, but O(n) extra space and misses the point.	`O(n)`	`O(n)`
Iterative three-pointer	Walk once, flipping each `next` as you go.	`O(n)`	`O(1)`
Recursive	Reverse the tail, then attach the head. Elegant, but O(n) stack — a real risk on long lists.	`O(n)`	`O(n)`

Solution — js

```
function reverseList(head) {
  let prev = null, cur = head;
  while (cur) {
    const next = cur.next;   // SAVE before overwriting
    cur.next = prev;         // flip the link
    prev = cur;              // advance both
    cur = next;
  }
  return prev;               // cur is null; prev is the new head
}
```

Solution — cpp

```cpp
class Solution {
public:
    ListNode* reverseList(ListNode* head) {
        ListNode *prev = nullptr, *cur = head;
        while (cur) {
            ListNode* next = cur->next;
            cur->next = prev;
            prev = cur;
            cur = next;
        }
        return prev;
    }
};
```

Solution — python

```python
class Solution:
    def reverseList(self, head: ListNode) -> ListNode:
        prev, cur = None, head
        while cur:
            nxt = cur.next
            cur.next = prev
            prev = cur
            cur = nxt
        return prev
```

Solution — java

```java
class Solution {
    public ListNode reverseList(ListNode head) {
        ListNode prev = null, cur = head;
        while (cur != null) {
            ListNode next = cur.next;
            cur.next = prev;
            prev = cur;
            cur = next;
        }
        return prev;
    }
}
```

WALKTHROUGH

TRACE `[1,2,3]`.

Start `prev=null, cur=1`. Save `next=2`, set `1.next=null`, move to `prev=1, cur=2`. Save `next=3`, set `2.next=1`, move to `prev=2, cur=3`. Save `next=null`, set `3.next=2`, move to `prev=3, cur=null`. Loop ends; return 3. The list is `3→2→1→null`, and the original head correctly terminates the list.

RETURNING `CUR` IS THE CLASSIC SLIP

— it is always `null` when the loop exits. The empty-list test catches it only if you also handle `head = null`, which this code does for free since the loop body never runs and `prev` is already `null`.

Merge two sorted lists Easy

Pattern: Dummy head + two pointers

Given the heads of two sorted linked lists, splice them into one sorted list by rearranging the existing nodes, and return its head.

Input	Output	Note
`l1 = [1,2,4], l2 = [1,3,4]`	`[1,1,2,3,4,4]`	
`l1 = [], l2 = []`	`[]`	
`l1 = [], l2 = [0]`	`[0]`	

HINTS

1. Use a dummy head so you never special-case which list supplies the first node.
2. Keep a `tail` pointer at the end of the result and append the smaller front node each step.
3. When one list runs out, the other is already sorted — attach it wholesale rather than looping.

Approach	Idea	Time	Space
Collect and sort	Gather all values, sort, rebuild. Throws away the fact that the inputs are sorted.	`O(n log n)`	`O(n)`
Dummy head + merge	Classic two-pointer merge, relinking existing nodes.	`O(n + m)`	`O(1)`

Solution — js

```
function mergeTwoLists(l1, l2) {
  const dummy = new ListNode(0);
  let tail = dummy;

  while (l1 && l2) {
    if (l1.val <= l2.val) { tail.next = l1; l1 = l1.next; }
    else                  { tail.next = l2; l2 = l2.next; }
    tail = tail.next;
  }
  // exactly one list may remain; it is already sorted
  tail.next = l1 ?? l2;

  return dummy.next;
}
```

Solution — cpp

```
class Solution {
public:
    ListNode* mergeTwoLists(ListNode* l1, ListNode* l2) {
        ListNode dummy(0);
        ListNode* tail = &dummy;
        while (l1 && l2) {
            if (l1->val <= l2->val) { tail->next = l1; l1 = l1->next; }
            else                    { tail->next = l2; l2 = l2->next; }
            tail = tail->next;
        }
        tail->next = l1 ? l1 : l2;
        return dummy.next;
    }
};
```

Solution — python

```python
class Solution:
    def mergeTwoLists(self, l1: ListNode, l2: ListNode) -> ListNode:
        dummy = ListNode(0)
        tail = dummy
        while l1 and l2:
            if l1.val <= l2.val:
                tail.next, l1 = l1, l1.next
            else:
                tail.next, l2 = l2, l2.next
            tail = tail.next
        tail.next = l1 or l2
        return dummy.next
```

Solution — java

```java
class Solution {
    public ListNode mergeTwoLists(ListNode l1, ListNode l2) {
        ListNode dummy = new ListNode(0), tail = dummy;
        while (l1 != null && l2 != null) {
            if (l1.val <= l2.val) { tail.next = l1; l1 = l1.next; }
            else                  { tail.next = l2; l2 = l2.next; }
            tail = tail.next;
        }
        tail.next = (l1 != null) ? l1 : l2;
        return dummy.next;
    }
}
```

WALKTHROUGH

THE DUMMY EARNS ITS PLACE TWICE HERE:

it removes the "which list has the smaller head?" special case at the start, and it means the empty-input cases need no code at all — the loop never runs and `tail.next = l1 ?? l2` attaches whatever exists (possibly nothing).

`<=` RATHER THAN `<`

keeps the merge *stable*: equal elements from `l1` come first. It does not change correctness here but it is the right habit, and it matters in merge sort.

THIS IS THE MERGE STEP OF MERGE SORT

, which is why the same routine solves "merge k sorted lists" — either by repeated pairwise merging in a divide-and-conquer tree (O(N log k)) or with a heap (chapter 22).

Remove the nth node from the end `Medium`

Pattern: Dummy head + gap of n+1

Given the head of a linked list, remove the `n`-th node from the **end** and return the head. Do it in **one pass**.

Input	Output	Note
`head = [1,2,3,4,5], n = 2`	`[1,2,3,5]`	
`head = [1], n = 1`	`[]`	
`head = [1,2], n = 2`	`[2]`	Removes the head — the case a dummy makes free.

HINTS

1. To delete a node you must reach the node *before* it.
2. Advance a `fast` pointer `n+1` steps ahead of `slow`, starting both at the dummy. When `fast` falls off the end, `slow` is exactly one before the target.
3. The `+1` and starting at the dummy rather than the head are what make removing the first node work.

Approach	Idea	Time	Space
Two passes	Count the length, then walk `len - n` nodes. Perfectly correct and worth stating.	`O(n)`	`O(1)`
One pass, gap of n+1	Two pointers separated by `n+1`, both starting at the dummy.	`O(n)`	`O(1)`

Solution — js

```
function removeNthFromEnd(head, n) {
  const dummy = new ListNode(0, head);
  let fast = dummy, slow = dummy;

  // open a gap of n+1 so slow lands BEFORE the target
  for (let i = 0; i <= n; i++) fast = fast.next;

  while (fast) { fast = fast.next; slow = slow.next; }

  slow.next = slow.next.next;   // unlink
  return dummy.next;
}
```

Solution — cpp

```
class Solution {
public:
    ListNode* removeNthFromEnd(ListNode* head, int n) {
        ListNode dummy(0, head);
        ListNode *fast = &dummy, *slow = &dummy;
        for (int i = 0; i <= n; ++i) fast = fast->next;
        while (fast) { fast = fast->next; slow = slow->next; }
        slow->next = slow->next->next;
        return dummy.next;
    }
};
```

Solution — python

```
class Solution:
    def removeNthFromEnd(self, head: ListNode, n: int) -> ListNode:
        dummy = ListNode(0, head)
        fast = slow = dummy
        for _ in range(n + 1):
            fast = fast.next
        while fast:
            fast = fast.next
            slow = slow.next
        slow.next = slow.next.next
        return dummy.next
```

Solution — java

```
class Solution {
    public ListNode removeNthFromEnd(ListNode head, int n) {
        ListNode dummy = new ListNode(0, head);
        ListNode fast = dummy, slow = dummy;
        for (int i = 0; i <= n; i++) fast = fast.next;
        while (fast != null) { fast = fast.next; slow = slow.next; }
        slow.next = slow.next.next;
        return dummy.next;
    }
}
```

WALKTHROUGH

WHY `N + 1` AND NOT `N`.

A gap of `n` leaves `slow` *on* the node to delete, and from there you cannot unlink it — you need its predecessor. One extra step puts `slow` one before the target. Starting both pointers at the `dummy` rather than at `head` is the other half: it gives the head itself a predecessor, so `[1], n=1` works with no special case.

CHECK THE LOOP BOUND.

`for (i = 0; i <= n; i++)` runs `n+1` times. Writing `<` is the off-by-one this problem is designed to expose; `[1,2], n=2` catches it.

Reverse a sublist `Medium`

Pattern: Dummy head + local reversal

Given the head of a list and two integers `left` and `right` with `1 <= left <= right <= n`, reverse the nodes from position `left` to position `right` (1-indexed) and return the head. One pass.

Input	Output	Note
`head = [1,2,3,4,5], left = 2, right = 4`	`[1,4,3,2,5]`	
`head = [5], left = 1, right = 1`	`[5]`	
`head = [3,5], left = 1, right = 2`	`[5,3]`	

HINTS

1. Walk to the node *before* position `left` and anchor there. A dummy makes this work when `left === 1`.
2. The head-insertion technique avoids tracking four separate pointers: repeatedly take the node after the current one and move it to the front of the reversed section.
3. Do exactly `right - left` moves.

Approach	Idea	Time	Space
Collect, reverse, rebuild	Extract the values in range, reverse them, write them back. Easy but O(n) extra space and not really a list problem.	`O(n)`	`O(n)`
Cut, reverse, rejoin	Remember the four boundary nodes, reverse the middle with the standard loop, then reconnect. Correct but easy to misjoin.	`O(n)`	`O(1)`

Approach	Idea	Time	Space
Head insertion in place	Anchor before `left`; move each following node to the front of the section. No rejoining needed.	`O(n)`	`O(1)`

Solution — js

```
function reverseBetween(head, left, right) {
  const dummy = new ListNode(0, head);
  let prev = dummy;

  // step to the node BEFORE position `left`
  for (let i = 1; i < left; i++) prev = prev.next;

  // head insertion: repeatedly move the node after `cur`
  // to the front of the reversed section
  const cur = prev.next;
  for (let i = 0; i < right - left; i++) {
    const moved = cur.next;      // the node to relocate
    cur.next = moved.next;       // unlink it
    moved.next = prev.next;      // put it at the front
    prev.next = moved;
  }
  return dummy.next;
}
```

Solution — cpp

```
class Solution {
public:
    ListNode* reverseBetween(ListNode* head, int left, int right) {
        ListNode dummy(0, head);
        ListNode* prev = &dummy;
        for (int i = 1; i < left; ++i) prev = prev->next;
        ListNode* cur = prev->next;
        for (int i = 0; i < right - left; ++i) {
            ListNode* moved = cur->next;
            cur->next = moved->next;
            moved->next = prev->next;
            prev->next = moved;
        }
        return dummy.next;
    }
};
```

Solution — python

```
class Solution:
    def reverseBetween(self, head: ListNode, left: int, right: int) -> ListNode:
        dummy = ListNode(0, head)
        prev = dummy
        for _ in range(left - 1):
            prev = prev.next
        cur = prev.next
        for _ in range(right - left):
            moved = cur.next
            cur.next = moved.next
            moved.next = prev.next
            prev.next = moved
        return dummy.next
```

Solution — java

```java
class Solution {
    public ListNode reverseBetween(ListNode head, int left, int right) {
        ListNode dummy = new ListNode(0, head), prev = dummy;
        for (int i = 1; i < left; i++) prev = prev.next;
        ListNode cur = prev.next;
        for (int i = 0; i < right - left; i++) {
            ListNode moved = cur.next;
            cur.next = moved.next;
            moved.next = prev.next;
            prev.next = moved;
        }
        return dummy.next;
    }
}
```

WALKTHROUGH

TRACE `[1,2,3,4,5], LEFT=2, RIGHT=4`.

`prev` stops at node 1, `cur` is node 2. Iteration 1: move node 3 to the front → `1→3→2→4→5`. Iteration 2: `cur` is still node 2, whose next is now 4; move it → `1→4→3→2→5`. Two iterations, which is `right - left`. Done.

WHY HEAD INSERTION BEATS CUT-AND-REJOIN.

The cut version needs four boundary pointers (before-left, the left node, the right node, after-right) and reconnecting them in the right order — a common source of lost tails. Head insertion keeps the list connected at every instant, so there is no rejoin step and nothing to lose. `cur` never moves; it simply drifts backwards as nodes are pulled in front of it, and ends up as the tail of the reversed section.

THE GENERALISATION:

reversing in groups of k ("reverse nodes in k-group") is this loop applied repeatedly, with a length check before each group.

Linked lists: fast and slow pointers

Two pointers moving at different speeds. It finds the middle in one pass, detects a cycle in O(1) space, and locates where the cycle begins — the last of which has a proof worth knowing.

The pattern

```
TWO POINTERS, ONE MOVING TWICE AS FAST.

  slow = head, fast = head
  while (fast && fast.next) {
      slow = slow.next;
      fast = fast.next.next;
  }

THE GUARD `fast && fast.next` IS BOTH CONDITIONS. Checking
only `fast` crashes on `fast.next.next` when fast is the
last node; checking only `fast.next` crashes when fast is
already null.

------------------------------------------------------------
USE 1 — FIND THE MIDDLE, one pass

  When fast reaches the end, slow is at the middle.

    1 -> 2 -> 3 -> 4 -> 5        odd:  slow lands on 3
    s    f
         s         f
              s              f=null -> slow = 3

    1 -> 2 -> 3 -> 4             even: slow lands on 3,
                                 the SECOND middle
  For the FIRST middle on even length, start
  `fast = head.next`. Decide which one the problem wants.

------------------------------------------------------------
USE 2 — CYCLE DETECTION (Floyd's tortoise and hare)

  If there is a cycle, fast eventually laps slow and they
  MEET. If there is none, fast runs off the end.

  WHY THEY MUST MEET: once both are inside the cycle,
  fast gains exactly one position on slow per step. The
  gap shrinks by 1 each step and cannot skip over zero,
  so it hits zero — they meet.

------------------------------------------------------------
USE 3 — FIND THE CYCLE'S START

  After they meet, reset one pointer to the head and
  advance BOTH ONE STEP AT A TIME. They meet at the entry.

     head ---- F ----> [ entry ]
                         |    ^
                         v    |
                         \____/   cycle length C

  THE PROOF, and it is short enough to give aloud:
    Let F = distance head -> entry,
        a = distance entry -> meeting point,
        C = cycle length.
    Slow travelled F + a. Fast travelled twice that, and
    is at the same place, so fast's distance is
    F + a + kC for some k >= 1.
      2(F + a) = F + a + kC
           F + a = kC
               F = kC - a
    So walking F steps from the head, and F steps forward
```

```
        from the meeting point, both land on the entry —
        because kC - a steps past the meeting point is exactly
        a whole number of laps back to the entry.

    COST: O(n) time, O(1) space — versus a hash set of visited
    nodes which is O(n) space. That space difference is the
    entire reason this pattern is asked.
```

When to reach for it

"Find the middle"

One pass instead of counting then walking half.

"Is there a cycle?" / "where does it start?"

Floyd's algorithm, O(1) space.

Palindrome linked list

Find the middle, reverse the second half, compare.

Duplicate number in an array

Treat `i → nums[i]` as a linked list; the duplicate creates a cycle.

Happy number

The digit-square sequence either reaches 1 or cycles.

Reorder / split a list

Middle first, then operate on each half.

Problems

How it shows up

Symptom	Cause
Crash reading `next` of null	Guard must be `fast && fast.next`, both
Middle is off by one on even length	Two valid definitions — start `fast` at `head` or `head.next`
Cycle detection never terminates	Moving both pointers at the same speed
Cycle start is wrong	Reset to head *after* the meeting, then move both by one
Reports a cycle on a clean list	Comparing values instead of node identity
Palindrome check fails on odd length	Middle node belongs to neither half — skip it
Input list left reversed	Restore the second half if the caller reuses the list

Check yourself

- ✓ Write the fast/slow loop and explain both halves of the guard.
- ✓ Say where `slow` lands for odd and even lengths, and how to shift it.
- ✓ Explain why fast and slow must meet inside a cycle.
- ✓ Give the proof that resetting to the head finds the cycle entry.
- ✓ State the space advantage over a visited set.
- ✓ Describe the palindrome algorithm in three steps.
- ✓ Explain how "find the duplicate number" becomes a cycle problem.

Problems

Middle of the linked list `Easy`

Pattern: Fast/slow

Given the head of a singly linked list, return the middle node. If there are two middle nodes, return the **second** one.

The judge compares the returned list, so returning the middle node means returning it *and everything after it*.

Input	Output	Note
`head = [1,2,3,4,5]`	`[3,4,5]`	
`head = [1,2,3,4,5,6]`	`[4,5,6]`	Second of the two middles.

HINTS

1. Counting the length then walking half is two passes. One pass is possible.
2. Move one pointer twice as fast as the other. When the fast one falls off the end, where is the slow one?
3. The loop guard must check both `fast` and `fast.next`.

Approach	Idea	Time	Space
Count then walk	Two passes: measure the length, then advance `n/2`.	`O(n)`	`O(1)`
Fast/slow	One pass; fast covers twice the ground.	`O(n)`	`O(1)`

Solution — js

```
function middleNode(head) {
  let slow = head, fast = head;
  while (fast && fast.next) {
    slow = slow.next;
    fast = fast.next.next;
  }
  return slow;
}
```

Solution — cpp

```
class Solution {
public:
    ListNode* middleNode(ListNode* head) {
        ListNode *slow = head, *fast = head;
        while (fast && fast->next) {
            slow = slow->next;
            fast = fast->next->next;
        }
        return slow;
    }
};
```

Solution — python

```
class Solution:
    def middleNode(self, head: ListNode) -> ListNode:
        slow = fast = head
        while fast and fast.next:
            slow = slow.next
            fast = fast.next.next
        return slow
```

Solution — java

```
class Solution {
    public ListNode middleNode(ListNode head) {
        ListNode slow = head, fast = head;
        while (fast != null && fast.next != null) {
            slow = slow.next;
            fast = fast.next.next;
        }
        return slow;
    }
}
```

WALKTHROUGH

WHY THIS LANDS ON THE MIDDLE.

Each iteration advances `slow` by 1 and `fast` by 2, so `fast` is always at twice `slow`'s offset. When `fast` has travelled the whole list, `slow` has travelled exactly half of it.

THE TWO MIDDLE CONVENTIONS.

With an even count, starting both at `head` lands `slow` on the *second* middle (index 3 of 6, zero-based). Starting `fast = head.next` shifts it to the *first*. Neither is more correct — read the problem statement, and say which you chose.

Linked list cycle `Easy`

Pattern: Floyd's cycle detection

Given a linked list, determine whether it has a cycle.

Because the judge takes arrays, this problem is given as `values` plus `pos` — the index the tail connects to, or `-1` for no cycle. Build the list, wire the cycle, and return `true` or `false`.

Input	Output	Note
`values = [3,2,0,-4], pos = 1`	`true`	
`values = [1,2], pos = 0`	`true`	
`values = [1], pos = -1`	`false`	

HINTS

1. A visited-node hash set works and is O(n) space. The point of this problem is O(1) space.
2. Two pointers at different speeds: if there is a loop, the faster one laps the slower and they collide.
3. If there is no loop, the fast pointer simply reaches the end.
4. Compare *nodes*, not values — duplicate values do not mean a cycle.

Approach	Idea	Time	Space
Visited set	Record each node; a repeat means a cycle.	`O(n)`	`O(n)`
Floyd tortoise and hare	Fast gains one position per step, so it must catch up inside a loop.	`O(n)`	`O(1)`

Solution — js

```
function hasCycle(values, pos) {
  const head = buildList(values);
  if (head && pos >= 0) {
    let tail = head; while (tail.next) tail = tail.next;
    let target = head; for (let i = 0; i < pos; i++) target = target.next;
    tail.next = target;
  }

  let slow = head, fast = head;
  while (fast && fast.next) {
    slow = slow.next;
    fast = fast.next.next;
    if (slow === fast) return true;   // node identity, not value
  }
  return false;                        // fast ran off the end
}
```

Solution — cpp

```
class Solution {
public:
    bool hasCycle(ListNode* head) {
        ListNode *slow = head, *fast = head;
        while (fast && fast->next) {
            slow = slow->next;
            fast = fast->next->next;
            if (slow == fast) return true;
        }
        return false;
    }
};
```

Solution — python

```python
class Solution:
    def hasCycle(self, head: ListNode) -> bool:
        slow = fast = head
        while fast and fast.next:
            slow = slow.next
            fast = fast.next.next
            if slow is fast:        # identity, not equality
                return True
        return False
```

Solution — java

```java
public class Solution {
    public boolean hasCycle(ListNode head) {
        ListNode slow = head, fast = head;
        while (fast != null && fast.next != null) {
            slow = slow.next;
            fast = fast.next.next;
            if (slow == fast) return true;
        }
        return false;
    }
}
```

WALKTHROUGH

WHY THEY ARE GUARANTEED TO MEET.

Once both pointers are inside the cycle, consider the gap from `fast` to `slow` measured forwards around the loop. Each step `fast` advances 2 and `slow` advances 1, so the gap decreases by exactly 1 per step. A quantity that decreases by exactly one each step cannot jump over zero — so it reaches zero and the pointers coincide. That argument is the answer to "how do you know it terminates?"

IDENTITY, NOT EQUALITY.

`[1,1,1,1]` with no cycle must return `false`. Comparing `slow.val === fast.val` would report a cycle immediately. In Python this is the difference between `is` and `==`, which is exactly why the test is there.

THE CHECK GOES AFTER THE MOVES.

Both start at `head`, so testing before advancing would report a cycle on step zero for every list.

Linked list cycle II — find the entry `Medium`

Pattern: Floyd + reset to head

Given a linked list, return the **index** of the node where the cycle begins, or `-1` if there is no cycle.

As before the list is given as `values` and `pos`; return the index of the entry node, which should equal `pos`.

Input	Output	Note
`values = [3,2,0,-4], pos = 1`	`1`	
`values = [1,2], pos = 0`	`0`	
`values = [1], pos = -1`	`-1`	

HINTS

1. First detect the cycle exactly as before, and stop at the meeting point.
2. Then reset one pointer to the head and advance
   BOTH ONE STEP AT A TIME
   . They meet at the entry.
3. The reason is arithmetic: if F is head-to-entry and a is entry-to-meeting, then F = kC − a, so F steps from the head and F steps from the meeting point land on the same node.
4. Count steps from the head to get the index.

Approach	Idea	Time	Space
Visited set with indices	Record each node and its index; the first repeat is the entry.	`O(n)`	`O(n)`
Floyd's two phases	Detect the meeting point, then walk both pointers at speed 1 from head and meeting point.	`O(n)`	`O(1)`

Solution — js

```
function detectCycle(values, pos) {
  const head = buildList(values);
  if (head && pos >= 0) {
    let tail = head; while (tail.next) tail = tail.next;
    let target = head; for (let i = 0; i < pos; i++) target = target.next;
    tail.next = target;
  }

  // PHASE 1: detect, and stop at the meeting point
  let slow = head, fast = head, met = null;
  while (fast && fast.next) {
    slow = slow.next;
    fast = fast.next.next;
    if (slow === fast) { met = slow; break; }
  }
  if (!met) return -1;

  // PHASE 2: head and meeting point advance at the SAME speed
  let p = head, idx = 0;
  while (p !== met) { p = p.next; met = met.next; idx++; }
  return idx;
}
```

Solution — cpp

```cpp
class Solution {
public:
    ListNode* detectCycle(ListNode* head) {
        ListNode *slow = head, *fast = head, *met = nullptr;
        while (fast && fast->next) {
            slow = slow->next;
            fast = fast->next->next;
            if (slow == fast) { met = slow; break; }
        }
        if (!met) return nullptr;
        ListNode* p = head;
        while (p != met) { p = p->next; met = met->next; }
        return p;
    }
};
```

Solution — python

```python
class Solution:
    def detectCycle(self, head: ListNode) -> ListNode:
        slow = fast = head
        met = None
        while fast and fast.next:
            slow = slow.next
            fast = fast.next.next
            if slow is fast:
                met = slow
                break
        if met is None:
            return None
        p = head
        while p is not met:
            p = p.next
            met = met.next
        return p
```

Solution — java

```java
public class Solution {
    public ListNode detectCycle(ListNode head) {
        ListNode slow = head, fast = head, met = null;
        while (fast != null && fast.next != null) {
            slow = slow.next;
            fast = fast.next.next;
            if (slow == fast) { met = slow; break; }
        }
        if (met == null) return null;
        ListNode p = head;
        while (p != met) { p = p.next; met = met.next; }
        return p;
    }
}
```

WALKTHROUGH

THE PROOF, WRITTEN OUT.

Let `F` be the number of steps from the head to the cycle entry, `a` the steps from the entry to the meeting point, and `C` the cycle length. When they meet, `slow` has taken `F + a` steps. `fast` has taken twice as many and is at the same node, so its distance is `F + a + kC` for some whole number of extra laps `k ≥ 1`. Setting them equal:

```
2(F + a) = F + a + kC
    F + a = kC
        F = kC − a
```

So advancing `F` steps from the *meeting point* covers `kC − a` steps, which combined with the `a` already travelled from the entry is exactly `k` whole laps — landing back on the entry. Meanwhile advancing `F` steps from the head also lands on the entry, by definition of `F`. Hence the two pointers meet there.

THE SINGLE-NODE SELF-LOOP

(`[1], pos = 0`) is the edge case: phase 1 meets immediately at the head, and phase 2 finds `p === met` without moving, returning index 0.

Palindrome linked list `Medium`

Pattern: Middle + reverse + compare

Given the head of a singly linked list, return `true` if it reads the same forwards and backwards.

Aim for O(n) time and **O(1) extra space**.

Input	Output	Note
`head = [1,2,2,1]`	`true`	
`head = [1,2]`	`false`	
`head = [1,2,3,2,1]`	`true`	

HINTS

1. Copying the values into an array and using two pointers is O(n) space — correct, and worth stating first.
2. For O(1) space: find the middle with fast/slow, reverse the second half, then walk the two halves in parallel.
3. With an odd length the middle node belongs to neither half; starting the comparison from `slow` handles it naturally.
4. Stop when the reversed half runs out — it is the shorter one.

Approach	Idea	Time	Space
Copy to an array	Then converge two pointers. Simple and clear.	`O(n)`	`O(n)`
Recursion	Compare the front against the unwinding stack. Still O(n) space, hidden in the call stack.	`O(n)`	`O(n)`

Approach	Idea	Time	Space
Reverse the second half	Find the middle, reverse from there, compare in parallel.	`O(n)`	`O(1)`

Solution — js

```
function isPalindrome(head) {
  if (!head || !head.next) return true;

  // 1. find the middle (slow ends on the second middle if even)
  let slow = head, fast = head;
  while (fast && fast.next) {
    slow = slow.next;
    fast = fast.next.next;
  }

  // 2. reverse from the middle onwards
  let prev = null, cur = slow;
  while (cur) {
    const next = cur.next;
    cur.next = prev;
    prev = cur;
    cur = next;
  }

  // 3. walk both halves; the reversed half is never longer
  let a = head, b = prev;
  while (b) {
    if (a.val !== b.val) return false;
    a = a.next;
    b = b.next;
  }
  return true;
}
```

Solution — cpp

```
class Solution {
public:
    bool isPalindrome(ListNode* head) {
        if (!head || !head->next) return true;
        ListNode *slow = head, *fast = head;
        while (fast && fast->next) { slow = slow->next; fast = fast->next->next; }
        ListNode *prev = nullptr, *cur = slow;
        while (cur) { ListNode* nx = cur->next; cur->next = prev; prev = cur; cur = nx; }
        ListNode *a = head, *b = prev;
        while (b) {
            if (a->val != b->val) return false;
            a = a->next; b = b->next;
        }
        return true;
    }
};
```

Solution — python

```python
class Solution:
    def isPalindrome(self, head: ListNode) -> bool:
        if not head or not head.next:
            return True
        slow = fast = head
        while fast and fast.next:
            slow = slow.next
            fast = fast.next.next
        prev, cur = None, slow
        while cur:
            nxt = cur.next
            cur.next = prev
            prev = cur
            cur = nxt
        a, b = head, prev
        while b:
            if a.val != b.val:
                return False
            a, b = a.next, b.next
        return True
```

Solution — java

```java
class Solution {
    public boolean isPalindrome(ListNode head) {
        if (head == null || head.next == null) return true;
        ListNode slow = head, fast = head;
        while (fast != null && fast.next != null) { slow = slow.next; fast = fast.next.next; }
        ListNode prev = null, cur = slow;
        while (cur != null) { ListNode nx = cur.next; cur.next = prev; prev = cur; cur = nx; }
        ListNode a = head, b = prev;
        while (b != null) {
            if (a.val != b.val) return false;
            a = a.next; b = b.next;
        }
        return true;
    }
}
```

WALKTHROUGH

WHY THE ODD CASE NEEDS NO SPECIAL HANDLING.

On `[1,2,3,2,1]`, `slow` stops on the `3`. Reversing from there gives `3 → 2 → 1` while the front half is still `1 → 2 → 3 …`. Comparing three pairs — 1/1, 2/2, 3/3 — succeeds, and the middle element compares against itself harmlessly. Looping while `b` is non-null rather than while both are, means the shorter reversed half controls termination and the front half's leftover nodes are ignored.

THE LIST IS LEFT PARTIALLY REVERSED.

That is a genuine side effect: if the caller uses the list afterwards it is corrupted. Interviewers often ask whether you noticed — the fix is to reverse the second half back before returning, which costs another O(n) pass and keeps the space at O(1).

Stacks: matching, expressions and design

Last in, first out. Whenever the most recent unresolved thing is the one you need next — a bracket, an operand, an undo step, a recursive call — the structure is a stack.

The pattern

```
THE OPERATIONS, all O(1):
  push(x)   put on top
  pop()     remove and return the top
  peek()    look at the top without removing
  isEmpty()

IN JAVASCRIPT an array IS a stack:
  st.push(x)      st.pop()      st[st.length - 1]

THE RECOGNITION SIGNALS:

  NESTING or MATCHING       brackets, tags, nested
                            structures
  "MOST RECENT" matters     undo, back button, call stack
  REVERSE something         a stack reverses order for free
  EXPRESSION EVALUATION     operands and operators
  RECURSION MADE ITERATIVE  the explicit stack IS the call
                            stack (chapter 23)
  NEXT GREATER / SMALLER    a MONOTONIC stack — chapter 20

------------------------------------------------------------
THE MATCHING TEMPLATE, which covers a whole family:

  for (const c of s) {
      if (isOpener(c)) st.push(c);
      else {
          if (st.length === 0) return false;   // nothing to
                                               // match
          if (!matches(st.pop(), c)) return false;
      }
  }
  return st.length === 0;      // NOTHING LEFT UNCLOSED

BOTH EMPTINESS CHECKS ARE NEEDED. Popping an empty stack
means a closer with no opener — ")(" fails here. A
non-empty stack at the end means an unclosed opener —
"(((" fails there. Miss either and half the tests pass.

------------------------------------------------------------
EXPRESSION EVALUATION

  POSTFIX (RPN): "3 4 + 2 *"
    push operands; on an operator, pop TWO, apply, push
    the result. ORDER MATTERS for - and /:
      b = pop(); a = pop(); push(a OP b);
    Popping in the wrong order silently breaks subtraction
    and division while addition still passes.

  INFIX with precedence: two stacks (operands and
  operators), or the shunting-yard algorithm. Rare in
  interviews; the postfix version is the common one.
```

When to reach for it

Balanced brackets / valid parentheses

The matching template.

Evaluate RPN, basic calculator

Operand stack; operator pops two.

Simplify a path, undo history

`..` pops, a name pushes.

Decode nested structures

`3[a2[c]]` — push the context on `[`, restore on `]`.

Iterative traversal

Replace recursion with an explicit stack (ch. 23).

Min stack / stack with extra queries

Store auxiliary data alongside each element.

Problems

How it shows up

Symptom	Cause
`"((("` reported valid	Missing the "stack empty at the end" check
`")("` reported valid	Missing the "pop from empty" check
Subtraction/division wrong in RPN	Popped operands in the wrong order
Crash on `pop()`	Empty stack — guard before popping
Min stack returns a stale minimum	Minimum not stored per element, or not popped alongside
Wrong mismatched pair accepted	Only counting brackets instead of checking the type
Stack overflow in recursion	Convert to an explicit stack

Check yourself

- ✓ Give the six recognition signals for a stack.
- ✓ Write the matching template and name both emptiness checks and what each catches.
- ✓ Explain the RPN pop order and which operators expose the bug.
- ✓ Say how a stack makes a recursive traversal iterative.
- ✓ Describe how to support O(1) `getMin` on a stack.
- ✓ Explain why an array is already a stack in most languages.

Problems

Valid parentheses Easy

Pattern: Matching template

Given a string containing only `()[]{}`, determine whether it is valid: every bracket is closed by the same type, and in the correct order.

Input	Output	Note
`s = "()[]{}"`	`true`	
`s = "(]"`	`false`	
`s = "([)]"`	`false`	Correct types but wrong nesting order.
`s = "{[]}"`	`true`	

HINTS

1. A closer must match the *most recent* unmatched opener — that is a stack.
2. Map each closer to its opener so the check is one lookup.
3. Two failure cases: a closer arriving with an empty stack, and openers left over at the end.

Approach	Idea	Time	Space
Repeatedly remove pairs	Delete `()`, `[]`, `{}` until nothing changes; valid if empty.	`O(n²)`	`O(n)`
Counters per type	**Wrong.** Counting cannot detect `([)]` — order is lost.	`O(n)`	`O(1)`
Stack	Push openers, match each closer against the top.	`O(n)`	`O(n)`

Solution — js

```
function isValid(s) {
  const pairs = { ")": "(", "]": "[", "}": "{" };
  const st = [];

  for (const c of s) {
    if (c === "(" || c === "[" || c === "{") {
      st.push(c);
    } else {
      // a closer: the top must be its matching opener
      if (st.pop() !== pairs[c]) return false;
    }
  }
  return st.length === 0;    // nothing left unclosed
}
```

Solution — cpp

```cpp
class Solution {
public:
    bool isValid(string s) {
        unordered_map<char,char> pairs{{')','('}, {']','['}, {'}','{'}};
        stack<char> st;
        for (char c : s) {
            if (!pairs.count(c)) st.push(c);
            else {
                if (st.empty() || st.top() != pairs[c]) return false;
                st.pop();
            }
        }
        return st.empty();
    }
};
```

Solution — python

```python
class Solution:
    def isValid(self, s: str) -> bool:
        pairs = {")": "(", "]": "[", "}": "{"}
        st = []
        for c in s:
            if c not in pairs:
                st.append(c)
            else:
                if not st or st.pop() != pairs[c]:
                    return False
        return not st
```

Solution — java

```java
class Solution {
    public boolean isValid(String s) {
        Map<Character,Character> pairs = Map.of(')','(', ']','[', '}','{');
        Deque<Character> st = new ArrayDeque<>();
        for (char c : s.toCharArray()) {
            if (!pairs.containsKey(c)) st.push(c);
            else {
                if (st.isEmpty() || st.pop() != pairs.get(c)) return false;
            }
        }
        return st.isEmpty();
    }
}
```

WALKTHROUGH

THE JAVASCRIPT VERSION EXPLOITS A CONVENIENCE:

`[].pop()` on an empty array returns `undefined`, which can never equal a bracket character, so the empty check is implicit. In C++ and Java popping an empty stack is undefined or throws, so the explicit `st.empty()` guard is mandatory — note the difference between the versions.

WHY COUNTING FAILS.

A tempting solution counts openers and closers of each type and checks they balance. `([])` has one of each and balances perfectly, yet is invalid. Only a stack records the *order* of nesting, which is what the problem is really about — a good thing to say aloud when you dismiss the counting approach.

THE TWO FAILURE TESTS TO KEEP:

`"((("` for leftover openers and `")("` for a closer with nothing to match.

Min stack `Medium`

Pattern: Store auxiliary data per element

Design a stack supporting `push`, `pop`, `top` and `getMin` — where `getMin` returns the smallest element currently in the stack — **all in O(1)**.

Implement `minStack(ops, args)`: apply each operation in order and return an array of the results of the query operations (`"top"` and `"getMin"`), in order.

Input	Output	Note
`ops = ["push","push","push","getMin","pop","top","getMin"], args = [[-2],[0],[-3],[],[],[],[]]`	`[-3,0,-2]`	

HINTS

1. Scanning for the minimum on every call is O(n). You need it precomputed.
2. Alongside each pushed value, record the minimum of the stack *at that moment*.
3. Then popping automatically restores the previous minimum — no recomputation.
4. The new minimum on push is `min(value, currentMin)`.

Approach	Idea	Time	Space
Scan on getMin	Walk the stack each time. Simple but O(n) per query.	`O(n) per getMin`	`O(n)`
Second stack of minima	Push to the min-stack only when a new value is ≤ the current minimum. Slightly less memory.	`O(1)`	`O(n)`
Pair (value, minSoFar)	Store both in each entry. Simplest to reason about and impossible to desynchronise.	`O(1)`	`O(n)`

Solution — js

```javascript
function minStack(ops, args) {
  const st = [];        // each entry: [value, minSoFar]
  const out = [];

  for (let i = 0; i < ops.length; i++) {
    const op = ops[i];
    if (op === "push") {
      const v = args[i][0];
      const prevMin = st.length ? st[st.length - 1][1] : Infinity;
      st.push([v, Math.min(v, prevMin)]);
    } else if (op === "pop") {
      st.pop();                       // the old min comes back
    } else if (op === "top") {
      out.push(st[st.length - 1][0]);
    } else if (op === "getMin") {
      out.push(st[st.length - 1][1]);
    }
  }
  return out;
}
```

Solution — cpp

```cpp
class MinStack {
    vector<pair<int,int>> st;   // (value, minSoFar)
public:
    void push(int v) {
        int m = st.empty() ? v : min(v, st.back().second);
        st.push_back({v, m});
    }
    void pop()      { st.pop_back(); }
    int  top()      { return st.back().first; }
    int  getMin()   { return st.back().second; }
};
```

Solution — python

```python
class MinStack:
    def __init__(self):
        self.st = []          # (value, min_so_far)

    def push(self, v: int) -> None:
        m = v if not self.st else min(v, self.st[-1][1])
        self.st.append((v, m))

    def pop(self) -> None:
        self.st.pop()

    def top(self) -> int:
        return self.st[-1][0]

    def getMin(self) -> int:
        return self.st[-1][1]
```

Solution — java

```
class MinStack {
    private final Deque<int[]> st = new ArrayDeque<>();  // {value, minSoFar}
    public void push(int v) {
        int m = st.isEmpty() ? v : Math.min(v, st.peek()[1]);
        st.push(new int[]{v, m});
    }
    public void pop()    { st.pop(); }
    public int  top()    { return st.peek()[0]; }
    public int  getMin() { return st.peek()[1]; }
}
```

WALKTHROUGH

THE INSIGHT IS THAT THE MINIMUM IS A PROPERTY OF A *PREFIX*, NOT OF THE WHOLE STRUCTURE.

When the stack holds `[a, b, c]`, the minimum is `min(a,b,c)`; after popping `c` it is `min(a,b)` — a value that existed earlier and can simply be remembered rather than recomputed. Storing it per entry makes pop restore it for free.

WHY THE ALTERNATIVE TWO-STACK VERSION NEEDS `<=`.

If you only push to the min-stack when a value is *strictly* smaller, duplicates of the minimum break it: pushing `2, 2` then popping once would remove the only recorded 2 and report the wrong minimum. The test `[2,2,1]` is there to catch exactly that. Storing the pair per entry sidesteps the issue entirely, which is why it is the recommended version.

Evaluate reverse Polish notation `Medium`

Pattern: Operand stack

Evaluate an arithmetic expression in Reverse Polish Notation. Valid operators are `+ - * /`; each operand is an integer or another expression.

Division truncates **toward zero**. The input is always valid.

Input	Output	Note
`tokens = ["2","1","+","3","*"]`	`9`	(2 + 1) × 3
`tokens = ["4","13","5","/","+"]`	`6`	4 + (13 / 5) = 4 + 2
`tokens = ["10","6","9","3","+","-11","*","/","*","17","+","5","+"]`	`22`	

HINTS

1. Push every number. When you meet an operator, pop two values, combine them, push the result.
2. The
   SECOND
   value popped is the left operand — the stack reverses the order.
3. Division must truncate toward zero, which is `Math.trunc`, not `Math.floor` (they differ for negatives).

Approach	Idea	Time	Space
Recursive parse	Parse right to left building a tree, then evaluate. Works, but more machinery than needed.	`O(n)`	`O(n)`

Approach	Idea	Time	Space
Operand stack	One linear pass; the stack holds pending operands.	`O(n)`	`O(n)`

Solution — js

```
function evalRPN(tokens) {
  const st = [];
  const ops = {
    "+": (a, b) => a + b,
    "-": (a, b) => a - b,
    "*": (a, b) => a * b,
    "/": (a, b) => Math.trunc(a / b)   // toward ZERO, not -inf
  };

  for (const t of tokens) {
    if (t in ops) {
      const b = st.pop();      // RIGHT operand pops first
      const a = st.pop();      // LEFT operand second
      st.push(ops[t](a, b));
    } else {
      st.push(Number(t));
    }
  }
  return st.pop();
}
```

Solution — cpp

```
class Solution {
public:
    int evalRPN(vector<string>& tokens) {
        stack<long> st;
        for (auto& t : tokens) {
            if (t == "+" || t == "-" || t == "*" || t == "/") {
                long b = st.top(); st.pop();
                long a = st.top(); st.pop();
                if      (t == "+") st.push(a + b);
                else if (t == "-") st.push(a - b);
                else if (t == "*") st.push(a * b);
                else               st.push(a / b);   // C++ truncates toward 0
            } else st.push(stol(t));
        }
        return (int)st.top();
    }
};
```

Solution — python

```python
class Solution:
    def evalRPN(self, tokens: list[str]) -> int:
        st = []
        for t in tokens:
            if t in ("+", "-", "*", "/"):
                b = st.pop()
                a = st.pop()
                if   t == "+": st.append(a + b)
                elif t == "-": st.append(a - b)
                elif t == "*": st.append(a * b)
                else:          st.append(int(a / b))  # toward zero
            else:
                st.append(int(t))
        return st.pop()
```

Solution — java

```java
class Solution {
    public int evalRPN(String[] tokens) {
        Deque<Integer> st = new ArrayDeque<>();
        for (String t : tokens) {
            switch (t) {
                case "+": { int b = st.pop(), a = st.pop(); st.push(a + b); break; }
                case "-": { int b = st.pop(), a = st.pop(); st.push(a - b); break; }
                case "*": { int b = st.pop(), a = st.pop(); st.push(a * b); break; }
                case "/": { int b = st.pop(), a = st.pop(); st.push(a / b); break; }
                default:  st.push(Integer.parseInt(t));
            }
        }
        return st.pop();
    }
}
```

WALKTHROUGH

POP ORDER IS THE BUG THIS PROBLEM EXISTS TO EXPOSE.

For `["7","2","-"]` the stack is `[7, 2]`; the first pop yields 2 and the second yields 7. Since the expression means `7 - 2`, the *second* pop is the left operand. Getting it backwards returns `-5` — and addition and multiplication still pass, so half the tests look fine. Both orderings are in the test list deliberately.

`MATH.TRUNC` VERSUS `MATH.FLOOR`.

For `-7 / 2`, truncation toward zero gives `-3` while flooring gives `-4`. The problem specifies toward zero, matching C++ and Java integer division. In Python, `//` floors, so the idiomatic solution uses `int(a / b)` instead — a real cross-language trap worth knowing.

Stacks: the monotonic stack

A stack kept sorted by construction. It answers "what is the next larger element?" for every position in one linear pass, and it is the key to several problems that look inescapably quadratic.

The pattern

```
A MONOTONIC STACK holds elements in sorted order —
increasing or decreasing from the bottom. You maintain
that by POPPING anything that would break it before
pushing.

THE RECOGNITION SIGNAL:
  "NEXT GREATER" / "NEXT SMALLER" / "PREVIOUS GREATER" /
  "PREVIOUS SMALLER" element — for EVERY position.
  Also: largest rectangle, span problems, trapping water,
  and "how far until something bigger?"

------------------------------------------------------
THE TEMPLATE — next greater to the RIGHT

  const out = new Array(n).fill(-1);
  const st = [];                      // holds INDICES
  for (let i = 0; i < n; i++) {
      while (st.length && a[st[st.length-1]] < a[i]) {
          out[st.pop()] = a[i];       // a[i] IS the answer
      }                               // for the popped index
      st.push(i);
  }
  // anything still on the stack has no greater element

  THE STACK HOLDS INDICES, NOT VALUES. You almost always
  need the position — to write the answer, or to compute
  a width.

  [2, 1, 2, 4, 3]
   i=0  push 0                st=[0]        (values 2)
   i=1  1 < 2, push 1         st=[0,1]      (2,1)
   i=2  2 > 1 -> out[1]=2     st=[0]
        2 = 2 not >, push 2   st=[0,2]      (2,2)
   i=3  4 > 2 -> out[2]=4
        4 > 2 -> out[0]=4     st=[]
        push 3                st=[3]        (4)
   i=4  3 < 4, push 4         st=[3,4]
   leftover 3,4 -> out = [4,2,4,-1,-1]

------------------------------------------------------
THE FOUR VARIANTS — only the comparison changes

  next GREATER right   iterate LEFT->RIGHT, pop while
                       stack top <  current   (decreasing
                                               stack)
  next SMALLER right   pop while stack top >  current
  prev GREATER left    iterate LEFT->RIGHT, the stack top
                       AFTER popping is the answer
  prev SMALLER left    same, flipped comparison

  Equivalently, iterate right-to-left for the "next"
  versions and read the top instead. Pick one convention
  and keep it.

------------------------------------------------------
WHY IT IS O(n) DESPITE THE NESTED WHILE

  EACH INDEX IS PUSHED EXACTLY ONCE AND POPPED AT MOST
  ONCE. So the total number of pops across the whole run
  is at most n, no matter how many happen in a single
  iteration. Amortised O(1) per element (chapter 02).
```

```
  THAT SENTENCE IS THE ANSWER TO "what is the
  complexity?" — say it exactly.

-------------------------------------------------------
THE >= VERSUS > DECISION

  Popping on EQUAL values or not changes which duplicate
  gets credited. For "next STRICTLY greater", pop while
  top < current (leave equals on the stack). For
  rectangle problems either works, because equal-height
  bars produce the same area — but be able to say why.
```

When to reach for it

Next / previous greater or smaller

Daily temperatures, next greater element, stock span.

Largest rectangle in a histogram

Each bar extends until a shorter one on each side.

Maximal rectangle in a binary matrix

Row by row, each becomes a histogram problem.

Trapping rain water

An alternative to the two-pointer solution (ch. 04).

Remove k digits / smallest subsequence

Greedily pop larger digits to make the result smaller.

Sum of subarray minimums

Count how many subarrays each element is the minimum of.

Problems

How it shows up

Symptom	Cause
Cannot compute widths	Stack holds values instead of indices
Leftover elements have no answer	Correct — they have no next greater; initialise to −1 or 0
Duplicates credited to the wrong index	`<` vs `<=` in the pop condition
Histogram misses the last bars	No sentinel — append a height of 0, or drain after the loop
Width off by one	Width is `i - st.top() - 1` after popping, not `i - popped`
Claimed O(n^2) complexity	It is amortised O(n) — each index pushed and popped once
Answer array wrong length	Must be sized n and pre-filled with the "none" value

Check yourself

- ✓ State the recognition signal and name four problems that match it.
- ✓ Write the next-greater template and say why the stack holds indices.
- ✓ Give the amortised argument for O(n) in one sentence.
- ✓ Explain what stays on the stack at the end and what it means.
- ✓ Describe the four variants and what changes between them.
- ✓ Explain the sentinel trick for the histogram problem.
- ✓ Give the correct width formula after a pop.

Problems

Daily temperatures `Medium`

Pattern: Next greater element

Given an array `temperatures`, return an array `answer` where `answer[i]` is the number of days you must wait after day `i` to get a warmer temperature. If no warmer day exists, put `0`.

Input	Output	Note
`temperatures = [73,74,75,71,69,72,76,73]`	`[1,1,4,2,1,1,0,0]`	
`temperatures = [30,40,50,60]`	`[1,1,1,0]`	
`temperatures = [30,60,90]`	`[1,1,0]`	

HINTS

1. This is "next strictly greater element", reported as a *distance* rather than a value.
2. Keep a stack of indices whose answer is still unknown, in decreasing temperature order.
3. When today is warmer than the top of the stack, today resolves it — the wait is the index difference.
4. Anything left on the stack at the end never gets a warmer day, so it keeps its 0.

Approach	Idea	Time	Space
For each day scan forward	Look ahead until a warmer day.	`O(n²)`	`O(1)`
Monotonic decreasing stack	Each index is pushed once and popped at most once.	`O(n)`	`O(n)`

Solution — js

```javascript
function dailyTemperatures(temperatures) {
  const n = temperatures.length;
  const out = new Array(n).fill(0);
  const st = [];   // indices awaiting a warmer day

  for (let i = 0; i < n; i++) {
    // today resolves every colder pending day
    while (st.length && temperatures[st[st.length - 1]] < temperatures[i]) {
      const j = st.pop();
      out[j] = i - j;          // the WAIT, not the temperature
    }
    st.push(i);
  }
  return out;                  // leftovers keep their 0
}
```

Solution — cpp

```cpp
class Solution {
public:
    vector<int> dailyTemperatures(vector<int>& t) {
        int n = t.size();
        vector<int> out(n, 0);
        stack<int> st;
        for (int i = 0; i < n; ++i) {
            while (!st.empty() && t[st.top()] < t[i]) {
                int j = st.top(); st.pop();
                out[j] = i - j;
            }
            st.push(i);
        }
        return out;
    }
};
```

Solution — python

```python
class Solution:
    def dailyTemperatures(self, temperatures: list[int]) -> list[int]:
        n = len(temperatures)
        out = [0] * n
        st = []
        for i, t in enumerate(temperatures):
            while st and temperatures[st[-1]] < t:
                j = st.pop()
                out[j] = i - j
            st.append(i)
        return out
```

Solution — java

```
class Solution {
    public int[] dailyTemperatures(int[] t) {
        int n = t.length;
        int[] out = new int[n];
        Deque<Integer> st = new ArrayDeque<>();
        for (int i = 0; i < n; i++) {
            while (!st.isEmpty() && t[st.peek()] < t[i]) {
                int j = st.pop();
                out[j] = i - j;
            }
            st.push(i);
        }
        return out;
    }
}
```

WALKTHROUGH

WHY STORING INDICES IS ESSENTIAL HERE.

The answer is a *distance*, so when day `i` resolves day `j` you need `j` itself to compute `i - j`. A stack of temperatures could tell you *that* a warmer day arrived but not how long the wait was.

THE STRICT `<` MATTERS FOR TIES.

`[50,50,60]` must give `[2,1,0]`: neither 50 resolves the other, because "warmer" means strictly greater. Using `<=` would pop the first 50 when the second arrives and wrongly report a wait of 1.

COMPLEXITY, SAID PROPERLY:

the `while` looks like it could make this quadratic, but every index enters the stack exactly once and leaves at most once, so the total pop count over the whole run is bounded by `n`. The algorithm is O(n) amortised — the same argument as the sliding window in chapter 05.

Next greater element in a circular array `Medium`

Pattern: Monotonic stack over a doubled array

Given a **circular** integer array `nums`, return the next greater number for every element. The next greater of `nums[i]` is the first larger value encountered when moving forwards, wrapping around to the start. If none exists, return `-1` for that position.

Input	Output	Note
`nums = [1,2,1]`	`[2,-1,2]`	The last 1 wraps around to find 2.
`nums = [1,2,3,4,3]`	`[2,3,4,-1,4]`	

HINTS

1. Handle the wrap by pretending the array is traversed twice — indices `0 .. 2n-1`, using `i % n`.
2. Do not actually build a doubled array; the modulo is enough.
3. On the second pass, only *resolve* pending indices — do not push new ones, or leftovers get answers they should not have.

Approach	Idea	Time	Space
For each i scan around	Walk up to n−1 positions forwards from every index.	`O(n²)`	`O(1)`
Monotonic stack, two passes	Iterate `2n` times with `i % n`; push only during the first pass.	`O(n)`	`O(n)`

Solution — js

```
function nextGreaterElements(nums) {
  const n = nums.length;
  const out = new Array(n).fill(-1);
  const st = [];                   // indices in 0..n-1

  // walk the array TWICE to cover the wrap-around
  for (let i = 0; i < 2 * n; i++) {
    const v = nums[i % n];
    while (st.length && nums[st[st.length - 1]] < v) {
      out[st.pop()] = v;
    }
    // only push during the FIRST pass
    if (i < n) st.push(i);
  }
  return out;
}
```

Solution — cpp

```
class Solution {
public:
    vector<int> nextGreaterElements(vector<int>& nums) {
        int n = nums.size();
        vector<int> out(n, -1);
        stack<int> st;
        for (int i = 0; i < 2 * n; ++i) {
            int v = nums[i % n];
            while (!st.empty() && nums[st.top()] < v) { out[st.top()] = v; st.pop(); }
            if (i < n) st.push(i);
        }
        return out;
    }
};
```

Solution — python

```
class Solution:
    def nextGreaterElements(self, nums: list[int]) -> list[int]:
        n = len(nums)
        out = [-1] * n
        st = []
        for i in range(2 * n):
            v = nums[i % n]
            while st and nums[st[-1]] < v:
                out[st.pop()] = v
            if i < n:
                st.append(i)
        return out
```

Solution — java

```
class Solution {
    public int[] nextGreaterElements(int[] nums) {
        int n = nums.length;
        int[] out = new int[n];
        Arrays.fill(out, -1);
        Deque<Integer> st = new ArrayDeque<>();
        for (int i = 0; i < 2 * n; i++) {
            int v = nums[i % n];
            while (!st.isEmpty() && nums[st.peek()] < v) out[st.pop()] = v;
            if (i < n) st.push(i);
        }
        return out;
    }
}
```

WALKTHROUGH

WHY TWO PASSES SUFFICE.

The next greater element, if it exists, is at most `n-1` positions ahead. Traversing the array twice therefore gives every index a full lap of lookahead, and a third pass could add nothing.

THE `IF (I < N)` GUARD IS THE WHOLE TRICK.

During the second pass the stack must only be *drained*, never refilled. Pushing again would let a second-pass index receive an answer from a third conceptual lap that does not exist, and would also leave stale entries. Elements still on the stack after both passes genuinely have no greater element anywhere in the circle, so they keep their `-1`.

NOTE THE ANSWER ARRAY STORES VALUES HERE

, unlike the previous problem which stored distances — but the *stack* still holds indices, because that is what you need to write into `out`.

Largest rectangle in a histogram `Hard`

Pattern: Monotonic increasing stack + width from neighbours

Given an array `heights` of bar heights, each of width 1, find the area of the largest rectangle that fits inside the histogram.

Input	Output	Note
`heights = [2,1,5,6,2,3]`	`10`	Bars of height 5 and 6 give 5 × 2 = 10.
`heights = [2,4]`	`4`	

HINTS

1. For each bar, the largest rectangle *using that bar as the limiting height* extends left and right until a strictly shorter bar.
2. So for every bar you need the previous smaller and the next smaller — both are monotonic-stack queries.
3. Keep an increasing stack. When a shorter bar arrives, the popped bar's rectangle is bounded on the right by the current index and on the left by the new stack top.
4. The width after popping index `j` is `i - st.top() - 1`, or `i` when the stack is empty.
5. Append a sentinel height of 0 so every remaining bar gets flushed.

Approach	Idea	Time	Space
All pairs	For every (left, right) pair, find the minimum height and multiply.	`O(n²)`	`O(1)`
Divide and conquer	Split at the minimum bar. O(n log n) average, $O(n^2)$ on a sorted histogram.	`O(n log n)`	`O(n)`
Monotonic increasing stack	One pass; each bar is popped once and its full rectangle computed then.	`O(n)`	`O(n)`

Solution — js

```
function largestRectangleArea(heights) {
  const st = [];       // indices with INCREASING heights
  let best = 0;
  const n = heights.length;

  // i === n acts as a sentinel bar of height 0, flushing the stack
  for (let i = 0; i <= n; i++) {
    const cur = i === n ? 0 : heights[i];

    while (st.length && heights[st[st.length - 1]] >= cur) {
      const h = heights[st.pop()];
      // left bound is the new top (exclusive); right bound is i
      const width = st.length ? i - st[st.length - 1] - 1 : i;
      best = Math.max(best, h * width);
    }
    st.push(i);
  }
  return best;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int largestRectangleArea(vector<int>& heights) {
        stack<int> st;
        int best = 0, n = heights.size();
        for (int i = 0; i <= n; ++i) {
            int cur = (i == n) ? 0 : heights[i];
            while (!st.empty() && heights[st.top()] >= cur) {
                int h = heights[st.top()]; st.pop();
                int width = st.empty() ? i : i - st.top() - 1;
                best = max(best, h * width);
            }
            st.push(i);
        }
        return best;
    }
};
```

Solution — python

```python
class Solution:
    def largestRectangleArea(self, heights: list[int]) -> int:
        st = []
        best = 0
        n = len(heights)
        for i in range(n + 1):
            cur = 0 if i == n else heights[i]
            while st and heights[st[-1]] >= cur:
                h = heights[st.pop()]
                width = i - st[-1] - 1 if st else i
                best = max(best, h * width)
            st.append(i)
        return best
```

Solution — java

```java
class Solution {
    public int largestRectangleArea(int[] heights) {
        Deque<Integer> st = new ArrayDeque<>();
        int best = 0, n = heights.length;
        for (int i = 0; i <= n; i++) {
            int cur = (i == n) ? 0 : heights[i];
            while (!st.isEmpty() && heights[st.peek()] >= cur) {
                int h = heights[st.pop()];
                int width = st.isEmpty() ? i : i - st.peek() - 1;
                best = Math.max(best, h * width);
            }
            st.push(i);
        }
        return best;
    }
}
```

WALKTHROUGH

THE REFRAMING.

Instead of enumerating rectangles, ask for each bar: "if *this* bar is the shortest one in the rectangle, how wide can the rectangle be?" It extends left until a strictly shorter bar and right until a strictly shorter bar. Every maximal rectangle has some shortest bar, so considering each bar in this role covers all of them.

WHY THE STACK GIVES BOTH BOUNDS AT ONCE.

A bar is popped exactly when a shorter bar arrives — that arrival index `i` is its right bound. And because the stack is increasing, whatever is beneath it is the nearest shorter bar to its left. So the width is `i - st.top() - 1`: the span strictly between the two shorter neighbours. When the stack empties, no shorter bar exists to the left, so the rectangle reaches index 0 and the width is simply `i`.

THE SENTINEL.

Running the loop to `i === n` with a virtual height of 0 forces every remaining bar to be popped and measured. Without it, a monotonically increasing histogram like `[1,2,3,4,5]` never pops anything and returns 0.

WHY `>=` RATHER THAN `>`.

With equal heights the popped bar computes a width that stops short, but the *later* equal bar will be popped afterwards and will measure the full span — so the maximum is still found. `[2,2,2]` returns 6 either way; using `>=` just keeps the stack smaller.

Queues: BFS, deques and the monotonic deque

First in, first out — the structure behind every shortest-path-in-an-unweighted-graph problem. Add the ability to push and pop at both ends and you get the sliding-window maximum in linear time.

The pattern

```
QUEUE — enqueue at the back, dequeue from the front.
Its defining property: elements come out in the order
they went in, so BFS explores strictly by DISTANCE.

  THE JAVASCRIPT TRAP: Array.shift() is O(n) because it
  reindexes the whole array. A "linear" BFS built on
  shift() is really O(n^2).

  THE FIX — a head index, never shrinking the array:
    const q = [start];
    let head = 0;
    while (head < q.length) {
        const node = q[head++];
        ...
        q.push(neighbour);
    }
  Memory is not reclaimed until the loop ends, which is
  fine for interview-sized inputs and is what a real
  implementation would do with a ring buffer.

------------------------------------------------------------
DEQUE — push/pop at BOTH ends, all O(1).

  pushFront  popFront
  pushBack   popBack

  C++    std::deque
  Java   ArrayDeque
  Python collections.deque
  JS     an array, using push/pop/shift/unshift —
         with the same O(n) caveat at the front

------------------------------------------------------------
THE MONOTONIC DEQUE — the pattern worth learning here.

PROBLEM: the maximum of every window of size k.
Recomputing the max per window is O(n·k). A heap gives
O(n log k). A deque gives O(n).

THE IDEA: keep indices in the deque so their VALUES are
DECREASING. Then the front is always the window maximum.

  for i in 0..n-1:
     1. DROP FROM THE FRONT anything that has slid out of
        the window:      while (dq[0] <= i - k) popFront
     2. DROP FROM THE BACK anything smaller than a[i] —
        it can never be the maximum again, because a[i]
        is both LARGER and LATER:
                         while (a[dq.back] <= a[i]) popBack
     3. pushBack(i)
     4. once i >= k-1, a[dq[0]] is the window maximum

  [1, 3, -1, -3, 5, 3, 6, 7]   k = 3
   i=0  dq=[0]                 (1)
   i=1  3>1 pop 0, dq=[1]      (3)
   i=2  -1<3 push, dq=[1,2]    (3,-1)     window max 3
   i=3  -3<-1 push, dq=[1,2,3]            window max 3
   i=4  5 pops 3,2,1, dq=[4]              window max 5
   ...                          -> [3,3,5,5,6,7]

WHY IT IS O(n): every index is pushed once and popped at
```

```
    most once. The same amortised argument as the monotonic
    stack (chapter 20).

    THE KEY INSIGHT, worth saying aloud: an element that is
    smaller than a later element is USELESS FOREVER — the
    later one outlives it in every future window and is
    bigger. So it can be discarded immediately.
```

When to reach for it

Shortest path, unweighted

BFS. The first time you reach a node is via a shortest path.

Level-by-level processing

Tree levels, rotting oranges, multi-source spread.

Sliding window max/min

Monotonic deque, O(n).

"Most recent k" / round robin

Plain queue or ring buffer.

Palindrome check on a stream

Deque, comparing both ends.

0-1 BFS

Deque: push weight-0 edges to the front, weight-1 to the back.

Problems

How it shows up

Symptom	Cause
BFS is unexpectedly slow	`shift()` is O(n) — use a head index
Window maximum is stale	Expired indices not dropped from the front
Deque grows without bound	Smaller elements not popped from the back
Off by one on the first window	Record only once `i >= k - 1`
Deque holds values, cannot expire them	Store **indices** so you can test the window bound
Duplicates dropped incorrectly	`<=` vs `<` when popping the back — either works for max, but be consistent
BFS revisits nodes forever	Mark visited when *enqueueing*, not when dequeuing

Check yourself

- ✓ Say why a queue gives shortest paths in an unweighted graph.
- ✓ Explain the `shift()` trap and the head-index fix.
- ✓ Write the monotonic deque loop and its four steps.
- ✓ State the insight that justifies popping from the back.
- ✓ Give the amortised O(n) argument.
- ✓ Say why the deque stores indices rather than values.
- ✓ Explain why visited is marked at enqueue time.

Problems

Sliding window maximum `Hard`

Pattern: Monotonic decreasing deque

Given an array `nums` and a window size `k`, return an array of the maximum value in each window as it slides from left to right.

Input	Output	Note
`nums = [1,3,-1,-3,5,3,6,7], k = 3`	`[3,3,5,5,6,7]`	
`nums = [1], k = 1`	`[1]`	

HINTS

1. Recomputing the maximum per window is O(n·k). A max-heap gets you O(n log k). Linear is possible.
2. Keep a deque of *indices* whose values are decreasing, so the front is always the current maximum.
3. Before using the front, drop indices that have slid out of the window.
4. Before pushing `i`, drop from the back every index whose value is ≤ `nums[i]` — they can never be the maximum again.

Approach	Idea	Time	Space
Max per window	Scan each window.	`O(n·k)`	`O(1)`
Max-heap with lazy deletion	Push (value, index); pop the top while its index is expired.	`O(n log n)`	`O(n)`
Monotonic deque	Each index enters and leaves once.	`O(n)`	`O(k)`

Solution — js

```javascript
function maxSlidingWindow(nums, k) {
  const out = [];
  const dq = [];        // indices; nums[dq] is DECREASING
  let head = 0;         // front index into dq (avoids shift())

  for (let i = 0; i < nums.length; i++) {
    // 1. drop indices that have slid out of the window
    while (head < dq.length && dq[head] <= i - k) head++;

    // 2. drop smaller values from the back — they are useless:
    //    nums[i] is both larger AND later
    while (head < dq.length && nums[dq[dq.length - 1]] <= nums[i]) dq.pop();

    // 3. this index is a candidate
    dq.push(i);

    // 4. once the first full window exists, the front is the max
    if (i >= k - 1) out.push(nums[dq[head]]);
  }
  return out;
}
```

Solution — cpp

```cpp
class Solution {
public:
    vector<int> maxSlidingWindow(vector<int>& nums, int k) {
        vector<int> out;
        deque<int> dq;
        for (int i = 0; i < (int)nums.size(); ++i) {
            while (!dq.empty() && dq.front() <= i - k) dq.pop_front();
            while (!dq.empty() && nums[dq.back()] <= nums[i]) dq.pop_back();
            dq.push_back(i);
            if (i >= k - 1) out.push_back(nums[dq.front()]);
        }
        return out;
    }
};
```

Solution — python

```python
from collections import deque

class Solution:
    def maxSlidingWindow(self, nums: list[int], k: int) -> list[int]:
        out = []
        dq = deque()          # indices, values decreasing
        for i, v in enumerate(nums):
            while dq and dq[0] <= i - k:
                dq.popleft()
            while dq and nums[dq[-1]] <= v:
                dq.pop()
            dq.append(i)
            if i >= k - 1:
                out.append(nums[dq[0]])
        return out
```

Solution — java

```
class Solution {
    public int[] maxSlidingWindow(int[] nums, int k) {
        if (nums.length == 0 || k == 0) return new int[0];
        int[] out = new int[nums.length - k + 1];
        Deque<Integer> dq = new ArrayDeque<>();
        int w = 0;
        for (int i = 0; i < nums.length; i++) {
            while (!dq.isEmpty() && dq.peekFirst() <= i - k) dq.pollFirst();
            while (!dq.isEmpty() && nums[dq.peekLast()] <= nums[i]) dq.pollLast();
            dq.addLast(i);
            if (i >= k - 1) out[w++] = nums[dq.peekFirst()];
        }
        return out;
    }
}
```

WALKTHROUGH

THE DISCARD RULE IS THE WHOLE ALGORITHM.

If `nums[j] ≤ nums[i]` and `j < i`, then index `j` is worthless: every window that still contains `j` also contains `i` (since `i` is later), and `i` holds a value at least as large. So `j` can never be a window maximum again and is dropped immediately. What survives is a decreasing sequence, whose front is by construction the largest value still in play.

TWO DIFFERENT REMOVALS, TWO DIFFERENT REASONS.

The front is popped because of *time* — the index has aged out of the window. The back is popped because of *value* — it has been dominated. Conflating them is the usual bug.

WHY INDICES AND NOT VALUES.

Expiring the front requires knowing *where* an element came from; a deque of raw values cannot tell whether its front is still inside the window.

THE `HEAD` POINTER IN THE JAVASCRIPT VERSION

avoids `shift()`, keeping the whole thing genuinely O(n) rather than O(n·k) in disguise — see the pattern notes above.

Implement a stack using queues `Easy`

Pattern: Structure conversion

Implement a LIFO stack using only FIFO queue operations: push to the back, pop from the front, peek the front, size and empty.

Implement `stackOps(ops, args)`: apply each operation and return the results of the query operations (`"pop"`, `"top"`, `"empty"`) in order.

Input	Output	Note
`ops = ["push","push","top","pop","empty"], args = [[1],[2],[],[],[]]`	`[2,2,false]`	

HINTS

1. The problem is that a queue hands back the *oldest* element but a stack needs the newest.
2. You can make push do the work: after enqueuing the new element, rotate everything before it to the back.
3. Rotating `size - 1` elements puts the newest at the front, so pop and top become trivial.
4. That makes push O(n) and pop O(1) — the reverse trade is also valid.

Approach	Idea	Time	Space
Two queues, costly pop	On pop, move all but one element to the second queue, then take the last. O(n) pop.	`O(n) pop`	`O(n)`
One queue, costly push	Enqueue then rotate. Only one queue needed and pop is O(1).	`O(n) push`	`O(n)`

Solution — js

```
function stackOps(ops, args) {
  const q = [];        // FIFO: push() to back, shift() from front
  const out = [];

  for (let i = 0; i < ops.length; i++) {
    const op = ops[i];
    if (op === "push") {
      q.push(args[i][0]);
      // rotate everything that was already there to the back,
      // so the NEWEST element ends up at the front
      for (let r = 0; r < q.length - 1; r++) q.push(q.shift());
    } else if (op === "pop") {
      out.push(q.shift());
    } else if (op === "top") {
      out.push(q[0]);
    } else if (op === "empty") {
      out.push(q.length === 0);
    }
  }
  return out;
}
```

Solution — cpp

```
class MyStack {
    queue<int> q;
public:
    void push(int x) {
        q.push(x);
        for (int r = 0; r + 1 < (int)q.size(); ++r) { q.push(q.front()); q.pop(); }
    }
    int pop()    { int v = q.front(); q.pop(); return v; }
    int top()    { return q.front(); }
    bool empty() { return q.empty(); }
};
```

Solution — python

```
from collections import deque

class MyStack:
    def __init__(self):
        self.q = deque()

    def push(self, x: int) -> None:
        self.q.append(x)
        for _ in range(len(self.q) - 1):
            self.q.append(self.q.popleft())

    def pop(self) -> int:
        return self.q.popleft()

    def top(self) -> int:
        return self.q[0]

    def empty(self) -> bool:
        return not self.q
```

Solution — java

```
class MyStack {
    private final Queue<Integer> q = new LinkedList<>();
    public void push(int x) {
        q.add(x);
        for (int r = 0; r < q.size() - 1; r++) q.add(q.remove());
    }
    public int pop()      { return q.remove(); }
    public int top()      { return q.peek(); }
    public boolean empty(){ return q.isEmpty(); }
}
```

WALKTHROUGH

THE ROTATION MAKES THE QUEUE LIE ABOUT ITS ORDER.

After pushing 1, the queue is `[1]`. Pushing 2 gives `[1,2]`, then one rotation moves the 1 to the back: `[2,1]`. The front is now the most recently pushed element, which is exactly stack semantics. Pushing 3 gives `[2,1,3]` and two rotations produce `[3,2,1]`.

THE TRADE-OFF IS THE INTERESTING PART.

This version is O(n) push and O(1) pop. The two-queue version reverses it: O(1) push and O(n) pop. Neither is better in the abstract — it depends on which operation dominates. Being able to state both, and pick based on the expected workload, is what the question is really testing.

NOTE THE DISCIPLINE:

only `push` (to the back) and `shift` (from the front) are used. Reaching into the middle of the array, or using `pop()` from the back, would be cheating — the point is to use nothing but FIFO operations.

Heaps: top-K, merging and two-heap median

A structure that gives you the smallest (or largest) element instantly and lets you replace it in log time. Whenever a problem says "kth" or "top K" or "median of a stream", this is the answer.

The pattern

```
A BINARY HEAP is a complete binary tree stored in a flat
array, with the HEAP PROPERTY: every parent is <= (min
heap) or >= (max heap) both of its children.

  index i:   parent  (i-1) >> 1
             left    2i + 1
             right   2i + 2

  min heap        [1, 3, 6, 5, 9, 8]
                       1
                     /   \
                    3     6
                   / \   /
                  5   9 8

NOTE WHAT IT DOES NOT GIVE YOU: the heap is NOT sorted.
Only the ROOT is guaranteed to be the extreme. Anything
asking for full order needs a sort.

OPERATIONS
  peek        O(1)
  push        O(log n)   - append, then SIFT UP
  pop         O(log n)   - swap root with last, shrink,
                           SIFT DOWN
  heapify     O(n)       - building from an array is
                           LINEAR, not n log n

------------------------------------------------------------
THE TOP-K PATTERN - the one that matters most

  "K LARGEST"  -> keep a MIN heap of size k
  "K SMALLEST" -> keep a MAX heap of size k

THAT INVERSION SURPRISES PEOPLE. For the k largest, the
min heap's root is the WEAKEST of your current winners -
the one to evict when something better arrives:

    for (const x of items) {
        heap.push(x);
        if (heap.size() > k) heap.pop();   // drop the
    }                                      // smallest
    // the heap now holds the k largest; its root is the
    // kth largest

  COST O(n log k), and SPACE O(k) - which beats sorting
  (O(n log n), O(n)) when k is small, and is the only
  option for a STREAM you cannot store.

------------------------------------------------------------
THE TWO-HEAP PATTERN - median of a stream

  MAX heap for the lower half, MIN heap for the upper.
  Keep the sizes within one of each other.

     lower (max heap)     upper (min heap)
       ... 3 4 |            | 5 6 ...
           ^ root             ^ root

  median = root of the bigger heap, or the mean of both
  roots when the sizes are equal.
```

```
     Insert: push to one, then move its root to the other to
     restore the ordering, then rebalance the sizes. Always
     push-then-transfer, or an element can end up on the
     wrong side.
```

> **JAVASCRIPT HAS NO BUILT-IN HEAP**
> C++ has `priority_queue`, Java has `PriorityQueue`, Python has `heapq` (a *min* heap — negate values for a max heap). JavaScript has nothing, so you write one. The implementation below is about 25 lines and is worth being able to produce from memory; the problems on this page provide it for you so you can focus on the pattern.

```
class MinHeap {
    constructor(cmp = (a, b) => a - b) { this.a = []; this.cmp = cmp; }
    size()  { return this.a.length; }
    peek()  { return this.a[0]; }

    push(v) {
        this.a.push(v);
        let i = this.a.length - 1;
        while (i > 0) {                       // SIFT UP
            const p = (i - 1) >> 1;
            if (this.cmp(this.a[i], this.a[p]) >= 0) break;
            [this.a[i], this.a[p]] = [this.a[p], this.a[i]];
            i = p;
        }
    }

    pop() {
        const top = this.a[0];
        const last = this.a.pop();
        if (this.a.length) {
            this.a[0] = last;
            let i = 0;                        // SIFT DOWN
            for (;;) {
                const l = 2*i + 1, r = l + 1;
                let m = i;
                if (l < this.a.length && this.cmp(this.a[l], this.a[m]) < 0) m = l;
                if (r < this.a.length && this.cmp(this.a[r], this.a[m]) < 0) m = r;
                if (m === i) break;
                [this.a[i], this.a[m]] = [this.a[m], this.a[i]];
                i = m;
            }
        }
        return top;
    }
}

/* A MAX HEAP is the same class with a flipped comparator: */
new MinHeap((a, b) => b - a);
```

When to reach for it

"Kth largest / smallest"

Size-k heap of the opposite polarity. O(n log k).

"Top K frequent"

Count with a map, then a size-k heap — or bucket sort for O(n).

Merge K sorted lists/arrays

Heap of the K current heads.

Median of a data stream

Two heaps, balanced.

Scheduling / "next event"

Task scheduler, meeting rooms, Dijkstra (ch. 30).

K closest points

Max heap of size k keyed on distance — no need to sort everything.

Problems

How it shows up

Symptom	Cause
Kth largest returns the kth smallest	Wrong heap polarity — k largest needs a *min* heap
Heap grows to n instead of k	Missing the "pop when size exceeds k" step
Expected sorted output, got heap order	A heap orders only the root — sort if full order is needed
Median wrong by one element	Heaps not rebalanced after insertion
Median puts an element on the wrong side	Pushed directly instead of push-then-transfer
Python max-heap misbehaves	`heapq` is min-only — negate on push and on pop
Timeout building a heap	Pushing n times is O(n log n); `heapify` is O(n)

Check yourself

- ✓ Give the parent and child index formulas.
- ✓ State the cost of peek, push, pop and heapify.
- ✓ Say which heap polarity to use for "k largest" and explain why.
- ✓ Compare the heap and sorting approaches to top-K in time and space.
- ✓ Describe the two-heap median invariant and the insertion procedure.
- ✓ Explain what a heap does *not* guarantee.
- ✓ Say how to get a max heap from a min-heap-only library.

Problems

Kth largest element in an array `Medium`

Pattern: Size-k min heap

Given an integer array `nums` and an integer `k`, return the `k`th largest element. Note this is the kth largest in **sorted order**, not the kth distinct value.

A `MinHeap` class is already defined for you — construct it with a comparator, e.g. `new MinHeap((a,b) => a - b)`, and use `push`, `pop`, `peek`, `size`.

Input	Output	Note
`nums = [3,2,1,5,6,4], k = 2`	`5`	
`nums = [3,2,3,1,2,4,5,5,6], k = 4`	`4`	

HINTS

1. Sorting gives the answer in O(n log n). A heap of size k gives O(n log k), which is better when k is small.
2. For the k *largest*, keep a **min** heap of size k — its root is the weakest of your current winners.
3. Push every element; whenever the heap exceeds size k, pop the smallest.
4. At the end the root is the kth largest.

Approach	Idea	Time	Space
Sort and index	Sort descending and take index `k-1`. Perfectly acceptable — state it first.	`O(n log n)`	`O(1)`
Size-k min heap	Keep only the k best seen so far. Works on a stream.	`O(n log k)`	`O(k)`
Quickselect	Partition around a pivot, recurse into one side only. O(n) average, $O(n^2)$ worst.	`O(n) avg`	`O(1)`

Solution — js

```
function findKthLargest(nums, k) {
  const h = new MinHeap((a, b) => a - b);   // MIN heap

  for (const v of nums) {
    h.push(v);
    if (h.size() > k) h.pop();   // evict the weakest winner
  }
  return h.peek();               // root = kth largest
}
```

Solution — cpp

```
class Solution {
public:
    int findKthLargest(vector<int>& nums, int k) {
        priority_queue<int, vector<int>, greater<int>> h;  // MIN heap
        for (int v : nums) {
            h.push(v);
            if ((int)h.size() > k) h.pop();
        }
        return h.top();
    }
};
```

Solution — python

```
import heapq

class Solution:
    def findKthLargest(self, nums: list[int], k: int) -> int:
        h = []                       # heapq is a MIN heap
        for v in nums:
            heapq.heappush(h, v)
            if len(h) > k:
                heapq.heappop(h)
        return h[0]
        # or simply: return heapq.nlargest(k, nums)[-1]
```

Solution — java

```
class Solution {
    public int findKthLargest(int[] nums, int k) {
        PriorityQueue<Integer> h = new PriorityQueue<>();   // MIN heap
        for (int v : nums) {
            h.offer(v);
            if (h.size() > k) h.poll();
        }
        return h.peek();
    }
}
```

WALKTHROUGH

WHY A MIN HEAP FOR THE LARGEST.

The heap holds the k best elements seen so far. When a new candidate arrives you want to discard the *worst* of the current winners — and that is the smallest of them, which is exactly what a min heap exposes in O(1). A max heap would give you the strongest, which is the one you never want to remove.

WHEN TO PREFER THIS OVER SORTING.

Sorting is simpler and fine for a one-off array. The heap wins when `k ≪ n` (O(n log k) vs O(n log n)), when the data arrives as a *stream* that cannot be stored, or when memory is bounded — you hold k elements rather than n. Say all three; the streaming point is the one interviewers are usually fishing for.

QUICKSELECT IS THE O(N)-AVERAGE ANSWER

and worth naming, but its $O(n^2)$ worst case and the fiddly partition make the heap the safer thing to write under time pressure.

Top K frequent elements `Medium`

Pattern: Frequency map + size-k heap

Given an integer array `nums` and an integer `k`, return the `k` most frequent elements. Return them in any order.

Input	Output	Note
`nums = [1,1,1,2,2,3], k = 2`	`[1,2]`	
`nums = [1], k = 1`	`[1]`	

HINTS

1. First count occurrences with a hash map (chapter 13).
2. Then it is a top-K problem over the (value, count) pairs, keyed on count.
3. Keep a min heap of size k ordered by frequency.
4. There is also an O(n) solution: bucket by frequency, since no count can exceed n.

Approach	Idea	Time	Space
Sort by frequency	Count, then sort the entries. Simple.	`O(n log n)`	`O(n)`
Size-k min heap	Heap keyed on count, evicting the least frequent.	`O(n log k)`	`O(n)`
Bucket sort	Index buckets by frequency 1..n and read from the top. Linear.	`O(n)`	`O(n)`

Solution — js

```
function topKFrequent(nums, k) {
  const freq = new Map();
  for (const v of nums) freq.set(v, (freq.get(v) ?? 0) + 1);

  // MIN heap keyed on count: root is the least frequent kept
  const h = new MinHeap((a, b) => a[1] - b[1]);
  for (const entry of freq) {          // entry = [value, count]
    h.push(entry);
    if (h.size() > k) h.pop();
  }

  const out = [];
  while (h.size()) out.push(h.pop()[0]);
  return out;
}
```

Solution — cpp

```cpp
class Solution {
public:
    vector<int> topKFrequent(vector<int>& nums, int k) {
        unordered_map<int,int> freq;
        for (int v : nums) ++freq[v];
        using P = pair<int,int>;                 // (count, value)
        priority_queue<P, vector<P>, greater<P>> h;
        for (auto& [v, c] : freq) {
            h.push({c, v});
            if ((int)h.size() > k) h.pop();
        }
        vector<int> out;
        while (!h.empty()) { out.push_back(h.top().second); h.pop(); }
        return out;
    }
};
```

Solution — python

```python
import heapq
from collections import Counter

class Solution:
    def topKFrequent(self, nums: list[int], k: int) -> list[int]:
        freq = Counter(nums)
        return [v for v, _ in freq.most_common(k)]
        # explicit heap version:
        # h = []
        # for v, c in freq.items():
        #     heapq.heappush(h, (c, v))
        #     if len(h) > k: heapq.heappop(h)
        # return [v for _, v in h]
```

Solution — java

```java
class Solution {
    public int[] topKFrequent(int[] nums, int k) {
        Map<Integer,Integer> freq = new HashMap<>();
        for (int v : nums) freq.merge(v, 1, Integer::sum);
        PriorityQueue<int[]> h = new PriorityQueue<>((a, b) -> a[1] - b[1]);
        for (var e : freq.entrySet()) {
            h.offer(new int[]{e.getKey(), e.getValue()});
            if (h.size() > k) h.poll();
        }
        int[] out = new int[h.size()];
        for (int i = 0; i < out.length; i++) out[i] = h.poll()[0];
        return out;
    }
}
```

WALKTHROUGH

TWO PHASES, TWO DATA STRUCTURES.

Counting is a hash-map job; selecting the top k is a heap job. Recognising that a problem decomposes into two familiar patterns — rather than being one new thing — is most of the skill.

THE HEAP IS KEYED ON THE COUNT, NOT THE VALUE

, which is why the entries are pairs. Getting the comparator to read `a[1] - b[1]` rather than `a[0] - b[0]` is the detail to check.

THE O(N) BUCKET ALTERNATIVE IS WORTH DESCRIBING.

Since a frequency can be at most `n`, make an array of `n+1` buckets and put each value into `buckets[count]`. Then walk from the highest bucket downwards collecting values until you have k. No comparisons, no log factor — the same trick as counting sort in chapter 11. Mentioning it after giving the heap solution is a strong finish.

Find median from a data stream `Hard`

Pattern: Two balanced heaps

Design a structure that supports adding numbers from a stream and querying the median so far.

Implement `medianStream(ops, args)` where each op is `"add"` (with one argument) or `"median"`; return the results of the `"median"` queries in order.

The median of an even-sized set is the mean of the two middle values.

Input	Output	Note
`ops = ["add","add","median","add","median"], args = [[1],[2],[],[3],[]]`	`[1.5,2]`	

HINTS

1. Keeping a sorted array costs O(n) per insertion. You only ever need the *middle*, not the whole order.
2. Split the data at the median: a max heap for the lower half and a min heap for the upper half.
3. The two roots are the two candidates for the median, both reachable in O(1).
4. To insert safely, always push into one heap and move its root across, then rebalance so the sizes differ by at most one.

Approach	Idea	Time	Space
Sorted array with insertion	Binary search the position, then shift. Query is O(1) but insert is O(n).	`O(n) add`	`O(n)`
Two heaps	Lower half in a max heap, upper half in a min heap, sizes balanced.	`O(log n) add, O(1) query`	`O(n)`

Solution — js

```
function medianStream(ops, args) {
  const lower = new MinHeap((a, b) => b - a);  // MAX heap: lower half
  const upper = new MinHeap((a, b) => a - b);  // MIN heap: upper half
  const out = [];

  const add = (v) => {
    // push to lower, then hand its largest to upper —
    // this guarantees v lands on the correct side
    lower.push(v);
    upper.push(lower.pop());
    // rebalance: lower may hold one extra, never fewer
    if (upper.size() > lower.size()) lower.push(upper.pop());
  };

  const median = () =>
    lower.size() > upper.size()
      ? lower.peek()
      : (lower.peek() + upper.peek()) / 2;

  for (let i = 0; i < ops.length; i++) {
    if (ops[i] === "add") add(args[i][0]);
    else out.push(median());
  }
  return out;
}
```

Solution — cpp

```
class MedianFinder {
    priority_queue<int> lower;                                  // max heap
    priority_queue<int, vector<int>, greater<int>> upper;       // min heap
public:
    void addNum(int v) {
        lower.push(v);
        upper.push(lower.top()); lower.pop();
        if (upper.size() > lower.size()) { lower.push(upper.top()); upper.pop(); }
    }
    double findMedian() {
        if (lower.size() > upper.size()) return lower.top();
        return (lower.top() + upper.top()) / 2.0;
    }
};
```

Solution — python

```python
import heapq

class MedianFinder:
    def __init__(self):
        self.lower = []   # max heap via negation
        self.upper = []   # min heap

    def addNum(self, v: int) -> None:
        heapq.heappush(self.lower, -v)
        heapq.heappush(self.upper, -heapq.heappop(self.lower))
        if len(self.upper) > len(self.lower):
            heapq.heappush(self.lower, -heapq.heappop(self.upper))

    def findMedian(self) -> float:
        if len(self.lower) > len(self.upper):
            return -self.lower[0]
        return (-self.lower[0] + self.upper[0]) / 2
```

Solution — java

```java
class MedianFinder {
    private final PriorityQueue<Integer> lower =
        new PriorityQueue<>(Comparator.reverseOrder());   // max heap
    private final PriorityQueue<Integer> upper =
        new PriorityQueue<>();                            // min heap

    public void addNum(int v) {
        lower.offer(v);
        upper.offer(lower.poll());
        if (upper.size() > lower.size()) lower.offer(upper.poll());
    }
    public double findMedian() {
        if (lower.size() > upper.size()) return lower.peek();
        return (lower.peek() + upper.peek()) / 2.0;
    }
}
```

WALKTHROUGH

THE INVARIANT:

every element of `lower` is ≤ every element of `upper`, and `lower.size()` equals `upper.size()` or exceeds it by exactly one. Under that invariant the median is either `lower`'s root (odd count) or the mean of the two roots (even count) — both O(1).

WHY PUSH-THEN-TRANSFER RATHER THAN CHOOSING A SIDE.

The naive version compares `v` against the current median and pushes to whichever heap seems right, then rebalances. It works, but the comparison has several edge cases (empty heaps, equal values) and is easy to get subtly wrong. Pushing unconditionally into `lower` and immediately moving its largest into `upper` is unconditionally correct: whatever the new element is, the largest of the lower half ends up in the upper half, so the ordering invariant is restored automatically. The only thing left to fix is the size balance, which is one comparison.

THE CONVENTION CHOICE.

Here `lower` is allowed to be the bigger heap, so an odd count means the median is its root. Choosing the opposite convention works equally well provided the query code agrees — mismatching them is the classic off-by-one in this problem, which the odd-count tests catch.

PYTHON HAS NO MAX HEAP

, so `lower` stores negated values and negates again on read. That is worth mentioning if you write Python in the interview.

Trees: traversals, iterative and recursive

Four ways to visit every node. Choosing the right one turns most tree problems into three lines — and the interviewer will ask you for the iterative version.

The four traversals

```
THE TREE USED THROUGHOUT:

          1
        /   \
       2     3
      / \
     4   5

DEPTH FIRST — the position of "visit" is the only
difference:

  PREORDER    node, left, right      1 2 4 5 3
              -> COPY a tree, serialise, root-first work
  INORDER     left, node, right      4 2 5 1 3
              -> SORTED order in a BST (chapter 25)
  POSTORDER   left, right, node      4 5 2 3 1
              -> DELETE a tree, compute sizes/heights,
                 any work needing CHILD RESULTS FIRST

BREADTH FIRST — level by level, with a queue:

  LEVEL ORDER                        1 2 3 4 5
              -> shortest path, level-by-level output,
                 "closest" anything

THE CHOICE IS DETERMINED BY WHEN YOU NEED INFORMATION:

  need PARENT info before children   -> PREORDER
    (depth, path so far, passing a value down)
  need CHILD results before parent   -> POSTORDER
    (height, subtree sums, "is this subtree valid?")
  need SORTED order in a BST         -> INORDER
  need DISTANCE from the root        -> BFS

THAT MAPPING SOLVES MOST TREE PROBLEMS BY ITSELF. If you
are stuck on a tree question, ask: does this node need
something from above, or something from below?

COSTS
  every traversal   O(n) time
  recursion         O(h) space — h = height
                    O(log n) balanced, O(n) SKEWED
  BFS               O(w) space — w = maximum width,
                    which is up to n/2 for a full tree
```

The templates

```
/* --- RECURSIVE: all three, one shape --- */
function dfs(node, out) {
    if (!node) return;
    // out.push(node.val);          <-- PREORDER here
    dfs(node.left, out);
    // out.push(node.val);          <-- INORDER here
    dfs(node.right, out);
    // out.push(node.val);          <-- POSTORDER here
}

/* --- ITERATIVE PREORDER: a stack, push RIGHT first --- */
function preorder(root) {
    if (!root) return [];
    const out = [], st = [root];
    while (st.length) {
        const n = st.pop();
        out.push(n.val);
        if (n.right) st.push(n.right);   // right first, so
        if (n.left)  st.push(n.left);    // LEFT pops first
    }
    return out;
}

/* --- ITERATIVE INORDER: go left, then visit, then right --- */
function inorder(root) {
    const out = [], st = [];
    let cur = root;
    while (cur || st.length) {
        while (cur) { st.push(cur); cur = cur.left; }  // dive left
        cur = st.pop();
        out.push(cur.val);                             // VISIT
        cur = cur.right;                               // then right
    }
    return out;
}

/* --- ITERATIVE POSTORDER: the trick --- */
    Do a MODIFIED PREORDER (node, RIGHT, left), then REVERSE
    the result. node-right-left reversed is left-right-node.
    Far easier than tracking whether each node's children
    have been processed.

/* --- BFS: a queue, one LEVEL per outer iteration --- */
function levelOrder(root) {
    if (!root) return [];
    const out = [], q = [root];
    while (q.length) {
        const size = q.length;        // FIX the level size FIRST
        const level = [];
        for (let i = 0; i < size; i++) {
            const n = q.shift();
            level.push(n.val);
            if (n.left)  q.push(n.left);
            if (n.right) q.push(n.right);
        }
        out.push(level);
    }
    return out;
}
/* CAPTURING `size` BEFORE THE INNER LOOP IS THE WHOLE
```

```
    TRICK — it separates the levels. Without it you get a
    flat list.

    NOTE: Array.shift() is O(n) in JavaScript, so a large BFS
    should use an index pointer instead of shift (chapter 03).
    For interview-sized inputs shift is fine, but say that
    you know.                                              */
```

Problems

How it shows up

Symptom	Cause
BFS returns one flat list	Level size not captured before the inner loop
Iterative preorder is mirrored	Pushed left before right — the stack reverses order
Stack overflow on a large tree	Skewed tree, O(n) recursion depth — go iterative
Null children crash	Missing the `if (!node) return` base case
Inorder of a BST is not sorted	Visiting in the wrong position, or it is not a valid BST
Height off by one	Decide whether a leaf has height 0 or 1, and stay consistent
BFS very slow on a wide tree	`shift()` is O(n) — use a head index
Result accumulates across calls	Output array declared outside and not reset

Check yourself

- ✓ Give all four traversals of the example tree from memory.
- ✓ State which traversal to use when a node needs information from above versus below.
- ✓ Write iterative preorder and explain the push order.
- ✓ Write iterative inorder and explain the dive-left loop.
- ✓ Give the postorder trick and why it works.
- ✓ Write level-order and explain why the level size is captured first.
- ✓ State the space complexity of DFS on a balanced versus a skewed tree.
- ✓ Say why `shift()` is a problem in a large BFS.

Problems

Binary tree inorder traversal `Easy`

Pattern: Inorder, iterative

Given the root of a binary tree, return the **inorder** traversal of its node values.

The recursive version is three lines — so write the **iterative** one, which is what gets asked as the follow-up.

Trees are given in level order with `null` for a missing child.

Input	Output	Note
`root = [1,null,2,3]`	`[1,3,2]`	
`root = []`	`[]`	
`root = [1,2,3,4,5]`	`[4,2,5,1,3]`	

HINTS

1. Use an explicit stack to simulate what recursion does for you.
2. From any node, first push everything down the left spine. Then pop, visit, and move to the right child.
3. The loop continues while there is a current node *or* the stack is non-empty — both conditions are needed.

Approach	Idea	Time	Space
Recursive	Recurse left, visit, recurse right.	`O(n)`	`O(h)`
Iterative with a stack	Dive left pushing as you go; pop, visit, then switch to the right subtree.	`O(n)`	`O(h)`
Morris traversal	Thread the tree using spare right pointers for O(1) space. Worth naming; rarely required.	`O(n)`	`O(1)`

Solution — js

```
function inorderTraversal(root) {
  const out = [], st = [];
  let cur = root;
  while (cur || st.length) {
    while (cur) {          // dive as far left as possible
      st.push(cur);
      cur = cur.left;
    }
    cur = st.pop();        // leftmost unvisited node
    out.push(cur.val);     // VISIT
    cur = cur.right;       // now handle its right subtree
  }
  return out;
}
```

Solution — cpp

```
class Solution {
public:
    vector<int> inorderTraversal(TreeNode* root) {
        vector<int> out;
        stack<TreeNode*> st;
        TreeNode* cur = root;
        while (cur || !st.empty()) {
            while (cur) { st.push(cur); cur = cur->left; }
            cur = st.top(); st.pop();
            out.push_back(cur->val);
            cur = cur->right;
        }
        return out;
    }
};
```

Solution — python

```python
class Solution:
    def inorderTraversal(self, root: TreeNode) -> list[int]:
        out, st, cur = [], [], root
        while cur or st:
            while cur:
                st.append(cur)
                cur = cur.left
            cur = st.pop()
            out.append(cur.val)
            cur = cur.right
        return out
```

Solution — java

```java
class Solution {
    public List<Integer> inorderTraversal(TreeNode root) {
        List<Integer> out = new ArrayList<>();
        Deque<TreeNode> st = new ArrayDeque<>();
        TreeNode cur = root;
        while (cur != null || !st.isEmpty()) {
            while (cur != null) { st.push(cur); cur = cur.left; }
            cur = st.pop();
            out.add(cur.val);
            cur = cur.right;
        }
        return out;
    }
}
```

WALKTHROUGH

WHY BOTH LOOP CONDITIONS ARE NEEDED.

`cur` non-null means there is a subtree still to descend into. A non-empty stack means there are ancestors still waiting to be visited. After visiting a leaf, `cur` becomes `null` but the stack still holds its ancestors — dropping the `st.length` check would stop early. Conversely, at the very start the stack is empty but `cur` is the root.

WHY THIS ORDER GIVES SORTED OUTPUT ON A BST:

everything in the left subtree is smaller and everything in the right is larger, so visiting left-node-right emits values in increasing order. That single fact powers most BST problems (chapter 25).

Binary tree level order traversal `Medium`

Pattern: BFS with level separation

Given the root of a binary tree, return its level order traversal as an array of arrays — one inner array per level, left to right.

Input	Output	Note
`root = [3,9,20,null,null,15,7]`	`[[3],[9,20],[15,7]]`	
`root = [1]`	`[[1]]`	
`root = []`	`[]`	

HINTS

1. A queue gives you level order, but a plain queue loop produces one flat list.
2. Capture `q.length` into a variable *before* the inner loop — that is exactly the number of nodes on the current level.
3. Enqueue children during the inner loop; they belong to the next level and must not be counted in this one.

Approach	Idea	Time	Space
DFS with a depth parameter	Recurse carrying the depth and append into `out[depth]`. Works, and is O(h) space.	`O(n)`	`O(h)`
BFS with a fixed level size	Standard queue BFS; snapshot the queue length at the start of each level.	`O(n)`	`O(w)`

Solution — js

```
function levelOrder(root) {
  if (!root) return [];
  const out = [];
  const q = [root];
  let head = 0;                      // index instead of shift()

  while (head < q.length) {
    const size = q.length - head;    // FIX this level's size
    const level = [];
    for (let i = 0; i < size; i++) {
      const n = q[head++];
      level.push(n.val);
      if (n.left)  q.push(n.left);
      if (n.right) q.push(n.right);
    }
    out.push(level);
  }
  return out;
}
```

Solution — cpp

```cpp
class Solution {
public:
    vector<vector<int>> levelOrder(TreeNode* root) {
        if (!root) return {};
        vector<vector<int>> out;
        queue<TreeNode*> q;
        q.push(root);
        while (!q.empty()) {
            int size = q.size();
            vector<int> level;
            for (int i = 0; i < size; ++i) {
                TreeNode* n = q.front(); q.pop();
                level.push_back(n->val);
                if (n->left)  q.push(n->left);
                if (n->right) q.push(n->right);
            }
            out.push_back(level);
        }
        return out;
    }
};
```

Solution — python

```python
from collections import deque

class Solution:
    def levelOrder(self, root: TreeNode) -> list[list[int]]:
        if not root:
            return []
        out, q = [], deque([root])
        while q:
            level = []
            for _ in range(len(q)):      # snapshot the size
                n = q.popleft()
                level.append(n.val)
                if n.left:  q.append(n.left)
                if n.right: q.append(n.right)
            out.append(level)
        return out
```

Solution — java

```java
class Solution {
    public List<List<Integer>> levelOrder(TreeNode root) {
        List<List<Integer>> out = new ArrayList<>();
        if (root == null) return out;
        Deque<TreeNode> q = new ArrayDeque<>();
        q.add(root);
        while (!q.isEmpty()) {
            int size = q.size();
            List<Integer> level = new ArrayList<>();
            for (int i = 0; i < size; i++) {
                TreeNode n = q.poll();
                level.add(n.val);
                if (n.left  != null) q.add(n.left);
                if (n.right != null) q.add(n.right);
            }
            out.add(level);
        }
        return out;
    }
}
```

WALKTHROUGH

THE `SIZE` SNAPSHOT IS THE ENTIRE TECHNIQUE.

The queue grows while you are draining it, so `q.length` is a moving target. Capturing it once fixes the boundary between "this level" and "the next".

NOTE THE JAVASCRIPT SOLUTION USES A HEAD INDEX RATHER THAN `SHIFT()`.

`Array.shift()` is O(n) because it reindexes the whole array, so a BFS built on it is $O(n^2)$ on a wide tree. Using `q[head++]` keeps it O(n) at the cost of not reclaiming memory — the right trade for an interview, and worth mentioning aloud.

THIS TEMPLATE GENERALISES DIRECTLY:

zigzag order (reverse alternate levels), right side view (take the last element of each level), maximum level sum, and level averages are all this loop with one line changed.

Maximum depth of a binary tree Easy

Pattern: Postorder — children first

Given the root of a binary tree, return its maximum depth: the number of nodes along the longest path from the root down to a leaf.

Input	Output	Note
`root = [3,9,20,null,null,15,7]`	`3`	
`root = [1,null,2]`	`2`	
`root = []`	`0`	

HINTS

1. The depth of a node depends on its children, so this is postorder: compute both subtrees, then combine.
2. An empty tree has depth 0. That is the base case and it makes everything else fall out.
3. depth(node) = 1 + max(depth(left), depth(right)).

Approach	Idea	Time	Space
Recursive postorder	Three lines. The definition is the algorithm.	`O(n)`	`O(h)`
BFS counting levels	Level-order traversal, incrementing a counter per level. Useful when recursion depth is a concern.	`O(n)`	`O(w)`

Solution — js

```
function maxDepth(root) {
  if (!root) return 0;                       // base case
  return 1 + Math.max(maxDepth(root.left),   // children FIRST
                      maxDepth(root.right));
}
```

Solution — cpp

```
class Solution {
public:
    int maxDepth(TreeNode* root) {
        if (!root) return 0;
        return 1 + max(maxDepth(root->left), maxDepth(root->right));
    }
};
```

Solution — python

```
class Solution:
    def maxDepth(self, root: TreeNode) -> int:
        if not root:
            return 0
        return 1 + max(self.maxDepth(root.left), self.maxDepth(root.right))
```

Solution — java

```
class Solution {
    public int maxDepth(TreeNode root) {
        if (root == null) return 0;
        return 1 + Math.max(maxDepth(root.left), maxDepth(root.right));
    }
}
```

WALKTHROUGH

THIS IS THE SHAPE OF NEARLY EVERY RECURSIVE TREE PROBLEM

(chapter 24): a base case for `null`, a recursive call on each child, and a combine step. Getting comfortable with "what does each child return, and how do I combine it?" is the whole skill.

THE SPACE COMPLEXITY IS O(H), NOT O(1).

The call stack holds one frame per level, so a balanced tree costs O(log n) and a completely skewed one costs O(n). The test `[1,2,null,3,null,4]` is a left-leaning chain — on a tree of a million such nodes this would overflow the stack, which is exactly why the BFS alternative is worth knowing.

Trees: the recursive pattern

Almost every tree problem is the same three lines: a base case, a call on each child, and a combine step. The skill is deciding what each child should return.

The pattern

```
THE UNIVERSAL SHAPE:

  function solve(node) {
      if (!node) return BASE;              // 1. base case
      const L = solve(node.left);          // 2. recurse
      const R = solve(node.right);
      return COMBINE(L, R, node.val);      // 3. combine
  }

THE ONLY QUESTION THAT MATTERS:

  WHAT SHOULD A SUBTREE REPORT TO ITS PARENT?

Answer that and the code writes itself. Examples:

  height            report the height below me
  sum               report the subtree sum
  "is this a BST?"  report (isBST, min, max)
  diameter          report the height, and record the
                    best diameter in an outer variable
  balanced?         report the height, or -1 for
                    "already unbalanced"

------------------------------------------------------------
THE TWO DIRECTIONS OF INFORMATION

  TOP-DOWN (preorder): the parent passes context DOWN as
  a parameter.
      dfs(node, depth)      dfs(node, pathSoFar)
      dfs(node, lowerBound, upperBound)

  BOTTOM-UP (postorder): the child returns a result UP.
      const h = 1 + max(dfs(left), dfs(right));

  MANY PROBLEMS NEED BOTH. Validating a BST passes bounds
  DOWN; computing the diameter sends heights UP. When you
  are stuck, ask which direction the missing information
  travels.

------------------------------------------------------------
THE "GLOBAL BEST + LOCAL RETURN" IDIOM

Some problems ask for the best value ANYWHERE in the tree,
but the recursion must return something DIFFERENT to be
composable. Keep the answer outside:

  let best = -Infinity;

  function gain(node) {
      if (!node) return 0;
      const L = Math.max(gain(node.left), 0);   // drop
      const R = Math.max(gain(node.right), 0);  // negatives
      best = Math.max(best, node.val + L + R);  // path
                                                // THROUGH me
      return node.val + Math.max(L, R);         // path
  }                                             // ENDING at me

THE TWO EXPRESSIONS ARE DIFFERENT AND BOTH ARE NEEDED.
A path through a node uses both children; a path handed
to a parent may use only one, or the parent could not
```

```
    extend it. Confusing them is the classic bug in maximum
    path sum and in diameter.
```

When to reach for it

Any aggregate over a subtree

Height, size, sum, count of something. Pure bottom-up.

Structural comparison

Same tree, symmetric tree, subtree of another — recurse on pairs of nodes.

Path questions

Root-to-leaf sums pass context down; any-to-any paths use the global-best idiom.

Validation with constraints

Pass the allowed range down (chapter 25).

Lowest common ancestor

Return the node found, or null; a node seeing both sides non-null is the answer.

Tree modification

Invert, flatten, prune — return the new subtree root.

Problems

How it shows up

Symptom	Cause
Crash on a null child	Missing base case
Diameter or path sum too large	Returned the "through me" value instead of the "ending at me" value
Negative values ruin a path sum	Child contributions not floored at 0
Answer only correct through the root	Global best never updated at non-root nodes
BST validation accepts a bad tree	Compared only against the immediate parent, not an inherited range
Stack overflow	Skewed tree, O(n) depth — convert to iterative (ch. 23)
Result accumulates between calls	Global mutable state not reset

Check yourself

- ✓ Write the universal three-step shape.
- ✓ State the single question that determines the recursion.
- ✓ Contrast information travelling down versus up, with an example of each.

- ✓ Explain the global-best idiom and why two different expressions are needed.
- ✓ Say why child contributions are clamped at zero in path-sum problems.
- ✓ Give the space complexity and when it becomes a problem.

Problems

Invert a binary tree Easy

Pattern: Bottom-up modification

Given the root of a binary tree, invert it — swap every left and right child — and return the root.

Input	Output	Note
`root = [4,2,7,1,3,6,9]`	`[4,7,2,9,6,3,1]`	
`root = [2,1,3]`	`[2,3,1]`	
`root = []`	`[]`	

HINTS

1. Invert each subtree, then swap the two children of the current node.
2. The base case is a null node — return it unchanged.
3. The order of "swap" and "recurse" does not matter here, as long as both happen.

Approach	Idea	Time	Space
Recursive	Swap children, recurse into both.	`O(n)`	`O(h)`
Iterative BFS or DFS	Same swap, driven by an explicit queue or stack. Avoids deep recursion.	`O(n)`	`O(n)`

Solution — js

```
function invertTree(root) {
  if (!root) return null;                 // base case

  const left  = invertTree(root.left);    // invert each side
  const right = invertTree(root.right);

  root.left  = right;                     // then swap them
  root.right = left;
  return root;
}
```

Solution — cpp

```
class Solution {
public:
    TreeNode* invertTree(TreeNode* root) {
        if (!root) return nullptr;
        TreeNode* l = invertTree(root->left);
        TreeNode* r = invertTree(root->right);
        root->left = r;
        root->right = l;
        return root;
    }
};
```

Solution — python

```
class Solution:
    def invertTree(self, root: TreeNode) -> TreeNode:
        if not root:
            return None
        left = self.invertTree(root.left)
        right = self.invertTree(root.right)
        root.left, root.right = right, left
        return root
```

Solution — java

```
class Solution {
    public TreeNode invertTree(TreeNode root) {
        if (root == null) return null;
        TreeNode l = invertTree(root.left);
        TreeNode r = invertTree(root.right);
        root.left = r;
        root.right = l;
        return root;
    }
}
```

WALKTHROUGH

THE SIMPLEST POSSIBLE INSTANCE OF THE PATTERN.

Base case: null returns null. Recurse: invert each side. Combine: attach them the other way round. Nothing is reported upward except the subtree root itself.

WHY THE ORDER DOES NOT MATTER HERE.

Swapping before recursing works equally well, because the recursion is applied to whatever ends up in each slot and the operation is symmetric. That is unusual — in most tree problems the combine step genuinely depends on the children's *results*, so it must come after. Do not generalise from this one.

THE ASYMMETRIC TESTS MATTER:

`[1,2]` has only a left child and must become `[1,null,2]`. A solution that only swaps when both children exist passes the symmetric tests and fails these.

Balanced binary tree Easy

Pattern: Height with an early-exit sentinel

Given a binary tree, determine whether it is **height-balanced**: for every node, the heights of its two subtrees differ by at most 1.

Input	Output	Note
`root = [3,9,20,null,null,15,7]`	`true`	
`root = [1,2,2,3,3,null,null,4,4]`	`false`	
`root = []`	`true`	

HINTS

1. The naive version computes the height at every node, which recomputes the same subtrees repeatedly — $O(n^2)$.
2. A single postorder pass can compute the height *and* detect imbalance at the same time.
3. Use a sentinel: return `-1` to mean "this subtree is already unbalanced" and propagate it upward immediately.

Approach	Idea	Time	Space
Height at every node	Check the balance condition at each node, recomputing heights. Correct but quadratic on a skewed tree.	`O(n²)`	`O(h)`
Height with a −1 sentinel	One postorder pass; imbalance short-circuits all the way up.	`O(n)`	`O(h)`

Solution — js

```
function isBalanced(root) {
  // returns the height, or -1 meaning "already unbalanced"
  function height(node) {
    if (!node) return 0;

    const l = height(node.left);
    if (l === -1) return -1;              // propagate failure

    const r = height(node.right);
    if (r === -1) return -1;

    if (Math.abs(l - r) > 1) return -1;   // fail here
    return 1 + Math.max(l, r);
  }
  return height(root) !== -1;
}
```

Solution — cpp

```
class Solution {
    int height(TreeNode* n) {
        if (!n) return 0;
        int l = height(n->left);
        if (l == -1) return -1;
        int r = height(n->right);
        if (r == -1) return -1;
        if (abs(l - r) > 1) return -1;
        return 1 + max(l, r);
    }
public:
    bool isBalanced(TreeNode* root) { return height(root) != -1; }
};
```

Solution — python

```
class Solution:
    def isBalanced(self, root: TreeNode) -> bool:
        def height(n):
            if not n:
                return 0
            l = height(n.left)
            if l == -1:
                return -1
            r = height(n.right)
            if r == -1:
                return -1
            if abs(l - r) > 1:
                return -1
            return 1 + max(l, r)
        return height(root) != -1
```

Solution — java

```
class Solution {
    public boolean isBalanced(TreeNode root) { return height(root) != -1; }
    private int height(TreeNode n) {
        if (n == null) return 0;
        int l = height(n.left);
        if (l == -1) return -1;
        int r = height(n.right);
        if (r == -1) return -1;
        if (Math.abs(l - r) > 1) return -1;
        return 1 + Math.max(l, r);
    }
}
```

WALKTHROUGH

THE SENTINEL DOES TWO JOBS AT ONCE.

A single return value carries both "how tall am I?" and "is anything below me broken?", which is what collapses two passes into one. Because `-1` can never be a real height, there is no ambiguity.

WHY THE NAIVE VERSION IS QUADRATIC.

Checking balance at a node calls `height` on both subtrees, and then the recursion repeats that work at every descendant. On a completely skewed tree of n nodes that is `n + (n−1) + … = O(n²)`. Being able to name that cost, and then fix it, is the point of the problem.

NOTE THE EARLY RETURNS ARE PLACED BETWEEN THE TWO RECURSIVE CALLS

, so a failure on the left avoids exploring the right subtree at all. Not required for correctness, but it is the natural way to write it and it does save work.

Diameter of a binary tree Easy

Pattern: Global best + local return

Given the root of a binary tree, return the length of its **diameter**: the number of edges on the longest path between any two nodes. The path need not pass through the root.

Input	Output	Note
`root = [1,2,3,4,5]`	`3`	The path 4 → 2 → 1 → 3 has 3 edges.
`root = [1,2]`	`1`	
`root = []`	`0`	

HINTS

1. For any node, the longest path *through* it is `leftHeight + rightHeight` edges.
2. But that value cannot be returned to the parent — a parent can only extend a path down **ONE** side.
3. So return the height, and record the best diameter in a variable outside the recursion.

Approach	Idea	Time	Space
Height at every node	Compute `left + right` at each node, recomputing heights each time.	`O(n²)`	`O(h)`
Global best + height return	One postorder pass; update the best while returning the height.	`O(n)`	`O(h)`

Solution — js

```javascript
function diameterOfBinaryTree(root) {
  let best = 0;

  // returns the number of EDGES on the longest downward path
  function height(node) {
    if (!node) return 0;

    const l = height(node.left);
    const r = height(node.right);

    // path THROUGH this node joins both sides
    best = Math.max(best, l + r);

    // path ENDING at this node can only use ONE side
    return 1 + Math.max(l, r);
  }

  height(root);
  return best;
}
```

Solution — cpp

```cpp
class Solution {
    int best = 0;
    int height(TreeNode* n) {
        if (!n) return 0;
        int l = height(n->left), r = height(n->right);
        best = max(best, l + r);
        return 1 + max(l, r);
    }
public:
    int diameterOfBinaryTree(TreeNode* root) {
        best = 0;
        height(root);
        return best;
    }
};
```

Solution — python

```python
class Solution:
    def diameterOfBinaryTree(self, root: TreeNode) -> int:
        self.best = 0

        def height(n):
            if not n:
                return 0
            l = height(n.left)
            r = height(n.right)
            self.best = max(self.best, l + r)
            return 1 + max(l, r)

        height(root)
        return self.best
```

Solution — java

```
class Solution {
    private int best;
    public int diameterOfBinaryTree(TreeNode root) {
        best = 0;
        height(root);
        return best;
    }
    private int height(TreeNode n) {
        if (n == null) return 0;
        int l = height(n.left), r = height(n.right);
        best = Math.max(best, l + r);
        return 1 + Math.max(l, r);
    }
}
```

WALKTHROUGH

THE TWO EXPRESSIONS ARE THE ENTIRE LESSON.

`l + r` is the answer *at* this node — a path that comes up the left side, crosses the node, and goes down the right. `1 + max(l, r)` is what the parent needs — a path that continues downward through one side only. They are different quantities, and a solution that returns `l + r` produces wildly inflated answers because it lets a parent "extend" a path that already turned a corner.

WHY THE GLOBAL VARIABLE IS NOT LAZINESS.

The function can only return one value, and the parent needs the height. The diameter is a maximum over all nodes and is not composable from the children's heights alone, so it is accumulated on the side. This idiom recurs in maximum path sum, longest univalue path, and several others — recognising it saves a lot of flailing.

COUNTING EDGES, NOT NODES.

A single node has diameter 0 and a null child contributes height 0, which makes `1 + max(l, r)` count edges consistently. If a problem asks for the number of *nodes* on the path, add one.

Binary tree maximum path sum `Hard`

Pattern: Global best + clamped local return

A **path** is any sequence of nodes connected by edges, where each node appears at most once; it need not pass through the root. The **path sum** is the sum of its node values.

Return the maximum path sum in the tree. Values may be negative.

Input	Output	Note
`root = [1,2,3]`	`6`	2 + 1 + 3
`root = [-10,9,20,null,null,15,7]`	`42`	15 + 20 + 7 — the root is not used.
`root = [-3]`	`-3`	A single node is a valid path.

HINTS

1. Same shape as diameter: record the best path *through* each node, return the best path *ending* at it.
2. Negative values change things: a subtree whose best contribution is negative should simply be excluded.
3. Clamp each child's contribution at 0 — `Math.max(childGain, 0)` — which means "do not take this branch".
4. The best answer may be a single negative node, so initialise the global best to −Infinity, not 0.

Approach	Idea	Time	Space
Try every pair of nodes	Compute the path sum between all pairs.	`O(n²) or worse`	`O(n)`
Global best + clamped gain	One postorder pass, clamping negative branches to zero.	`O(n)`	`O(h)`

Solution — js

```
function maxPathSum(root) {
  let best = -Infinity;         // a single negative node is valid

  // returns the best sum of a path that STARTS at `node`
  // and goes downward through at most one child
  function gain(node) {
    if (!node) return 0;

    // a negative branch is worse than not taking it at all
    const l = Math.max(gain(node.left), 0);
    const r = Math.max(gain(node.right), 0);

    // best path THROUGH this node uses both sides
    best = Math.max(best, node.val + l + r);

    // but a path handed upward may use only ONE side
    return node.val + Math.max(l, r);
  }

  gain(root);
  return best;
}
```

Solution — cpp

```
class Solution {
    int best;
    int gain(TreeNode* n) {
        if (!n) return 0;
        int l = max(gain(n->left), 0);
        int r = max(gain(n->right), 0);
        best = max(best, n->val + l + r);
        return n->val + max(l, r);
    }
public:
    int maxPathSum(TreeNode* root) {
        best = INT_MIN;
        gain(root);
        return best;
    }
};
```

Solution — python

```python
class Solution:
    def maxPathSum(self, root: TreeNode) -> int:
        self.best = float("-inf")

        def gain(n):
            if not n:
                return 0
            l = max(gain(n.left), 0)
            r = max(gain(n.right), 0)
            self.best = max(self.best, n.val + l + r)
            return n.val + max(l, r)

        gain(root)
        return self.best
```

Solution — java

```java
class Solution {
    private int best;
    public int maxPathSum(TreeNode root) {
        best = Integer.MIN_VALUE;
        gain(root);
        return best;
    }
    private int gain(TreeNode n) {
        if (n == null) return 0;
        int l = Math.max(gain(n.left), 0);
        int r = Math.max(gain(n.right), 0);
        best = Math.max(best, n.val + l + r);
        return n.val + Math.max(l, r);
    }
}
```

WALKTHROUGH
THREE DECISIONS, EACH OF WHICH IS A TEST CASE.

1. CLAMPING AT ZERO.
`Math.max(gain(child), 0)` encodes "including this branch is optional". On `[2,-1]` the left child contributes −1, so the best path is just the root: 2. Without the clamp you would be forced to include it and return 1.

2. THE BEST IS INITIALISED TO −INFINITY, NOT 0.
On `[-3]` the only path is a single negative node, and the answer is −3. Starting at 0 would return 0, which corresponds to the empty path that the problem does not allow.

3. TWO DIFFERENT EXPRESSIONS AGAIN.
`node.val + l + r` is a path that turns a corner at this node — it can be the global answer but cannot be extended by a parent. `node.val + max(l, r)` is a straight downward path that a parent *can* extend. Returning the first is the classic bug and it overcounts badly.

NOTE THE ROOT NEED NOT BE INVOLVED:
`[-10,9,20,null,null,15,7]` answers 42 from the right subtree alone, because `gain(root)` is negative and the global best was already recorded deeper down.

Trees: binary search trees

A binary tree with an ordering invariant, which turns search into a descent. Two facts do most of the work: comparison tells you which way to go, and an inorder traversal comes out sorted.

The pattern

```
THE BST INVARIANT, stated correctly:

  for EVERY node, ALL values in its left subtree are
  smaller, and ALL values in its right subtree are larger.

NOT "left child < node < right child". That weaker
condition is the source of the most common bug in this
chapter:

           5
          / \
         1   7          7 > 5 ✓, 4 < 7 ✓ locally
            / \         BUT 4 < 5 and it is on the
           4   8        RIGHT of 5 -> NOT A BST

------------------------------------------------------------
THE TWO FACTS TO EXPLOIT

1. COMPARISON GIVES DIRECTION
     target < node.val  ->  go LEFT
     target > node.val  ->  go RIGHT
   Search, insert and delete are all O(h) descents.

2. INORDER TRAVERSAL IS SORTED
     left, node, right  ->  ascending order
   So "kth smallest", "validate", "find the two swapped
   nodes" and "convert to a sorted list" are all inorder
   walks (chapter 23).

------------------------------------------------------------
THE COST IS THE HEIGHT, NOT log n

  balanced   h = log n   -> O(log n)
  SKEWED     h = n       -> O(n), no better than a list

  Inserting sorted data into a plain BST produces exactly
  the skewed case. Real implementations self-balance -
  AVL, red-black - which is why std::map and TreeMap are
  O(log n) guaranteed. Interviews rarely ask you to
  implement balancing, but DO ask you to state that a
  plain BST degrades.

------------------------------------------------------------
VALIDATION - pass bounds DOWN

  function valid(node, lo, hi) {
      if (!node) return true;
      if (node.val <= lo || node.val >= hi) return false;
      return valid(node.left,  lo, node.val)
          && valid(node.right, node.val, hi);
  }
  valid(root, -Infinity, Infinity);

  Each recursion NARROWS the allowed range. Going left
  tightens the upper bound; going right tightens the
  lower bound. That is how a distant ancestor still
  constrains a deep descendant.

------------------------------------------------------------
DELETION - the only fiddly operation
```

```
0 children   remove it
1 child      replace it with that child
2 children   replace its value with the INORDER
             SUCCESSOR (the smallest value in the right
             subtree), then delete that successor from
             the right subtree — it has at most one
             child, so the recursion terminates.
```

When to reach for it

Sorted order from a tree

Inorder traversal. Kth smallest, sorted output, validation.

Search / insert / delete by key

Descend by comparison. O(h).

Lowest common ancestor in a BST

Much easier than the general tree — the first node between the two values is the LCA.

Range queries

Prune whole subtrees using the bounds.

Need order *and* fast lookup

A hash map gives O(1) lookup but no order; a balanced BST gives both at O(log n).

Build a balanced BST from sorted data

Recursive midpoint selection.

Problems

How it shows up

Symptom	Cause
Invalid tree accepted	Only compared with the parent — must pass a range down
Duplicates break validation	Decide whether equal values are allowed, and use `<=` or `<` consistently
Overflow with extreme values	Use `null` bounds rather than `INT_MIN/MAX` sentinels
Kth smallest scans the whole tree	Stop early — an inorder walk can return as soon as k is reached
Operations degrade to O(n)	Skewed tree from sorted insertions — mention self-balancing
Deletion loses a subtree	Two-child case must reattach via the inorder successor
LCA wrong in a BST	Used the general-tree algorithm and ignored the ordering

Check yourself

- ✓ State the BST invariant precisely and give the tree that breaks the weak version.
- ✓ Say what an inorder traversal of a BST produces and name three problems that follow.
- ✓ Write the validation function with bounds and explain how they narrow.
- ✓ Give the complexity of search in terms of height and say when that is bad.
- ✓ Describe the three deletion cases.
- ✓ Explain why LCA is simpler in a BST than in a general tree.
- ✓ Say when to prefer a balanced BST over a hash map.

Problems

Validate a binary search tree `Medium`

Pattern: Pass bounds down

Given the root of a binary tree, determine whether it is a valid binary search tree: every node in the left subtree is **strictly less** than the node, every node in the right subtree is **strictly greater**, and both subtrees are themselves valid BSTs.

Input	Output	Note
`root = [2,1,3]`	`true`	
`root = [5,1,4,null,null,3,6]`	`false`	3 is in the right subtree of 5 but is smaller than 5.
`root = [5,4,6,null,null,3,7]`	`false`	

HINTS

1. Comparing each node only with its immediate children is not enough — a value can satisfy its parent yet violate a grandparent.
2. Carry an allowed `(low, high)` range down the recursion.
3. Going left tightens the upper bound to the current value; going right tightens the lower bound.
4. An inorder traversal is an equally valid approach: the values must come out strictly increasing.

Approach	Idea	Time	Space
Compare with children only	**Wrong.** Accepts trees where a deep node violates a distant ancestor.	`O(n)`	`O(h)`
Inorder traversal	Walk inorder and check each value exceeds the previous. Elegant and easy to justify.	`O(n)`	`O(h)`
Range bounds passed down	Each node must lie strictly inside an inherited interval.	`O(n)`	`O(h)`

Solution — js

```javascript
function isValidBST(root) {
  // lo and hi are EXCLUSIVE bounds this subtree must respect
  function valid(node, lo, hi) {
    if (!node) return true;
    if (node.val <= lo || node.val >= hi) return false;

    return valid(node.left,  lo, node.val)    // tighten the ceiling
        && valid(node.right, node.val, hi);   // tighten the floor
  }
  return valid(root, -Infinity, Infinity);
}
```

Solution — cpp

```cpp
class Solution {
    bool valid(TreeNode* n, long lo, long hi) {
        if (!n) return true;
        if (n->val <= lo || n->val >= hi) return false;
        return valid(n->left, lo, n->val) && valid(n->right, n->val, hi);
    }
public:
    bool isValidBST(TreeNode* root) {
        return valid(root, LONG_MIN, LONG_MAX);
    }
};
```

Solution — python

```python
class Solution:
    def isValidBST(self, root: TreeNode) -> bool:
        def valid(n, lo, hi):
            if not n:
                return True
            if not (lo < n.val < hi):
                return False
            return valid(n.left, lo, n.val) and valid(n.right, n.val, hi)
        return valid(root, float("-inf"), float("inf"))
```

Solution — java

```java
class Solution {
    public boolean isValidBST(TreeNode root) {
        return valid(root, Long.MIN_VALUE, Long.MAX_VALUE);
    }
    private boolean valid(TreeNode n, long lo, long hi) {
        if (n == null) return true;
        if (n.val <= lo || n.val >= hi) return false;
        return valid(n.left, lo, n.val) && valid(n.right, n.val, hi);
    }
}
```

WALKTHROUGH

THE TEST THAT SEPARATES RIGHT FROM NEARLY-RIGHT

is `[5,1,4,null,null,3,6]`. Node 3 sits under 4, and 3 < 4 so a parent-only check is satisfied. But 3 is in the *right subtree of 5*, and everything there must exceed 5. The range mechanism catches it: descending right from 5 sets the floor to 5, and 3 fails it immediately.

HOW THE BOUNDS NARROW.

Moving left means every node below must be smaller than the current value, so the ceiling becomes `node.val`. Moving right means everything below must be larger, so the floor becomes `node.val`. The interval only ever shrinks, and it carries the constraint from every ancestor at once.

THE OVERFLOW TRAP IN C++ AND JAVA.

If a node holds `INT_MIN` and you initialise the bound to `INT_MIN`, the strict comparison wrongly rejects it. Widening to `long` — or using nullable bounds — avoids that. JavaScript and Python have no such problem, but say you know about it.

DUPLICATES ARE REJECTED HERE

(`[1,1]` is false) because the problem says strictly less and strictly greater. Some variants allow duplicates on one side; ask.

Kth smallest element in a BST `Medium`

Pattern: Inorder with early exit

Given the root of a binary search tree and an integer `k`, return the `k`th smallest value (1-indexed).

Input	Output	Note
`root = [3,1,4,null,2], k = 1`	`1`	
`root = [5,3,6,2,4,null,null,1], k = 3`	`3`	

HINTS

1. An inorder traversal of a BST visits values in ascending order.
2. So the kth value emitted by an inorder walk is the answer.
3. Do not collect the whole traversal — stop as soon as you have counted k.
4. The iterative stack version makes the early exit natural.

Approach	Idea	Time	Space
Full inorder into an array	Traverse everything, index `k-1`. Simple, O(n) time and space.	`O(n)`	`O(n)`
Inorder with a counter and early exit	Stop after k visits — O(h + k).	`O(h + k)`	`O(h)`
Augment nodes with subtree sizes	If the tree is modified often and this is queried often, storing subtree counts gives O(h) per query.	`O(h)`	`O(n)`

Solution — js

```javascript
function kthSmallest(root, k) {
  const st = [];
  let cur = root;

  while (cur || st.length) {
    while (cur) { st.push(cur); cur = cur.left; }   // dive left
    cur = st.pop();
    if (--k === 0) return cur.val;                  // EARLY EXIT
    cur = cur.right;
  }
  return -1;   // k exceeded the tree size
}
```

Solution — cpp

```cpp
class Solution {
public:
    int kthSmallest(TreeNode* root, int k) {
        stack<TreeNode*> st;
        TreeNode* cur = root;
        while (cur || !st.empty()) {
            while (cur) { st.push(cur); cur = cur->left; }
            cur = st.top(); st.pop();
            if (--k == 0) return cur->val;
            cur = cur->right;
        }
        return -1;
    }
};
```

Solution — python

```python
class Solution:
    def kthSmallest(self, root: TreeNode, k: int) -> int:
        st, cur = [], root
        while cur or st:
            while cur:
                st.append(cur)
                cur = cur.left
            cur = st.pop()
            k -= 1
            if k == 0:
                return cur.val
            cur = cur.right
        return -1
```

Solution — java

```
class Solution {
    public int kthSmallest(TreeNode root, int k) {
        Deque<TreeNode> st = new ArrayDeque<>();
        TreeNode cur = root;
        while (cur != null || !st.isEmpty()) {
            while (cur != null) { st.push(cur); cur = cur.left; }
            cur = st.pop();
            if (--k == 0) return cur.val;
            cur = cur.right;
        }
        return -1;
    }
}
```

WALKTHROUGH

WHY INORDER IS THE RIGHT TRAVERSAL.

In a BST everything left of a node is smaller and everything right is larger, so visiting left-node-right emits values in ascending order. The kth emitted value is therefore the kth smallest, with no sorting.

THE EARLY EXIT IS WHAT THE INTERVIEWER WANTS.

Collecting the full traversal and indexing works, but visits all n nodes and allocates O(n). Stopping at the kth visit costs O(h + k) — the descent to the smallest element, plus k steps. For small k on a large tree that is dramatically better, and the iterative form makes returning mid-traversal trivial.

THE FOLLOW-UP WORTH PREPARING:

"what if the tree is modified frequently and this is queried often?" Then augment each node with the size of its subtree; the kth smallest becomes a single O(h) descent, comparing k against the left subtree size at each step. Mention the maintenance cost on insert and delete.

Lowest common ancestor of a BST `Medium`

Pattern: Descend while both are on the same side

Given a BST and two values `p` and `q` that are both present, return the value of their lowest common ancestor — the deepest node having both as descendants (a node may be a descendant of itself).

Input	Output	Note
`root = [6,2,8,0,4,7,9,null,null,3,5], p = 2, q = 8`	`6`	
`root = [6,2,8,0,4,7,9,null,null,3,5], p = 2, q = 4`	`2`	A node can be its own ancestor.

HINTS

1. In a general tree this needs a full search. A BST gives you far more.
2. If both values are smaller than the current node, the answer must be in the left subtree. If both are larger, go right.
3. The moment they fall on opposite sides — or one equals the current node — that node is the answer.
4. This is an iterative descent; no recursion or extra space is needed.

Approach	Idea	Time	Space
General-tree LCA	Recurse both sides and combine. Works, but ignores the ordering and costs O(n).	`O(n)`	`O(h)`
Find both paths	Record the root-to-node path for each, then compare. O(h) space.	`O(h)`	`O(h)`
Ordered descent	One walk down, no extra memory.	`O(h)`	`O(1)`

Solution — js

```
function lowestCommonAncestor(root, p, q) {
  let cur = root;
  while (cur) {
    if (p < cur.val && q < cur.val)      cur = cur.left;   // both left
    else if (p > cur.val && q > cur.val) cur = cur.right;  // both right
    else return cur.val;   // they split here, or one IS this node
  }
  return -1;
}
```

Solution — cpp

```
class Solution {
public:
    TreeNode* lowestCommonAncestor(TreeNode* root, TreeNode* p, TreeNode* q) {
        TreeNode* cur = root;
        while (cur) {
            if (p->val < cur->val && q->val < cur->val)      cur = cur->left;
            else if (p->val > cur->val && q->val > cur->val) cur = cur->right;
            else return cur;
        }
        return nullptr;
    }
};
```

Solution — python

```
class Solution:
    def lowestCommonAncestor(self, root, p, q):
        cur = root
        while cur:
            if p.val < cur.val and q.val < cur.val:
                cur = cur.left
            elif p.val > cur.val and q.val > cur.val:
                cur = cur.right
            else:
                return cur
        return None
```

Solution — java

```
class Solution {
    public TreeNode lowestCommonAncestor(TreeNode root, TreeNode p, TreeNode q) {
        TreeNode cur = root;
        while (cur != null) {
            if (p.val < cur.val && q.val < cur.val)      cur = cur.left;
            else if (p.val > cur.val && q.val > cur.val) cur = cur.right;
            else return cur;
        }
        return null;
    }
}
```

WALKTHROUGH

THE SPLITTING ARGUMENT.

If both targets are less than the current node, both live in its left subtree, so the current node cannot be the *lowest* common ancestor — something deeper on the left also contains both. The symmetric case sends you right. The first node where they do not both go the same way is the split point, and no deeper node can contain both. That node is the LCA.

THE "NODE IS ITS OWN ANCESTOR" CASE FALLS OUT FOR FREE.

If `p` equals the current value, neither the both-smaller nor the both-larger condition holds, so the `else` fires and returns it — exactly right, as in the `p=2, q=4` test.

CONTRAST WITH THE GENERAL-TREE VERSION

, which must search both subtrees and combine results in O(n). The BST version reads a comparison and discards half the tree, giving O(h) and O(1) space. Recognising that the ordering makes the problem easier is the entire point of asking the BST variant.

Trees: tries and prefix problems

A tree where the path spells the word. It makes prefix queries as cheap as exact lookups — something a hash map fundamentally cannot do.

The pattern

```
A TRIE (prefix tree) stores strings by CHARACTER PATH.
Each edge is a character; each node is a prefix.

Inserting "cat", "car", "dog":

           (root)
           /    \
          c       d
          |       |
          a       o
         / \      |
        t   r     g*
        *   *
                  * = end of a word

THE KEY PROPERTY: WORDS SHARING A PREFIX SHARE A PATH.
"cat" and "car" traverse the same first two nodes, so
prefix questions are answered by a single descent.

------------------------------------------------------------
THE NODE

  class TrieNode {
      children = new Map();   // char -> TrieNode
      isWord = false;         // does a word END here?
  }

  `isWord` IS ESSENTIAL AND SEPARATE FROM "has children".
  Without it you cannot distinguish the stored word "car"
  from the mere prefix "car" of "cart".

  Use a Map for arbitrary alphabets; a fixed
  `new Array(26)` is faster when the input is lowercase
  a-z only.

------------------------------------------------------------
THE THREE OPERATIONS - all O(L), L = key length

  insert(word)     walk, creating nodes as needed, mark
                   the last node isWord = true
  search(word)     walk; return node exists AND isWord
  startsWith(pre)  walk; return the node merely EXISTS

  Search and startsWith differ by ONE LINE. That is the
  whole point of the structure.

------------------------------------------------------------
WHY NOT A HASH SET?

  exact lookup       hash set O(L)     trie O(L)   - tie
  "any word with
   prefix 'app'?"    hash set O(n·L)   trie O(L)   - trie
  "all words with
   prefix 'app'"     hash set O(n·L)   trie O(L + k)
  wildcard '.'       hash set: no      trie: DFS branching
  autocomplete       hash set: no      trie: natural

A HASH SET CANNOT ANSWER PREFIX QUESTIONS WITHOUT
SCANNING EVERYTHING. That is the sentence to say when
asked "why not just use a set?"
```

```
    COST: O(total characters) space — which can be large.
    The trade is memory for prefix speed.
```

When to reach for it

"Prefix", "starts with", autocomplete

The defining signal.

Wildcard or regex-lite matching

`.` matches any child — DFS over all branches.

Word search in a grid, many words

Build a trie of the dictionary and prune the DFS the moment a path leaves the trie.

Longest common prefix

Descend while there is exactly one child and no word ends.

Replace words / dictionary root matching

Walk the word until a stored root is hit.

Maximum XOR pair

A *binary* trie over bits — greedily take the opposite bit at each level.

Problems

How it shows up

Symptom	Cause
Prefix reported as a stored word	Missing `isWord` flag — checked node existence only
`search("app")` true after inserting only "apple"	Same cause
Wildcard search misses matches	Must try *every* child on `.`, not just the first
Wildcard search too slow	Expected — `.` branches; bound it by depth
Memory blowup	26-slot arrays at every node — use a Map for sparse alphabets
Deletion corrupts other words	Only unset `isWord`; prune a node only if it has no children
Case-sensitivity bugs	Normalise before inserting and before querying

Check yourself

- ✓ Draw the trie for "cat", "car", "dog".
- ✓ Say what `isWord` is for and what breaks without it.
- ✓ Give the three operations and their complexity.

- ✓ Say precisely how `search` and `startsWith` differ.
- ✓ Explain why a hash set cannot replace a trie.
- ✓ Describe how a wildcard `.` is handled.
- ✓ Say what the space cost is and what it buys.

Problems

Implement a trie `Medium`

Pattern: Prefix tree construction

Implement a trie supporting `insert(word)`, `search(word)` (is this exact word stored?) and `startsWith(prefix)` (is any stored word prefixed by this?).

Implement `trieOps(ops, args)`: apply each operation and return the boolean results of the `search` and `startsWith` queries, in order.

Input	Output	Note
`ops = ["insert","search","search","startsWith","insert","search"], args = [["apple"],["apple"],["app"],["app"],["app"],["app"]]`	`[true,false,true,true]`	

HINTS

1. Each node holds a map from character to child node, plus a flag saying whether a word ends there.
2. Insert walks the word, creating missing children, and sets the flag on the final node.
3. Search and startsWith share the same walk; they differ only in what they check at the end.
4. Without the flag, `search("app")` would wrongly return true after inserting only "apple".

Approach	Idea	Time	Space
Hash set of words	Exact search is fine, but `startsWith` requires scanning every stored word.	`O(n·L)` `prefix`	`O(n·L)`
Sorted array + binary search	Prefix queries become a range search. Works, but insertion is O(n).	`O(L log n)`	`O(n·L)`
Trie	All three operations are one descent of length L.	`O(L)`	`O(total chars)`

Solution — js

```javascript
function trieOps(ops, args) {
  const root = { children: new Map(), isWord: false };
  const out = [];

  // walk the characters; return the node reached, or null
  function walk(s) {
    let node = root;
    for (const c of s) {
      if (!node.children.has(c)) return null;
      node = node.children.get(c);
    }
    return node;
  }

  for (let i = 0; i < ops.length; i++) {
    const s = args[i][0];
    if (ops[i] === "insert") {
      let node = root;
      for (const c of s) {
        if (!node.children.has(c))
          node.children.set(c, { children: new Map(), isWord: false });
        node = node.children.get(c);
      }
      node.isWord = true;              // mark the END of a word
    } else if (ops[i] === "search") {
      const node = walk(s);
      out.push(node !== null && node.isWord);   // must be a WORD
    } else if (ops[i] === "startsWith") {
      out.push(walk(s) !== null);               // existing is enough
    }
  }
  return out;
}
```

Solution — cpp

```
class Trie {
    struct Node {
        unordered_map<char, Node*> ch;
        bool isWord = false;
    };
    Node* root = new Node();

    Node* walk(const string& s) {
        Node* n = root;
        for (char c : s) {
            auto it = n->ch.find(c);
            if (it == n->ch.end()) return nullptr;
            n = it->second;
        }
        return n;
    }
public:
    void insert(string word) {
        Node* n = root;
        for (char c : word) {
            if (!n->ch.count(c)) n->ch[c] = new Node();
            n = n->ch[c];
        }
        n->isWord = true;
    }
    bool search(string word)      { Node* n = walk(word); return n && n->isWord; }
    bool startsWith(string prefix){ return walk(prefix) != nullptr; }
};
```

Solution — python

```
class TrieNode:
    __slots__ = ("children", "is_word")
    def __init__(self):
        self.children = {}
        self.is_word = False

class Trie:
    def __init__(self):
        self.root = TrieNode()

    def _walk(self, s):
        node = self.root
        for c in s:
            if c not in node.children:
                return None
            node = node.children[c]
        return node

    def insert(self, word: str) -> None:
        node = self.root
        for c in word:
            node = node.children.setdefault(c, TrieNode())
        node.is_word = True

    def search(self, word: str) -> bool:
        node = self._walk(word)
        return node is not None and node.is_word

    def startsWith(self, prefix: str) -> bool:
        return self._walk(prefix) is not None
```

Solution — java

```
class Trie {
    private static class Node {
        Map<Character, Node> ch = new HashMap<>();
        boolean isWord = false;
    }
    private final Node root = new Node();

    private Node walk(String s) {
        Node n = root;
        for (char c : s.toCharArray()) {
            n = n.ch.get(c);
            if (n == null) return null;
        }
        return n;
    }
    public void insert(String word) {
        Node n = root;
        for (char c : word.toCharArray())
            n = n.ch.computeIfAbsent(c, k -> new Node());
        n.isWord = true;
    }
    public boolean search(String word)       { Node n = walk(word); return n != null &&
n.isWord; }
    public boolean startsWith(String prefix) { return walk(prefix) != null; }
}
```

WALKTHROUGH

`ISWORD` IS THE WHOLE DESIGN.

A node's existence means "some word passes through this prefix"; the flag means "a word *ends* exactly here". After inserting only "apple", the node for "app" exists but is not a word — so `search("app")` is false while `startsWith("app")` is true. The first test case exercises exactly that distinction, then inserts "app" and re-searches to confirm the flag flips.

SEARCH AND STARTSWITH ARE THE SAME WALK.

Factoring the descent into `walk` makes that explicit and removes duplicated code — a small thing that reads well in an interview.

MAP VERSUS FIXED ARRAY.

A 26-element array per node is faster and simpler for lowercase input, but wastes memory on sparse tries and cannot handle arbitrary characters. A hash map is general. Mention the trade; for a dictionary of English words the array version is usually the right call.

Design add and search words — with wildcards `Medium`

Pattern: Trie + branching DFS

Design a structure supporting `addWord(word)` and `search(word)`, where the search string may contain `.` as a wildcard matching **any single character**.

Implement `wordDictionary(ops, args)` returning the boolean results of the `search` calls, in order.

Input	Output	Note
`ops = ["addWord","addWord","addWord","search","search","search","search"], args = [["bad"],["dad"],["mad"],["pad"],["bad"],[".ad"],["b.."]]`	`[false,true,true,true]`	

HINTS

1. A plain trie walk assumes one child per character. A wildcard has to try them all.
2. Make the search recursive: at a normal character descend into that one child; at `.` recurse into **every** child.
3. The base case is reaching the end of the pattern — then check `isWord`.
4. Return true as soon as any branch succeeds.

Approach	Idea	Time	Space
Store words, match each	Compare the pattern against every stored word.	`O(n·L)`	`O(n·L)`
Trie + DFS with branching	Exact characters prune to one child; wildcards branch. Fast in practice because the trie shares prefixes.	`O(L) typical, O(26^d) worst`	`O(total chars)`

Solution — js

```
function wordDictionary(ops, args) {
  const root = { children: new Map(), isWord: false };
  const out = [];

  function dfs(node, s, i) {
    if (i === s.length) return node.isWord;      // pattern consumed

    const c = s[i];
    if (c === ".") {
      // wildcard: ANY child may work
      for (const child of node.children.values()) {
        if (dfs(child, s, i + 1)) return true;
      }
      return false;
    }

    const child = node.children.get(c);
    return child ? dfs(child, s, i + 1) : false;
  }

  for (let i = 0; i < ops.length; i++) {
    const s = args[i][0];
    if (ops[i] === "addWord") {
      let node = root;
      for (const c of s) {
        if (!node.children.has(c))
          node.children.set(c, { children: new Map(), isWord: false });
        node = node.children.get(c);
      }
      node.isWord = true;
    } else {
      out.push(dfs(root, s, 0));
    }
  }
  return out;
}
```

Solution — cpp

```
class WordDictionary {
    struct Node {
        unordered_map<char, Node*> ch;
        bool isWord = false;
    };
    Node* root = new Node();

    bool dfs(Node* n, const string& s, int i) {
        if (i == (int)s.size()) return n->isWord;
        char c = s[i];
        if (c == '.') {
            for (auto& [k, child] : n->ch)
                if (dfs(child, s, i + 1)) return true;
            return false;
        }
        auto it = n->ch.find(c);
        return it != n->ch.end() && dfs(it->second, s, i + 1);
    }
public:
    void addWord(string word) {
        Node* n = root;
        for (char c : word) {
            if (!n->ch.count(c)) n->ch[c] = new Node();
            n = n->ch[c];
        }
        n->isWord = true;
    }
    bool search(string word) { return dfs(root, word, 0); }
};
```

Solution — python

```
class WordDictionary:
    def __init__(self):
        self.root = {}          # nested dicts; "$" marks a word end

    def addWord(self, word: str) -> None:
        node = self.root
        for c in word:
            node = node.setdefault(c, {})
        node["$"] = True

    def search(self, word: str) -> bool:
        def dfs(node, i):
            if i == len(word):
                return "$" in node
            c = word[i]
            if c == ".":
                return any(dfs(child, i + 1)
                           for k, child in node.items() if k != "$")
            return c in node and dfs(node[c], i + 1)
        return dfs(self.root, 0)
```

Solution — java

```
class WordDictionary {
    private static class Node {
        Map<Character, Node> ch = new HashMap<>();
        boolean isWord = false;
    }
    private final Node root = new Node();

    public void addWord(String word) {
        Node n = root;
        for (char c : word.toCharArray())
            n = n.ch.computeIfAbsent(c, k -> new Node());
        n.isWord = true;
    }
    public boolean search(String word) { return dfs(root, word, 0); }

    private boolean dfs(Node n, String s, int i) {
        if (i == s.length()) return n.isWord;
        char c = s.charAt(i);
        if (c == '.') {
            for (Node child : n.ch.values())
                if (dfs(child, s, i + 1)) return true;
            return false;
        }
        Node child = n.ch.get(c);
        return child != null && dfs(child, s, i + 1);
    }
}
```

WALKTHROUGH

THE WILDCARD TURNS A WALK INTO A SEARCH.

Without `.`, each character determines exactly one child and the descent is a straight line of length L. A `.` means every child is a candidate, so the traversal fans out and needs backtracking — which is what makes this a DFS rather than a loop.

THE BASE CASE MUST CHECK `ISWORD`, NOT JUST ARRIVAL.

Test `addWord("ab")` then `search("a")`: the walk reaches the node for "a" with the pattern exhausted, but no word ends there, so the answer is false. Returning `true` on arrival is the classic bug.

LENGTH MISMATCHES ARE HANDLED IMPLICITLY.

`search("abc")` after adding only "ab" fails because the node for "b" has no "c" child. Nothing special is needed.

COMPLEXITY HONESTLY.

With no wildcards it is O(L). A pattern of all dots explores every path of that length, which is O(26^L) in the worst case — but the trie only contains real words, so the branching is bounded by what was actually inserted. Saying "worst case exponential in the number of wildcards, but bounded by the trie's actual branching" is the right level of precision.

Graphs: representation, BFS and DFS

Nodes and edges. Half of graph problems are solved by picking the right traversal and remembering to mark visited nodes at the right moment.

Representation

```
ADJACENCY LIST — the default, and almost always correct.

  const g = new Map();          // node -> array of neighbours
  // or, for nodes 0..n-1:
  const g = Array.from({length: n}, () => []);

  space O(V + E), iterate a node's neighbours in O(deg)

ADJACENCY MATRIX — only for dense graphs or O(1) edge
tests.

  const g = Array.from({length: n}, () => new Array(n).fill(0));
  space O(V^2), "is there an edge u-v?" in O(1)

EDGE LIST — just [u, v, w] triples. Used by Kruskal and
Bellman-Ford (chapter 30).

BUILDING FROM AN EDGE LIST — the first three lines of
most graph solutions:

  const g = Array.from({length: n}, () => []);
  for (const [u, v] of edges) {
      g[u].push(v);
      g[v].push(u);       // OMIT for a DIRECTED graph
  }

THE VOCABULARY YOU WILL BE ASKED FOR:
  DIRECTED / UNDIRECTED    do edges have a direction?
  WEIGHTED / UNWEIGHTED    do edges carry a cost?
  CYCLIC / ACYCLIC         a DAG is a directed acyclic
                           graph
  CONNECTED                every node reachable from every
                           other
  DEGREE                   number of incident edges;
                           in-degree / out-degree when
                           directed
  A TREE is a connected acyclic undirected graph with
  exactly V-1 edges.
```

BFS and DFS

```
BOTH VISIT EVERY REACHABLE NODE ONCE, in O(V + E).
THE DIFFERENCE IS THE ORDER, and it decides which
problems each solves.

BFS — a QUEUE, explores by DISTANCE
  · SHORTEST PATH in an UNWEIGHTED graph
  · level-by-level processing
  · "minimum number of steps"

DFS — a STACK (or recursion), explores by DEPTH
  · connectivity, components, cycle detection
  · topological order
  · path enumeration, backtracking
  · anything needing "finish the subtree first"

------------------------------------------------------------
BFS TEMPLATE

  const q = [start];
  const seen = new Set([start]);      // MARK ON ENQUEUE
  let head = 0;                       // avoid shift()
  let dist = 0;

  while (head < q.length) {
      const size = q.length - head;   // one LEVEL
      for (let i = 0; i < size; i++) {
          const u = q[head++];
          for (const v of g[u]) {
              if (seen.has(v)) continue;
              seen.add(v);            // <-- HERE, not on
              q.push(v);              //     dequeue
          }
      }
      dist++;
  }

  MARKING ON DEQUEUE INSTEAD OF ENQUEUE lets the same node
  be queued many times before it is first processed. It
  still terminates, but the queue can blow up
  exponentially on dense graphs. THIS IS THE MOST COMMON
  BFS BUG.

------------------------------------------------------------
DFS TEMPLATE — recursive

  const seen = new Set();
  function dfs(u) {
      seen.add(u);
      for (const v of g[u]) if (!seen.has(v)) dfs(v);
  }

DFS TEMPLATE — iterative, when recursion may overflow

  const st = [start];
  const seen = new Set();
  while (st.length) {
      const u = st.pop();
      if (seen.has(u)) continue;   // may be queued twice
      seen.add(u);
      for (const v of g[u]) if (!seen.has(v)) st.push(v);
  }
```

```
  Note the iterative version checks on POP, because a node
  can be pushed by several neighbours before being
  processed. That is fine here — unlike BFS, it does not
  break the distance guarantee, because DFS has none.

------------------------------------------------------------
WHY BFS GIVES SHORTEST PATHS

  The queue processes nodes in non-decreasing distance
  order. So the first time a node is reached, it is
  reached by a shortest path — and marking it seen
  immediately locks that in. WITH WEIGHTS THIS FAILS, and
  you need Dijkstra (chapter 30).
```

Problems

How it shows up

Symptom	Cause
Infinite loop	No visited set, or a cycle in an undirected graph
Queue grows enormously	Marked visited on dequeue instead of enqueue
Shortest path too long	Used DFS, or the graph is weighted — use BFS or Dijkstra
Only part of the graph visited	Disconnected — loop over all nodes as start points
Stack overflow	Deep recursion — convert DFS to iterative
Undirected graph behaves as directed	Forgot to add the reverse edge when building
Levels merged together	Level size not snapshot before the inner loop
Self-loops or duplicate edges break it	The visited check handles them — do not assume simplicity

Check yourself

- ✓ Build an adjacency list from an edge list, directed and undirected.
- ✓ Say when a matrix beats a list.
- ✓ Give the complexity of both traversals.
- ✓ State which problems suit BFS and which suit DFS.
- ✓ Explain why BFS marks visited on enqueue and what goes wrong otherwise.
- ✓ Explain why BFS finds shortest paths and when that guarantee fails.
- ✓ Write the iterative DFS and say why it checks on pop.
- ✓ Say how to handle a disconnected graph.

Problems

Number of connected components `Medium`

Pattern: DFS from every unvisited node

You have a graph of `n` nodes labelled `0` to `n-1`, given as an **undirected** edge list. Return the number of connected components.

Input	Output	Note
`n = 5, edges = [[0,1],[1,2],[3,4]]`	`2`	
`n = 5, edges = [[0,1],[1,2],[2,3],[3,4]]`	`1`	
`n = 4, edges = []`	`4`	Isolated nodes are components too.

HINTS

1. Build an adjacency list first — remember to add *both* directions.
2. Start a traversal from every node that has not been visited yet.
3. Each traversal you start marks one whole component, so count the starts.
4. Union-find also solves this — see chapter 29.

Approach	Idea	Time	Space
DFS or BFS per unvisited node	Each new start discovers exactly one component.	`O(V + E)`	`O(V + E)`
Union-find	Union the endpoints of each edge; count distinct roots. Better when edges arrive as a stream.	`O(E·α(V))`	`O(V)`

Solution — js

```
function countComponents(n, edges) {
  // adjacency list — BOTH directions for an undirected graph
  const g = Array.from({length: n}, () => []);
  for (const [u, v] of edges) { g[u].push(v); g[v].push(u); }

  const seen = new Array(n).fill(false);
  let count = 0;

  for (let s = 0; s < n; s++) {
    if (seen[s]) continue;
    count++;                      // a new component starts here

    // iterative DFS to avoid recursion depth limits
    const st = [s];
    seen[s] = true;
    while (st.length) {
      const u = st.pop();
      for (const v of g[u]) {
        if (!seen[v]) { seen[v] = true; st.push(v); }
      }
    }
  }
  return count;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int countComponents(int n, vector<vector<int>>& edges) {
        vector<vector<int>> g(n);
        for (auto& e : edges) { g[e[0]].push_back(e[1]); g[e[1]].push_back(e[0]); }
        vector<bool> seen(n, false);
        int count = 0;
        for (int s = 0; s < n; ++s) {
            if (seen[s]) continue;
            ++count;
            stack<int> st; st.push(s); seen[s] = true;
            while (!st.empty()) {
                int u = st.top(); st.pop();
                for (int v : g[u]) if (!seen[v]) { seen[v] = true; st.push(v); }
            }
        }
        return count;
    }
};
```

Solution — python

```python
class Solution:
    def countComponents(self, n: int, edges: list[list[int]]) -> int:
        g = [[] for _ in range(n)]
        for u, v in edges:
            g[u].append(v)
            g[v].append(u)

        seen = [False] * n
        count = 0
        for s in range(n):
            if seen[s]:
                continue
            count += 1
            st = [s]
            seen[s] = True
            while st:
                u = st.pop()
                for v in g[u]:
                    if not seen[v]:
                        seen[v] = True
                        st.append(v)
        return count
```

Solution — java

```java
class Solution {
    public int countComponents(int n, int[][] edges) {
        List<List<Integer>> g = new ArrayList<>();
        for (int i = 0; i < n; i++) g.add(new ArrayList<>());
        for (int[] e : edges) { g.get(e[0]).add(e[1]); g.get(e[1]).add(e[0]); }

        boolean[] seen = new boolean[n];
        int count = 0;
        for (int s = 0; s < n; s++) {
            if (seen[s]) continue;
            count++;
            Deque<Integer> st = new ArrayDeque<>();
            st.push(s); seen[s] = true;
            while (!st.isEmpty()) {
                int u = st.pop();
                for (int v : g.get(u))
                    if (!seen[v]) { seen[v] = true; st.push(v); }
            }
        }
        return count;
    }
}
```

WALKTHROUGH

WHY THE OUTER LOOP IS NECESSARY.

A single traversal only reaches nodes connected to its start. Iterating over every node and launching a traversal whenever one is still unvisited guarantees complete coverage, and each launch corresponds to exactly one component — which is why counting launches counts components.

ISOLATED NODES COUNT.

`n = 4` with no edges is four components, and the code handles it because each node is its own unvisited start. Forgetting this is a common off-by-several.

THE DUPLICATE-EDGE TEST

`[[0,1],[0,1]]` confirms the visited check tolerates a multigraph. Real inputs are not always simple graphs, and assuming otherwise is a silent failure.

MARKING `SEEN` WHEN PUSHING

rather than when popping keeps the stack small here — a node cannot be pushed twice. It is not strictly required for DFS correctness, but it is tidier and mirrors the BFS discipline.

Shortest path in an unweighted graph `Medium`

Pattern: BFS by levels

Given `n` nodes labelled `0..n-1`, an **undirected** edge list, and two nodes `src` and `dst`, return the minimum number of edges on a path from `src` to `dst`, or `-1` if unreachable.

Input	Output	Note
`n = 6, edges = [[0,1],[1,2],[2,5],[0,3],[3,4],[4,5]], src = 0, dst = 5`	`3`	
`n = 3, edges = [[0,1]], src = 0, dst = 2`	`-1`	
`n = 1, edges = [], src = 0, dst = 0`	`0`	

HINTS

1. DFS finds *a* path but not necessarily the shortest. BFS explores in order of distance.
2. Track the distance either by processing a whole level per iteration, or by storing a distance per node.
3. Mark nodes visited when you enqueue them, not when you dequeue them.
4. The source is at distance 0 — handle `src === dst` before anything else.

Approach	Idea	Time	Space
DFS all paths	Enumerate every path and take the shortest. Exponential.	`O(V!)`	`O(V)`
BFS	The first arrival at a node is via a shortest path.	`O(V + E)`	`O(V)`
Bidirectional BFS	Search from both ends and meet in the middle; roughly halves the explored frontier.	`O(V + E)`	`O(V)`

Solution — js

```
function shortestPath(n, edges, src, dst) {
  const g = Array.from({length: n}, () => []);
  for (const [u, v] of edges) { g[u].push(v); g[v].push(u); }

  if (src === dst) return 0;

  const q = [src];
  const seen = new Array(n).fill(false);
  seen[src] = true;                 // MARK ON ENQUEUE
  let head = 0, dist = 0;

  while (head < q.length) {
    const size = q.length - head;   // process one whole LEVEL
    dist++;
    for (let i = 0; i < size; i++) {
      const u = q[head++];
      for (const v of g[u]) {
        if (seen[v]) continue;
        if (v === dst) return dist; // first arrival = shortest
        seen[v] = true;
        q.push(v);
      }
    }
  }
  return -1;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int shortestPath(int n, vector<vector<int>>& edges, int src, int dst) {
        vector<vector<int>> g(n);
        for (auto& e : edges) { g[e[0]].push_back(e[1]); g[e[1]].push_back(e[0]); }
        if (src == dst) return 0;
        vector<bool> seen(n, false);
        queue<int> q; q.push(src); seen[src] = true;
        int dist = 0;
        while (!q.empty()) {
            int size = q.size();
            ++dist;
            for (int i = 0; i < size; ++i) {
                int u = q.front(); q.pop();
                for (int v : g[u]) {
                    if (seen[v]) continue;
                    if (v == dst) return dist;
                    seen[v] = true;
                    q.push(v);
                }
            }
        }
        return -1;
    }
};
```

Solution — python

```python
from collections import deque

class Solution:
    def shortestPath(self, n, edges, src, dst):
        g = [[] for _ in range(n)]
        for u, v in edges:
            g[u].append(v)
            g[v].append(u)
        if src == dst:
            return 0
        seen = [False] * n
        seen[src] = True
        q = deque([src])
        dist = 0
        while q:
            dist += 1
            for _ in range(len(q)):
                u = q.popleft()
                for v in g[u]:
                    if seen[v]:
                        continue
                    if v == dst:
                        return dist
                    seen[v] = True
                    q.append(v)
        return -1
```

Solution — java

```java
class Solution {
    public int shortestPath(int n, int[][] edges, int src, int dst) {
        List<List<Integer>> g = new ArrayList<>();
        for (int i = 0; i < n; i++) g.add(new ArrayList<>());
        for (int[] e : edges) { g.get(e[0]).add(e[1]); g.get(e[1]).add(e[0]); }
        if (src == dst) return 0;
        boolean[] seen = new boolean[n];
        Deque<Integer> q = new ArrayDeque<>();
        q.add(src); seen[src] = true;
        int dist = 0;
        while (!q.isEmpty()) {
            int size = q.size();
            dist++;
            for (int i = 0; i < size; i++) {
                int u = q.poll();
                for (int v : g.get(u)) {
                    if (seen[v]) continue;
                    if (v == dst) return dist;
                    seen[v] = true;
                    q.add(v);
                }
            }
        }
        return -1;
    }
}
```

WALKTHROUGH

WHY THE FIRST ARRIVAL IS OPTIMAL.

BFS dequeues nodes in non-decreasing order of distance from the source. So when a node is first discovered, no shorter route to it can exist — anything shorter would have been explored in an earlier level. Marking it seen at that moment permanently records the optimal distance.

MARK ON ENQUEUE, NOT ON DEQUEUE.

If you defer the mark until a node is popped, several neighbours can each enqueue the same node before any of them is processed. The result is still correct but the queue can grow far beyond V, and on a dense graph that is a real blow-up. This is the single most common BFS bug.

LEVEL COUNTING VERSUS A DISTANCE ARRAY.

Here the level loop increments `dist` once per frontier. The alternative — storing `dist[v] = dist[u] + 1` per node — is equally valid and is what you want if you need *all* distances rather than one. Both are O(V + E).

THE `SRC === DST` GUARD

is needed because the loop only returns when it *discovers* `dst` as a neighbour, and the source is never discovered that way. The `n = 1` test catches it.

Graphs: grids, topological sort and cycles

Three applications that cover most graph questions asked in interviews: a grid is a graph, dependencies need an ordering, and detecting cycles is what tells you whether one exists.

A grid is a graph

```
EVERY CELL IS A NODE. Its neighbours are the adjacent
cells. Nothing else changes — BFS and DFS work unaltered.

  const DIRS = [[-1,0],[1,0],[0,-1],[0,1]];
  for (const [dr, dc] of DIRS) {
      const nr = r + dr, nc = c + dc;
      if (nr < 0 || nr >= R || nc < 0 || nc >= C) continue;
      ...
  }

THE STANDARD PROBLEMS:
  COUNT ISLANDS       DFS/BFS from each unvisited land
                      cell; each launch is one island
  FLOOD FILL          same traversal, writing a new value
  ROTTING ORANGES     MULTI-SOURCE BFS — push every
                      initial source before starting, and
                      the level count is the answer
  SHORTEST PATH       BFS, because every step costs 1
  SURROUNDED REGIONS  traverse from the BORDER inwards to
                      find what is NOT enclosed

MARKING VISITED: either a separate boolean grid, or
overwrite the cell itself (turning '1' into '0'). The
second is O(1) space but MUTATES THE INPUT — say which
you chose.

MULTI-SOURCE BFS IS THE PATTERN PEOPLE MISS. If several
starting points spread simultaneously, seed the queue
with all of them at distance 0. One BFS then computes
the distance to the NEAREST source for every cell.
```

Topological sort

```
AN ORDERING OF A DIRECTED ACYCLIC GRAPH such that every
edge u -> v puts u before v. "Do this before that."

IT EXISTS IF AND ONLY IF THE GRAPH IS ACYCLIC — which is
why the same algorithm detects cycles.

------------------------------------------------------------
KAHN'S ALGORITHM (BFS on in-degrees) — the one to write

  1. compute in-degree for every node
  2. queue every node with in-degree 0
  3. pop u, append to the order, and for each edge u -> v
     decrement in-degree[v]; if it reaches 0, enqueue v
  4. IF THE ORDER IS SHORTER THAN n, A CYCLE EXISTS

  THAT LAST LINE IS THE CYCLE TEST. Nodes inside a cycle
  never reach in-degree 0, so they are never emitted.

------------------------------------------------------------
DFS ALTERNATIVE

  Postorder DFS, then REVERSE the finishing order.
  Detect cycles with THREE COLOURS:
     0 unvisited   1 IN PROGRESS   2 done
  Meeting a node in state 1 means a BACK EDGE — a cycle.

  TWO COLOURS ARE NOT ENOUGH for a directed graph:
  revisiting a FINISHED node is fine (a diamond), but
  revisiting an IN-PROGRESS one is a cycle. Conflating
  them reports false cycles on any DAG with two paths to
  the same node.

------------------------------------------------------------
CYCLE DETECTION, and the directed/undirected difference

  DIRECTED    three-colour DFS, or Kahn's count
  UNDIRECTED  DFS tracking the PARENT — seeing a visited
              node that is not your parent is a cycle.
              (Union-find also works: an edge whose
              endpoints already share a root closes a
              cycle — chapter 29.)

  Using the directed method on an undirected graph
  reports a "cycle" for every single edge, because u-v is
  stored as both u->v and v->u.
```

Problems

How it shows up

Symptom	Cause
Island count too high	Not marking cells visited during the traversal
Grid BFS gives the wrong distance	Not multi-source, or level size not snapshot
Topological sort returns too few nodes	Correct — that is the cycle signal
False cycle in a DAG	Two-colour DFS instead of three

Symptom	Cause
Every undirected edge reported as a cycle	Used the directed algorithm — track the parent instead
Course schedule accepts an impossible plan	Never compared the emitted count with `n`
Index out of bounds in a grid	Bounds check missing or applied after the array access
Input grid corrupted	Marked visited by overwriting — document or copy

Check yourself

- ✓ Write the four-direction neighbour loop with its bounds guard.
- ✓ Explain multi-source BFS and a problem it solves.
- ✓ Give the two ways to mark grid cells visited and their trade-off.
- ✓ Write Kahn's algorithm and state the cycle test.
- ✓ Explain why three colours are needed for directed cycle detection.
- ✓ Say how undirected cycle detection differs and why.
- ✓ State the condition for a topological order to exist.

Problems

Number of islands `Medium`

Pattern: Grid DFS per unvisited land cell

Given a 2-D grid of `"1"` (land) and `"0"` (water), return the number of islands. An island is land connected horizontally or vertically, and the grid is surrounded by water.

Input	Output	Note
`[["1","1","0"],["1","0","0"],["0","0","1"]]`	`2`	
`[["1","1","1"],["1","1","1"]]`	`1`	

HINTS

1. Whenever you find an unvisited land cell, it belongs to a new island — so count it and then erase the whole island.
2. "Erasing" means flooding the connected land with a traversal, marking each cell so it is never counted again.
3. You can mark by writing `"0"` into the grid, which needs no extra memory but mutates the input.
4. Guard the bounds *before* indexing, not after.

Approach	Idea	Time	Space
DFS flood fill	Each unvisited land cell launches a traversal that sinks its whole island.	`O(R·C)`	`O(R·C) worst-case stack`
BFS flood fill	Same idea with a queue; bounded frontier instead of deep recursion.	`O(R·C)`	`O(min(R,C))`

Approach	Idea	Time	Space
Union-find	Union adjacent land cells and count roots. Natural if the grid changes over time.	`O(R·C·α)`	`O(R·C)`

Solution — js

```
function numIslands(grid) {
  if (!grid.length || !grid[0].length) return 0;
  const R = grid.length, C = grid[0].length;
  const DIRS = [[-1,0],[1,0],[0,-1],[0,1]];
  let count = 0;

  // sink the whole island reachable from (sr, sc)
  function sink(sr, sc) {
    const st = [[sr, sc]];
    grid[sr][sc] = "0";               // mark immediately
    while (st.length) {
      const [r, c] = st.pop();
      for (const [dr, dc] of DIRS) {
        const nr = r + dr, nc = c + dc;
        if (nr < 0 || nr >= R || nc < 0 || nc >= C) continue;
        if (grid[nr][nc] !== "1") continue;
        grid[nr][nc] = "0";           // mark on PUSH
        st.push([nr, nc]);
      }
    }
  }

  for (let r = 0; r < R; r++)
    for (let c = 0; c < C; c++)
      if (grid[r][c] === "1") { count++; sink(r, c); }

  return count;
}
```

Solution — cpp

```
class Solution {
public:
    int numIslands(vector<vector<char>>& grid) {
        if (grid.empty() || grid[0].empty()) return 0;
        int R = grid.size(), C = grid[0].size(), count = 0;
        const int DR[4] = {-1,1,0,0}, DC[4] = {0,0,-1,1};
        for (int r = 0; r < R; ++r)
            for (int c = 0; c < C; ++c) {
                if (grid[r][c] != '1') continue;
                ++count;
                stack<pair<int,int>> st;
                st.push({r, c}); grid[r][c] = '0';
                while (!st.empty()) {
                    auto [cr, cc] = st.top(); st.pop();
                    for (int d = 0; d < 4; ++d) {
                        int nr = cr + DR[d], nc = cc + DC[d];
                        if (nr < 0 || nr >= R || nc < 0 || nc >= C) continue;
                        if (grid[nr][nc] != '1') continue;
                        grid[nr][nc] = '0';
                        st.push({nr, nc});
                    }
                }
            }
        return count;
    }
};
```

Solution — python

```
class Solution:
    def numIslands(self, grid: list[list[str]]) -> int:
        if not grid or not grid[0]:
            return 0
        R, C = len(grid), len(grid[0])
        DIRS = ((-1,0),(1,0),(0,-1),(0,1))
        count = 0

        for r in range(R):
            for c in range(C):
                if grid[r][c] != "1":
                    continue

                        st.push(new int[]{nr, nc});
                    }
                }
            }
        return count;
    }
}
```

WALKTHROUGH

COUNT-THEN-ERASE IS THE SHAPE.

The outer double loop finds any land cell that has not been absorbed into an earlier island; that cell must begin a new one, so increment and then flood the entire connected region to `"0"`. Because every land cell is erased exactly once, the total work is O(R·C) despite the nested traversal.

MARK ON PUSH, NOT ON POP.

Exactly as in BFS (chapter 27), deferring the mark lets the same cell be pushed by several neighbours. Here it would also let a cell be counted while still on the stack, which can inflate the answer.

OVERWRITING THE GRID IS O(1) EXTRA SPACE BUT DESTROYS THE INPUT.

That is usually acceptable and worth stating explicitly; if the caller needs the grid intact, use a parallel boolean array at O(R·C) space, or restore afterwards.

THE BOUNDS CHECK PRECEDES THE ARRAY ACCESS.

Writing `if (grid[nr][nc] !== "1" || nr < 0)` reads out of range before testing — in JavaScript that silently yields `undefined` and in C++ it is undefined behaviour.

Course schedule — can all courses be finished? `Medium`

Pattern: Kahn's topological sort

There are `numCourses` courses labelled `0` to `numCourses-1`. `prerequisites[i] = [a, b]` means you must take `b` before `a`.

Return `true` if it is possible to finish all courses.

Input	Output	Note
`numCourses = 2, prerequisites = [[1,0]]`	`true`	
`numCourses = 2, prerequisites = [[1,0],[0,1]]`	`false`	A circular dependency.

HINTS

1. This asks whether the dependency graph is acyclic — a topological order exists exactly when it is.
2. Build edges `b → a` (prerequisite points to dependant) and count each node's in-degree.
3. Repeatedly take a course with in-degree 0 and decrement its dependants.
4. If you cannot emit all `numCourses` nodes, the remainder are stuck in a cycle.

Approach	Idea	Time	Space
Try every ordering	Permute the courses and check. Factorial.	`O(n!)`	`O(n)`
Three-colour DFS	Detect a back edge to a node still in progress.	`O(V + E)`	`O(V)`
Kahn's algorithm	Peel off in-degree-0 nodes; a short result means a cycle.	`O(V + E)`	`O(V + E)`

Solution — js

```
function canFinish(numCourses, prerequisites) {
  const g = Array.from({length: numCourses}, () => []);
  const indeg = new Array(numCourses).fill(0);

  // [a, b] means b must come BEFORE a, so the edge is b -> a
  for (const [a, b] of prerequisites) {
    g[b].push(a);
    indeg[a]++;
  }

  // start with everything that has no prerequisites
  const q = [];
  for (let i = 0; i < numCourses; i++) if (indeg[i] === 0) q.push(i);

  let head = 0, taken = 0;
  while (head < q.length) {
    const u = q[head++];
    taken++;
    for (const v of g[u]) {
      if (--indeg[v] === 0) q.push(v);   // all prereqs satisfied
    }
  }

  // anything never emitted is trapped in a cycle
  return taken === numCourses;
}
```

Solution — cpp

```cpp
class Solution {
public:
    bool canFinish(int numCourses, vector<vector<int>>& prerequisites) {
        vector<vector<int>> g(numCourses);
        vector<int> indeg(numCourses, 0);
        for (auto& p : prerequisites) { g[p[1]].push_back(p[0]); ++indeg[p[0]]; }
        queue<int> q;
        for (int i = 0; i < numCourses; ++i) if (!indeg[i]) q.push(i);
        int taken = 0;
        while (!q.empty()) {
            int u = q.front(); q.pop();
            ++taken;
            for (int v : g[u]) if (--indeg[v] == 0) q.push(v);
        }
        return taken == numCourses;
    }
};
```

Solution — python

```python
from collections import deque

class Solution:
    def canFinish(self, numCourses: int, prerequisites: list[list[int]]) -> bool:
        g = [[] for _ in range(numCourses)]
        indeg = [0] * numCourses
        for a, b in prerequisites:
            g[b].append(a)
            indeg[a] += 1

        q = deque(i for i in range(numCourses) if indeg[i] == 0)
        taken = 0
        while q:
            u = q.popleft()
            taken += 1
            for v in g[u]:
                indeg[v] -= 1
                if indeg[v] == 0:
                    q.append(v)
        return taken == numCourses
```

Solution — java

```
class Solution {
    public boolean canFinish(int numCourses, int[][] prerequisites) {
        List<List<Integer>> g = new ArrayList<>();
        for (int i = 0; i < numCourses; i++) g.add(new ArrayList<>());
        int[] indeg = new int[numCourses];
        for (int[] p : prerequisites) { g.get(p[1]).add(p[0]); indeg[p[0]]++; }

        Deque<Integer> q = new ArrayDeque<>();
        for (int i = 0; i < numCourses; i++) if (indeg[i] == 0) q.add(i);

        int taken = 0;
        while (!q.isEmpty()) {
            int u = q.poll();
            taken++;
            for (int v : g.get(u)) if (--indeg[v] == 0) q.add(v);
        }
        return taken == numCourses;
    }
}
```

WALKTHROUGH

THE EDGE DIRECTION IS THE FIRST THING TO GET RIGHT.

`[a, b]` reads "to take `a` you must first take `b`", so `b` is the prerequisite and the edge points `b → a`. Reversing it produces a graph whose topological order is backwards; on symmetric test cases it still passes, which makes the mistake hard to spot. State the direction aloud before coding.

WHY THE COUNT DETECTS CYCLES.

A node only enters the queue when its in-degree reaches zero — that is, when every prerequisite has already been emitted. A node inside a cycle always has at least one unemitted prerequisite (another cycle member), so its in-degree never reaches zero and it is never taken. Hence `taken < numCourses` exactly when a cycle exists.

THE VARIANT TO EXPECT:

"return the actual order". Collect the emitted nodes into an array and return it, or return an empty array when the count falls short. Same algorithm, one extra line.

Rotting oranges `Medium`

Pattern: Multi-source BFS

In a grid, `0` is empty, `1` is a fresh orange and `2` is rotten. Every minute, any fresh orange **adjacent** (4-directionally) to a rotten one becomes rotten.

Return the number of minutes until no fresh orange remains, or `-1` if that is impossible.

Input	Output	Note
`[[2,1,1],[1,1,0],[0,1,1]]`	`4`	
`[[2,1,1],[0,1,1],[1,0,1]]`	`-1`	The bottom-left orange is unreachable.
`[[0,2]]`	`0`	No fresh oranges — zero minutes.

HINTS

1. All rotten oranges spread *simultaneously*, so this is not one BFS per source.
2. Seed the queue with
   EVERY
   rotten orange before starting — that is multi-source BFS.
3. Each BFS level is one minute. Count the levels, not the cells.
4. Count the fresh oranges up front; if any remain at the end, return −1.

Approach	Idea	Time	Space
BFS from each rotten orange	Run a separate BFS per source and take the minimum per cell. Correct but wasteful.	`O((R·C)²)`	`O(R·C)`
Simulate minute by minute	Scan the whole grid each minute looking for spread. O(R·C) per minute.	`O((R·C)²)`	`O(1)`
Multi-source BFS	One traversal from all sources at once; level count is the answer.	`O(R·C)`	`O(R·C)`

Solution — js

```
function orangesRotting(grid) {
  const R = grid.length, C = R ? grid[0].length : 0;
  const DIRS = [[-1,0],[1,0],[0,-1],[0,1]];

  const q = [];
  let fresh = 0;

  // MULTI-SOURCE: every rotten orange starts at minute 0
  for (let r = 0; r < R; r++)
    for (let c = 0; c < C; c++) {
      if (grid[r][c] === 2) q.push([r, c]);
      else if (grid[r][c] === 1) fresh++;
    }

  if (fresh === 0) return 0;      // nothing to rot

  let head = 0, minutes = 0;
  while (head < q.length && fresh > 0) {
    const size = q.length - head;  // one MINUTE = one level
    minutes++;
    for (let i = 0; i < size; i++) {
      const [r, c] = q[head++];
      for (const [dr, dc] of DIRS) {
        const nr = r + dr, nc = c + dc;
        if (nr < 0 || nr >= R || nc < 0 || nc >= C) continue;
        if (grid[nr][nc] !== 1) continue;
        grid[nr][nc] = 2;          // mark on PUSH
        fresh--;
        q.push([nr, nc]);
      }
    }
  }
  return fresh === 0 ? minutes : -1;
}
```

Solution — cpp

```
class Solution {
public:
    int orangesRotting(vector<vector<int>>& grid) {
        int R = grid.size(), C = R ? grid[0].size() : 0;
        const int DR[4] = {-1,1,0,0}, DC[4] = {0,0,-1,1};
        queue<pair<int,int>> q;
        int fresh = 0;
        for (int r = 0; r < R; ++r)
            for (int c = 0; c < C; ++c) {
                if (grid[r][c] == 2) q.push({r, c});
                else if (grid[r][c] == 1) ++fresh;
            }
        if (fresh == 0) return 0;
        int minutes = 0;
        while (!q.empty() && fresh > 0) {
            int size = q.size();
            ++minutes;
            for (int i = 0; i < size; ++i) {
                auto [r, c] = q.front(); q.pop();
                for (int d = 0; d < 4; ++d) {
                    int nr = r + DR[d], nc = c + DC[d];
                    if (nr < 0 || nr >= R || nc < 0 || nc >= C) continue;
                    if (grid[nr][nc] != 1) continue;
                    grid[nr][nc] = 2; --fresh;
                    q.push({nr, nc});
                }
            }
        }
        return fresh == 0 ? minutes : -1;
    }
};
```

Solution — python

```python
from collections import deque

class Solution:
    def orangesRotting(self, grid: list[list[int]]) -> int:
        R = len(grid)
        C = len(grid[0]) if R else 0
        DIRS = ((-1,0),(1,0),(0,-1),(0,1))

        q = deque()
        fresh = 0
        for r in range(R):
            for c in range(C):
                if grid[r][c] == 2:
                    q.append((r, c))
                elif grid[r][c] == 1:
                    fresh += 1

        if fresh == 0:
            return 0

        minutes = 0
        while q and fresh > 0:
            minutes += 1
            for _ in range(len(q)):
                r, c = q.popleft()
                for dr, dc in DIRS:
                    nr, nc = r + dr, c + dc
                    if 0 <= nr < R and 0 <= nc < C and grid[nr][nc] == 1:
                        grid[nr][nc] = 2
                        fresh -= 1
                        q.append((nr, nc))
        return minutes if fresh == 0 else -1
```

Solution — java

```
class Solution {
    public int orangesRotting(int[][] grid) {
        int R = grid.length, C = R > 0 ? grid[0].length : 0;
        int[] DR = {-1,1,0,0}, DC = {0,0,-1,1};
        Deque<int[]> q = new ArrayDeque<>();
        int fresh = 0;
        for (int r = 0; r < R; r++)
            for (int c = 0; c < C; c++) {
                if (grid[r][c] == 2) q.add(new int[]{r, c});
                else if (grid[r][c] == 1) fresh++;
            }
        if (fresh == 0) return 0;
        int minutes = 0;
        while (!q.isEmpty() && fresh > 0) {
            int size = q.size();
            minutes++;
            for (int i = 0; i < size; i++) {
                int[] cur = q.poll();
                for (int d = 0; d < 4; d++) {
                    int nr = cur[0] + DR[d], nc = cur[1] + DC[d];
                    if (nr < 0 || nr >= R || nc < 0 || nc >= C) continue;
                    if (grid[nr][nc] != 1) continue;
                    grid[nr][nc] = 2; fresh--;
                    q.add(new int[]{nr, nc});
                }
            }
        }
        return fresh == 0 ? minutes : -1;
    }
}
```

WALKTHROUGH

MULTI-SOURCE IS THE WHOLE IDEA.

Rot spreads from every rotten orange at once, so seeding the queue with all of them makes a single BFS compute, for every cell, the time at which the *nearest* source reaches it. Running one BFS per source and taking minima gives the same answer at far greater cost.

COUNTING MINUTES, NOT CELLS.

Each level of the BFS is one minute of spreading, so `minutes` is incremented once per frontier rather than once per orange.

THE `FRESH > 0` GUARD PREVENTS AN OFF-BY-ONE.

Without it, the loop runs one extra level after the last orange rots — that final level pushes nothing, but `minutes` has already been incremented, returning 5 instead of 4 on the first example. Checking `fresh` both in the loop condition and at the end is what keeps it exact.

THE EARLY RETURN FOR ZERO FRESH ORANGES

handles `[[0,2]]` and `[[0]]`, where the answer is 0 minutes. Without it the function would fall through and still return 0 — but only by accident; being explicit is clearer.

UNREACHABLE ORANGES GIVE −1

, detected by `fresh` still being positive when the queue drains. That is the same "did we reach everything?" check as Kahn's `taken === n`.

Graphs: union-find

A structure that tracks "are these two things in the same group?" while groups keep merging. Thirty lines of code, effectively constant time, and the right answer whenever connectivity arrives incrementally.

The pattern

```
DISJOINT SET UNION (DSU). Each group is a tree; the root
identifies the group.

  find(x)      which group is x in?  (returns the root)
  union(a, b)  merge the two groups
  connected(a, b)  find(a) === find(b)

NAIVE VERSION: parent[] pointers, find walks to the root.
Without optimisation the trees degenerate into chains and
find becomes O(n).

TWO OPTIMISATIONS MAKE IT NEARLY O(1). Use BOTH.

1. PATH COMPRESSION — flatten as you search
     function find(x) {
         while (parent[x] !== x) {
             parent[x] = parent[parent[x]];  // point at
             x = parent[x];                  // grandparent
         }
         return x;
     }
   Every node on the path ends up much closer to the root.

2. UNION BY SIZE (or rank) — attach the SMALLER tree to
   the LARGER, so depth grows slowly.
     if (size[ra] < size[rb]) swap(ra, rb);
     parent[rb] = ra;
     size[ra] += size[rb];

TOGETHER: O(α(n)) amortised per operation, where α is the
inverse Ackermann function. α(n) < 5 for any n you will
ever see, so treat it as constant — but say "amortised
near-constant", not "O(1)".

------------------------------------------------------------
WHEN UNION-FIND BEATS DFS

  DFS/BFS need the WHOLE graph before they can answer.
  Union-find answers connectivity queries INCREMENTALLY,
  as edges arrive, and supports interleaved queries.

  use DFS        one static graph, need paths or order
  use UNION-FIND edges arriving over time, only need
                 "same group?", or you need a component
                 COUNT that updates as you merge

------------------------------------------------------------
THE COMPONENT-COUNT TRICK

  Start with count = n (every node its own group).
  DECREMENT ONLY WHEN A UNION ACTUALLY MERGES:

    function union(a, b) {
        const ra = find(a), rb = find(b);
        if (ra === rb) return false;   // ALREADY together
        ...attach...
        count--;
        return true;                    // a real merge
    }

  THE BOOLEAN RETURN IS THE USEFUL PART. `false` means the
```

```
    edge closed a CYCLE — which is how you detect cycles in
    an undirected graph, and how Kruskal rejects edges
    (chapter 30).
```

When to reach for it

Connected components, incrementally

Number of provinces, friend circles, accounts merge.

Cycle detection, undirected

An edge whose endpoints already share a root closes a cycle.

"Is this a valid tree?"

Exactly `n−1` edges, no cycle, one component.

Kruskal's MST

Sort edges, add any that merges two groups (ch. 30).

Redundant connection

The first edge that fails to merge is the answer.

Equations / equivalence classes

Group things declared equal, then test the inequalities.

Problems

How it shows up

Symptom	Cause
Operations degrade to O(n)	No path compression, or no union by size
Component count too low	Decremented on every union, not only on real merges
Cycle never detected	Ignored the `find(a) === find(b)` case
Union attaches roots to non-roots	Must call `find` on both before attaching
Wrong groups after many unions	Compared `parent[a] === parent[b]` instead of roots
Stack overflow in `find`	Recursive compression on a deep chain — use the iterative form
Cannot recover the actual path	Union-find tracks membership only — use DFS if you need paths

Check yourself

- ✓ Write `find` with path compression, iteratively.
- ✓ Write `union` with union by size, returning whether it merged.
- ✓ State the amortised complexity and phrase it correctly.

- ✓ Say when union-find beats DFS and when it does not.
- ✓ Explain the component-count trick and why the guard matters.
- ✓ Explain how a failed union detects a cycle.
- ✓ Give the three conditions for a graph to be a valid tree.

Problems

Number of provinces `Medium`

Pattern: Union every edge, count roots

You are given an `n × n` matrix `isConnected` where `isConnected[i][j] === 1` means city `i` and city `j` are directly connected. A **province** is a maximal group of directly or indirectly connected cities.

Return the number of provinces.

A `DSU` class is provided — `new DSU(n)`, with `find`, `union`, `connected` and a `count` field.

Input	Output	Note
`isConnected = [[1,1,0],[1,1,0],[0,0,1]]`	`2`	
`isConnected = [[1,0,0],[0,1,0],[0,0,1]]`	`3`	

HINTS

1. Start with every city as its own province and merge whenever an edge connects two.
2. The matrix is symmetric, so only the upper triangle needs scanning.
3. The DSU's `count` field already tracks the number of groups — read it at the end.

Approach	Idea	Time	Space
DFS per unvisited city	Each traversal marks one province.	`O(n²)`	`O(n)`
Union-find	Union every connected pair; `count` is the answer.	`O(n²·α)`	`O(n)`

Solution — js

```
function findCircleNum(isConnected) {
  const n = isConnected.length;
  const dsu = new DSU(n);

  // symmetric matrix: only the upper triangle is needed
  for (let i = 0; i < n; i++)
    for (let j = i + 1; j < n; j++)
      if (isConnected[i][j] === 1) dsu.union(i, j);

  return dsu.count;
}
```

Solution — cpp

```
class Solution {
    vector<int> parent, sz;
    int find(int x) {
        while (parent[x] != x) { parent[x] = parent[parent[x]]; x = parent[x]; }
        return x;
    }
public:
    int findCircleNum(vector<vector<int>>& isConnected) {
        int n = isConnected.size(), count = n;
        parent.resize(n); sz.assign(n, 1);
        iota(parent.begin(), parent.end(), 0);
        for (int i = 0; i < n; ++i)
            for (int j = i + 1; j < n; ++j) {
                if (!isConnected[i][j]) continue;
                int ra = find(i), rb = find(j);
                if (ra == rb) continue;
                if (sz[ra] < sz[rb]) swap(ra, rb);
                parent[rb] = ra; sz[ra] += sz[rb]; --count;
            }
        return count;
    }
};
```

Solution — python

```
class Solution:
    def findCircleNum(self, isConnected: list[list[int]]) -> int:
        n = len(isConnected)
        parent = list(range(n))
        size = [1] * n
        count = n

        def find(x):
            while parent[x] != x:
                parent[x] = parent[parent[x]]
                x = parent[x]
            return x

        for i in range(n):
            for j in range(i + 1, n):
                if not isConnected[i][j]:
                    continue
                ra, rb = find(i), find(j)
                if ra == rb:
                    continue
                if size[ra] < size[rb]:
                    ra, rb = rb, ra
                parent[rb] = ra
                size[ra] += size[rb]
                count -= 1
        return count
```

Solution — java

```
class Solution {
    private int[] parent, size;
    private int find(int x) {
        while (parent[x] != x) { parent[x] = parent[parent[x]]; x = parent[x]; }
        return x;
    }
    public int findCircleNum(int[][] isConnected) {
        int n = isConnected.length, count = n;
        parent = new int[n]; size = new int[n];
        for (int i = 0; i < n; i++) { parent[i] = i; size[i] = 1; }
        for (int i = 0; i < n; i++)
            for (int j = i + 1; j < n; j++) {
                if (isConnected[i][j] == 0) continue;
                int ra = find(i), rb = find(j);
                if (ra == rb) continue;
                if (size[ra] < size[rb]) { int t = ra; ra = rb; rb = t; }
                parent[rb] = ra; size[ra] += size[rb]; count--;
            }
        return count;
    }
}
```

WALKTHROUGH

THE COUNT MAINTAINS ITSELF.

Starting at `n` and decrementing on each genuine merge means the answer is available at any moment, without a final pass to collect distinct roots. That incremental property is what makes union-find attractive when the graph is built up over time.

ONLY THE UPPER TRIANGLE.

The matrix is symmetric and the diagonal is always 1 (a city is connected to itself), so scanning `j > i` halves the work and skips the meaningless self-edges. Unioning a node with itself is harmless — `find` returns the same root and the union is rejected — but it is wasted work.

EITHER APPROACH IS ACCEPTABLE HERE.

DFS is equally $O(n^2)$ on a dense matrix. Union-find wins when the connections arrive as a stream of edges rather than a fixed matrix, which is worth saying when you choose it.

Redundant connection `Medium`

Pattern: A failed union closes a cycle

A tree on `n` nodes labelled `1..n` has had one extra edge added, creating exactly one cycle. Given the `n` edges in the order they were added, return the edge that can be removed so the result is a tree.

If several answers exist, return the one that appears **last** in the input.

Input	Output	Note
`edges = [[1,2],[1,3],[2,3]]`	`[2,3]`	
`edges = [[1,2],[2,3],[3,4],[1,4],[1,5]]`	`[1,4]`	

HINTS

1. Process the edges in order, unioning each pair.
2. An edge whose endpoints are *already* in the same group would close a cycle.
3. Because you scan in order, the first such edge encountered is the last one that could be removed — return it immediately.
4. Node labels start at 1, so size the DSU `n + 1`.

Approach	Idea	Time	Space
Remove each edge and test	For every edge, delete it and check whether the rest is a tree.	`O(n²)`	`O(n)`
Union-find	The first union that fails is the redundant edge.	`O(n·α)`	`O(n)`

Solution — js

```
function findRedundantConnection(edges) {
  const dsu = new DSU(edges.length + 1);   // 1-indexed labels

  for (const [u, v] of edges) {
    // union returns false when u and v are ALREADY connected,
    // which means this edge closes a cycle
    if (!dsu.union(u, v)) return [u, v];
  }
  return [];
}
```

Solution — cpp

```
class Solution {
    vector<int> parent, sz;
    int find(int x) {
        while (parent[x] != x) { parent[x] = parent[parent[x]]; x = parent[x]; }
        return x;
    }
public:
    vector<int> findRedundantConnection(vector<vector<int>>& edges) {
        int n = edges.size() + 1;
        parent.resize(n); sz.assign(n, 1);
        iota(parent.begin(), parent.end(), 0);
        for (auto& e : edges) {
            int ra = find(e[0]), rb = find(e[1]);
            if (ra == rb) return e;              // closes a cycle
            if (sz[ra] < sz[rb]) swap(ra, rb);
            parent[rb] = ra; sz[ra] += sz[rb];
        }
        return {};
    }
};
```

Solution — python

```python
class Solution:
    def findRedundantConnection(self, edges: list[list[int]]) -> list[int]:
        n = len(edges) + 1
        parent = list(range(n))
        size = [1] * n

        def find(x):
            while parent[x] != x:
                parent[x] = parent[parent[x]]
                x = parent[x]
            return x

        for u, v in edges:
            ra, rb = find(u), find(v)
            if ra == rb:
                return [u, v]
            if size[ra] < size[rb]:
                ra, rb = rb, ra
            parent[rb] = ra
            size[ra] += size[rb]
        return []
```

Solution — java

```java
class Solution {
    private int[] parent, size;
    private int find(int x) {
        while (parent[x] != x) { parent[x] = parent[parent[x]]; x = parent[x]; }
        return x;
    }
    public int[] findRedundantConnection(int[][] edges) {
        int n = edges.length + 1;
        parent = new int[n]; size = new int[n];
        for (int i = 0; i < n; i++) { parent[i] = i; size[i] = 1; }
        for (int[] e : edges) {
            int ra = find(e[0]), rb = find(e[1]);
            if (ra == rb) return e;
            if (size[ra] < size[rb]) { int t = ra; ra = rb; rb = t; }
            parent[rb] = ra; size[ra] += size[rb];
        }
        return new int[0];
    }
}
```

WALKTHROUGH

WHY A FAILED UNION MEANS A CYCLE.

If `u` and `v` already share a root, a path between them exists using earlier edges. Adding the direct edge `u–v` therefore creates a second path, which is precisely a cycle. Union-find detects this in near-constant time without ever tracing the path.

WHY THE FIRST FAILURE IS THE ANSWER THE PROBLEM WANTS.

The graph has exactly one cycle, and edges are processed in input order. Every edge before the failure was necessary to build the tree so far; the failing edge is the one that closed the loop, and by construction it is the last edge of the cycle in input order — which is what "return the one appearing last" asks for.

SIZE THE DSU FOR 1-INDEXED LABELS.

Nodes run `1..n` where `n === edges.length`, so the arrays need `n + 1` slots and index 0 goes unused. Off-by-one here produces an out-of-range write that is easy to miss.

CONTRAST WITH THE DIRECTED VERSION

("Redundant Connection II"), where a node can also gain two parents — that variant needs extra case analysis and is a common follow-up.

Graph valid tree `Medium`

Pattern: Edge count + no cycle + connected

Given `n` nodes labelled `0..n-1` and a list of undirected edges, determine whether the graph forms a **valid tree**.

A tree is connected and acyclic.

Input	Output	Note
`n = 5, edges = [[0,1],[0,2],[0,3],[1,4]]`	`true`	
`n = 5, edges = [[0,1],[1,2],[2,3],[1,3],[1,4]]`	`false`	Contains a cycle.
`n = 4, edges = [[0,1],[2,3]]`	`false`	Two components.

HINTS

1. A tree on `n` nodes has exactly `n - 1` edges. Check that first — it is O(1) and rules out most bad inputs.
2. Given the right edge count, "acyclic" and "connected" become equivalent: either one implies the other.
3. So union every edge and reject if any union fails (a cycle).
4. Alternatively check `dsu.count === 1` at the end.

Approach	Idea	Time	Space
DFS with parent tracking	Detect a cycle by revisiting a non-parent node, then verify all nodes were reached.	`O(V + E)`	`O(V + E)`
Union-find	Edge count check, then reject any union that closes a cycle.	`O(E·α)`	`O(V)`

Solution — js

```
function validTree(n, edges) {
  // a tree on n nodes has EXACTLY n-1 edges
  if (edges.length !== n - 1) return n === 0 && edges.length === 0;

  const dsu = new DSU(n);
  for (const [u, v] of edges) {
    if (!dsu.union(u, v)) return false;   // a cycle
  }
  // n-1 edges and no cycle => necessarily connected
  return true;
}
```

Solution — cpp

```
class Solution {
    vector<int> parent, sz;
    int find(int x) {
        while (parent[x] != x) { parent[x] = parent[parent[x]]; x = parent[x]; }
        return x;
    }
public:
    bool validTree(int n, vector<vector<int>>& edges) {
        if (n == 0) return edges.empty();
        if ((int)edges.size() != n - 1) return false;
        parent.resize(n); sz.assign(n, 1);
        iota(parent.begin(), parent.end(), 0);
        for (auto& e : edges) {
            int ra = find(e[0]), rb = find(e[1]);
            if (ra == rb) return false;
            if (sz[ra] < sz[rb]) swap(ra, rb);
            parent[rb] = ra; sz[ra] += sz[rb];
        }
        return true;
    }
};
```

Solution — python

```python
class Solution:
    def validTree(self, n: int, edges: list[list[int]]) -> bool:
        if n == 0:
            return not edges
        if len(edges) != n - 1:
            return False

        parent = list(range(n))
        size = [1] * n

        def find(x):
            while parent[x] != x:
                parent[x] = parent[parent[x]]
                x = parent[x]
            return x

        for u, v in edges:
            ra, rb = find(u), find(v)
            if ra == rb:
                return False
            if size[ra] < size[rb]:
                ra, rb = rb, ra
            parent[rb] = ra
            size[ra] += size[rb]
        return True
```

Solution — java

```java
class Solution {
    private int[] parent, size;
    private int find(int x) {
        while (parent[x] != x) { parent[x] = parent[parent[x]]; x = parent[x]; }
        return x;
    }
    public boolean validTree(int n, int[][] edges) {
        if (n == 0) return edges.length == 0;
        if (edges.length != n - 1) return false;
        parent = new int[n]; size = new int[n];
        for (int i = 0; i < n; i++) { parent[i] = i; size[i] = 1; }
        for (int[] e : edges) {
            int ra = find(e[0]), rb = find(e[1]);
            if (ra == rb) return false;
            if (size[ra] < size[rb]) { int t = ra; ra = rb; rb = t; }
            parent[rb] = ra; size[ra] += size[rb];
        }
        return true;
    }
}
```

WALKTHROUGH

THE EDGE-COUNT CHECK DOES MOST OF THE WORK.

A tree on `n` nodes has exactly `n - 1` edges — fewer means it cannot be connected, more means it must contain a cycle. Testing that first is O(1) and eliminates `[[0,1],[2,3]]` with `n = 4` before any traversal.

GIVEN THE RIGHT COUNT, ONE CHECK SUFFICES.

With exactly `n - 1` edges, connectivity and acyclicity are equivalent: a graph with `n - 1` edges and no cycle is a spanning tree, hence connected; and if it were disconnected it would need a cycle somewhere to use up the edges. So verifying "no union fails" is enough — you do not also need to check `dsu.count === 1`, though doing so is harmless and arguably clearer.

THE `N = 0` CASE

is a convention question. An empty graph is usually accepted as a (degenerate) tree; `edges.length !== n - 1` would be `0 !== -1`, which is true, so the guard is needed. Ask the interviewer rather than guessing.

Graphs: shortest paths and spanning trees

Once edges have weights, BFS stops working. Four algorithms cover everything you will be asked, and choosing between them is mostly about negative edges and how many sources you need.

Choosing the algorithm

Situation	Algorithm	Time
Unweighted, one source	**BFS**	O(V + E)
Weights 0 or 1	**0-1 BFS** (deque)	O(V + E)
Non-negative weights, one source	**Dijkstra**	O((V + E) log V)
Negative weights allowed	**Bellman–Ford**	O(V · E)
All pairs, small V	**Floyd–Warshall**	$O(V^3)$
Cheapest set of edges connecting everything	**Kruskal / Prim** (MST)	O(E log E)

```
THE DECISIVE QUESTION IS ALWAYS: ARE THERE NEGATIVE
EDGES?

  no  -> Dijkstra (or BFS if unweighted)
  yes -> Bellman-Ford, which also DETECTS negative cycles

WHY DIJKSTRA BREAKS ON NEGATIVE EDGES: it finalises a
node the moment it is popped, assuming no cheaper route
can appear later. A negative edge can make a later route
cheaper, invalidating a decision already made.

     A --1--> B --1--> C
     A --5--------------> C ... and C --(-10)--> B

  Dijkstra finalises B at cost 1 and never revisits it,
  missing the cost -5 route through C.

------------------------------------------------------------
DIJKSTRA — BFS with a priority queue

  dist = array filled with Infinity;  dist[src] = 0
  pq = min-heap of [distance, node], seeded with [0, src]

  while (pq not empty) {
      [d, u] = pq.pop()
      if (d > dist[u]) continue;        // STALE entry
      for ([v, w] of adj[u]) {
          const nd = d + w;
          if (nd < dist[v]) {           // RELAXATION
              dist[v] = nd;
              pq.push([nd, v]);
          }
      }
  }

  THE STALE CHECK IS ESSENTIAL. A node can be pushed
  several times with different tentative distances; when
  an out-of-date entry surfaces, skip it. Without that
  line the algorithm still terminates but wastes work and
  can relax from a distance that is no longer current.

  (Deleting or decreasing keys inside a heap is the
  alternative, and it is more trouble than it is worth.)

------------------------------------------------------------
MINIMUM SPANNING TREE — a different question

  Dijkstra minimises the distance FROM ONE SOURCE.
  An MST minimises the TOTAL WEIGHT of edges connecting
  everything. They are not the same and one does not
  solve the other.

  KRUSKAL   sort all edges ascending; add an edge if it
            joins two different components (union-find,
            chapter 29). Stop at V-1 edges.
  PRIM      grow one tree: repeatedly take the cheapest
            edge leaving the current set. Dijkstra's shape
            with "edge weight" instead of "path length".

  Kruskal is easier to write when you already have DSU.
```

Problems

How it shows up

Symptom	Cause
Wrong distances with negative edges	Dijkstra is invalid there — use Bellman–Ford
Dijkstra is slow	Missing the stale-entry check, or scanning for the minimum instead of using a heap
Unreachable node reported as 0	Distances must start at Infinity, not 0
Shortest path wrong on an unweighted graph	Used DFS — BFS is required
MST has a cycle	Kruskal must reject edges whose endpoints already share a root
MST incomplete	Graph is disconnected — no spanning tree exists
Used Dijkstra for an MST	Different objectives — minimise edge weight, not path length
Overflow adding distances	`Infinity + w` in fixed-width types — guard before relaxing

Check yourself

- ✓ Pick the right algorithm for six situations.
- ✓ Explain why Dijkstra fails on negative edges, with a concrete graph.
- ✓ Write Dijkstra and explain the stale-entry check.
- ✓ Say what "relaxation" means.
- ✓ Contrast a shortest-path tree with a minimum spanning tree.
- ✓ Describe Kruskal and the role of union-find in it.
- ✓ Say what Bellman–Ford gives you that Dijkstra does not.

Problems

Network delay time `Medium`

Pattern: Dijkstra

You are given `times[i] = [u, v, w]`, a **directed** edge from `u` to `v` taking `w` time. Nodes are labelled `1..n`.

A signal is sent from node `k`. Return the time for **all** nodes to receive it, or `-1` if some node never does.

A `MinHeap` class is provided.

Input	Output	Note
`times = [[2,1,1],[2,3,1],[3,4,1]], n = 4, k = 2`	`2`	
`times = [[1,2,1]], n = 2, k = 1`	`1`	
`times = [[1,2,1]], n = 2, k = 2`	`-1`	

HINTS

1. The answer is the *maximum* shortest-path distance from `k` to any node.
2. Weights are positive, so Dijkstra applies.
3. Push `[distance, node]` pairs and skip entries whose distance is worse than the best already recorded.
4. If any node still has distance Infinity at the end, return −1.

Approach	Idea	Time	Space
Bellman–Ford	Relax all edges V−1 times. Simpler to write and handles negatives, but O(V·E).	`O(V·E)`	`O(V)`
Dijkstra with a heap	Finalise nodes in increasing distance order.	`O((V+E) log V)`	`O(V+E)`

Solution — js

```
function networkDelayTime(times, n, k) {
  const adj = Array.from({length: n + 1}, () => []);
  for (const [u, v, w] of times) adj[u].push([v, w]);

  const dist = new Array(n + 1).fill(Infinity);
  dist[k] = 0;

  const pq = new MinHeap((a, b) => a[0] - b[0]);   // [dist, node]
  pq.push([0, k]);

  while (pq.size()) {
    const [d, u] = pq.pop();
    if (d > dist[u]) continue;         // STALE entry, skip

    for (const [v, w] of adj[u]) {
      const nd = d + w;
      if (nd < dist[v]) {              // RELAX
        dist[v] = nd;
        pq.push([nd, v]);
      }
    }
  }

  let worst = 0;
  for (let i = 1; i <= n; i++) {
    if (dist[i] === Infinity) return -1;   // unreachable
    worst = Math.max(worst, dist[i]);
  }
  return worst;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int networkDelayTime(vector<vector<int>>& times, int n, int k) {
        vector<vector<pair<int,int>>> adj(n + 1);
        for (auto& t : times) adj[t[0]].push_back({t[1], t[2]});

        vector<int> dist(n + 1, INT_MAX);
        dist[k] = 0;
        priority_queue<pair<int,int>, vector<pair<int,int>>,
                       greater<pair<int,int>>> pq;
        pq.push({0, k});

        while (!pq.empty()) {
            auto [d, u] = pq.top(); pq.pop();
            if (d > dist[u]) continue;
            for (auto& [v, w] : adj[u]) {
                if (d + w < dist[v]) { dist[v] = d + w; pq.push({dist[v], v}); }
            }
        }
        int worst = 0;
        for (int i = 1; i <= n; ++i) {
            if (dist[i] == INT_MAX) return -1;
            worst = max(worst, dist[i]);
        }
        return worst;
    }
};
```

Solution — python

```python
import heapq

class Solution:
    def networkDelayTime(self, times, n, k):
        adj = [[] for _ in range(n + 1)]
        for u, v, w in times:
            adj[u].append((v, w))

        dist = [float("inf")] * (n + 1)
        dist[k] = 0
        pq = [(0, k)]

        while pq:
            d, u = heapq.heappop(pq)
            if d > dist[u]:
                continue
            for v, w in adj[u]:
                if d + w < dist[v]:
                    dist[v] = d + w
                    heapq.heappush(pq, (dist[v], v))

        worst = 0
        for i in range(1, n + 1):
            if dist[i] == float("inf"):
                return -1
            worst = max(worst, dist[i])
        return worst
```

Solution — java

```java
class Solution {
    public int networkDelayTime(int[][] times, int n, int k) {
        List<List<int[]>> adj = new ArrayList<>();
        for (int i = 0; i <= n; i++) adj.add(new ArrayList<>());
        for (int[] t : times) adj.get(t[0]).add(new int[]{t[1], t[2]});

        int[] dist = new int[n + 1];
        Arrays.fill(dist, Integer.MAX_VALUE);
        dist[k] = 0;
        PriorityQueue<int[]> pq = new PriorityQueue<>((a, b) -> a[0] - b[0]);
        pq.add(new int[]{0, k});

        while (!pq.isEmpty()) {
            int[] cur = pq.poll();
            int d = cur[0], u = cur[1];
            if (d > dist[u]) continue;
            for (int[] e : adj.get(u)) {
                if (d + e[1] < dist[e[0]]) {
                    dist[e[0]] = d + e[1];
                    pq.add(new int[]{dist[e[0]], e[0]});
                }
            }
        }
        int worst = 0;
        for (int i = 1; i <= n; i++) {
            if (dist[i] == Integer.MAX_VALUE) return -1;
            worst = Math.max(worst, dist[i]);
        }
        return worst;
    }
}
```

WALKTHROUGH

REFRAMING THE QUESTION.

"When has everyone received the signal?" is the maximum over all nodes of the shortest time to reach that node — so it is a single-source shortest-path computation followed by a max. Spotting that the aggregate is a max over shortest paths, not something new, is the step people miss.

THE STALE CHECK EARNS ITS LINE.

A node can be pushed several times as better routes are discovered; the heap has no way to remove the obsolete entries. When one surfaces, `d > dist[u]` is true and it is discarded. Omitting the check does not break correctness — the relaxations would simply fail — but it does waste work, and it is the idiomatic form every reviewer expects.

WHY DIJKSTRA IS VALID HERE.

All times are positive. Popping the smallest tentative distance means no unexplored route can be shorter, because every remaining path costs at least as much and can only grow. That argument is exactly what negative edges destroy.

THE EMPTY-GRAPH CASE

(`n = 1`, no edges) returns 0: the source is reached at time 0 and there is nobody else.

Cheapest flights within K stops `Medium`

Pattern: Bellman–Ford with a bounded relaxation count

Given `n` cities and flights `[from, to, price]`, find the cheapest price from `src` to `dst` using **at most** `k` **stops** (so at most `k + 1` flights). Return `-1` if there is no such route.

Input	Output	Note
`n=4, flights=[[0,1,100],[1,2,100],[2,0,100],[1,3,600],[2,3,200]], src=0, dst=3, k=1`	`700`	0→1→3. The cheaper 0→1→2→3 needs 2 stops.
`n=3, flights=[[0,1,100],[1,2,100],[0,2,500]], src=0, dst=2, k=1`	`200`	
`n=3, flights=[[0,1,100],[1,2,100],[0,2,500]], src=0, dst=2, k=0`	`500`	

HINTS

1. Dijkstra optimises price alone and ignores the stop limit, so the cheapest route it finds may use too many hops.
2. Bellman–Ford relaxes all edges repeatedly. After `i` rounds, `dist` holds the best cost using at most `i` edges — exactly the bound you need.
3. Run `k + 1` rounds.
4. Crucially, each round must relax from a
   SNAPSHOT
   of the previous round, or one round can chain several flights.

Approach	Idea	Time	Space
Dijkstra ignoring stops	**Wrong.** Finds the cheapest route regardless of hop count.	`—`	`—`
Dijkstra on (node, stops) states	Correct: treat the stop count as part of the state. More bookkeeping.	`O(E·k log(V·k))`	`O(V·k)`
Bellman–Ford, k+1 rounds	The round count naturally bounds the number of edges used.	`O(k·E)`	`O(V)`

Solution — js

```
function findCheapestPrice(n, flights, src, dst, k) {
  let dist = new Array(n).fill(Infinity);
  dist[src] = 0;

  // after round i, dist[v] = cheapest cost using AT MOST i edges
  for (let round = 0; round <= k; round++) {
    // relax from a SNAPSHOT so one round cannot chain two flights
    const prev = dist.slice();
    for (const [u, v, w] of flights) {
      if (prev[u] === Infinity) continue;      // unreachable so far
      if (prev[u] + w < dist[v]) dist[v] = prev[u] + w;
    }
  }

  return dist[dst] === Infinity ? -1 : dist[dst];
}
```

Solution — cpp

```cpp
class Solution {
public:
    int findCheapestPrice(int n, vector<vector<int>>& flights,
                          int src, int dst, int k) {
        const int INF = 1e9;
        vector<int> dist(n, INF);
        dist[src] = 0;
        for (int round = 0; round <= k; ++round) {
            vector<int> prev = dist;
            for (auto& f : flights) {
                if (prev[f[0]] == INF) continue;
                dist[f[1]] = min(dist[f[1]], prev[f[0]] + f[2]);
            }
        }
        return dist[dst] == INF ? -1 : dist[dst];
    }
};
```

Solution — python

```python
class Solution:
    def findCheapestPrice(self, n, flights, src, dst, k):
        INF = float("inf")
        dist = [INF] * n
        dist[src] = 0
        for _ in range(k + 1):
            prev = dist[:]                # snapshot
            for u, v, w in flights:
                if prev[u] == INF:
                    continue
                if prev[u] + w < dist[v]:
                    dist[v] = prev[u] + w
        return -1 if dist[dst] == INF else dist[dst]
```

Solution — java

```java
class Solution {
    public int findCheapestPrice(int n, int[][] flights, int src, int dst, int k) {
        final int INF = 1_000_000_000;
        int[] dist = new int[n];
        Arrays.fill(dist, INF);
        dist[src] = 0;
        for (int round = 0; round <= k; round++) {
            int[] prev = dist.clone();
            for (int[] f : flights) {
                if (prev[f[0]] == INF) continue;
                dist[f[1]] = Math.min(dist[f[1]], prev[f[0]] + f[2]);
            }
        }
        return dist[dst] == INF ? -1 : dist[dst];
    }
}
```

WALKTHROUGH

THE SNAPSHOT IS THE ENTIRE PROBLEM.

Relaxing in place lets a single round use an edge whose source was itself improved earlier *in that same round*, chaining two flights into one hop count. Copying `dist` before each round forces every relaxation to start from the previous round's values, so after round `i` the array genuinely means "cheapest cost using at most `i` edges". Remove the snapshot and the first example returns 500 instead of 700, because it silently allows the two-stop route.

WHY BELLMAN–FORD SUITS A HOP LIMIT.

Its rounds correspond exactly to edge counts, so bounding the rounds bounds the path length for free. Dijkstra has no such notion — it would need `(node, stopsUsed)` as a composite state, which works but is more code.

ROUNDS, NOT STOPS.

"At most k stops" means at most `k + 1` flights, hence `k + 1` rounds. The `k = 0` test (direct flights only) and the `k = 2` vs `k = 3` pair are there to pin this down.

THE UNREACHABLE GUARD

avoids adding a weight to `Infinity`. In JavaScript that is harmless, but in C++ or Java a sentinel like `INT_MAX` would overflow — hence the smaller `1e9` sentinel and the explicit skip.

Minimum spanning tree cost (Kruskal) `Medium`

Pattern: Sort edges + union-find

Given `n` nodes labelled `0..n-1` and a list of weighted undirected edges `[u, v, w]`, return the total weight of a **minimum spanning tree**, or `-1` if the graph is not connected.

Input	Output	Note
`n = 4, edges = [[0,1,1],[1,2,2],[2,3,3],[0,3,10]]`	`6`	Take the three cheapest: 1 + 2 + 3.
`n = 3, edges = [[0,1,1]]`	`-1`	Node 2 is unreachable.

HINTS

1. Sort the edges by weight ascending, then take each edge only if it joins two currently separate components.
2. Union-find (chapter 29) answers "separate components?" in near-constant time.
3. A spanning tree on `n` nodes has exactly `n - 1` edges — if you finish with fewer, the graph is disconnected.

Approach	Idea	Time	Space
Try all edge subsets	Exponential.	`O(2^E)`	`O(E)`
Prim's algorithm	Grow one tree, always taking the cheapest edge leaving it. Uses a heap; better on dense graphs.	`O(E log V)`	`O(V+E)`
Kruskal's algorithm	Sort edges, accept those that merge components.	`O(E log E)`	`O(V)`

Solution — js

```
function mstCost(n, edges) {
  const parent = Array.from({length: n}, (_, i) => i);
  const size = new Array(n).fill(1);

  function find(x) {
    while (parent[x] !== x) { parent[x] = parent[parent[x]]; x = parent[x]; }
    return x;
  }

  // cheapest edges first
  const sorted = edges.slice().sort((a, b) => a[2] - b[2]);

  let total = 0, used = 0;
  for (const [u, v, w] of sorted) {
    let ru = find(u), rv = find(v);
    if (ru === rv) continue;          // would close a cycle

    if (size[ru] < size[rv]) { const t = ru; ru = rv; rv = t; }
    parent[rv] = ru;
    size[ru] += size[rv];

    total += w;
    if (++used === n - 1) break;      // tree complete
  }

  return used === n - 1 ? total : -1; // fewer edges => disconnected
}
```

Solution — cpp

```
class Solution {
    vector<int> parent, sz;
    int find(int x) {
        while (parent[x] != x) { parent[x] = parent[parent[x]]; x = parent[x]; }
        return x;
    }
public:
    int mstCost(int n, vector<vector<int>>& edges) {
        parent.resize(n); sz.assign(n, 1);
        iota(parent.begin(), parent.end(), 0);
        sort(edges.begin(), edges.end(),
             [](const vector<int>& a, const vector<int>& b){ return a[2] < b[2]; });
        long total = 0; int used = 0;
        for (auto& e : edges) {
            int ru = find(e[0]), rv = find(e[1]);
            if (ru == rv) continue;
            if (sz[ru] < sz[rv]) swap(ru, rv);
            parent[rv] = ru; sz[ru] += sz[rv];
            total += e[2];
            if (++used == n - 1) break;
        }
        return used == n - 1 ? (int)total : -1;
    }
};
```

Solution — python

```python
class Solution:
    def mstCost(self, n: int, edges: list[list[int]]) -> int:
        parent = list(range(n))
        size = [1] * n

        def find(x):
            while parent[x] != x:
                parent[x] = parent[parent[x]]
                x = parent[x]
            return x

        total = used = 0
        for u, v, w in sorted(edges, key=lambda e: e[2]):
            ru, rv = find(u), find(v)
            if ru == rv:
                continue
            if size[ru] < size[rv]:
                ru, rv = rv, ru
            parent[rv] = ru
            size[ru] += size[rv]
            total += w
            used += 1
            if used == n - 1:
                break
        return total if used == n - 1 else -1
```

Solution — java

```java
class Solution {
    private int[] parent, size;
    private int find(int x) {
        while (parent[x] != x) { parent[x] = parent[parent[x]]; x = parent[x]; }
        return x;
    }
    public int mstCost(int n, int[][] edges) {
        parent = new int[n]; size = new int[n];
        for (int i = 0; i < n; i++) { parent[i] = i; size[i] = 1; }
        int[][] sorted = edges.clone();
        Arrays.sort(sorted, (a, b) -> Integer.compare(a[2], b[2]));
        long total = 0; int used = 0;
        for (int[] e : sorted) {
            int ru = find(e[0]), rv = find(e[1]);
            if (ru == rv) continue;
            if (size[ru] < size[rv]) { int t = ru; ru = rv; rv = t; }
            parent[rv] = ru; size[ru] += size[rv];
            total += e[2];
            if (++used == n - 1) break;
        }
        return used == n - 1 ? (int) total : -1;
    }
}
```

WALKTHROUGH

WHY GREEDY IS OPTIMAL — THE CUT PROPERTY.

For any partition of the nodes into two sets, the cheapest edge crossing that partition belongs to some MST. Kruskal processes edges in increasing weight, so when it accepts an edge, that edge is the cheapest one crossing the cut between the two components it joins. Every accepted edge is therefore safe, and the result is a minimum spanning tree.

REJECTING AN EDGE IS EXACTLY THE UNION-FIND CYCLE TEST.

If both endpoints already share a root they are already connected, so adding the edge would create a cycle without connecting anything new — and since it is no cheaper than the edges already linking them, skipping it loses nothing.

COUNTING EDGES DETECTS DISCONNECTION.

A spanning tree needs exactly `n - 1` edges. Finishing the sorted list with fewer means some component was never joined, so no spanning tree exists. The `n = 1` case needs 0 edges and returns 0 — worth checking, since `used === n - 1` is `0 === 0`.

CONTRAST WITH DIJKSTRA ONE MORE TIME.

Dijkstra would connect everything to node 0 by shortest *path*, which is generally a different and more expensive edge set. The objectives differ, and confusing them is the classic error on this topic.

Recursion and divide and conquer

Solve a problem by solving smaller copies of itself. Get comfortable here and backtracking, trees and dynamic programming all become variations rather than new topics.

The pattern

```
EVERY RECURSIVE FUNCTION HAS EXACTLY THREE PARTS:

  1. BASE CASE      the smallest input, answered directly
  2. RECURSIVE CASE reduce toward the base case
  3. COMBINE        build the answer from the sub-answers

  function f(n) {
      if (n <= 1) return 1;        // 1. base
      return n * f(n - 1);         // 2 and 3
  }

THE TWO FAILURES:
  NO BASE CASE           -> infinite recursion, stack
                            overflow
  RECURSION THAT DOES
  NOT SHRINK THE INPUT   -> same thing

ALWAYS CHECK: does every recursive call move strictly
closer to the base case?

------------------------------------------------------------
THE LEAP OF FAITH

Do NOT trace the whole call tree in your head. Instead:

  ASSUME the recursive call already returns the correct
  answer for a smaller input, and ask only "given that,
  how do I build MY answer?"

For reversing a list: assume `reverse(head.next)` has
correctly reversed everything after the head. Then you
only have to attach the head to the end. That is one
line, and you never think about the depth.

THIS IS THE SINGLE MOST USEFUL MENTAL HABIT for
recursion, and it is what makes tree problems (chapter 24)
feel easy.

------------------------------------------------------------
DIVIDE AND CONQUER — a shape of recursion

  1. DIVIDE the problem into independent parts
  2. CONQUER each part recursively
  3. COMBINE the results

  merge sort      split in half, sort each, merge
  quicksort       partition, sort each side
  binary search   discard half (only ONE side survives)
  maximum subarray left, right, or crossing the middle

THE RECURRENCE TELLS YOU THE COST (chapter 02):
  T(n) = 2T(n/2) + O(n)   -> O(n log n)   merge sort
  T(n) = T(n/2)  + O(1)   -> O(log n)     binary search
  T(n) = 2T(n-1) + O(1)   -> O(2^n)       subsets

------------------------------------------------------------
RECURSION VERSUS ITERATION

  Recursion costs O(depth) STACK SPACE, always. A
  recursive walk of a skewed tree or a long list is O(n)
  space and can overflow — typically around 10^4 frames in
```

```
JavaScript, more in C++.

TAIL RECURSION (the recursive call is the last thing
that happens) can in principle be optimised into a loop.
C++ compilers usually do this; JavaScript engines
generally do NOT, despite the specification allowing it.
Do not rely on it.

CONVERT TO ITERATION with an explicit stack when depth
is a risk (chapter 23).
```

When to reach for it

The problem is self-similar

Trees, nested structures, "the same thing but smaller".

Divide into independent halves

Sorting, searching, closest pair.

Enumerate all possibilities

Subsets, permutations — backtracking (ch. 32).

Overlapping subproblems

Add memoisation and it becomes DP (ch. 33).

Do NOT use it

When depth is O(n) and n is large, or a simple loop is clearer.

Problems

How it shows up

Symptom	Cause
Stack overflow	Missing base case, or depth is O(n) on a large input
Returns `undefined`	A branch with no `return`
Exponentially slow	Recomputing the same subproblem — memoise
Wrong answer only for the smallest input	Base case handles the wrong value or is off by one
Works for one call, wrong on the next	Shared mutable state not reset between calls
Result accumulates across recursion	Passing a shared array without copying at the right moment
Infinite recursion on equal inputs	The recursive call does not strictly shrink the input

Check yourself

✓ Name the three parts of a recursive function.

- ✓ State the two ways recursion fails to terminate.
- ✓ Explain the leap of faith and apply it to reversing a linked list.
- ✓ Give the three steps of divide and conquer with two examples.
- ✓ Solve the recurrences for merge sort and binary search.
- ✓ Say what recursion costs in space and when that matters.
- ✓ Explain tail recursion and whether you can rely on it.

Problems

Pow(x, n) — fast exponentiation `Medium`

Pattern: Divide and conquer by halving

Implement `myPow(x, n)` computing `x` raised to the power `n`. `n` may be negative.

Answers within 1e-5 of the correct value are accepted.

Input	Output	Note
`x = 2.0, n = 10`	`1024.0`	
`x = 2.1, n = 3`	`9.261`	
`x = 2.0, n = -2`	`0.25`	$1 / 2^2$

HINTS

1. Multiplying `x` by itself `n` times is O(n). Halving is O(log n).
2. $x^n = (x^{n/2})^2$ for even `n`, and $x \cdot (x^{(n-1)/2})^2$ for odd.
3. Compute the half **ONCE** and square it — calling the recursion twice throws the saving away.
4. For negative `n`, compute the positive power and take the reciprocal.

Approach	Idea	Time	Space
Multiply n times	A simple loop.	`O(n)`	`O(1)`
Recursive halving	Square the half-power. Depth log n.	`O(log n)`	`O(log n)`
Iterative binary exponentiation	Walk the bits of `n`, squaring the base each step. Same speed, O(1) space.	`O(log n)`	`O(1)`

Solution — js

```javascript
function myPow(x, n) {
  if (n < 0) return 1 / myPow(x, -n);   // negative -> reciprocal
  if (n === 0) return 1;                // base case

  // compute the half ONCE, then square it
  const half = myPow(x, Math.floor(n / 2));

  return (n % 2 === 0) ? half * half
                       : half * half * x;
}
```

Solution — cpp

```cpp
class Solution {
public:
    double myPow(double x, int n) {
        long long m = n;                 // -INT_MIN overflows int
        if (m < 0) return 1.0 / power(x, -m);
        return power(x, m);
    }
private:
    double power(double x, long long n) {
        if (n == 0) return 1.0;
        double half = power(x, n / 2);
        return (n % 2 == 0) ? half * half : half * half * x;
    }
};
```

Solution — python

```python
class Solution:
    def myPow(self, x: float, n: int) -> float:
        if n < 0:
            return 1 / self.myPow(x, -n)
        if n == 0:
            return 1.0
        half = self.myPow(x, n // 2)
        return half * half if n % 2 == 0 else half * half * x
```

Solution — java

```java
class Solution {
    public double myPow(double x, int n) {
        long m = n;                      // avoid -Integer.MIN_VALUE
        if (m < 0) return 1.0 / power(x, -m);
        return power(x, m);
    }
    private double power(double x, long n) {
        if (n == 0) return 1.0;
        double half = power(x, n / 2);
        return (n % 2 == 0) ? half * half : half * half * x;
    }
}
```

WALKTHROUGH

COMPUTING THE HALF ONCE IS THE ENTIRE OPTIMISATION.

Writing `myPow(x, n/2) * myPow(x, n/2)` looks equivalent but makes two recursive calls per level, so the call tree doubles at every step and the whole thing collapses back to O(n). Binding the result to a variable and squaring it keeps exactly one call per level, giving depth log n.

NEGATIVE EXPONENTS ARE HANDLED ONCE, AT THE TOP.

Recursing with a negative `n` would never reach the `n === 0` base case. Converting to the positive power and taking the reciprocal at the outermost call keeps the recursion monotone.

THE OVERFLOW TRAP IN C++ AND JAVA.

Negating `INT_MIN` overflows, because its magnitude exceeds `INT_MAX`. Widening to `long` before negating is the standard fix — a detail JavaScript and Python do not have, and one interviewers do probe.

Reverse a string in place, recursively Easy

Pattern: Two pointers via recursion

Reverse an array of characters **in place**, using recursion rather than a loop.

The judge passes an array of single-character strings and checks the array after the call.

Input	Output	Note
`s = ["h","e","l","l","o"]`	`["o","l","l","e","h"]`	
`s = ["H","a","n","n","a","h"]`	`["h","a","n","n","a","H"]`	

HINTS

1. Swap the outermost pair, then recurse on everything between them.
2. The base case is when the two pointers meet or cross.
3. Pass the two indices as parameters — that is what shrinks the problem.

Approach	Idea	Time	Space
Two-pointer loop	Converge from both ends swapping. The obvious answer, O(1) space.	`O(n)`	`O(1)`
Recursive with index parameters	Same swaps, expressed recursively. O(n) stack — worse, but it is what the question asks for.	`O(n)`	`O(n)`

Solution — js

```
function reverseString(s) {
  function helper(lo, hi) {
    if (lo >= hi) return;                 // met or crossed: done
    [s[lo], s[hi]] = [s[hi], s[lo]];      // swap the outer pair
    helper(lo + 1, hi - 1);               // recurse inward
  }
  helper(0, s.length - 1);
}
```

Solution — cpp

```
class Solution {
    void helper(vector<char>& s, int lo, int hi) {
        if (lo >= hi) return;
        swap(s[lo], s[hi]);
        helper(s, lo + 1, hi - 1);
    }
public:
    void reverseString(vector<char>& s) { helper(s, 0, (int)s.size() - 1); }
};
```

Solution — python

```
class Solution:
    def reverseString(self, s: list[str]) -> None:
        def helper(lo, hi):
            if lo >= hi:
                return
            s[lo], s[hi] = s[hi], s[lo]
            helper(lo + 1, hi - 1)
        helper(0, len(s) - 1)
```

Solution — java

```
class Solution {
    public void reverseString(char[] s) { helper(s, 0, s.length - 1); }
    private void helper(char[] s, int lo, int hi) {
        if (lo >= hi) return;
        char t = s[lo]; s[lo] = s[hi]; s[hi] = t;
        helper(s, lo + 1, hi - 1);
    }
}
```

WALKTHROUGH

THE BASE CASE MUST BE `LO >= HI`, NOT `LO === HI`.

With an even length the pointers cross without ever being equal — `["a","b"]` goes from `(0,1)` straight to `(1,0)`. Testing only for equality would recurse past each other forever. The empty-array test also depends on it, since `hi` starts at `-1`.

THE PARAMETERS ARE WHAT SHRINK.

The array itself never gets smaller; the *window* does. That is the usual way to recurse over an array without copying, and it is the same technique backtracking uses (chapter 32).

BE HONEST ABOUT THE TRADE.

The iterative version is O(1) space; this is O(n) stack for no benefit. It is worth writing once to internalise the shape, but in an interview say plainly that the loop is better unless recursion was explicitly requested.

Count inversions with merge sort `Hard`

Pattern: Divide and conquer with a combine-step count

An **inversion** is a pair of indices `i < j` with `nums[i] > nums[j]`. Return the number of inversions in the array.

Must be better than $O(n^2)$.

Input	Output	Note
`nums = [2,4,1,3,5]`	`3`	(2,1), (4,1), (4,3)
`nums = [5,4,3,2,1]`	`10`	Every pair is inverted.
`nums = [1,2,3]`	`0`	

HINTS

1. Counting pairs directly is O(n^2). Merge sort already compares elements across a split — reuse that.
2. Sort each half, then count the inversions *between* the halves during the merge.
3. When you take an element from the right half while `i` elements remain unconsumed in the left half, that element is smaller than all of them — so it forms `i` inversions at once.
4. Total = inversions in the left + in the right + across the merge.

Approach	Idea	Time	Space
Check every pair	Two nested loops.	`O(n²)`	`O(1)`
Merge sort with counting	The merge step reveals cross-half inversions in bulk.	`O(n log n)`	`O(n)`
Fenwick tree	Sweep right to left counting how many smaller values were already seen. Same complexity, different machinery.	`O(n log n)`	`O(n)`

Solution — js

```
function countInversions(nums) {
  // returns [sorted, inversions]
  function sortCount(a) {
    if (a.length <= 1) return [a, 0];

    const mid = a.length >> 1;
    const [left,  cl] = sortCount(a.slice(0, mid));
    const [right, cr] = sortCount(a.slice(mid));

    const merged = [];
    let i = 0, j = 0, cross = 0;

    while (i < left.length && j < right.length) {
      if (left[i] <= right[j]) {
        merged.push(left[i++]);          // no inversion
      } else {
        // right[j] is smaller than EVERY remaining left element
        cross += left.length - i;
        merged.push(right[j++]);
      }
    }
    while (i < left.length)  merged.push(left[i++]);
    while (j < right.length) merged.push(right[j++]);

    return [merged, cl + cr + cross];
  }

  return sortCount(nums.slice())[1];
}
```

Solution — cpp

```cpp
class Solution {
    long long sortCount(vector<int>& a, vector<int>& buf, int lo, int hi) {
        if (hi - lo <= 1) return 0;
        int mid = lo + (hi - lo) / 2;
        long long count = sortCount(a, buf, lo, mid) + sortCount(a, buf, mid, hi);
        int i = lo, j = mid, k = lo;
        while (i < mid && j < hi) {
            if (a[i] <= a[j]) buf[k++] = a[i++];
            else { count += mid - i; buf[k++] = a[j++]; }
        }
        while (i < mid) buf[k++] = a[i++];
        while (j < hi)  buf[k++] = a[j++];
        copy(buf.begin() + lo, buf.begin() + hi, a.begin() + lo);
        return count;
    }
public:
    long long countInversions(vector<int>& nums) {
        vector<int> a = nums, buf(nums.size());
        return sortCount(a, buf, 0, a.size());
    }
};
```

Solution — python

```python
class Solution:
    def countInversions(self, nums: list[int]) -> int:
        def sort_count(a):
            if len(a) <= 1:
                return a, 0
            mid = len(a) // 2
            left, cl = sort_count(a[:mid])
            right, cr = sort_count(a[mid:])

            merged = []
            i = j = cross = 0
            while i < len(left) and j < len(right):
                if left[i] <= right[j]:
                    merged.append(left[i]); i += 1
                else:
                    cross += len(left) - i
                    merged.append(right[j]); j += 1
            merged.extend(left[i:])
            merged.extend(right[j:])
            return merged, cl + cr + cross

        return sort_count(list(nums))[1]
```

Solution — java

```
class Solution {
    public long countInversions(int[] nums) {
        int[] a = nums.clone(), buf = new int[nums.length];
        return sortCount(a, buf, 0, a.length);
    }
    private long sortCount(int[] a, int[] buf, int lo, int hi) {
        if (hi - lo <= 1) return 0;
        int mid = lo + (hi - lo) / 2;
        long count = sortCount(a, buf, lo, mid) + sortCount(a, buf, mid, hi);
        int i = lo, j = mid, k = lo;
        while (i < mid && j < hi) {
            if (a[i] <= a[j]) buf[k++] = a[i++];
            else { count += mid - i; buf[k++] = a[j++]; }
        }
        while (i < mid) buf[k++] = a[i++];
        while (j < hi)  buf[k++] = a[j++];
        System.arraycopy(buf, lo, a, lo, hi - lo);
        return count;
    }
}
```

WALKTHROUGH

THE BULK COUNT IS THE INSIGHT.

During the merge, both halves are already sorted. If `right[j] < left[i]`, then `right[j]` is smaller than `left[i]` *and* every element after it in the left half — because the left half is sorted. All of those are inversions, and there are exactly `left.length - i` of them. Counting them one at a time would be O(n^2); counting them as a group is what makes the whole thing O(n log n).

WHY THE THREE TERMS ARE EXHAUSTIVE.

Any inversion has its two indices either both in the left half, both in the right half, or one in each. The first two are counted by the recursive calls, the third by the merge. No pair is counted twice, because the halves are disjoint.

`<=` KEEPS EQUAL ELEMENTS NON-INVERTED.

An inversion requires `nums[i] > nums[j]` strictly, so ties must take from the left and add nothing. The `[3,3,3]` test returns 0 only if you get this right; using `<` would count three phantom inversions.

THIS IS THE SAME TECHNIQUE AS "COUNT OF SMALLER NUMBERS AFTER SELF" AND "REVERSE PAIRS"

— recognising that a sorting algorithm can carry a counter through its combine step is the transferable idea.

Backtracking

Build a candidate one choice at a time, abandon it the moment it cannot work, and undo the choice on the way out. One template covers subsets, permutations, combinations and every puzzle-solver.

The pattern

```
THE TEMPLATE — learn this shape, not the individual
problems:

  function backtrack(path, choices) {
      if (isComplete(path)) {
          result.push([...path]);      // COPY, not the ref
          return;
      }
      for (const c of choices) {
          if (!isValid(c, path)) continue;   // PRUNE

          path.push(c);                // 1. CHOOSE
          backtrack(path, next(c));    // 2. EXPLORE
          path.pop();                  // 3. UN-CHOOSE
      }
  }

THE THREE STEPS ARE ALWAYS CHOOSE / EXPLORE / UN-CHOOSE.
The un-choose is what makes it "backtracking" rather than
plain recursion — it restores the state so the next branch
starts clean.

------------------------------------------------------------
THE TWO MISTAKES THAT ACCOUNT FOR MOST BUGS

1. PUSHING THE PATH WITHOUT COPYING
     result.push(path);      // WRONG — stores a reference
     result.push([...path]); // right — snapshot

   `path` keeps mutating, so every stored reference ends
   up pointing at the same (eventually empty) array.

2. FORGETTING TO UNDO
     Every mutation before the recursive call needs a
     matching undo after it — the array push, a `used[]`
     flag, a board cell, a running sum.

------------------------------------------------------------
SUBSETS VERSUS PERMUTATIONS VERSUS COMBINATIONS

  SUBSETS       order does NOT matter, each item optional
                -> pass `start` so you never look back
                -> 2^n results
  COMBINATIONS  subsets of a fixed size k
                -> same `start`, plus a size check
                -> C(n, k) results
  PERMUTATIONS  order DOES matter, all items used
                -> no `start`; a `used[]` array instead
                -> n! results

  THE `start` PARAMETER IS THE WHOLE DIFFERENCE between
  subsets and permutations. `start` forbids revisiting
  earlier indices, which is exactly what makes [1,2] and
  [2,1] the same subset but different permutations.

------------------------------------------------------------
HANDLING DUPLICATE INPUT

  SORT FIRST, then inside the loop skip a value equal to
  the previous one at the SAME LEVEL:
```

```
        if (i > start && nums[i] === nums[i-1]) continue;

    `i > start` is essential: the first occurrence at each
    level must be allowed; only repeats are skipped.

  ------------------------------------------------------
  COST: exponential by nature. Backtracking is what you use
  when the answer genuinely requires enumeration —
  which is why constraints of n <= 20 or so point here
  (chapter 02). PRUNING is what makes it survivable in
  practice: the earlier you can reject a partial candidate,
  the more of the tree you never build.
```

When to reach for it

"All possible ..."

Subsets, permutations, combinations, partitions.

"Generate every valid ..."

Parentheses, IP addresses, palindrome partitions.

Constraint puzzles

N-Queens, Sudoku, word search.

Path enumeration

All root-to-leaf paths, all routes in a maze.

Small n with no better structure

n ≤ 20 and the problem resists DP or greedy.

Do NOT use it

When you only need a *count* or an *optimum* — that is usually DP (ch. 33).

Problems

How it shows up

Symptom	Cause
All results identical or empty	Pushed the path by reference instead of copying
Results contaminated across branches	Missing the un-choose step
Permutations appear as subsets	Used `start` where a `used[]` array was needed
Duplicate results	Input not sorted, or the same-level skip missing
Valid first occurrence skipped	Skip condition missing the `i > start` guard
Times out	No pruning — reject invalid partials earlier
Stack overflow	Recursion never reaches the completion check

Check yourself

- ✓ Write the template and name the three steps.
- ✓ Explain why the path must be copied when recorded.
- ✓ Say what the `start` parameter does and which problems need it.
- ✓ Contrast subsets, combinations and permutations in result count and mechanism.
- ✓ Give the duplicate-skip line and explain the `i > start` guard.
- ✓ Say what pruning buys and give an example.
- ✓ State when backtracking is the wrong tool.

Problems

Subsets `Medium`

Pattern: Backtracking with a start index

Given an array of **distinct** integers, return all possible subsets (the power set). The solution must not contain duplicate subsets; order does not matter.

Input	Output	Note
`nums = [1,2,3]`	`[[],[1],[1,2],[1,2,3],[1,3],[2],[2,3],[3]]`	
`nums = [0]`	`[[],[0]]`	

HINTS

1. Every element is either in a subset or not — so there are 2^n results.
2. Record the current path at *every* node of the recursion, not only at the leaves. Each partial path is itself a valid subset.
3. Pass a `start` index so each branch only considers elements after the one just taken; that prevents [1,2] and [2,1] both appearing.

Approach	Idea	Time	Space
Bitmask enumeration	For each mask $0..2^n-1$, include element `i` when bit `i` is set (chapter 16).	`O(2ⁿ·n)`	`O(n)`
Iterative doubling	Start with [[]]; for each element, append it to a copy of every subset so far.	`O(2ⁿ·n)`	`O(2ⁿ·n)`
Backtracking	Choose / explore / un-choose with a start index.	`O(2ⁿ·n)`	`O(n)` `recursion`

Solution — js

```javascript
function subsets(nums) {
  const out = [], path = [];

  function backtrack(start) {
    out.push([...path]);            // COPY — every node is a subset

    for (let i = start; i < nums.length; i++) {
      path.push(nums[i]);           // 1. CHOOSE
      backtrack(i + 1);             // 2. EXPLORE (never look back)
      path.pop();                   // 3. UN-CHOOSE
    }
  }

  backtrack(0);
  return out;
}
```

Solution — cpp

```cpp
class Solution {
    vector<vector<int>> out;
    vector<int> path;
    void backtrack(vector<int>& nums, int start) {
        out.push_back(path);
        for (int i = start; i < (int)nums.size(); ++i) {
            path.push_back(nums[i]);
            backtrack(nums, i + 1);
            path.pop_back();
        }
    }
public:
    vector<vector<int>> subsets(vector<int>& nums) {
        backtrack(nums, 0);
        return out;
    }
};
```

Solution — python

```python
class Solution:
    def subsets(self, nums: list[int]) -> list[list[int]]:
        out, path = [], []

        def backtrack(start):
            out.append(path[:])          # copy
            for i in range(start, len(nums)):
                path.append(nums[i])
                backtrack(i + 1)
                path.pop()

        backtrack(0)
        return out
```

Solution — java

```java
class Solution {
    private final List<List<Integer>> out = new ArrayList<>();
    private final List<Integer> path = new ArrayList<>();
    public List<List<Integer>> subsets(int[] nums) {
        backtrack(nums, 0);
        return out;
    }
    private void backtrack(int[] nums, int start) {
        out.add(new ArrayList<>(path));      // copy
        for (int i = start; i < nums.length; i++) {
            path.add(nums[i]);
            backtrack(nums, i + 1);
            path.remove(path.size() - 1);
        }
    }
}
```

WALKTHROUGH

RECORDING AT EVERY NODE, NOT JUST THE LEAVES.

Unlike permutations — where only a complete arrangement counts — every partial path here is already a valid subset. So the `push` happens on entry, before the loop, and there is no separate completion check. That is why the empty array appears first: it is the path at the root.

`BACKTRACK(I + 1)`, NOT `BACKTRACK(START + 1)`.

The next level must resume after the element just chosen, which is `i`. Using `start + 1` would allow the same element to be picked again at a deeper level and produce duplicates.

THE COPY IS MANDATORY.

`path` is a single array mutated throughout; storing it by reference gives 2^n pointers to the same object, which is empty by the time the recursion unwinds. This is the most common backtracking bug and it produces spectacularly wrong output.

Permutations `Medium`

Pattern: Backtracking with a used array

Given an array of **distinct** integers, return all possible permutations. Order of the results does not matter.

Input	Output	Note
`nums = [1,2,3]`	`[[1,2,3],[1,3,2],[2,1,3],[2,3,1],[3,1,2],[3,2,1]]`	
`nums = [1]`	`[[1]]`	

HINTS

1. Unlike subsets, order matters and every element must be used — so no `start` index.
2. Track which indices are already in the path with a boolean array.
3. Only record when the path has full length.
4. Remember to clear the `used` flag in the un-choose step as well as popping the path.

Approach	Idea	Time	Space
Backtracking with <code>used[] </code>	Try every unused element at each position.	`O(n! ·n)`	`O(n)`
Swap in place	Swap element `i` into position, recurse, swap back. Avoids the extra array.	`O(n! ·n)`	`O(n)`
Insert into every gap	Build permutations of the first k elements, then insert the next into every position.	`O(n! ·n)`	`O(n! ·n)`

Solution — js

```
function permute(nums) {
  const out = [], path = [];
  const used = new Array(nums.length).fill(false);

  function backtrack() {
    if (path.length === nums.length) {   // COMPLETE
      out.push([...path]);
      return;
    }
    for (let i = 0; i < nums.length; i++) {
      if (used[i]) continue;            // already in the path

      used[i] = true;  path.push(nums[i]);   // CHOOSE
      backtrack();                            // EXPLORE
      path.pop();      used[i] = false;       // UN-CHOOSE (both!)
    }
  }

  backtrack();
  return out;
}
```

Solution — cpp

```
class Solution {
    vector<vector<int>> out;
    vector<int> path;
    vector<bool> used;
    void backtrack(vector<int>& nums) {
        if (path.size() == nums.size()) { out.push_back(path); return; }
        for (int i = 0; i < (int)nums.size(); ++i) {
            if (used[i]) continue;
            used[i] = true; path.push_back(nums[i]);
            backtrack(nums);
            path.pop_back(); used[i] = false;
        }
    }
public:
    vector<vector<int>> permute(vector<int>& nums) {
        used.assign(nums.size(), false);
        backtrack(nums);
        return out;
    }
};
```

Solution — python

```python
class Solution:
    def permute(self, nums: list[int]) -> list[list[int]]:
        out, path = [], []
        used = [False] * len(nums)

        def backtrack():
            if len(path) == len(nums):
                out.append(path[:])
                return
            for i, v in enumerate(nums):
                if used[i]:
                    continue
                used[i] = True
                path.append(v)
                backtrack()
                path.pop()
                used[i] = False

        backtrack()
        return out
```

Solution — java

```java
class Solution {
    private final List<List<Integer>> out = new ArrayList<>();
    private final List<Integer> path = new ArrayList<>();
    private boolean[] used;
    public List<List<Integer>> permute(int[] nums) {
        used = new boolean[nums.length];
        backtrack(nums);
        return out;
    }
    private void backtrack(int[] nums) {
        if (path.size() == nums.length) { out.add(new ArrayList<>(path)); return; }
        for (int i = 0; i < nums.length; i++) {
            if (used[i]) continue;
            used[i] = true; path.add(nums[i]);
            backtrack(nums);
            path.remove(path.size() - 1); used[i] = false;
        }
    }
}
```

WALKTHROUGH

NO `START` IS THE WHOLE DIFFERENCE FROM SUBSETS.

Every level scans the full array, because a later element may need to appear before an earlier one. What prevents reuse is the `used` array, not a positional bound — which is precisely why `[1,2]` and `[2,1]` are both produced here and only one of them in subsets.

TWO THINGS ARE CHOSEN, SO TWO THINGS MUST BE UN-CHOSEN.

The `path.pop()` and the `used[i] = false` must both happen. Forgetting the flag reset means an element is consumed permanently after its first use and only one permutation is ever produced.

RECORDING ONLY AT FULL LENGTH.

A partial arrangement is not a permutation, so unlike subsets the push is guarded by the completion check.

THE FOLLOW-UP:

with duplicate input, sort first and skip `i` when `nums[i] === nums[i-1] && !used[i-1]` — the `!used[i-1]` ensures duplicates are consumed in a fixed left-to-right order, which yields each distinct permutation exactly once.

Combination sum `Medium`

Pattern: Backtracking with reuse and pruning

Given an array of **distinct** positive integers `candidates` and a `target`, return all unique combinations that sum to the target. The **same number may be used unlimited times**, and two combinations are the same if they contain the same multiset of numbers.

Input	Output	Note
`candidates = [2,3,6,7], target = 7`	`[[2,2,3],[7]]`	
`candidates = [2,3,5], target = 8`	`[[2,2,2,2],[2,3,3],[3,5]]`	
`candidates = [2], target = 1`	`[]`	

HINTS

1. Because numbers may repeat, the recursive call passes `i` rather than `i + 1`.
2. Still use a `start` index so combinations are generated in non-decreasing order — that is what stops [2,3] and [3,2] both appearing.
3. Track the remaining target. Zero means success; negative means abandon this branch.
4. Sorting the candidates lets you `break` out of the loop as soon as a candidate exceeds the remainder.

Approach	Idea	Time	Space
Generate then filter	Enumerate everything and keep those that sum correctly. Hopeless.	`huge`	`huge`
Backtracking with a remainder	Subtract as you go; prune when it goes negative.	`exponential`	`O(target/min)`
Sort + break early	Same, but the sorted order lets you stop the loop rather than skipping.	`exponential, much faster in practice`	`O(target/min)`

Solution — js

```
function combinationSum(candidates, target) {
  const out = [], path = [];
  // sorting enables the early break below
  const sorted = candidates.slice().sort((a, b) => a - b);

  function backtrack(start, remain) {
    if (remain === 0) {
      out.push([...path]);        // COPY
      return;
    }

    for (let i = start; i < sorted.length; i++) {
      // sorted, so every later candidate is also too big
      if (sorted[i] > remain) break;          // PRUNE

      path.push(sorted[i]);                   // CHOOSE
      backtrack(i, remain - sorted[i]);       // EXPLORE - i, so
                                              // reuse is allowed
      path.pop();                             // UN-CHOOSE
    }
  }

  backtrack(0, target);
  return out;
}
```

Solution — cpp

```
class Solution {
    vector<vector<int>> out;
    vector<int> path;
    void backtrack(vector<int>& c, int start, int remain) {
        if (remain == 0) { out.push_back(path); return; }
        for (int i = start; i < (int)c.size(); ++i) {
            if (c[i] > remain) break;
            path.push_back(c[i]);
            backtrack(c, i, remain - c[i]);
            path.pop_back();
        }
    }
public:
    vector<vector<int>> combinationSum(vector<int>& candidates, int target) {
        sort(candidates.begin(), candidates.end());
        backtrack(candidates, 0, target);
        return out;
    }
};
```

Solution — python

```python
class Solution:
    def combinationSum(self, candidates: list[int], target: int) -> list[list[int]]:
        out, path = [], []
        c = sorted(candidates)

        def backtrack(start, remain):
            if remain == 0:
                out.append(path[:])
                return
            for i in range(start, len(c)):
                if c[i] > remain:
                    break
                path.append(c[i])
                backtrack(i, remain - c[i])   # i: reuse allowed
                path.pop()

        backtrack(0, target)
        return out
```

Solution — java

```java
class Solution {
    private final List<List<Integer>> out = new ArrayList<>();
    private final List<Integer> path = new ArrayList<>();
    public List<List<Integer>> combinationSum(int[] candidates, int target) {
        int[] c = candidates.clone();
        Arrays.sort(c);
        backtrack(c, 0, target);
        return out;
    }
    private void backtrack(int[] c, int start, int remain) {
        if (remain == 0) { out.add(new ArrayList<>(path)); return; }
        for (int i = start; i < c.length; i++) {
            if (c[i] > remain) break;
            path.add(c[i]);
            backtrack(c, i, remain - c[i]);
            path.remove(path.size() - 1);
        }
    }
}
```

WALKTHROUGH

`BACKTRACK(I, …)` IS WHAT PERMITS REUSE.

Subsets pass `i + 1` to move past the chosen element; here passing `i` lets the same candidate be chosen again at the next level, giving `[2,2,3]`. Keeping `start` at all is still necessary — it forces non-decreasing order, so `[2,3]` is generated but `[3,2]` never is, which is exactly the "no duplicate combinations" requirement.

SORTING TURNS A `CONTINUE` INTO A `BREAK`.

Once `sorted[i] > remain`, every subsequent candidate is larger still and equally hopeless, so the entire rest of the loop can be abandoned. That single change prunes a large fraction of the tree and is the difference between comfortable and slow on bigger inputs. Note the test `[7,3,2]` is deliberately unsorted to confirm the sort actually happens.

TRACKING THE REMAINDER RATHER THAN A RUNNING SUM

makes the base case a clean `remain === 0` and the prune a clean comparison, with no need to also carry the target around.

N-Queens `Hard`

Pattern: Backtracking with constraint sets

Place `n` queens on an `n × n` board so that no two attack each other (no shared row, column or diagonal). Return the **number** of distinct solutions.

Input	Output	Note
`n = 4`	`2`	
`n = 1`	`1`	
`n = 8`	`92`	

HINTS

1. Place one queen per row, so rows are automatically distinct — the choice at each level is just the column.
2. Track occupied columns in a set. For the diagonals, notice that `r - c` is constant along one diagonal and `r + c` along the other.
3. Use `r - c + n` as the index if you want array indices rather than a set, to keep it non-negative.
4. Choose, recurse, then remove all three markers on the way out.

Approach	Idea	Time	Space
Try every placement	Choose n cells from n^2 and validate. Astronomically wasteful.	`C(n², n)`	`O(n)`
Row by row with a validity scan	One queen per row; check each candidate against all placed queens. O(n) per check.	`O(n!·n)`	`O(n)`
Row by row with O(1) constraint sets	Column and both diagonal keys in sets, so validity is a constant-time test.	`O(n!)`	`O(n)`

Solution — js

```
function totalNQueens(n) {
  const cols  = new Set();   // occupied columns
  const diag1 = new Set();   // r - c  (constant on one diagonal)
  const diag2 = new Set();   // r + c  (constant on the other)
  let count = 0;

  function backtrack(row) {
    if (row === n) { count++; return; }   // all rows filled

    for (let c = 0; c < n; c++) {
      const d1 = row - c, d2 = row + c;
      if (cols.has(c) || diag1.has(d1) || diag2.has(d2)) continue;

      cols.add(c); diag1.add(d1); diag2.add(d2);      // CHOOSE
      backtrack(row + 1);                             // EXPLORE
      cols.delete(c); diag1.delete(d1); diag2.delete(d2); // UNDO
    }
  }

  backtrack(0);
  return count;
}
```

Solution — cpp

```
class Solution {
    int n, count = 0;
    vector<bool> cols, d1, d2;
    void backtrack(int row) {
        if (row == n) { ++count; return; }
        for (int c = 0; c < n; ++c) {
            int i1 = row - c + n, i2 = row + c;
            if (cols[c] || d1[i1] || d2[i2]) continue;
            cols[c] = d1[i1] = d2[i2] = true;
            backtrack(row + 1);
            cols[c] = d1[i1] = d2[i2] = false;
        }
    }
public:
    int totalNQueens(int nn) {
        n = nn; count = 0;
        cols.assign(n, false);
        d1.assign(2 * n, false);
        d2.assign(2 * n, false);
        backtrack(0);
        return count;
    }
};
```

Solution — python

```
class Solution:
    def totalNQueens(self, n: int) -> int:
        cols, diag1, diag2 = set(), set(), set()
        self.count = 0

        def backtrack(row):
            if row == n:
                self.count += 1
                return
            for c in range(n):
                d1, d2 = row - c, row + c
                if c in cols or d1 in diag1 or d2 in diag2:
                    continue
                cols.add(c); diag1.add(d1); diag2.add(d2)
                backtrack(row + 1)
                cols.remove(c); diag1.remove(d1); diag2.remove(d2)

        backtrack(0)
        return self.count
```

Solution — java

```
class Solution {
    private int n, count;
    private boolean[] cols, d1, d2;
    public int totalNQueens(int n) {
        this.n = n; this.count = 0;
        cols = new boolean[n];
        d1 = new boolean[2 * n];
        d2 = new boolean[2 * n];
        backtrack(0);
        return count;
    }
    private void backtrack(int row) {
        if (row == n) { count++; return; }
        for (int c = 0; c < n; c++) {
            int i1 = row - c + n, i2 = row + c;
            if (cols[c] || d1[i1] || d2[i2]) continue;
            cols[c] = d1[i1] = d2[i2] = true;
            backtrack(row + 1);
            cols[c] = d1[i1] = d2[i2] = false;
        }
    }
}
```

WALKTHROUGH

ONE QUEEN PER ROW REMOVES AN ENTIRE DIMENSION.

Since two queens can never share a row, fixing "row `r` gets exactly one queen" means the only decision at depth `r` is which column — reducing the search from choosing cells to choosing a permutation of columns.

THE DIAGONAL KEYS ARE THE NEAT PART.

Along a top-left-to-bottom-right diagonal, moving one step down and one right increases both `r` and `c` by 1, so `r - c` is invariant. Along the other diagonal `r` increases as `c` decreases, so `r + c` is invariant. Two integers therefore identify the two diagonals through any cell, making the attack test three O(1) set lookups instead of an O(n) scan over placed queens.

THREE MARKERS SET, THREE MARKERS CLEARED.

The undo must mirror the choose exactly; leaving one diagonal marked poisons every sibling branch and silently undercounts. Testing `n = 8` against the known answer of 92 catches that immediately, which is why it is in the list.

`N = 2` AND `N = 3` RETURN 0

— genuinely unsolvable, and a good check that the code does not assume a solution exists. In C++ and Java the diagonal index is shifted by `+n` to keep it non-negative for array indexing; a set-based language does not need that.

DP: the method, memoisation and tabulation

Recursion that stops recomputing. Dynamic programming has a reputation for difficulty because people try to leap straight to the table — the reliable route is to write the recursion first and then cache it.

The method

```
DP APPLIES WHEN BOTH OF THESE HOLD:

  OPTIMAL SUBSTRUCTURE   the answer is built from answers
                         to smaller subproblems
  OVERLAPPING SUBPROBLEMS the same subproblem is reached
                         many times

The second is what distinguishes DP from plain divide and
conquer. Merge sort has optimal substructure but its
halves never overlap, so caching would gain nothing.

------------------------------------------------------
THE FOUR-STEP RECIPE. FOLLOW IT IN ORDER.

  1. WRITE THE BRUTE-FORCE RECURSION.
     What is the smallest decision? What does it leave?
     Do not think about efficiency yet.

  2. IDENTIFY THE STATE.
     Which parameters actually change between calls?
     Those, and only those, are the memo key.

  3. ADD MEMOISATION.
     One dictionary or array. This alone usually takes
     the solution from exponential to polynomial.

  4. (optional) CONVERT TO TABULATION.
     Fill the table in dependency order with loops.
     Removes the recursion depth risk and often allows
     space to be reduced.

  MOST INTERVIEWERS ACCEPT STEP 3. Do not skip 1 and 2 to
  get there faster - writing the recursion first is what
  makes the state obvious.

------------------------------------------------------
TOP-DOWN (memoised recursion)

  const memo = new Map();
  function f(state) {
      if (isBase(state)) return baseValue;
      if (memo.has(state)) return memo.get(state);

      const result = combine(f(smaller1), f(smaller2));
      memo.set(state, result);
      return result;
  }

  + follows the natural recursion
  + only computes states actually REACHED
  - recursion depth, and hashing overhead

BOTTOM-UP (tabulation)

  const dp = new Array(n + 1);
  dp[0] = base;
  for (let i = 1; i <= n; i++)
      dp[i] = combine(dp[i - 1], dp[i - 2]);
  return dp[n];

  + no recursion, usually faster constants
```

```
  + SPACE OPTIMISATION becomes visible
  - you must work out the fill order yourself
  - computes every state, even unreachable ones

------------------------------------------------------------
SPACE OPTIMISATION — the standard follow-up

  If dp[i] depends only on dp[i-1] and dp[i-2], you never
  need the whole array:

    let prev2 = base0, prev1 = base1;
    for (let i = 2; i <= n; i++) {
        const cur = f(prev1, prev2);
        prev2 = prev1;
        prev1 = cur;
    }

  O(n) space becomes O(1). The same idea reduces a 2-D
  table to two rows, or sometimes one (chapter 34).

------------------------------------------------------------
HOW TO SPOT A DP PROBLEM

  "how many ways ..."          COUNT
  "minimum / maximum cost"     OPTIMISE
  "is it possible to ..."      DECIDE
  "longest / shortest ..."     OPTIMISE

  plus: choices at each step, and the same situation
  reachable by several routes.

  IF THE PROBLEM ASKS FOR THE ACTUAL LIST OF SOLUTIONS,
  it is backtracking, not DP (chapter 32). DP gives you
  a count or an optimum, not an enumeration.
```

Problems

How it shows up

Symptom	Cause
Exponentially slow	Memoisation missing, or the key does not match the real state
Memo never hits	Key includes a parameter that always differs — narrow the state
Wrong answer, right shape	Base case wrong or off by one
Stack overflow	Deep top-down recursion — convert to tabulation
Table reads uninitialised entries	Fill order does not respect dependencies
Space-optimised version wrong	Overwrote a value still needed — check the iteration direction
Cached results leak between calls	Memo declared outside the function and not reset

Check yourself

- ✓ State the two conditions for DP and say which one excludes merge sort.
- ✓ Give the four-step recipe in order.
- ✓ Write the memoisation template and the tabulation template.

- ✓ Give one advantage and one drawback of each direction.
- ✓ Explain how to reduce O(n) space to O(1) and when it is possible.
- ✓ Name the four question shapes that signal DP.
- ✓ Say when a problem is backtracking rather than DP.

Problems

Climbing stairs Easy

Pattern: One-dimensional DP

You are climbing a staircase of `n` steps. Each move you may climb 1 or 2 steps. In how many distinct ways can you reach the top?

Input	Output	Note
`n = 2`	`2`	1+1, or 2
`n = 3`	`3`	1+1+1, 1+2, 2+1
`n = 5`	`8`	

HINTS

1. To arrive at step `n` your last move came from step `n-1` or step `n-2`.
2. So `ways(n) = ways(n-1) + ways(n-2)` — the Fibonacci recurrence.
3. Base cases: one way to stand at step 0 (do nothing), one way to reach step 1.
4. Only the last two values are ever needed, so O(1) space is achievable.

Approach	Idea	Time	Space
Plain recursion	Recompute both branches every time. The call tree is a Fibonacci tree.	`O(2ⁿ)`	`O(n)`
Memoised recursion	Cache each `n`. Linear, but O(n) stack.	`O(n)`	`O(n)`
Tabulation, two variables	Roll forward keeping only the previous two.	`O(n)`	`O(1)`

Solution — js

```
function climbStairs(n) {
  // one way to be at step 0 (stand still), one way to reach step 1
  let prev2 = 1, prev1 = 1;

  for (let i = 2; i <= n; i++) {
    const cur = prev1 + prev2;   // arrive from i-1 or i-2
    prev2 = prev1;
    prev1 = cur;
  }
  return prev1;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int climbStairs(int n) {
        long prev2 = 1, prev1 = 1;
        for (int i = 2; i <= n; ++i) {
            long cur = prev1 + prev2;
            prev2 = prev1;
            prev1 = cur;
        }
        return (int)prev1;
    }
};
```

Solution — python

```python
class Solution:
    def climbStairs(self, n: int) -> int:
        prev2 = prev1 = 1
        for _ in range(2, n + 1):
            prev2, prev1 = prev1, prev1 + prev2
        return prev1
```

Solution — java

```java
class Solution {
    public int climbStairs(int n) {
        int prev2 = 1, prev1 = 1;
        for (int i = 2; i <= n; i++) {
            int cur = prev1 + prev2;
            prev2 = prev1;
            prev1 = cur;
        }
        return prev1;
    }
}
```

WALKTHROUGH

DERIVING THE RECURRENCE BY LOOKING BACKWARDS.

Ask what the *final* move must have been: either a single step from `n-1` or a double step from `n-2`. Those two cases are disjoint and cover everything, so the counts simply add. Looking at the last decision rather than the first is the habit that makes most DP recurrences fall out.

WHY `N = 0` IS 1, NOT 0.

There is exactly one way to be at the bottom: do nothing. That convention is what makes `n = 2` come out as 2 rather than 1. Base cases in counting problems are almost always "one empty way", not "no ways".

THE SPACE OPTIMISATION IS VISIBLE ONLY AFTER TABULATION.

Once written as `dp[i] = dp[i-1] + dp[i-2]`, it is obvious that entries older than two steps are never read — so two scalars suffice. That recognition is exactly the follow-up interviewers ask for, and it generalises to every DP whose dependencies reach back a fixed distance.

House robber `Medium`

Pattern: Take-or-skip DP

Each house holds some money, but robbing two **adjacent** houses triggers the alarm. Given an array `nums`, return the maximum you can rob.

Input	Output	Note
`nums = [1,2,3,1]`	`4`	Houses 0 and 2.
`nums = [2,7,9,3,1]`	`12`	Houses 0, 2 and 4.

HINTS

1. At each house you have exactly two options: rob it (and skip the previous) or skip it.
2. So `best(i) = max(nums[i] + best(i-2), best(i-1))`.
3. Greedily taking the largest houses does not work — try `[2,1,1,2]`.
4. Only the previous two answers are needed, so O(1) space again.

Approach	Idea	Time	Space
Try every valid subset	Enumerate non-adjacent subsets. Exponential.	`O(2ⁿ)`	`O(n)`
Greedy on largest values	**Wrong.** `[2,1,1,2]` defeats it — the answer is 4, not 3.	`—`	`—`
DP, two rolling variables	Take-or-skip at each index.	`O(n)`	`O(1)`

Solution — js

```
function rob(nums) {
  // best if we stop before the previous house / at the previous house
  let prev2 = 0, prev1 = 0;

  for (const v of nums) {
    // rob this one (adding prev2) or skip it (keeping prev1)
    const cur = Math.max(v + prev2, prev1);
    prev2 = prev1;
    prev1 = cur;
  }
  return prev1;
}
```

Solution — cpp

```
class Solution {
public:
    int rob(vector<int>& nums) {
        int prev2 = 0, prev1 = 0;
        for (int v : nums) {
            int cur = max(v + prev2, prev1);
            prev2 = prev1;
            prev1 = cur;
        }
        return prev1;
    }
};
```

Solution — python

```python
class Solution:
    def rob(self, nums: list[int]) -> int:
        prev2 = prev1 = 0
        for v in nums:
            prev2, prev1 = prev1, max(v + prev2, prev1)
        return prev1
```

Solution — java

```java
class Solution {
    public int rob(int[] nums) {
        int prev2 = 0, prev1 = 0;
        for (int v : nums) {
            int cur = Math.max(v + prev2, prev1);
            prev2 = prev1;
            prev1 = cur;
        }
        return prev1;
    }
}
```

WALKTHROUGH

WHY GREEDY FAILS, CONCRETELY.

On `[2,1,1,2]` a greedy rule that grabs the largest available house takes a 2, then must skip its neighbour, and ends at 3. The DP takes both 2s — houses 0 and 3 are not adjacent — for 4. Being able to produce a counterexample on demand is worth more than asserting "greedy does not work".

THE TWO VARIABLES HAVE PRECISE MEANINGS.

`prev1` is the best total considering all houses up to and including the previous one; `prev2` is the best up to the one before that. Robbing the current house is only legal on top of `prev2`, which is exactly what enforces non-adjacency.

BOTH START AT 0

, which handles the empty array and the single-house case without special-casing: with one house the loop runs once and returns `max(v, 0)`.

THE VARIANTS WORTH KNOWING:

"House Robber II" puts the houses in a circle, solved by running this twice — once excluding the first house, once excluding the last — and taking the better. "House Robber III" puts them in a tree, solved with the tree-recursion pattern from chapter 24 returning a (robbed, skipped) pair.

Coin change — fewest coins `Medium`

Pattern: Unbounded choice DP

Given coin denominations `coins` and an `amount`, return the fewest coins needed to make that amount. You have an unlimited supply of each coin. Return `-1` if it cannot be made.

Input	Output	Note
`coins = [1,2,5], amount = 11`	`3`	5 + 5 + 1
`coins = [2], amount = 3`	`-1`	

Input	Output	Note
`coins = [1], amount = 0`	`0`	

HINTS

1. Greedily taking the largest coin fails — try `coins = [1,3,4]`, `amount = 6`.
2. For each amount `a`, the answer is `1 + min(best(a − c))` over every coin `c` that fits.
3. Fill a table from 0 up to the target so every dependency is already computed.
4. Use `Infinity` for "not makeable" and convert it to −1 at the end.

Approach	Idea	Time	Space
Greedy largest first	**Wrong.** With `[1,3,4]` and amount 6, greedy gives 4+1+1 = 3 coins; the optimum is 3+3 = 2.	`—`	`—`
Backtracking over combinations	Try every combination and keep the shortest. Exponential.	`exponential`	`O(amount)`
Bottom-up DP	One table entry per amount, each computed from smaller amounts.	`O(amount · coins)`	`O(amount)`

Solution — js

```
function coinChange(coins, amount) {
  // dp[a] = fewest coins to make amount a
  const dp = new Array(amount + 1).fill(Infinity);
  dp[0] = 0;                        // zero coins make zero

  for (let a = 1; a <= amount; a++) {
    for (const c of coins) {
      if (c > a) continue;                     // does not fit
      if (dp[a - c] === Infinity) continue;    // unreachable
      dp[a] = Math.min(dp[a], dp[a - c] + 1);
    }
  }

  return dp[amount] === Infinity ? -1 : dp[amount];
}
```

Solution — cpp

```
class Solution {
public:
    int coinChange(vector<int>& coins, int amount) {
        const int INF = 1e9;
        vector<int> dp(amount + 1, INF);
        dp[0] = 0;
        for (int a = 1; a <= amount; ++a)
            for (int c : coins) {
                if (c > a || dp[a - c] == INF) continue;
                dp[a] = min(dp[a], dp[a - c] + 1);
            }
        return dp[amount] == INF ? -1 : dp[amount];
    }
};
```

Solution — python

```python
class Solution:
    def coinChange(self, coins: list[int], amount: int) -> int:
        INF = float("inf")
        dp = [INF] * (amount + 1)
        dp[0] = 0
        for a in range(1, amount + 1):
            for c in coins:
                if c <= a and dp[a - c] != INF:
                    dp[a] = min(dp[a], dp[a - c] + 1)
        return -1 if dp[amount] == INF else dp[amount]
```

Solution — java

```java
class Solution {
    public int coinChange(int[] coins, int amount) {
        final int INF = 1_000_000_000;
        int[] dp = new int[amount + 1];
        Arrays.fill(dp, INF);
        dp[0] = 0;
        for (int a = 1; a <= amount; a++)
            for (int c : coins) {
                if (c > a || dp[a - c] == INF) continue;
                dp[a] = Math.min(dp[a], dp[a - c] + 1);
            }
        return dp[amount] == INF ? -1 : dp[amount];
    }
}
```

WALKTHROUGH

THE GREEDY COUNTEREXAMPLE IS THE POINT OF THIS PROBLEM.

With `[1,3,4]` and amount 6, taking the largest coin first gives 4, then 1, then 1 — three coins. The optimum is 3 + 3, two coins. Greedy happens to work for real-world currency systems because they are designed to be "canonical", but it is not valid in general, and the interviewer will supply a counterexample if you do not.

FILLING UPWARDS GUARANTEES THE DEPENDENCIES.

`dp[a]` reads only `dp[a - c]` for positive `c`, so every value it needs has a smaller index and is already final. That is the fill-order reasoning tabulation always requires.

`DP[0] = 0` IS THE BASE CASE AND IT IS DOING REAL WORK

— it is what lets a single coin equal to the amount produce an answer of 1.

THE UNREACHABLE GUARD.

Skipping when `dp[a - c]` is `Infinity` keeps the arithmetic clean; in C++ or Java adding 1 to a sentinel like `INT_MAX` would overflow to a negative number and silently corrupt the minimum. Using `1e9` instead of `INT_MAX` is the usual defence.

NOTE THE CONTRAST WITH THE COUNTING VARIANT.

"In how many ways can you make the amount?" is the same table with `+=` instead of `min` — and it needs the loop order reversed to avoid counting permutations. That is chapter 34.

DP: knapsack and subset problems

A family of problems all reducible to one question: which items do I take, subject to a capacity? The loop order tells you whether each item may be reused, and that single detail decides correctness.

The pattern

```
THE 0/1 KNAPSACK: n items with weights and values, a
capacity W, each item taken AT MOST ONCE. Maximise value.

  dp[i][w] = best value using the first i items with
             capacity w

  dp[i][w] = max( dp[i-1][w],                    // skip
                  dp[i-1][w - wt[i]] + val[i] )  // take

THE SHAPE - "for each item, take it or skip it" - is the
whole family.

-----------------------------------------------------------
THE SPACE OPTIMISATION AND THE LOOP-ORDER RULE

Each row depends only on the previous row, so one array
suffices. But the ITERATION DIRECTION now carries meaning:

  0/1 KNAPSACK (each item once):
     for (item of items)
         for (w = W; w >= wt; w--)     // BACKWARDS
             dp[w] = max(dp[w], dp[w - wt] + val);

  UNBOUNDED (unlimited copies):
     for (item of items)
         for (w = wt; w <= W; w++)     // FORWARDS
             dp[w] = max(dp[w], dp[w - wt] + val);

WHY. Going backwards, dp[w - wt] still holds the PREVIOUS
row's value - the item has not been used yet at that
capacity - so it can be taken at most once. Going
forwards, dp[w - wt] has ALREADY been updated with this
item, so taking it again is allowed.

ONE CHARACTER SEPARATES 0/1 FROM UNBOUNDED. If a knapsack
answer is wrong and the structure looks right, check the
direction first.

-----------------------------------------------------------
THE OTHER LOOP-ORDER RULE: COMBINATIONS VS PERMUTATIONS

For COUNTING problems the nesting order matters too:

  items OUTSIDE, capacity inside   -> COMBINATIONS
                                      (1+2 and 2+1 count
                                       once)
  capacity OUTSIDE, items inside   -> PERMUTATIONS
                                      (counted separately)

"Coin change 2" wants combinations; "combination sum IV"
(badly named) wants permutations. Same table, swapped
loops.

-----------------------------------------------------------
THE FAMILY, all the same table

  subset sum          "can I hit exactly T?"   boolean dp
  partition equal
    subset sum        subset sum with T = total/2
  target sum          assign +/- to each number
  coin change         unbounded, minimise count
```

```
coin change 2       unbounded, count combinations
last stone weight II minimise |difference| = subset sum
                     near total/2
ones and zeroes      knapsack with TWO capacities
```

Problems

How it shows up

Symptom	Cause
Items used more than once in 0/1	Inner loop runs forwards — must go backwards
Unbounded version misses reuse	Inner loop runs backwards — must go forwards
Count too high	Loops nested the wrong way — counting permutations, not combinations
Odd total reported as partitionable	Missing the parity check before halving
Off by one in the capacity array	Table needs `W + 1` entries, indices 0..W
Base case wrong	`dp[0]` must be `true`/0 — the empty selection
Timeout on large capacity	Pseudo-polynomial: O(n·W) grows with the *value* of W

Check yourself

- ✓ Write the 0/1 knapsack recurrence and say what each branch means.
- ✓ Give the loop direction for 0/1 versus unbounded, and explain why.
- ✓ Explain how the nesting order distinguishes combinations from permutations.
- ✓ Reduce "partition into two equal subsets" to subset sum.
- ✓ Say why the base case is the empty selection.
- ✓ Explain what "pseudo-polynomial" means and why it matters.
- ✓ Name four problems in this family.

Problems

Partition equal subset sum `Medium`

Pattern: 0/1 subset sum

Given an array of positive integers, determine whether it can be split into two subsets with **equal sums**.

Input	Output	Note
`nums = [1,5,11,5]`	`true`	[1,5,5] and [11]
`nums = [1,2,3,5]`	`false`	

HINTS

1. Two equal halves means each sums to `total / 2` — so if the total is odd, stop immediately.
2. The question becomes: is there a subset summing to exactly `total / 2`?
3. That is 0/1 subset sum: a boolean table over achievable sums.
4. Iterate the capacity
   BACKWARDS
   so each number is used at most once.

Approach	Idea	Time	Space
Try every subset	Enumerate all 2^n subsets and check the sums.	`O(2ⁿ)`	`O(n)`
2-D boolean table	`dp[i][s]` = can the first `i` items reach sum `s`?	`O(n·S)`	`O(n·S)`
1-D backwards	One boolean array over sums, filled right to left per item.	`O(n·S)`	`O(S)`

Solution — js

```
function canPartition(nums) {
  const total = nums.reduce((a, b) => a + b, 0);
  if (total % 2 !== 0) return false;     // cannot halve an odd total

  const target = total / 2;
  const dp = new Array(target + 1).fill(false);
  dp[0] = true;                          // empty subset sums to 0

  for (const v of nums) {
    // BACKWARDS: dp[s - v] must still be the PREVIOUS row,
    // so v is used at most once
    for (let s = target; s >= v; s--) {
      if (dp[s - v]) dp[s] = true;
    }
  }
  return dp[target];
}
```

Solution — cpp

```
class Solution {
public:
    bool canPartition(vector<int>& nums) {
        int total = accumulate(nums.begin(), nums.end(), 0);
        if (total % 2) return false;
        int target = total / 2;
        vector<char> dp(target + 1, false);
        dp[0] = true;
        for (int v : nums)
            for (int s = target; s >= v; --s)
                if (dp[s - v]) dp[s] = true;
        return dp[target];
    }
};
```

Solution — python

```python
class Solution:
    def canPartition(self, nums: list[int]) -> bool:
        total = sum(nums)
        if total % 2:
            return False
        target = total // 2
        dp = [False] * (target + 1)
        dp[0] = True
        for v in nums:
            for s in range(target, v - 1, -1):   # backwards
                if dp[s - v]:
                    dp[s] = True
        return dp[target]
```

Solution — java

```java
class Solution {
    public boolean canPartition(int[] nums) {
        int total = 0;
        for (int v : nums) total += v;
        if (total % 2 != 0) return false;
        int target = total / 2;
        boolean[] dp = new boolean[target + 1];
        dp[0] = true;
        for (int v : nums)
            for (int s = target; s >= v; s--)
                if (dp[s - v]) dp[s] = true;
        return dp[target];
    }
}
```

WALKTHROUGH

THE REDUCTION IS THE INSIGHT.

"Split into two equal halves" sounds like a partitioning problem, but the second half is determined by the first — so it is enough to find *one* subset summing to `total / 2`. That turns an unfamiliar question into textbook subset sum.

THE PARITY CHECK IS NOT AN OPTIMISATION, IT IS CORRECTNESS.

An odd total cannot be halved into integers at all, and without the check `target` would be fractional and the array size nonsensical. `[1,2,5]` has total 8 and is still false, so parity alone is not sufficient — but it is necessary.

BACKWARDS IS WHAT MAKES IT 0/1.

Reading `dp[s - v]` at a *lower* index that has not yet been touched in this pass means it still reflects the state before `v` was available. Iterating forwards would let `dp[s - v]` already include `v`, effectively allowing the same number to be used twice — and `[1]` would wrongly report `true` for target 0.5-style reasoning, or more visibly `[1,1]` vs `[2]` cases would diverge. Try flipping the direction in the editor and watch which tests break.

Coin change 2 — count the combinations `Medium`

Pattern: Unbounded knapsack, counting combinations

Given coin denominations and an `amount`, return the **number of distinct combinations** that make up that amount. You have unlimited coins of each kind, and combinations differing only in order count as **one**.

Input	Output	Note
`amount = 5, coins = [1,2,5]`	`4`	5; 2+2+1; 2+1+1+1; 1×5
`amount = 3, coins = [2]`	`0`	
`amount = 10, coins = [10]`	`1`	

HINTS

1. This is a counting problem, so the table accumulates with `+=` rather than `min`.
2. Coins may repeat, so the capacity loop runs **FORWARDS** .
3. To count combinations rather than permutations, put the **COIN LOOP OUTSIDE** and the amount loop inside.
4. Swapping the loops counts 1+2 and 2+1 separately — which is a different problem.

Approach	Idea	Time	Space
Backtracking	Enumerate every combination and count. Exponential.	`exponential`	`O(amount)`
2-D table over (coin, amount)	Explicit rows per coin. Clear, more memory.	`O(n·amount)`	`O(n·amount)`
1-D, coins outside	One array; the outer coin loop enforces combination counting.	`O(n·amount)`	`O(amount)`

Solution — js

```
function change(amount, coins) {
  const dp = new Array(amount + 1).fill(0);
  dp[0] = 1;                 // exactly one way to make 0: take nothing

  // COIN LOOP OUTSIDE -> each combination is counted once,
  // because coins are always considered in a fixed order
  for (const c of coins) {
    // FORWARDS -> the same coin may be reused
    for (let a = c; a <= amount; a++) {
      dp[a] += dp[a - c];
    }
  }
  return dp[amount];
}
```

Solution — cpp

```
class Solution {
public:
    int change(int amount, vector<int>& coins) {
        vector<unsigned long long> dp(amount + 1, 0);
        dp[0] = 1;
        for (int c : coins)
            for (int a = c; a <= amount; ++a)
                dp[a] += dp[a - c];
        return (int)dp[amount];
    }
};
```

Solution — python

```
class Solution:
    def change(self, amount: int, coins: list[int]) -> int:
        dp = [0] * (amount + 1)
        dp[0] = 1
        for c in coins:                      # coins outside
            for a in range(c, amount + 1):    # forwards
                dp[a] += dp[a - c]
        return dp[amount]
```

Solution — java

```
class Solution {
    public int change(int amount, int[] coins) {
        int[] dp = new int[amount + 1];
        dp[0] = 1;
        for (int c : coins)
            for (int a = c; a <= amount; a++)
                dp[a] += dp[a - c];
        return dp[amount];
    }
}
```

WALKTHROUGH

TWO LOOP DECISIONS, TWO DIFFERENT MEANINGS — THIS PROBLEM IS THE CLEAREST PLACE TO LEARN THEM.

FORWARDS VERSUS BACKWARDS

controls reuse. Reading `dp[a - c]` after it has already been updated with coin `c` in this pass means `c` can be used again, which is exactly what "unlimited supply" requires. Backwards would make each coin single-use.

COINS OUTSIDE VERSUS AMOUNT OUTSIDE

controls what counts as distinct. With coins outside, every combination is built in a fixed coin order — all the 1s are considered before any 2s — so `1+2` and `2+1` are the same path through the table and are counted once. Putting the amount loop outside would let each amount consider every coin as the "last" one added, counting orderings separately. Swap the loops on the `amount = 5, coins = [1,2,5]` test: you get 9 instead of 4.

`DP[0] = 1` IS THE SEED FOR THE WHOLE COUNT.

Every combination ultimately bottoms out at "make zero from nothing", and that must count as one way, not zero — otherwise the entire table stays at 0.

THE LARGE TEST EXISTS TO CHECK OVERFLOW.

35 million fits in 32 bits here, but in C++ intermediate sums can exceed it, hence the wider accumulator.

Target sum `Medium`

Pattern: Sign assignment reduced to subset sum

Given an array of non-negative integers `nums` and an integer `target`, assign either `+` or `-` to each number so the resulting expression equals the target. Return the number of ways to do so.

Input	Output	Note
`nums = [1,1,1,1,1], target = 3`	`5`	
`nums = [1], target = 1`	`1`	
`nums = [1], target = 2`	`0`	

HINTS

1. Let `P` be the numbers given a plus and `N` those given a minus. Then `P - N = target` and `P + N = total`.
2. Adding those: `2P = target + total`, so `P = (target + total) / 2`.
3. So the question becomes: how many subsets sum to `P`? That is counting subset sum.
4. Reject impossible cases first: if `target + total` is odd or negative, the answer is 0.

Approach	Idea	Time	Space
Try all 2^n sign assignments	Backtracking over the signs.	`O(2^n)`	`O(n)`
Memoised (index, runningSum)	Cache on the pair. Works, but the state is larger than needed.	`O(n·S)`	`O(n·S)`

Approach	Idea	Time	Space
Reduce to counting subset sum	Algebra turns it into a 1-D 0/1 knapsack count.	`O(n·P)`	`O(P)`

Solution — js

```
function findTargetSumWays(nums, target) {
  const total = nums.reduce((a, b) => a + b, 0);

  // P − N = target,  P + N = total  =>  P = (target + total) / 2
  const twiceP = target + total;
  if (twiceP < 0 || twiceP % 2 !== 0) return 0;   // impossible
  const P = twiceP / 2;
  if (P > total) return 0;

  // count subsets summing to P − 0/1, so iterate BACKWARDS
  const dp = new Array(P + 1).fill(0);
  dp[0] = 1;                        // one way: the empty subset

  for (const v of nums) {
    for (let s = P; s >= v; s--) {
      dp[s] += dp[s − v];
    }
  }
  return dp[P];
}
```

Solution — cpp

```
class Solution {
public:
    int findTargetSumWays(vector<int>& nums, int target) {
        int total = accumulate(nums.begin(), nums.end(), 0);
        int twiceP = target + total;
        if (twiceP < 0 || twiceP % 2) return 0;
        int P = twiceP / 2;
        if (P > total) return 0;
        vector<int> dp(P + 1, 0);
        dp[0] = 1;
        for (int v : nums)
            for (int s = P; s >= v; --s)
                dp[s] += dp[s − v];
        return dp[P];
    }
};
```

Solution — python

```python
class Solution:
    def findTargetSumWays(self, nums: list[int], target: int) -> int:
        total = sum(nums)
        twice_p = target + total
        if twice_p < 0 or twice_p % 2:
            return 0
        P = twice_p // 2
        if P > total:
            return 0
        dp = [0] * (P + 1)
        dp[0] = 1
        for v in nums:
            for s in range(P, v - 1, -1):
                dp[s] += dp[s - v]
        return dp[P]
```

Solution — java

```java
class Solution {
    public int findTargetSumWays(int[] nums, int target) {
        int total = 0;
        for (int v : nums) total += v;
        int twiceP = target + total;
        if (twiceP < 0 || twiceP % 2 != 0) return 0;
        int P = twiceP / 2;
        if (P > total) return 0;
        int[] dp = new int[P + 1];
        dp[0] = 1;
        for (int v : nums)
            for (int s = P; s >= v; s--)
                dp[s] += dp[s - v];
        return dp[P];
    }
}
```

WALKTHROUGH

THE ALGEBRA IS WORTH DOING ON THE WHITEBOARD.

Splitting the numbers into a plus-set `P` and a minus-set `N` gives two equations — `P - N = target` and `P + N = total` — and adding them eliminates `N` entirely, leaving `P = (target + total) / 2`. A problem about signs becomes a problem about choosing a subset, which you already know how to count.

THE REJECTION TESTS MATTER.

If `target + total` is odd there is no integer subset sum, and if it is negative (or `P` exceeds `total`) the target is unreachable. Both return 0 immediately. `[1], target = 2` exercises the first path.

ZEROS DOUBLE THE COUNT, AND THE TABLE HANDLES IT FOR FREE.

A zero can be signed either way without changing the sum, so `[0,0,…,0,1]` with target 1 has $2^8 = 256$ answers. In the subset formulation, `v = 0` makes the inner loop run with `s - v === s`, doubling `dp[s]` exactly as required. That test is there because naive backtracking-with-pruning solutions often get it wrong.

BACKWARDS AGAIN

, because each number is signed exactly once — this is 0/1, not unbounded.

DP: string problems

Two strings, one table. Nearly every two-string problem is the same grid with a different combine rule, and recognising that turns edit distance, LCS and pattern matching into one technique.

The pattern

```
THE STATE IS ALWAYS A PAIR OF PREFIX LENGTHS:

  dp[i][j] = answer for the first i characters of s
             and the first j characters of t

The table is (m+1) x (n+1) — the extra row and column are
the EMPTY prefixes, and they are where the base cases live.

THE RECURRENCE ALWAYS SPLITS ON ONE QUESTION:
DO THE LAST TWO CHARACTERS MATCH?

  if (s[i-1] === t[j-1])
      dp[i][j] = f(dp[i-1][j-1])          // consume both
  else
      dp[i][j] = g(dp[i-1][j], dp[i][j-1], dp[i-1][j-1])

NOTE THE INDEX SHIFT: dp[i] refers to the first i
characters, so the LAST one is s[i-1]. Mixing this up is
the single most common bug in this chapter.

------------------------------------------------------------
THE THREE NEIGHBOURS AND WHAT THEY MEAN

     dp[i-1][j-1]   dp[i-1][j]
     dp[i][j-1]     dp[i][j]

  dp[i-1][j-1]  both consumed  -> match / replace
  dp[i-1][j]    only s consumed -> delete from s
  dp[i][j-1]    only t consumed -> insert into s

EDIT DISTANCE IS EXACTLY THAT READING:
  match   -> dp[i-1][j-1]
  replace -> dp[i-1][j-1] + 1
  delete  -> dp[i-1][j]   + 1
  insert  -> dp[i][j-1]   + 1

------------------------------------------------------------
THE FAMILY

  LCS                     longest common subsequence
  edit distance           insert / delete / replace
  is subsequence          greedy two-pointer, no DP needed
  longest common substring  must be CONTIGUOUS: reset to
                          0 on a mismatch, and the answer
                          is the table MAXIMUM, not the
                          corner
  distinct subsequences   count instead of maximise
  regex / wildcard match  extra cases for * and ?
  shortest common
    supersequence         m + n - LCS

------------------------------------------------------------
SUBSEQUENCE VERSUS SUBSTRING — the distinction that
decides the recurrence:

  SUBSEQUENCE  characters need not be adjacent; on a
               mismatch you carry the best so far forward
  SUBSTRING    must be contiguous; on a mismatch the run
               is BROKEN and the entry resets to 0

------------------------------------------------------------
```

```
    SPACE: each row depends only on the row above, so two rows
    suffice — O(min(m, n)) after swapping so the shorter
    string indexes the columns.
```

Problems

How it shows up

Symptom	Cause
Off by one everywhere	`dp[i]` means *i characters*, so the last is `s[i-1]`
Empty-string cases wrong	Row 0 and column 0 not initialised
Substring answer too long	Did not reset to 0 on a mismatch
Substring answer read from the corner	For substrings the answer is the table maximum
Edit distance one too high	Counted a replace when the characters already matched
Rolling-array version wrong	Overwrote `dp[i-1][j-1]` before using it — keep a diagonal temp
Counting version overflows	Distinct-subsequence counts grow fast — use a wide type

Check yourself

- ✓ State what `dp[i][j]` means and why the table is `(m+1)×(n+1)`.
- ✓ Explain the index shift between `dp[i]` and `s[i-1]`.
- ✓ Give the meaning of each of the three neighbouring cells.
- ✓ Map the four edit-distance operations onto those cells.
- ✓ Contrast the subsequence and substring recurrences.
- ✓ Say where the answer is read from in each case.
- ✓ Explain how to reduce the table to two rows and the trap in doing so.

Problems

Longest common subsequence `Medium`

Pattern: Two-string grid DP

Given two strings, return the length of their longest common **subsequence** — a sequence of characters appearing in both, in the same order but not necessarily contiguously. Return 0 if there is none.

Input	Output	Note
`text1 = "abcde", text2 = "ace"`	`3`	"ace"
`text1 = "abc", text2 = "abc"`	`3`	
`text1 = "abc", text2 = "def"`	`0`	

HINTS

1. Let `dp[i][j]` be the LCS length of the first `i` characters of one string and the first `j` of the other.
2. If the last characters match, they can both be used: `1 + dp[i-1][j-1]`.
3. If they do not, drop one character from either string and take the better: `max(dp[i-1][j], dp[i][j-1])`.
4. Row 0 and column 0 are all zeros — an empty string shares nothing.

Approach	Idea	Time	Space
Enumerate subsequences	Generate all 2^m subsequences of one string and test each.	`O(2^m·n)`	`O(m)`
Memoised recursion	Cache on `(i, j)`. Same complexity as the table, plus stack.	`O(m·n)`	`O(m·n)`
Bottom-up table	Fill row by row; the answer is the bottom-right corner.	`O(m·n)`	`O(m·n)`

Solution — js

```
function longestCommonSubsequence(text1, text2) {
  const m = text1.length, n = text2.length;
  // dp[i][j] = LCS of the first i chars of text1 and first j of text2
  const dp = Array.from({length: m + 1}, () => new Array(n + 1).fill(0));

  for (let i = 1; i <= m; i++) {
    for (let j = 1; j <= n; j++) {
      if (text1[i - 1] === text2[j - 1]) {
        dp[i][j] = 1 + dp[i - 1][j - 1];      // use both characters
      } else {
        dp[i][j] = Math.max(dp[i - 1][j],      // drop from text1
                            dp[i][j - 1]);     // drop from text2
      }
    }
  }
  return dp[m][n];
}
```

Solution — cpp

```
class Solution {
public:
    int longestCommonSubsequence(string a, string b) {
        int m = a.size(), n = b.size();
        vector<vector<int>> dp(m + 1, vector<int>(n + 1, 0));
        for (int i = 1; i <= m; ++i)
            for (int j = 1; j <= n; ++j)
                dp[i][j] = (a[i-1] == b[j-1])
                         ? 1 + dp[i-1][j-1]
                         : max(dp[i-1][j], dp[i][j-1]);
        return dp[m][n];
    }
};
```

Solution — python

```python
class Solution:
    def longestCommonSubsequence(self, text1: str, text2: str) -> int:
        m, n = len(text1), len(text2)
        dp = [[0] * (n + 1) for _ in range(m + 1)]
        for i in range(1, m + 1):
            for j in range(1, n + 1):
                if text1[i-1] == text2[j-1]:
                    dp[i][j] = 1 + dp[i-1][j-1]
                else:
                    dp[i][j] = max(dp[i-1][j], dp[i][j-1])
        return dp[m][n]
```

Solution — java

```java
class Solution {
    public int longestCommonSubsequence(String a, String b) {
        int m = a.length(), n = b.length();
        int[][] dp = new int[m + 1][n + 1];
        for (int i = 1; i <= m; i++)
            for (int j = 1; j <= n; j++)
                dp[i][j] = (a.charAt(i-1) == b.charAt(j-1))
                         ? 1 + dp[i-1][j-1]
                         : Math.max(dp[i-1][j], dp[i][j-1]);
        return dp[m][n];
    }
}
```

WALKTHROUGH

WHY THE MATCH CASE TAKES THE DIAGONAL AND ADDS ONE.

If the last characters agree, there is always an optimal LCS that uses them as a matched pair — so the rest of the answer is the LCS of both prefixes with that pair removed, which is `dp[i-1][j-1]`. Taking `max(dp[i-1][j], dp[i][j-1])` in the match case is not *wrong*, just never better, which is why the simpler form is used.

THE MISMATCH CASE IS A GENUINE CHOICE.

The final characters cannot both be in the subsequence, so at least one must be discarded — try both and keep the better.

THE ZERO ROW AND COLUMN ARE THE BASE CASES

, and they need no explicit code because the array is initialised to 0: an empty prefix shares nothing with anything.

THIS ONE TABLE ANSWERS SEVERAL QUESTIONS.

The shortest common supersequence is `m + n − LCS`. The minimum deletions to make two strings equal is `m + n − 2·LCS`. And the longest palindromic subsequence of a string is the LCS of that string with its own reverse — the `"abcba"` test hints at that.

Edit distance `Hard`

Pattern: Grid DP with three operations

Given two words, return the minimum number of operations to convert the first into the second. The permitted operations are **insert** a character, **delete** a character, and **replace** a character.

Input	Output	Note
`word1 = "horse", word2 = "ros"`	`3`	horse → rorse → rose → ros
`word1 = "intention", word2 = "execution"`	`5`	

HINTS

1. Same table as LCS, but minimising a cost rather than maximising a length.
2. If the last characters match, no operation is needed: carry `dp[i-1][j-1]` through unchanged.
3. Otherwise take the cheapest of replace (`dp[i-1][j-1]`), delete (`dp[i-1][j]`) and insert (`dp[i][j-1]`), plus one.
4. The base cases are not zero here: turning a prefix into an empty string costs one deletion per character.

Approach	Idea	Time	Space
Try every edit sequence	Explore all operation orders. Exponential.	`exponential`	`O(m+n)`
Memoised recursion on (i, j)	Natural top-down form of the same recurrence.	`O(m·n)`	`O(m·n)`
Bottom-up table	Explicit base rows, then fill.	`O(m·n)`	`O(m·n)`

Solution — js

```
function minDistance(word1, word2) {
  const m = word1.length, n = word2.length;
  const dp = Array.from({length: m + 1}, () => new Array(n + 1).fill(0));

  // base cases: i deletions to empty, j insertions from empty
  for (let i = 0; i <= m; i++) dp[i][0] = i;
  for (let j = 0; j <= n; j++) dp[0][j] = j;

  for (let i = 1; i <= m; i++) {
    for (let j = 1; j <= n; j++) {
      if (word1[i - 1] === word2[j - 1]) {
        dp[i][j] = dp[i - 1][j - 1];        // FREE — no operation
      } else {
        dp[i][j] = 1 + Math.min(
          dp[i - 1][j - 1],                 // replace
          dp[i - 1][j],                     // delete from word1
          dp[i][j - 1]                      // insert into word1
        );
      }
    }
  }
  return dp[m][n];
}
```

Solution — cpp

```cpp
class Solution {
public:
    int minDistance(string a, string b) {
        int m = a.size(), n = b.size();
        vector<vector<int>> dp(m + 1, vector<int>(n + 1, 0));
        for (int i = 0; i <= m; ++i) dp[i][0] = i;
        for (int j = 0; j <= n; ++j) dp[0][j] = j;
        for (int i = 1; i <= m; ++i)
            for (int j = 1; j <= n; ++j)
                dp[i][j] = (a[i-1] == b[j-1])
                         ? dp[i-1][j-1]
                         : 1 + min({dp[i-1][j-1], dp[i-1][j], dp[i][j-1]});
        return dp[m][n];
    }
};
```

Solution — python

```python
class Solution:
    def minDistance(self, word1: str, word2: str) -> int:
        m, n = len(word1), len(word2)
        dp = [[0] * (n + 1) for _ in range(m + 1)]
        for i in range(m + 1):
            dp[i][0] = i
        for j in range(n + 1):
            dp[0][j] = j
        for i in range(1, m + 1):
            for j in range(1, n + 1):
                if word1[i-1] == word2[j-1]:
                    dp[i][j] = dp[i-1][j-1]
                else:
                    dp[i][j] = 1 + min(dp[i-1][j-1], dp[i-1][j], dp[i][j-1])
        return dp[m][n]
```

Solution — java

```java
class Solution {
    public int minDistance(String a, String b) {
        int m = a.length(), n = b.length();
        int[][] dp = new int[m + 1][n + 1];
        for (int i = 0; i <= m; i++) dp[i][0] = i;
        for (int j = 0; j <= n; j++) dp[0][j] = j;
        for (int i = 1; i <= m; i++)
            for (int j = 1; j <= n; j++)
                dp[i][j] = (a.charAt(i-1) == b.charAt(j-1))
                         ? dp[i-1][j-1]
                         : 1 + Math.min(dp[i-1][j-1],
                               Math.min(dp[i-1][j], dp[i][j-1]));
        return dp[m][n];
    }
}
```

WALKTHROUGH

THE BASE CASES CARRY REAL INFORMATION HERE, UNLIKE LCS.

`dp[i][0] = i` says that turning an `i`-character prefix into the empty string costs `i` deletions, and `dp[0][j] = j` says building a `j`-character string from nothing costs `j` insertions. Leaving them at zero — as LCS can — silently makes every conversion look free from one direction, and the `["", "abc"]` tests catch it.

EACH NEIGHBOUR IS ONE OPERATION, AND THE MAPPING IS WORTH STATING ALOUD.

Moving diagonally consumes a character from both strings, which is a replacement. Moving up consumes only from `word1`, which is a deletion. Moving left consumes only from `word2`, which is an insertion into `word1`. The recurrence is just "pick the cheapest predecessor and pay one".

THE MATCH CASE COSTS NOTHING.

Writing `1 + min(...)` unconditionally is the classic off-by-one: identical strings would then cost their full length instead of 0.

THIS IS LEVENSHTEIN DISTANCE

, used in spell-checkers, diff tools and DNA alignment. Weighted variants — where a replacement costs 2, or different characters cost differently — change only the constants in the same recurrence.

Longest palindromic substring `Medium`

Pattern: Expand around centre

Given a string `s`, return the longest **substring** (contiguous) that is a palindrome.

If several are tied for longest, any one of them is acceptable — the tests use inputs with a unique answer.

Input	Output	Note
`s = "babad"`	`"bab"`	"aba" is also valid; the tests avoid such ties.
`s = "cbbd"`	`"bb"`	
`s = "a"`	`"a"`	

HINTS

1. Checking every substring for palindromicity is $O(n^3)$.
2. A palindrome is defined by its *centre*. There are `2n - 1` centres: one at each character, and one between each adjacent pair.
3. From each centre, expand outwards while the characters match.
4. The even-length centres are the ones people forget — "cbbd" has no odd-length answer longer than 1.

Approach	Idea	Time	Space
Check every substring	$O(n^2)$ substrings, O(n) to verify each.	`O(n³)`	`O(1)`
DP table of palindromic ranges	`dp[i][j]` = is `s[i..j]` a palindrome? Fill by increasing length.	`O(n²)`	`O(n²)`
Expand around centre	Same time, constant space, and much shorter to write.	`O(n²)`	`O(1)`
Manacher's algorithm	Linear time. Worth naming; almost never required.	`O(n)`	`O(n)`

Solution — js

```
function longestPalindrome(s) {
  if (s.length === 0) return "";

  let bestStart = 0, bestLen = 1;

  // grow outwards while the ends match; return the span found
  function expand(lo, hi) {
    while (lo >= 0 && hi < s.length && s[lo] === s[hi]) {
      lo--; hi++;
    }
    // the loop overshot by one on each side
    const len = hi - lo - 1;
    if (len > bestLen) { bestLen = len; bestStart = lo + 1; }
  }

  for (let i = 0; i < s.length; i++) {
    expand(i, i);       // ODD  length centre: one character
    expand(i, i + 1);   // EVEN length centre: between two
  }

  return s.slice(bestStart, bestStart + bestLen);
}
```

Solution — cpp

```
class Solution {
    int bestStart = 0, bestLen = 1;
    void expand(const string& s, int lo, int hi) {
        while (lo >= 0 && hi < (int)s.size() && s[lo] == s[hi]) { --lo; ++hi; }
        int len = hi - lo - 1;
        if (len > bestLen) { bestLen = len; bestStart = lo + 1; }
    }
public:
    string longestPalindrome(string s) {
        if (s.empty()) return "";
        bestStart = 0; bestLen = 1;
        for (int i = 0; i < (int)s.size(); ++i) {
            expand(s, i, i);
            expand(s, i, i + 1);
        }
        return s.substr(bestStart, bestLen);
    }
};
```

Solution — python

```python
class Solution:
    def longestPalindrome(self, s: str) -> str:
        if not s:
            return ""
        self.best_start, self.best_len = 0, 1

        def expand(lo, hi):
            while lo >= 0 and hi < len(s) and s[lo] == s[hi]:
                lo -= 1
                hi += 1
            length = hi - lo - 1
            if length > self.best_len:
                self.best_len = length
                self.best_start = lo + 1

        for i in range(len(s)):
            expand(i, i)
            expand(i, i + 1)
        return s[self.best_start:self.best_start + self.best_len]
```

Solution — java

```java
class Solution {
    private int bestStart = 0, bestLen = 1;
    public String longestPalindrome(String s) {
        if (s.isEmpty()) return "";
        bestStart = 0; bestLen = 1;
        for (int i = 0; i < s.length(); i++) {
            expand(s, i, i);
            expand(s, i, i + 1);
        }
        return s.substring(bestStart, bestStart + bestLen);
    }
    private void expand(String s, int lo, int hi) {
        while (lo >= 0 && hi < s.length() && s.charAt(lo) == s.charAt(hi)) {
            lo--; hi++;
        }
        int len = hi - lo - 1;
        if (len > bestLen) { bestLen = len; bestStart = lo + 1; }
    }
}
```

WALKTHROUGH

BOTH CENTRE KINDS ARE REQUIRED.

An odd-length palindrome is centred on a character; an even-length one is centred between two. Calling `expand(i, i)` only would return `"c"` for `"cbbd"` instead of `"bb"`. That is why the loop makes two calls per index, giving `2n - 1` centres in total.

THE OFF-BY-ONE AFTER THE LOOP.

The `while` exits having already moved `lo` one too far left and `hi` one too far right, so the valid span is `[lo+1, hi-1]` and its length is `(hi-1) - (lo+1) + 1 = hi - lo - 1`. Deriving that on the spot rather than guessing is the difference between this working first time and not.

WHY EXPANSION BEATS THE DP TABLE HERE.

Both are $O(n^2)$ time, but expansion is O(1) space and about eight lines. The table version is worth mentioning because it generalises to counting palindromic substrings, but for this question expansion is strictly better.

NOTE THIS IS A *SUBSTRING* PROBLEM

, so contiguity matters — contrast with longest palindromic *subsequence*, which is the LCS of the string with its reverse and uses the grid from the first problem on this page.

DP: grids and sequences

Two more shapes: paths through a grid, where each cell depends on its neighbours, and increasing subsequences, where the classic $O(n^2)$ has a genuinely clever $O(n \log n)$ alternative.

Grid DP

```
THE STATE IS THE CELL. Movement is restricted — usually
right and down only — which is what makes it acyclic and
therefore a DP rather than a graph search.

  dp[r][c] = answer for the subproblem ending at (r, c)

  dp[r][c] = f(dp[r-1][c], dp[r][c-1])
                ^ from above   ^ from the left

COUNT PATHS       dp[r][c] = dp[r-1][c] + dp[r][c-1]
MINIMUM PATH SUM  dp[r][c] = grid[r][c]
                           + min(dp[r-1][c], dp[r][c-1])
MAXIMUM SQUARE    dp[r][c] = 1 + min(up, left, diagonal)
                           when grid[r][c] === 1

BASE CASES ARE THE FIRST ROW AND FIRST COLUMN — they have
only one predecessor each, so they accumulate in a
straight line.

THE OBSTACLE VARIANT: a blocked cell gets dp = 0 and is
skipped, which propagates naturally. Blocking the START
makes the whole answer 0.

SPACE: each row depends only on the row above, so one
row updated left to right suffices — O(n) instead of
O(m·n).

IF MOVEMENT IS UNRESTRICTED (any direction, or weights
vary), it is no longer a DP — it is a shortest-path
problem and needs BFS or Dijkstra (chapter 30).

————————————————————————————————————————
LONGEST INCREASING SUBSEQUENCE

THE O(n^2) DP:
  dp[i] = length of the longest increasing subsequence
          ENDING at index i

  dp[i] = 1 + max(dp[j])  over all j < i with a[j] < a[i]
  answer = max(dp)

  Note the answer is the MAXIMUM of the table, not
  dp[n-1] — the best subsequence need not use the last
  element.

THE O(n log n) VERSION — patience sorting:

  tails[k] = the SMALLEST possible tail value of an
             increasing subsequence of length k+1

  for (x of a) {
      i = lowerBound(tails, x);   // first tail >= x
      if (i === tails.length) tails.push(x);
      else tails[i] = x;          // REPLACE, keep it small
  }
  return tails.length;

  `tails` IS NOT THE SUBSEQUENCE. It is only guaranteed to
  have the right LENGTH. Recovering the actual sequence
  needs parent pointers.
```

```
    THE INTUITION: a shorter tail leaves more room for
    future elements, so always keep the smallest tail for
    each length. Binary searching that array is what
    removes the inner loop.
```

Problems

How it shows up

Symptom	Cause
Grid answer off by a row or column	First row and column not seeded before the main loops
Obstacle grid returns a positive count when blocked at the start	Start cell not checked
LIS returns the last table entry	The answer is the *maximum* over the table
LIS counts equal values as increasing	Use strict `<`; for non-decreasing use upper bound instead
Patience version returns a wrong sequence	`tails` holds lengths, not the actual subsequence
Rolling row gives wrong results	Updated in the wrong direction, clobbering a needed value
Path count overflows	Binomial growth — use a wide type

Check yourself

- ✓ Give the grid recurrence for path counting and for minimum path sum.
- ✓ Say why the first row and column are the base cases.
- ✓ Explain when a grid problem stops being DP and becomes a graph search.
- ✓ Write the $O(n^2)$ LIS recurrence and say where the answer is read.
- ✓ Explain what `tails[k]` means in the O(n log n) version.
- ✓ Say why keeping the smallest tail is correct.
- ✓ State what `tails` does *not* give you.

Problems

Unique paths with obstacles `Medium`

Pattern: Grid path counting

A robot starts at the top-left of an `m × n` grid and must reach the bottom-right, moving only **right or down**. Cells containing `1` are obstacles and cannot be entered.

Return the number of distinct paths.

Input	Output	Note
`[[0,0,0],[0,1,0],[0,0,0]]`	`2`	
`[[0,1],[0,0]]`	`1`	
`[[1]]`	`0`	The start itself is blocked.

HINTS

1. Every cell is reached only from above or from the left, so the counts simply add.
2. An obstacle contributes zero paths — set its cell to 0 and the zero propagates.
3. Seed the start at 1, then fill row by row.
4. Check the start and end cells for obstacles; a blocked start makes the answer 0.

Approach	Idea	Time	Space
Backtracking	Explore every route. Exponential.	`O(2^(m+n))`	`O(m+n)`
Full 2-D table	One entry per cell, filled top-left to bottom-right.	`O(m·n)`	`O(m·n)`
Rolling single row	Each row needs only the one above, so a single array updated left to right suffices.	`O(m·n)`	`O(n)`

Solution — js

```
function uniquePathsWithObstacles(grid) {
  const m = grid.length, n = m ? grid[0].length : 0;
  if (!m || !n || grid[0][0] === 1) return 0;   // blocked start

  const dp = Array.from({length: m}, () => new Array(n).fill(0));
  dp[0][0] = 1;

  for (let r = 0; r < m; r++) {
    for (let c = 0; c < n; c++) {
      if (grid[r][c] === 1) { dp[r][c] = 0; continue; }   // obstacle
      if (r > 0) dp[r][c] += dp[r - 1][c];   // from above
      if (c > 0) dp[r][c] += dp[r][c - 1];   // from the left
    }
  }
  return dp[m - 1][n - 1];
}
```

Solution — cpp

```
class Solution {
public:
    int uniquePathsWithObstacles(vector<vector<int>>& grid) {
        int m = grid.size(), n = m ? grid[0].size() : 0;
        if (!m || !n || grid[0][0] == 1) return 0;
        vector<vector<long long>> dp(m, vector<long long>(n, 0));
        dp[0][0] = 1;
        for (int r = 0; r < m; ++r)
            for (int c = 0; c < n; ++c) {
                if (grid[r][c] == 1) { dp[r][c] = 0; continue; }
                if (r > 0) dp[r][c] += dp[r-1][c];
                if (c > 0) dp[r][c] += dp[r][c-1];
            }
        return (int)dp[m-1][n-1];
    }
};
```

Solution — python

```
class Solution:
    def uniquePathsWithObstacles(self, grid: list[list[int]]) -> int:
        m = len(grid)
        n = len(grid[0]) if m else 0
        if not m or not n or grid[0][0] == 1:
            return 0
        dp = [[0] * n for _ in range(m)]
        dp[0][0] = 1
        for r in range(m):
            for c in range(n):
                if grid[r][c] == 1:
                    dp[r][c] = 0
                    continue
                if r > 0:
                    dp[r][c] += dp[r-1][c]
                if c > 0:
                    dp[r][c] += dp[r][c-1]
        return dp[m-1][n-1]
```

Solution — java

```
class Solution {
    public int uniquePathsWithObstacles(int[][] grid) {
        int m = grid.length, n = m > 0 ? grid[0].length : 0;
        if (m == 0 || n == 0 || grid[0][0] == 1) return 0;
        int[][] dp = new int[m][n];
        dp[0][0] = 1;
        for (int r = 0; r < m; r++)
            for (int c = 0; c < n; c++) {
                if (grid[r][c] == 1) { dp[r][c] = 0; continue; }
                if (r > 0) dp[r][c] += dp[r-1][c];
                if (c > 0) dp[r][c] += dp[r][c-1];
            }
        return dp[m-1][n-1];
    }
}
```

WALKTHROUGH

WHY THE COUNTS ADD RATHER THAN COMBINE SOME OTHER WAY.

The last move into `(r, c)` was either downward from `(r-1, c)` or rightward from `(r, c-1)`. Those two sets of paths are disjoint — they differ in their final step — and together they are all of them. So the total is the sum, and the same reasoning as in climbing stairs applies, one dimension up.

OBSTACLES NEED NO SPECIAL PROPAGATION.

Setting a blocked cell to 0 means it contributes nothing to its right and lower neighbours, and the effect ripples outward automatically. The only case that needs an explicit check is a blocked *start*, because `dp[0][0]` is seeded before the loop runs.

SEEDING THEN ADDING HANDLES THE FIRST ROW AND COLUMN.

`dp[0][0] = 1` is set outside, and the `r > 0` / `c > 0` guards mean edge cells accumulate from their single predecessor. Note that `dp[0][0]` is not overwritten in the loop because both guards fail there.

THE ROLLING-ROW VERSION

updates one array left to right: `dp[c] += dp[c-1]`, where `dp[c]` already holds the value from the row above. That is the O(n)-space follow-up, and the direction matters — going right to left would use the wrong neighbour.

Minimum path sum `Medium`

Pattern: Grid DP, minimising

Given an `m × n` grid of non-negative numbers, find a path from top-left to bottom-right that minimises the sum of the numbers along it. You may move only **right or down**.

Input	Output	Note
`[[1,3,1],[1,5,1],[4,2,1]]`	`7`	1→3→1→1→1
`[[1,2,3],[4,5,6]]`	`12`	

HINTS

1. Same grid, same movement — only the combine rule changes from `+` to `min`.
2. Each cell costs its own value plus the cheaper of the two ways to arrive.
3. The first row and first column have only one predecessor, so they are running totals.
4. You can write the result into the input grid for O(1) extra space, if mutation is acceptable.

Approach	Idea	Time	Space
Explore every path	Exponentially many routes.	`O(2^(m+n))`	`O(m+n)`
Dijkstra	Works, but the movement restriction makes the graph acyclic — the log factor is wasted.	`O(m·n·log)`	`O(m·n)`
Grid DP	Fill top-left to bottom-right taking the cheaper predecessor.	`O(m·n)`	`O(1) if in place`

Solution — js

```
function minPathSum(grid) {
  const m = grid.length, n = m ? grid[0].length : 0;
  if (!m || !n) return 0;

  const dp = Array.from({length: m}, () => new Array(n).fill(0));
  dp[0][0] = grid[0][0];

  // first column: only one way in — from above
  for (let r = 1; r < m; r++) dp[r][0] = dp[r - 1][0] + grid[r][0];
  // first row: only one way in — from the left
  for (let c = 1; c < n; c++) dp[0][c] = dp[0][c - 1] + grid[0][c];

  for (let r = 1; r < m; r++)
    for (let c = 1; c < n; c++)
      dp[r][c] = grid[r][c] + Math.min(dp[r - 1][c], dp[r][c - 1]);

  return dp[m - 1][n - 1];
}
```

Solution — cpp

```cpp
class Solution {
public:
    int minPathSum(vector<vector<int>>& grid) {
        int m = grid.size(), n = m ? grid[0].size() : 0;
        if (!m || !n) return 0;
        vector<vector<int>> dp(m, vector<int>(n, 0));
        dp[0][0] = grid[0][0];
        for (int r = 1; r < m; ++r) dp[r][0] = dp[r-1][0] + grid[r][0];
        for (int c = 1; c < n; ++c) dp[0][c] = dp[0][c-1] + grid[0][c];
        for (int r = 1; r < m; ++r)
            for (int c = 1; c < n; ++c)
                dp[r][c] = grid[r][c] + min(dp[r-1][c], dp[r][c-1]);
        return dp[m-1][n-1];
    }
};
```

Solution — python

```python
class Solution:
    def minPathSum(self, grid: list[list[int]]) -> int:
        m = len(grid)
        n = len(grid[0]) if m else 0
        if not m or not n:
            return 0
        dp = [[0] * n for _ in range(m)]
        dp[0][0] = grid[0][0]
        for r in range(1, m):
            dp[r][0] = dp[r-1][0] + grid[r][0]
        for c in range(1, n):
            dp[0][c] = dp[0][c-1] + grid[0][c]
        for r in range(1, m):
            for c in range(1, n):
                dp[r][c] = grid[r][c] + min(dp[r-1][c], dp[r][c-1])
        return dp[m-1][n-1]
```

Solution — java

```java
class Solution {
    public int minPathSum(int[][] grid) {
        int m = grid.length, n = m > 0 ? grid[0].length : 0;
        if (m == 0 || n == 0) return 0;
        int[][] dp = new int[m][n];
        dp[0][0] = grid[0][0];
        for (int r = 1; r < m; r++) dp[r][0] = dp[r-1][0] + grid[r][0];
        for (int c = 1; c < n; c++) dp[0][c] = dp[0][c-1] + grid[0][c];
        for (int r = 1; r < m; r++)
            for (int c = 1; c < n; c++)
                dp[r][c] = grid[r][c] + Math.min(dp[r-1][c], dp[r][c-1]);
        return dp[m-1][n-1];
    }
}
```

WALKTHROUGH

ONLY THE COMBINE RULE CHANGED.

Counting paths added the two predecessors; minimising takes the smaller and adds the current cell's cost. The traversal order, the base cases and the state are identical — which is the point of recognising a problem *family* rather than memorising individual solutions.

SEEDING THE EDGES EXPLICITLY

is slightly more verbose than the guard-based style used in the previous problem, but it reads more clearly for a minimisation: an edge cell has no choice to make, so writing it as a running total says so directly. Either style is fine; be consistent.

WHY DIJKSTRA IS OVERKILL.

Because movement is restricted to right and down, the grid is a DAG and every cell's predecessors are guaranteed to be computed before it. That removes any need for a priority queue. If diagonal or upward movement were allowed the graph would have cycles and Dijkstra would become the right tool — that is the follow-up question to be ready for.

Longest increasing subsequence `Medium`

Pattern: Patience sorting with binary search

Given an integer array `nums`, return the length of the longest **strictly increasing subsequence**. Elements need not be contiguous.

Aim for O(n log n).

Input	Output	Note
`nums = [10,9,2,5,3,7,101,18]`	`4`	[2,3,7,101]
`nums = [0,1,0,3,2,3]`	`4`	
`nums = [7,7,7,7]`	`1`	Strictly increasing, so equal values do not extend.

HINTS

1. The O(n^2) version is `dp[i] = 1 + max(dp[j])` over earlier smaller elements — write that first.
2. For O(n log n): maintain `tails`, where `tails[k]` is the smallest tail among all increasing subsequences of length `k+1`.
3. `tails` is always sorted, so binary search for the first entry ≥ the current value.
4. If nothing is ≥ it, the value extends the longest run — append. Otherwise replace that entry, keeping tails as small as possible.

Approach	Idea	Time	Space
Try every subsequence	Exponential.	`O(2ⁿ)`	`O(n)`
O(n^2) DP	`dp[i]` = LIS ending at `i`; answer is the table maximum. Easy to derive and to explain.	`O(n²)`	`O(n)`

Approach	Idea	Time	Space
Patience sorting	Binary search into a tails array; length of the array is the answer.	`O(n log n)`	`O(n)`

Solution — js

```
function lengthOfLIS(nums) {
  // tails[k] = smallest possible tail of an increasing
  // subsequence of length k+1.  Always sorted ascending.
  const tails = [];

  for (const x of nums) {
    // lower bound: first index whose tail is >= x
    let lo = 0, hi = tails.length;
    while (lo < hi) {
      const mid = lo + ((hi - lo) >> 1);
      if (tails[mid] >= x) hi = mid;
      else                 lo = mid + 1;
    }

    if (lo === tails.length) tails.push(x);  // extends the longest
    else                     tails[lo] = x;  // better tail, same length
  }

  return tails.length;
}
```

Solution — cpp

```
class Solution {
public:
    int lengthOfLIS(vector<int>& nums) {
        vector<int> tails;
        for (int x : nums) {
            auto it = lower_bound(tails.begin(), tails.end(), x);
            if (it == tails.end()) tails.push_back(x);
            else                   *it = x;
        }
        return tails.size();
    }
};
```

Solution — python

```
import bisect

class Solution:
    def lengthOfLIS(self, nums: list[int]) -> int:
        tails = []
        for x in nums:
            i = bisect.bisect_left(tails, x)   # first tail >= x
            if i == len(tails):
                tails.append(x)
            else:
                tails[i] = x
        return len(tails)
```

Solution — java

```
class Solution {
    public int lengthOfLIS(int[] nums) {
        int[] tails = new int[nums.length];
        int size = 0;
        for (int x : nums) {
            int lo = 0, hi = size;
            while (lo < hi) {
                int mid = lo + (hi - lo) / 2;
                if (tails[mid] >= x) hi = mid;
                else                 lo = mid + 1;
            }
            tails[lo] = x;
            if (lo == size) size++;
        }
        return size;
    }
}
```

WALKTHROUGH

WHY KEEPING THE SMALLEST TAIL IS CORRECT.

Suppose two increasing subsequences both have length 3, ending in 9 and in 5. Any future element that can extend the one ending in 9 can also extend the one ending in 5, but not conversely. So the larger tail is never useful and can be discarded — the array only ever needs the smallest tail per length. That greedy exchange argument is the whole justification, and it is what an interviewer will ask for.

`TAILS` IS SORTED, WHICH IS WHAT PERMITS THE BINARY SEARCH.

It stays sorted because each operation either appends a value larger than everything (extending the longest run) or replaces an entry with something smaller than it but larger than its predecessor.

LOWER BOUND VERSUS UPPER BOUND IS THE STRICTNESS SWITCH.

Searching for the first tail `>= x` means an equal value *replaces* rather than extends, giving strictly increasing — which is why `[7,7,7,7]` returns 1. For a non-decreasing LIS, search for the first tail `> x` instead. One comparison, two different problems.

THE HONEST CAVEAT:

`tails` ends up with the right *length* but is generally not itself a valid subsequence of the input. Reconstructing the actual sequence requires recording, for each element, the index it was placed at and its predecessor — worth mentioning if asked to return the subsequence rather than its length.

DP: interval, tree and bitmask

Three state shapes beyond the linear ones. Each is recognisable from the constraints, and each has a fill order that is the whole difficulty.

Interval DP

```
STATE: a RANGE.   dp[i][j] = answer for the segment
                             a[i..j]

RECURRENCE: split the range at every possible point and
take the best.

  dp[i][j] = best over k in (i, j) of
               dp[i][k] + dp[k][j] + cost(i, k, j)

THE FILL ORDER IS THE WHOLE TRICK: iterate by INCREASING
LENGTH, not by increasing i.

  for (len = 2; len <= n; len++)
      for (i = 0; i + len <= n; i++) {
          j = i + len - 1;
          ...
      }

Filling by rows would read dp[i][k] and dp[k][j] before
they exist, because both are SHORTER ranges that live on
later rows or earlier columns.

COST: O(n^3) - n^2 states, O(n) split points each. Which
is exactly why the constraint is typically n <= 100..500
(chapter 02).

THE FAMILY: burst balloons, matrix chain multiplication,
minimum cost to merge stones, palindrome partitioning II,
optimal BST.

------------------------------------------------------------
TREE DP

STATE: a NODE, usually with a small extra flag.
The children are the subproblems, so a POSTORDER
traversal is automatically a valid fill order - no
ordering work needed (chapter 24).

  function dfs(node) {
      if (!node) return baseCase;
      const L = dfs(node.left), R = dfs(node.right);
      return combine(L, R, node.val);
  }

THE COMMON SHAPE returns a PAIR: "best if I take this
node" and "best if I do not". House Robber III is exactly
that, and so are most tree-selection problems.

------------------------------------------------------------
BITMASK DP

STATE: a SUBSET, encoded as an integer (chapter 16).

  dp[mask] = answer having already used the items in mask

2^n states, so it is only viable for n <= 20 or so.
THAT CONSTRAINT IS THE SIGNAL: if you see n <= 20 and the
problem is about assignments or orderings, think bitmask.

THE TWO STANDARD FORMS:
```

```
    ITERATE OVER SUBSETS
      for (mask = 0; mask < (1 << n); mask++)
          for (i = 0; i < n; i++)
              if (!(mask & (1 << i)))
                  dp[mask | (1<<i)] = best(dp[mask] + cost)

    TRAVELLING-SALESMAN STYLE — dp[mask][last]
      state also records WHERE you currently are.
      O(2^n * n^2).

  THE FAMILY: assignment problems, TSP, partition into k
  equal subsets, shortest superstring, "can I win this
  game?".
```

Problems

How it shows up

Symptom	Cause
Interval DP reads zeros	Filled by row instead of by increasing length
Burst balloons double-counts	Think of the balloon burst *last*, not first
Out-of-range index at the interval edges	Pad the array with sentinel 1s and use an exclusive range
Tree DP returns one value where two are needed	Return a (take, skip) pair
Bitmask table too large	2^n only survives to about n = 20–25
Bitmask transitions skip states	Iterate masks in increasing order so predecessors are ready
Popcount recomputed in the inner loop	Precompute it, or derive the index from the mask

Check yourself

- ✓ Give the interval DP recurrence and its fill order, and say why the order matters.
- ✓ State the complexity of interval DP and the constraint that signals it.
- ✓ Say why a postorder traversal is automatically a valid tree-DP fill order.
- ✓ Describe the (take, skip) pair pattern.
- ✓ Say what `dp[mask]` means and the n at which bitmask DP stops being viable.
- ✓ Give the two standard bitmask iteration forms.
- ✓ Explain the "burst last" reframing.

Problems

Burst balloons `Hard`

Pattern: Interval DP

You have `n` balloons, each painted with a number. Bursting balloon `i` earns `nums[left] × nums[i] × nums[right]`, where `left` and `right` are its **current** neighbours; balloons outside the array count as 1.

Return the maximum coins obtainable by bursting all of them.

Input	Output	Note
`nums = [3,1,5,8]`	`167`	3·1·5 + 3·5·8 + 1·3·8 + 1·8·1
`nums = [1,5]`	`10`	

HINTS

1. Thinking about which balloon to burst *first* fails — the array changes and the subproblems overlap in a way that does not decompose.
2. Instead ask: which balloon in this range is burst **LAST** ?
3. If `k` is burst last in the open range `(i, j)`, then everything to its left and right is already gone, so its neighbours are exactly `i` and `j`.
4. That makes the two sides independent: `dp[i][k] + dp[k][j] + nums[i]·nums[k]·nums[j]`.
5. Pad the array with 1 at both ends so the boundary balloons need no special case.

Approach	Idea	Time	Space
Try every burst order	n! orderings.	`O(n!)`	`O(n)`
DP on "burst first"	**Does not work.** After bursting one balloon the two sides are *not* independent — the surviving neighbours change.	`—`	`—`
Interval DP on "burst last"	Fix the last balloon in each range; the sides become independent.	`O(n³)`	`O(n²)`

Solution — js

```
function maxCoins(nums) {
  const a = [1, ...nums, 1];        // virtual 1s at both ends
  const n = a.length;
  // dp[i][j] = max coins from bursting everything STRICTLY
  // between i and j (an OPEN range)
  const dp = Array.from({length: n}, () => new Array(n).fill(0));

  // fill by increasing span so shorter ranges are ready
  for (let span = 2; span < n; span++) {
    for (let i = 0; i + span < n; i++) {
      const j = i + span;

      for (let k = i + 1; k < j; k++) {
        // k is burst LAST, so its neighbours are i and j
        const coins = a[i] * a[k] * a[j] + dp[i][k] + dp[k][j];
        if (coins > dp[i][j]) dp[i][j] = coins;
      }
    }
  }
  return dp[0][n - 1];
}
```

Solution — cpp

```cpp
class Solution {
public:
    int maxCoins(vector<int>& nums) {
        vector<int> a;
        a.push_back(1);
        for (int v : nums) a.push_back(v);
        a.push_back(1);
        int n = a.size();
        vector<vector<int>> dp(n, vector<int>(n, 0));
        for (int span = 2; span < n; ++span)
            for (int i = 0; i + span < n; ++i) {
                int j = i + span;
                for (int k = i + 1; k < j; ++k)
                    dp[i][j] = max(dp[i][j],
                                   a[i]*a[k]*a[j] + dp[i][k] + dp[k][j]);
            }
        return dp[0][n-1];
    }
};
```

Solution — python

```python
class Solution:
    def maxCoins(self, nums: list[int]) -> int:
        a = [1] + nums + [1]
        n = len(a)
        dp = [[0] * n for _ in range(n)]
        for span in range(2, n):
            for i in range(0, n - span):
                j = i + span
                for k in range(i + 1, j):
                    dp[i][j] = max(dp[i][j],
                                   a[i]*a[k]*a[j] + dp[i][k] + dp[k][j])
        return dp[0][n-1]
```

Solution — java

```java
class Solution {
    public int maxCoins(int[] nums) {
        int n = nums.length + 2;
        int[] a = new int[n];
        a[0] = a[n-1] = 1;
        for (int i = 0; i < nums.length; i++) a[i+1] = nums[i];
        int[][] dp = new int[n][n];
        for (int span = 2; span < n; span++)
            for (int i = 0; i + span < n; i++) {
                int j = i + span;
                for (int k = i + 1; k < j; k++)
                    dp[i][j] = Math.max(dp[i][j],
                               a[i]*a[k]*a[j] + dp[i][k] + dp[k][j]);
            }
        return dp[0][n-1];
    }
}
```

WALKTHROUGH

WHY "FIRST" FAILS AND "LAST" WORKS.

If you burst `k` first, the two remaining halves are not independent — a balloon in the left half may later become adjacent to one in the right half, so their scores are coupled and the problem does not decompose. If instead `k` is burst *last* within the open range `(i, j)`, then by definition everything strictly between `i` and `k`, and between `k` and `j`, has already gone. At the moment `k` pops, its neighbours are exactly `i` and `j` — fixed and known — and the two sides never interact. That reframing is the entire problem.

THE PADDING REMOVES EVERY BOUNDARY CASE.

Prepending and appending 1 means the outermost real balloons have well-defined neighbours worth 1, matching the problem statement, with no `if (i === 0)` anywhere.

THE OPEN-RANGE CONVENTION.

`dp[i][j]` covers the balloons strictly between `i` and `j`, so `dp[i][i+1]` is empty and worth 0 — which is why `span` starts at 2 and the answer is `dp[0][n-1]`, the range strictly inside both sentinels.

FILL BY SPAN, NOT BY ROW.

`dp[i][k]` and `dp[k][j]` are both strictly shorter ranges. Iterating `i` in the outer loop would reach `dp[0][n-1]` while its shorter sub-ranges are still zero, silently returning a wrong answer rather than crashing — which makes it a nasty bug to spot.

House robber III — on a tree `Medium`

Pattern: Tree DP with a (take, skip) pair

Houses are arranged as a binary tree. Robbing two **directly connected** houses — a parent and its child — triggers the alarm.

Return the maximum amount that can be robbed.

Input	Output	Note
`root = [3,2,3,null,3,null,1]`	`7`	3 + 3 + 1 (the root and both grandchildren).
`root = [3,4,5,1,3,null,1]`	`9`	4 + 5.

HINTS

1. A single number per node is not enough — the parent needs to know both outcomes.
2. Return a pair: the best total for this subtree *if this node is robbed*, and *if it is not*.
3. If robbed: `node.val` plus the "skipped" values of both children.
4. If skipped: each child independently contributes `max(itsRobbed, itsSkipped)`.

Approach	Idea	Time	Space
Memoised on the node	Recurse over children and grandchildren, caching per node. Works, but recomputes grandchildren.	`O(n)`	`O(n)`
(take, skip) pair per node	One postorder pass, constant work per node, no memo needed.	`O(n)`	`O(h)`

Solution — js

```
function rob(root) {
  // returns [best if this node IS robbed, best if it is NOT]
  function dfs(node) {
    if (!node) return [0, 0];

    const [lRob, lSkip] = dfs(node.left);
    const [rRob, rSkip] = dfs(node.right);

    // rob here -> both children MUST be skipped
    const robbed = node.val + lSkip + rSkip;

    // skip here -> each child does whatever is best for it
    const skipped = Math.max(lRob, lSkip) + Math.max(rRob, rSkip);

    return [robbed, skipped];
  }

  const [a, b] = dfs(root);
  return Math.max(a, b);
}
```

Solution — cpp

```
class Solution {
    pair<int,int> dfs(TreeNode* n) {
        if (!n) return {0, 0};
        auto [lRob, lSkip] = dfs(n->left);
        auto [rRob, rSkip] = dfs(n->right);
        int robbed  = n->val + lSkip + rSkip;
        int skipped = max(lRob, lSkip) + max(rRob, rSkip);
        return {robbed, skipped};
    }
public:
    int rob(TreeNode* root) {
        auto [a, b] = dfs(root);
        return max(a, b);
    }
};
```

Solution — python

```
class Solution:
    def rob(self, root: TreeNode) -> int:
        def dfs(node):
            if not node:
                return (0, 0)
            l_rob, l_skip = dfs(node.left)
            r_rob, r_skip = dfs(node.right)
            robbed = node.val + l_skip + r_skip
            skipped = max(l_rob, l_skip) + max(r_rob, r_skip)
            return (robbed, skipped)

        return max(dfs(root))
```

Solution — java

```
class Solution {
    public int rob(TreeNode root) {
        int[] r = dfs(root);
        return Math.max(r[0], r[1]);
    }
    // returns {robbedHere, skippedHere}
    private int[] dfs(TreeNode n) {
        if (n == null) return new int[]{0, 0};
        int[] l = dfs(n.left), r = dfs(n.right);
        int robbed  = n.val + l[1] + r[1];
        int skipped = Math.max(l[0], l[1]) + Math.max(r[0], r[1]);
        return new int[]{robbed, skipped};
    }
}
```

WALKTHROUGH

WHY ONE NUMBER PER NODE IS INSUFFICIENT.

If a child reports only "the best I can do", the parent cannot tell whether that best involved robbing the child — which is exactly what determines whether the parent may rob itself. Returning both outcomes gives the parent the information it needs, and is the tree analogue of the two rolling variables in the array version (chapter 33).

THE ASYMMETRY IN THE TWO BRANCHES.

Robbing here *forces* both children to be skipped, so it uses their skip values specifically. Skipping here *frees* each child to choose, so it takes each child's maximum independently. Using `max` in the robbed branch is the classic bug and it silently overcounts adjacent houses.

`[1,10,10]` **IS THE DISCRIMINATING TEST:**

the root is worth 1 and its two children are worth 10 each, so the answer is 20 — skipping the root. A greedy or root-biased solution returns 1 or 11.

POSTORDER IS THE FILL ORDER, FOR FREE.

Because both recursive calls complete before the combine, every dependency is satisfied without any explicit ordering logic — the recursion structure *is* the topological sort.

Partition into k equal-sum subsets `Hard`

Pattern: Bitmask DP over subsets

Given an array `nums` and an integer `k`, decide whether it can be partitioned into `k` non-empty subsets all having the **same sum**.

`nums.length` is at most 16.

Input	Output	Note
`nums = [4,3,2,3,5,2,1], k = 4`	`true`	(5), (1,4), (2,3), (2,3)
`nums = [1,2,3,4], k = 3`	`false`	

HINTS

1. `n ≤ 16` is the signal: 2^n states are affordable, so encode "which elements are used" as a bitmask.
2. If the total is not divisible by `k`, or any element exceeds the target, the answer is immediately false.
3. Track the running sum *within the current subset* as `usedSum(mask) % target` — you never need to know which subset you are on.
4. Only add an element if it fits in the current partial subset; that single rule keeps every completed subset at exactly the target.

Approach	Idea	Time	Space
Backtracking over k buckets	Assign each number to a bucket. Works with good pruning, but exponential and fiddly.	`O(kⁿ)`	`O(n)`
Bitmask DP	`dp[mask]` = is this set of elements reachable as a sequence of complete subsets plus a valid partial one?	`O(2ⁿ·n)`	`O(2ⁿ)`

Solution — js

```
function canPartitionKSubsets(nums, k) {
  const total = nums.reduce((a, b) => a + b, 0);
  if (k <= 0 || total % k !== 0) return false;

  const target = total / k;
  if (Math.max(...nums) > target) return false;

  const n = nums.length;
  const full = (1 << n) - 1;

  const dp   = new Array(1 << n).fill(false);  // reachable?
  const used = new Array(1 << n).fill(0);      // sum of mask
  dp[0] = true;

  for (let mask = 0; mask <= full; mask++) {
    if (!dp[mask]) continue;

    // how full the CURRENT partial subset is
    const partial = used[mask] % target;

    for (let i = 0; i < n; i++) {
      if (mask & (1 << i)) continue;          // already used
      if (partial + nums[i] > target) continue; // would overflow

      const next = mask | (1 << i);
      if (!dp[next]) {
        dp[next] = true;
        used[next] = used[mask] + nums[i];
      }
    }
  }
  return dp[full];
}
```

Solution — cpp

```cpp
class Solution {
public:
    bool canPartitionKSubsets(vector<int>& nums, int k) {
        int total = accumulate(nums.begin(), nums.end(), 0);
        if (k <= 0 || total % k) return false;
        int target = total / k;
        if (*max_element(nums.begin(), nums.end()) > target) return false;
        int n = nums.size(), full = (1 << n) - 1;
        vector<char> dp(1 << n, false);
        vector<int> used(1 << n, 0);
        dp[0] = true;
        for (int mask = 0; mask <= full; ++mask) {
            if (!dp[mask]) continue;
            int partial = used[mask] % target;
            for (int i = 0; i < n; ++i) {
                if (mask & (1 << i)) continue;
                if (partial + nums[i] > target) continue;
                int nxt = mask | (1 << i);
                if (!dp[nxt]) { dp[nxt] = true; used[nxt] = used[mask] + nums[i]; }
            }
        }
        return dp[full];
    }
};
```

Solution — python

```python
class Solution:
    def canPartitionKSubsets(self, nums: list[int], k: int) -> bool:
        total = sum(nums)
        if k <= 0 or total % k:
            return False
        target = total // k
        if max(nums) > target:
            return False

        n = len(nums)
        full = (1 << n) - 1
        dp = [False] * (1 << n)
        used = [0] * (1 << n)
        dp[0] = True

        for mask in range(full + 1):
            if not dp[mask]:
                continue
            partial = used[mask] % target
            for i, v in enumerate(nums):
                if mask & (1 << i):
                    continue
                if partial + v > target:
                    continue
                nxt = mask | (1 << i)
                if not dp[nxt]:
                    dp[nxt] = True
                    used[nxt] = used[mask] + v
        return dp[full]
```

Solution — java

```java
class Solution {
    public boolean canPartitionKSubsets(int[] nums, int k) {
        int total = 0, mx = 0;
        for (int v : nums) { total += v; mx = Math.max(mx, v); }
        if (k <= 0 || total % k != 0) return false;
        int target = total / k;
        if (mx > target) return false;
        int n = nums.length, full = (1 << n) - 1;
        boolean[] dp = new boolean[1 << n];
        int[] used = new int[1 << n];
        dp[0] = true;
        for (int mask = 0; mask <= full; mask++) {
            if (!dp[mask]) continue;
            int partial = used[mask] % target;
            for (int i = 0; i < n; i++) {
                if ((mask & (1 << i)) != 0) continue;
                if (partial + nums[i] > target) continue;
                int nxt = mask | (1 << i);
                if (!dp[nxt]) { dp[nxt] = true; used[nxt] = used[mask] + nums[i]; }
            }
        }
        return dp[full];
    }
}
```

WALKTHROUGH

THE MODULO TRICK IS WHAT KEEPS THE STATE SMALL.

You might expect to need `dp[mask][subsetIndex][partialSum]`. But if every completed subset sums to exactly `target`, then `used[mask] % target` *is* the partial sum of the subset currently being filled, and `used[mask] / target` is how many are finished. Both are derivable from the mask, so the state collapses to a single dimension of size 2^n.

THE FIT CHECK ENFORCES THE INVARIANT.

Refusing to add an element that would push the partial sum past `target` means a subset can only ever be closed by hitting `target` exactly — at which point the modulo wraps to 0 and the next element begins a fresh subset. No explicit "start a new subset" step is needed.

MASKS ARE VISITED IN INCREASING NUMERICAL ORDER

, which is a valid topological order because `mask | (1 << i)` is always strictly greater than `mask`. Every predecessor is therefore final before it is read.

THE EARLY REJECTIONS ARE NOT JUST OPTIMISATIONS.

If any element exceeds `target` it can never be placed, and the loop would simply never reach the full mask — returning the right answer, but after doing 2^n pointless work. Checking divisibility first also avoids a fractional `target` and a meaningless modulo.

The interview itself, and a mixed final set

The last chapter. What actually happens in the room, how you are scored, and a final set of problems presented without telling you which pattern they use — which is the only realistic test.

What you are actually scored on

```
MOST CANDIDATES BELIEVE THE SCORE IS "did you solve it?"
It is not. A typical rubric has four axes:

  PROBLEM SOLVING   did you make progress systematically?
                    did you use hints well?
  CODING            is the code clean, correct, and does
                    it match what you said?
  VERIFICATION      did you test it yourself, or wait to
                    be told?
  COMMUNICATION     could the interviewer follow your
                    reasoning throughout?

A CANDIDATE WHO REASONS CLEARLY TO AN O(n log n) SOLUTION
USUALLY OUTSCORES ONE WHO SILENTLY TYPES A MEMORISED
O(n) ANSWER. Two of the four axes are not about the
algorithm at all.

------------------------------------------------------------
THE TIMELINE OF A 45-MINUTE INTERVIEW

  0-5    introductions, the problem is stated
  5-10   YOU CLARIFY. Restate it. Ask about constraints,
         edge cases, input size, whether you may modify
         the input.
  10-15  YOU DISCUSS APPROACHES. Brute force first, with
         its complexity. Then improve it. State the plan
         and the target complexity BEFORE coding.
  15-32  YOU CODE, narrating.
  32-40  YOU TEST. Trace the example by hand. Then the
         edge cases.
  40-45  follow-ups, and your questions for them.

THE MOST COMMON TIMING FAILURE is starting to code at
minute 6. The five minutes of clarification are the
highest-value part of the whole interview, and skipping
them is how people solve the wrong problem.

------------------------------------------------------------
WHAT TO SAY WHEN YOU ARE STUCK

Silence is the only genuinely bad option. Say one of:

  "Let me work through a small example by hand."
  "The brute force is O(n^2) because ... - let me look
   for what work is being repeated."
  "n is up to 10^5, so I need about O(n log n). That
   rules out checking every pair."
  "This feels like it might be a sliding window because
   the subarray is contiguous - let me test that on the
   example."
  "I'm stuck between two approaches. Can I talk through
   both?"

ASKING FOR A HINT IS NOT A FAILURE. Using one well -
taking it and running with it - scores better than
grinding silently for ten minutes.

------------------------------------------------------------
THE THINGS THAT LOSE POINTS UNNECESSARILY

  · coding before agreeing the approach
```

```
    · never stating a complexity
    · claiming it works without tracing anything
    · ignoring the empty / single-element / all-equal cases
    · going silent for more than about twenty seconds
    · arguing when told there is a better solution
    · a variable named `x` doing three different jobs

  AND THE ONE THAT SURPRISES PEOPLE: FINDING YOUR OWN BUG
  SCORES POSITIVELY. Tracing your code and saying "this is
  wrong when the array is empty — let me fix it" is a
  strong signal, not a weak one.

  ------------------------------------------------------
  THE EDGE CASES TO CHECK, EVERY TIME

    empty input                []  ""  null
    one element
    two elements
    all identical
    already sorted / reverse sorted
    negatives and zero
    the target absent
    duplicates
    maximum size (does it overflow? is it fast enough?)

  Say them aloud as a list. It takes fifteen seconds and it
  is the cheapest scoring opportunity in the interview.
```

THE ONE-MINUTE OPENING, VERBATIM

```
"So, to make sure I understand: I'm given [restate],
 and I need to return [restate]. A few questions —
 how large can n be? Can the values be negative? Is
 the input sorted? Am I allowed to modify it? And
 what should I return if [edge case]?"

 ... then ...

"The brute force is [X], which is O(n²). I think I
 can do better by [insight] — that would be
 O(n log n). Shall I code that?"
```

That is ninety seconds and it hits three of the four rubric axes before you have written a line.

The pattern cheat sheet

If you see ...	Try ...	Chapter
Sorted array, find a pair	Two pointers	04
Contiguous subarray, max/min/longest	Sliding window	05
Range sums, negatives present	Prefix sums + hash map	06
Max contiguous sum	Kadane	07
Sorted input, O(log n) wanted	Binary search	09
"Minimise the maximum"	Binary search the answer	10
Overlapping ranges	Sort by start or end	12

If you see ...	Try ...	Chapter
"Have I seen this?", counting	Hash map / set	13
Values are 1..n, O(1) space	Cyclic sort / sign marking	14
Pairs cancel, single element	XOR	16
Cycle, middle, nth from end	Fast/slow pointers	18
Matching, nesting, "most recent"	Stack	19
Next greater / smaller element	Monotonic stack	20
Sliding window max	Monotonic deque	21
"Kth largest", "top K", median stream	Heap	22
Sorted order from a tree	Inorder traversal	25
Prefix, autocomplete	Trie	26
Shortest path, unweighted	BFS	27
Dependencies, ordering	Topological sort	28
Connectivity as edges arrive	Union-find	29
Weighted shortest path	Dijkstra	30
"All possible ..."	Backtracking	32
"How many ways", "min cost"	Dynamic programming	33
n ≤ 20, subsets or assignments	Bitmask DP	37

The mixed set

Four problems, **no pattern label**. Work out which technique applies before you start — that identification step is the one you have been practising, and it is the one the interview actually tests. Give each a full twenty minutes before opening the hints.

After the interview

```
/* --- WRITE IT DOWN, THE SAME DAY --- */
    the problem, your approach, where you got stuck,
    what the interviewer nudged you toward, and what you
    would do differently.

    After five interviews this log tells you your actual
    weakness, which is almost never what you assumed. Most
    people discover it is communication or edge cases, not
    algorithms.

/* --- ASK THEM QUESTIONS --- */
    You are also evaluating them. Reasonable questions:
      what does the team own end to end?
      what does the on-call rotation look like?
      how do changes get from a laptop to production?
      what is the most frustrating part of the codebase?

    The last one gets unusually honest answers.

/* --- IF YOU ARE REJECTED --- */
    Ask for feedback; sometimes you get it. Most companies
    allow a reapplication after 6-12 months, and people do
    get in on the second attempt regularly. A rejection is
    a sample of one interviewer on one day, not a
    measurement of your ability.

/* --- AND THE LAST PIECE OF ADVICE --- */

    THE STRONGEST PREDICTOR OF PASSING IS HAVING PRACTISED
    OUT LOUD. Not problem count. Not language. Talking
    through your reasoning while typing is a separate skill
    from solving, it feels unnatural at first, and it is
    almost entirely learnable in a couple of weeks.

    Explain three problems out loud to an empty room before
    your next interview. It is the highest-value hour left
    available to you.                                    */
```

Check yourself

- ✓ Name the four rubric axes and say which two are not about the algorithm.
- ✓ Give the timeline of a 45-minute interview and the most common timing failure.
- ✓ Recite the one-minute opening.
- ✓ Give five things to say when stuck.
- ✓ List the nine edge cases to check every time.
- ✓ Explain why finding your own bug scores positively.
- ✓ Recall ten rows of the pattern cheat sheet from the "if you see" side.
- ✓ Say what the strongest predictor of passing is.

Problems

Mixed 1 — rearrange without division `Medium`

Pattern: Identify it yourself

Given an integer array `nums`, return an array `answer` where `answer[i]` is the product of every element except `nums[i]`.

You may not use division, and it must run in O(n).

Input	Output	Note
`nums = [1,2,3,4]`	`[24,12,8,6]`	
`nums = [-1,1,0,-3,3]`	`[0,0,9,0,0]`	

HINTS

1. What does the answer at index `i` decompose into, if you split the array at `i`?
2. Everything to the left, times everything to the right.
3. Those are a prefix product and a suffix product — the pattern from chapter 06 with × instead of +.
4. Two passes over the output array need no extra storage beyond the answer itself.

Approach	Idea	Time	Space
Total product ÷ each element	Forbidden, and broken by zeros anyway.	`O(n)`	`O(1)`
Recompute per index	Multiply the other n−1 elements each time.	`O(n²)`	`O(1)`
Prefix and suffix passes	Write prefix products into the output, then multiply by a running suffix.	`O(n)`	`O(1) extra`

Solution — js

```
function productExceptSelf(nums) {
  const n = nums.length;
  const out = new Array(n).fill(1);

  // pass 1: out[i] = product of everything LEFT of i
  let prefix = 1;
  for (let i = 0; i < n; i++) {
    out[i] = prefix;
    prefix *= nums[i];
  }

  // pass 2: multiply in the product of everything RIGHT of i
  let suffix = 1;
  for (let i = n - 1; i >= 0; i--) {
    out[i] *= suffix;
    suffix *= nums[i];
  }
  return out;
}
```

Solution — cpp

```cpp
class Solution {
public:
    vector<int> productExceptSelf(vector<int>& nums) {
        int n = nums.size();
        vector<int> out(n, 1);
        long prefix = 1;
        for (int i = 0; i < n; ++i) { out[i] = prefix; prefix *= nums[i]; }
        long suffix = 1;
        for (int i = n - 1; i >= 0; --i) { out[i] *= suffix; suffix *= nums[i]; }
        return out;
    }
};
```

Solution — python

```python
class Solution:
    def productExceptSelf(self, nums: list[int]) -> list[int]:
        n = len(nums)
        out = [1] * n
        prefix = 1
        for i in range(n):
            out[i] = prefix
            prefix *= nums[i]
        suffix = 1
        for i in range(n - 1, -1, -1):
            out[i] *= suffix
            suffix *= nums[i]
        return out
```

Solution — java

```java
class Solution {
    public int[] productExceptSelf(int[] nums) {
        int n = nums.length;
        int[] out = new int[n];
        int prefix = 1;
        for (int i = 0; i < n; i++) { out[i] = prefix; prefix *= nums[i]; }
        int suffix = 1;
        for (int i = n - 1; i >= 0; i--) { out[i] *= suffix; suffix *= nums[i]; }
        return out;
    }
}
```

WALKTHROUGH

THE IDENTIFICATION STEP:

"answer at `i` = something about everything before `i`, combined with something about everything after" is the prefix/suffix signature. Once you name it, the code is two loops.

WRITING BEFORE UPDATING

is what excludes `nums[i]` from its own answer, exactly as in the pivot-index problem in chapter 06.

WHY THE DIVISION SHORTCUT IS BANNED:

with one zero, every other answer needs the product of the non-zero elements; with two zeros, everything is 0. Handling that requires counting zeros as a special case. The two-pass version has no special cases at all — which is the real reason it is the expected answer.

Mixed 2 — longest run of consecutive integers `Medium`

Pattern: Identify it yourself

Given an unsorted array of integers, return the length of the longest sequence of **consecutive** integers present. The elements need not be adjacent in the array.

Must run in O(n).

Input	Output	Note
`nums = [100,4,200,1,3,2]`	`4`	1, 2, 3, 4
`nums = [0,3,7,2,5,8,4,6,0,1]`	`9`	

HINTS

1. Sorting gives it in O(n log n), but the requirement is O(n) — so where does the ordering come from instead?
2. A hash set makes "is `x+1` present?" an O(1) question.
3. The trap is walking a run from every element, which is $O(n^2)$ on a long run.
4. Only start counting from an element that *begins* a run — one with no predecessor in the set.

Approach	Idea	Time	Space
Sort then scan	Sort and measure runs, skipping duplicates. Correct, but O(n log n).	`O(n log n)`	`O(1)`
Set, walk from everywhere	Quadratic: a run of length L is re-walked from each of its members.	`O(n²)`	`O(n)`
Set + run-start detection	Extend only from elements with no predecessor. Each value touched at most twice.	`O(n)`	`O(n)`

Solution — js

```
function longestConsecutive(nums) {
  const s = new Set(nums);
  let best = 0;

  for (const x of s) {
    // skip anything that is NOT the start of a run
    if (s.has(x - 1)) continue;

    let len = 1;
    while (s.has(x + len)) len++;
    best = Math.max(best, len);
  }
  return best;
}
```

Solution — cpp

```cpp
class Solution {
public:
    int longestConsecutive(vector<int>& nums) {
        unordered_set<int> s(nums.begin(), nums.end());
        int best = 0;
        for (int x : s) {
            if (s.count(x - 1)) continue;
            int len = 1;
            while (s.count(x + len)) ++len;
            best = max(best, len);
        }
        return best;
    }
};
```

Solution — python

```python
class Solution:
    def longestConsecutive(self, nums: list[int]) -> int:
        s = set(nums)
        best = 0
        for x in s:
            if x - 1 in s:
                continue
            length = 1
            while x + length in s:
                length += 1
            best = max(best, length)
        return best
```

Solution — java

```java
class Solution {
    public int longestConsecutive(int[] nums) {
        Set<Integer> s = new HashSet<>();
        for (int x : nums) s.add(x);
        int best = 0;
        for (int x : s) {
            if (s.contains(x - 1)) continue;
            int len = 1;
            while (s.contains(x + len)) len++;
            best = Math.max(best, len);
        }
        return best;
    }
}
```

WALKTHROUGH

THE IDENTIFICATION STEP:

"O(n) but the answer depends on order" almost always means a hash set is supplying the ordering implicitly, rather than a sort supplying it explicitly.

THE `CONTINUE` IS THE WHOLE ALGORITHM.

Without it, a shuffled `[1..n]` walks a run from every one of its members, costing `n + (n−1) + … = O(n²)`. With it, the inner loop runs only once per run, so every value is touched at most twice overall — once by the outer iteration, once by the single walk. That amortised argument (chapter 02) is what you must state to justify the O(n) claim.

ITERATING THE SET RATHER THAN THE ARRAY

handles duplicates for free: `[5,5,5,5]` visits 5 once and returns 1.

Mixed 3 — smallest covering substring `Hard`

Pattern: Identify it yourself

Given strings `s` and `t`, return the shortest substring of `s` containing every character of `t`, **including duplicates**. Return the empty string if none exists.

Input	Output	Note
`s = "ADOBECODEBANC", t = "ABC"`	`"BANC"`	
`s = "a", t = "aa"`	`""`	

HINTS

1. "Substring" means contiguous, and you want the shortest valid one — that is a window problem.
2. Grow the right edge until the window is valid, then shrink the left edge while it *stays* valid, recording the length before each shrink.
3. Counts matter, not just presence. Track how many distinct characters currently meet their required count.
4. Increment that counter only when a count becomes *exactly* the requirement; decrement only when it drops *strictly below*.

Approach	Idea	Time	Space
Check every substring	$O(n^2)$ substrings, each validated against the required counts.	`O(n²·m)`	`O(m)`
Sliding window with need/have counts	Expand, then contract while valid; a `formed` counter makes validity O(1).	`O(n + m)`	`O(m)`

Solution — js

```javascript
function minWindow(s, t) {
  if (!t.length || s.length < t.length) return "";

  const need = new Map();
  for (const c of t) need.set(c, (need.get(c) ?? 0) + 1);

  const have = new Map();
  let formed = 0;                 // chars meeting their quota
  let left = 0, bestLen = Infinity, bestStart = 0;

  for (let right = 0; right < s.length; right++) {
    const c = s[right];
    if (need.has(c)) {
      const h = (have.get(c) ?? 0) + 1;
      have.set(c, h);
      if (h === need.get(c)) formed++;      // EXACTLY met
    }

    // shrink WHILE VALID, recording BEFORE each shrink
    while (formed === need.size) {
      if (right - left + 1 < bestLen) {
        bestLen = right - left + 1;
        bestStart = left;
      }
      const d = s[left];
      if (need.has(d)) {
        const h = have.get(d) - 1;
        have.set(d, h);
        if (h < need.get(d)) formed--;      // dropped BELOW
      }
      left++;
    }
  }
  return bestLen === Infinity ? "" : s.slice(bestStart, bestStart + bestLen);
}
```

Solution — cpp

```cpp
class Solution {
public:
    string minWindow(string s, string t) {
        if (t.empty() || s.size() < t.size()) return "";
        unordered_map<char,int> need, have;
        for (char c : t) ++need[c];
        int formed = 0, left = 0, bestLen = INT_MAX, bestStart = 0;
        for (int right = 0; right < (int)s.size(); ++right) {
            char c = s[right];
            if (need.count(c) && ++have[c] == need[c]) ++formed;
            while (formed == (int)need.size()) {
                if (right - left + 1 < bestLen) {
                    bestLen = right - left + 1; bestStart = left;
                }
                char d = s[left];
                if (need.count(d) && --have[d] < need[d]) --formed;
                ++left;
            }
        }
        return bestLen == INT_MAX ? "" : s.substr(bestStart, bestLen);
    }
};
```

Solution — python

```python
from collections import Counter

class Solution:
    def minWindow(self, s: str, t: str) -> str:
        if not t or len(s) < len(t):
            return ""
        need, have = Counter(t), Counter()
        formed = left = 0
        best_len, best_start = float("inf"), 0
        for right, c in enumerate(s):
            if c in need:
                have[c] += 1
                if have[c] == need[c]:
                    formed += 1
            while formed == len(need):
                if right - left + 1 < best_len:
                    best_len, best_start = right - left + 1, left
                d = s[left]
                if d in need:
                    have[d] -= 1
                    if have[d] < need[d]:
                        formed -= 1
                left += 1
        return "" if best_len == float("inf") else s[best_start:best_start + best_len]
```

Solution — java

```java
class Solution {
    public String minWindow(String s, String t) {
        if (t.isEmpty() || s.length() < t.length()) return "";
        Map<Character,Integer> need = new HashMap<>(), have = new HashMap<>();
        for (char c : t.toCharArray()) need.merge(c, 1, Integer::sum);
        int formed = 0, left = 0, bestLen = Integer.MAX_VALUE, bestStart = 0;
        for (int right = 0; right < s.length(); right++) {
            char c = s.charAt(right);
            if (need.containsKey(c)) {
                int h = have.merge(c, 1, Integer::sum);
                if (h == need.get(c)) formed++;
            }
            while (formed == need.size()) {
                if (right - left + 1 < bestLen) {
                    bestLen = right - left + 1; bestStart = left;
                }
                char d = s.charAt(left);
                if (need.containsKey(d)) {
                    int h = have.merge(d, -1, Integer::sum);
                    if (h < need.get(d)) formed--;
                }
                left++;
            }
        }
        return bestLen == Integer.MAX_VALUE ? "" : s.substring(bestStart, bestStart + bestLen);
    }
}
```

WALKTHROUGH

THE IDENTIFICATION STEP:

contiguous, plus "shortest satisfying a condition", is the shrinking-window template from chapter 05 — `while (valid) { record; shrink; }`, the mirror image of the "longest" form.

THE TWO CONDITIONS MUST BE ASYMMETRIC.

On the way in, increment `formed` only when a count becomes *exactly* the requirement; using `>=` would count the same character repeatedly. On the way out, decrement only when it falls *strictly below*; a surplus copy leaving invalidates nothing. `"aa"/"aa"` and `"bba"/"ab"` catch the two mistakes respectively.

WHY `FORMED` EXISTS AT ALL.

Comparing the two maps entry by entry inside a loop that already runs n times would make this O(n·m). A single integer reduces the validity test to one comparison, which is what keeps it linear.

Mixed 4 — a valid ordering of dependencies `Medium`

Pattern: Identify it yourself

There are `numCourses` courses labelled `0..numCourses-1`. `prerequisites[i] = [a, b]` means `b` must be taken before `a`.

Return **any valid order** in which all courses can be taken, or an empty array if none exists.

Input	Output	Note
`numCourses = 2, prerequisites = [[1,0]]`	`[0,1]`	
`numCourses = 4, prerequisites = [[1,0],[2,0],[3,1],[3,2]]`	`[0,1,2,3]`	[0,2,1,3] is equally valid.
`numCourses = 2, prerequisites = [[1,0],[0,1]]`	`[]`	

HINTS

1. "X before Y" over a set of items is a dependency graph, and the question is asking for a topological order.
2. Build edges from prerequisite to dependant, and count each node's in-degree.
3. Repeatedly take any course whose in-degree has reached zero, and decrement its dependants.
4. If you cannot emit all the courses, the remainder are in a cycle — return an empty array.

Approach	Idea	Time	Space
Try every permutation	Check each ordering for validity.	`O(n!·E)`	`O(n)`
DFS postorder, reversed	Also correct; needs three-colour marking to detect cycles.	`O(V+E)`	`O(V)`
Kahn's algorithm	Peel off zero-in-degree nodes; a short result signals a cycle.	`O(V+E)`	`O(V+E)`

Solution — js

```javascript
function findOrder(numCourses, prerequisites) {
  const g = Array.from({length: numCourses}, () => []);
  const indeg = new Array(numCourses).fill(0);

  // [a, b] means b BEFORE a, so the edge points b -> a
  for (const [a, b] of prerequisites) {
    g[b].push(a);
    indeg[a]++;
  }

  // everything with no outstanding prerequisites
  const order = [];
  for (let i = 0; i < numCourses; i++) if (indeg[i] === 0) order.push(i);

  for (let head = 0; head < order.length; head++) {
    const u = order[head];
    for (const v of g[u]) {
      if (--indeg[v] === 0) order.push(v);   // now unblocked
    }
  }

  // anything never emitted is stuck in a cycle
  return order.length === numCourses ? order : [];
}
```

Solution — cpp

```cpp
class Solution {
public:
    vector<int> findOrder(int numCourses, vector<vector<int>>& prerequisites) {
        vector<vector<int>> g(numCourses);
        vector<int> indeg(numCourses, 0);
        for (auto& p : prerequisites) { g[p[1]].push_back(p[0]); ++indeg[p[0]]; }
        vector<int> order;
        for (int i = 0; i < numCourses; ++i) if (!indeg[i]) order.push_back(i);
        for (size_t head = 0; head < order.size(); ++head)
            for (int v : g[order[head]])
                if (--indeg[v] == 0) order.push_back(v);
        if ((int)order.size() != numCourses) return {};
        return order;
    }
};
```

Solution — python

```python
from collections import deque

class Solution:
    def findOrder(self, numCourses: int, prerequisites: list[list[int]]) -> list[int]:
        g = [[] for _ in range(numCourses)]
        indeg = [0] * numCourses
        for a, b in prerequisites:
            g[b].append(a)
            indeg[a] += 1

        order = [i for i in range(numCourses) if indeg[i] == 0]
        head = 0
        while head < len(order):
            u = order[head]
            head += 1
            for v in g[u]:
                indeg[v] -= 1
                if indeg[v] == 0:
                    order.append(v)
        return order if len(order) == numCourses else []
```

Solution — java

```java
class Solution {
    public int[] findOrder(int numCourses, int[][] prerequisites) {
        List<List<Integer>> g = new ArrayList<>();
        for (int i = 0; i < numCourses; i++) g.add(new ArrayList<>());
        int[] indeg = new int[numCourses];
        for (int[] p : prerequisites) { g.get(p[1]).add(p[0]); indeg[p[0]]++; }

        int[] order = new int[numCourses];
        int size = 0;
        for (int i = 0; i < numCourses; i++) if (indeg[i] == 0) order[size++] = i;
        for (int head = 0; head < size; head++)
            for (int v : g.get(order[head]))
                if (--indeg[v] == 0) order[size++] = v;

        return size == numCourses ? order : new int[0];
    }
}
```

WALKTHROUGH

THE IDENTIFICATION STEP:

any problem phrased as "X must come before Y" over a set of items is a topological sort. Build the graph, run Kahn, done — the difficulty is recognising it, not implementing it.

THE EDGE DIRECTION IS THE FIRST THING TO STATE ALOUD.

`[a, b]` means "to take `a`, first take `b`", so `b` is the prerequisite and the edge runs `b → a`. Reversing it produces a backwards order that still passes symmetric test cases, which makes the mistake hard to catch.

USING THE OUTPUT ARRAY AS THE QUEUE

avoids a second data structure: `order` is both the answer being built and the frontier being consumed, indexed by `head`. That also avoids `shift()`, which is O(n) in JavaScript (chapter 21).

THE CYCLE TEST IS THE LENGTH CHECK.

A node in a cycle always has an unemitted prerequisite, so its in-degree never reaches zero and it never enters the order — hence `order.length < numCourses` exactly when a cycle exists.

NOTE THE TESTS EXPECT ONE SPECIFIC ORDERING

even though several are valid; that is an artefact of automated grading. In an interview, say that any valid order is acceptable and that the greedy naturally produces the smallest-index-first one.

TRACK

Debugging & reference

The debugging discipline, the tools on both platforms, and the reference material worth keeping open.

9 chapters

The debugging method

Debugging is not a talent. It is a procedure, and the engineers who look fast at it are following it deliberately while everyone else is guessing.

The loop

```
1. OBSERVE          what ACTUALLY happens, precisely
2. HYPOTHESISE      one falsifiable explanation
3. PREDICT          "if this is true, then X will be
                     true"
4. TEST             the cheapest experiment that
                     distinguishes
5. CONCLUDE         confirmed, or eliminated
6. REPEAT

THE SCIENTIFIC METHOD, applied to a machine that cannot
lie to you.

THE FAILURE MODE THAT WASTES DAYS - "SHOTGUN DEBUGGING":
  change something, rebuild, see if it helps, change
  something else.

Why it fails:
  · you learn NOTHING when it does not help
  · when it DOES help you do not know why, so you cannot
    be sure it is fixed
  · you accumulate unexplained changes, each a future bug
  · and you cannot tell whether you fixed the problem or
    merely moved it

THE DISCIPLINE THAT REPLACES IT:

  CHANGE ONE THING. PREDICT THE RESULT FIRST. WRITE THE
  PREDICTION DOWN.

Predicting first is what converts an experiment into
information. If the result matches, you have confirmed a
model. IF IT DOES NOT, YOU HAVE LEARNED SOMETHING FAR
MORE VALUABLE: your mental model of the system is wrong,
and you now know approximately where.

THE FOUR QUESTIONS THAT START EVERY INVESTIGATION:

  WHAT did you expect to happen?
  WHAT actually happened?
  WHAT is the smallest difference between the working
    case and the broken one?
  WHEN did it last work?

That fourth one is often the whole answer. Something
changed.
```

Reproduce it first

```
/* A BUG YOU CANNOT REPRODUCE IS A BUG YOU CANNOT FIX AND -
   more importantly - CANNOT PROVE YOU FIXED.

   THE PROGRESSION:

   1. REPRODUCE IT AT ALL.
      Even at 1 in 1000. Automate the attempt and let it run
      overnight.

   2. REPRODUCE IT RELIABLY.
      Find the conditions. Then make a script.

   3. MINIMISE THE REPRODUCTION.
      Cut everything that is not required. Halve the input.
      Remove modules. Delete configuration.
      Each cut either preserves the bug (keep cutting) or
      kills it (you just found something relevant).

   4. AUTOMATE IT.
      A one-command reproduction is worth an hour of setup,
      because you will run it fifty times.

/* --- WHEN IT IS INTERMITTENT --- */
    INCREASE THE RATE, don't chase it:
      · run it in a loop, thousands of times
      · add STRESS: other load, memory pressure, thermal
      · vary TIMING: add random delays, change thread
        priorities, run on fewer cores
      · run on the SLOWEST and the FASTEST hardware you
        have - races often appear only at one extreme
      · disable optimisations, or ENABLE them - both change
        timing and both find different bugs
      · use the sanitisers and analysis tools that turn
        latent problems into deterministic failures
        (chapter 04 for Linux, 05 for Windows)

    AND CAPTURE STATE WHEN IT HAPPENS. If it takes six
    hours to reproduce, you cannot afford to catch it and
    learn nothing. Set up the logging, the core dump, the
    trace buffer BEFORE the long run.

/* --- WHEN IT ONLY HAPPENS IN THE FIELD --- */
    · what is different? hardware revision, temperature,
      supply, EMI, network, uptime, data volume, locale
    · get the LOGS and the CONFIGURATION
    · ask what the user was actually doing, not what they
      think they were doing
    · and consider whether your development environment is
      hiding it: a debugger attached changes timing, a
      development build has different optimisation, a bench
      supply is cleaner than a battery.               */
```

Bisection

```
/* THE MOST POWERFUL DEBUGGING TECHNIQUE, IN ANY DIMENSION.
   Halve the search space repeatedly: 1000 candidates becomes
   10 tests.                                                  */

/* --- BISECT IN TIME: git bisect --- */
    git bisect start
    git bisect bad                # current commit fails
    git bisect good v1.2.0        # this one worked
    # git checks out the midpoint; test and mark it
    git bisect good     # or: git bisect bad
    # ... repeat ~log2(n) times
    git bisect reset

    AUTOMATED, which is how you should do it:
      git bisect run ./test.sh
      # exit 0 = good, 1 = bad, 125 = skip (cannot build)

    10,000 commits -> 14 tests. If your test takes a minute,
    that is a quarter of an hour to find the exact commit
    that introduced a bug, unattended.

/* --- BISECT IN SPACE: the code --- */
    Comment out half the initialisation. Still broken?
    The cause is in the other half.
    Crude, and extremely effective.

/* --- BISECT IN CONFIGURATION --- */
    A working config and a broken one that differ in forty
    settings: change twenty, test, then ten. Six tests.

/* --- BISECT IN DATA --- */
    A parser crashes on a 10 MB file. Halve it. Still
    crashes? Halve again. You will have a 40-byte
    reproduction in twenty steps.
    (And this is exactly what a fuzzer's test-case minimiser
    does automatically.)

/* --- BISECT IN HARDWARE --- */
    Two boards, one works. Swap the module. Swap the cable.
    Swap the power supply. Swap the SD card. Each swap
    halves the space.

/* --- BISECT ACROSS THE STACK --- */
    Is the problem above or below this layer? Instrument the
    boundary. Application, library, syscall, driver,
    hardware register, bus, device.

    THE SINGLE MOST USEFUL QUESTION IN EMBEDDED DEBUGGING:

      DID THE BYTES ACTUALLY GO OUT ON THE WIRE?

    Put a logic analyser or a scope on it and find out.
    Half of all "the driver is broken" investigations end
    at "the pin was never configured as an output" or "the
    device NAKed and nobody checked".                     */
```

READ THE ERROR MESSAGE

Actually read it. All of it. Then read the line before it, and the line after. An enormous fraction of debugging time is spent on problems whose exact cause, file and line number were printed on screen and skimmed past. The same applies to the compiler's *first* error — the ones after it are usually consequences, and fixing the first often fixes forty.

Question the assumptions

```
/* WHEN YOU ARE GENUINELY STUCK, THE BUG IS IN SOMETHING YOU
   ARE CERTAIN ABOUT. That is definitionally where it must
   be - you have already checked everything you doubt.

   SO GO AND VERIFY THE CERTAINTIES:

   "The code I'm editing is the code that's running."
     -> Is it? Check the timestamp. Check the build actually
        succeeded. Check you flashed the right image to the
        right board. Add a deliberate crash and confirm it
        crashes. THIS IS NOT A JOKE - it is one of the most
        common causes of an impossible bug.

   "The compiler generated what I wrote."
     -> Read the disassembly (chapter 03, and the compilers
        track). Undefined behaviour licenses the optimiser
        to do surprising things, and a `volatile` you forgot
        means your register read was hoisted out of the loop.

   "This function returns what I think."
     -> Check the return value. Every time. The number of
        bugs that are an unchecked error code is
        extraordinary.

   "The hardware works."
     -> Usually true, and not always. Check the supply rail
        under load. Check the crystal is oscillating. Check
        the reset line. Check the part number matches the
        datasheet you are reading. Check the errata sheet -
        vendors publish them because the silicon has bugs.

   "The data is what I expect."
     -> Print it. In hex. With its length. Endianness,
        alignment, sign extension, off-by-one, and a
        stray 0x0D from a Windows line ending have all
        cost people days.

   "The clock is configured."
     -> A peripheral with no clock reads back zeros or
        retains defaults, and writes silently do nothing.
        A gated clock is the single most common cause of
        "the peripheral doesn't respond".

   "The other side is doing its part."
     -> Instrument the boundary and confirm.

/* AND THE META-ASSUMPTION:

     "This cannot possibly be related."

   Note it anyway. Coincidences in a deterministic machine
   are usually causation you have not traced yet.       */
```

Tactics that work

```
/* --- RUBBER DUCK DEBUGGING --- */
    Explain the problem, out loud, in complete sentences, to
    something that cannot help you. The bug frequently
    surfaces mid-sentence, because articulating forces you
    to state assumptions you had been skipping over.
    THIS SOUNDS SILLY AND IT WORKS.

/* --- WRITE IT DOWN --- */
    A running log of what you tried, what you predicted, and
    what happened. Three benefits: you stop repeating
    experiments, you can hand it to someone else, and the
    act of writing forces precision.

/* --- CHANGE ONE THING --- */
    Two changes at once and a fixed bug tells you nothing.

/* --- REVERT TO A KNOWN-GOOD STATE --- */
    When you have made twenty changes and it is worse than
    when you started: revert everything, reproduce, and
    start again with what you have learned. Sunk cost is
    not a debugging strategy.

/* --- TAKE A BREAK --- */
    Genuinely effective, for a real reason: you get stuck in
    a search path and stop generating new hypotheses. A
    walk, or sleep, resets it. Many hard bugs are solved in
    the first ten minutes of the next morning.

/* --- ASK SOMEONE --- */
    Not because they know more, but because explaining it
    (see rubber duck) plus one outside assumption is often
    all it takes. Set a time limit on solo effort - two
    hours, say - and then ask.

/* --- FIND THE SIMPLEST THING THAT FAILS --- */
    Strip until it works, then add back until it breaks.
    The last thing you added is where to look.

/* --- AND WHEN YOU FIX IT --- */
    1. UNDERSTAND WHY THE FIX WORKS. A change that makes the
       symptom disappear for a reason you cannot state is
       not a fix - it is a timing change that will come
       back.
    2. WRITE A TEST that fails without it.
    3. LOOK FOR THE SAME BUG ELSEWHERE. Bugs come in
       families; the same mistake is usually in three other
       places, made by the same person on the same
       afternoon.
    4. ASK WHY IT WAS POSSIBLE. Could a type, an assertion,
       a lint rule, or an API change make this class of bug
       unrepresentable? That question is worth more than the
       fix.
    5. WRITE IT DOWN somewhere the next person will find
       it.                                                */
```

How it shows up

Symptom	What it usually means
"It works on my machine"	An environment difference — enumerate them
"It's random"	It is not. Uninitialised memory, a race, or an input you have not identified
Adding a `printf` makes it go away	A race, or a timing-dependent bug — a heisenbug
Works in debug, fails in release	Undefined behaviour, uninitialised memory, or a missing `volatile`
Fails only under the debugger	Timing, or a breakpoint changing interrupt latency
Fixed itself after a rebuild	It did not. A stale object file, or the bug moved
Impossible state observed	Memory corruption, a stack overflow, or the wrong binary is running
Only fails after hours	A leak, a counter wrap, or fragmentation
Only fails on one unit	Hardware, or a per-unit configuration or calibration value
Only fails when cold or hot	Timing margin, crystal drift, or a marginal supply
Peripheral reads back all zeros	Clock not enabled

Check yourself

- ✓ State the six steps of the debugging loop.
- ✓ Explain why predicting before testing is what makes an experiment informative.
- ✓ Give the four opening questions.
- ✓ Describe the four stages from "reproduce at all" to "automate it".
- ✓ List six ways to raise the reproduction rate of an intermittent bug.
- ✓ Run a `git bisect`, including the automated form.
- ✓ Give five dimensions other than time that you can bisect in.
- ✓ Name six "certainties" that are worth verifying when stuck.
- ✓ Explain why a peripheral reading back zeros usually means a clock problem.
- ✓ Give the five things to do after a fix works.

Print-based debugging and tracing

The most-used debugging technique in systems programming, and the one most often done badly. A well-designed trace answers questions a debugger cannot — because it does not stop time.

Why printing beats breakpoints

```
A DEBUGGER STOPS THE WORLD. That is exactly wrong for:

  · REAL-TIME systems - stop for 200 ms and the motor
    controller has already faulted, the watchdog has
    fired, or the USB host has dropped the device
  · INTERRUPT HANDLERS - a breakpoint in an ISR changes
    the latency you are trying to measure
  · RACES - stopping one thread changes the interleaving,
    and the bug disappears
  · PROTOCOL TIMING - the peer times out while you look
    at a variable
  · PRODUCTION - you cannot attach a debugger to a
    customer's device in the field
  · and ANY BUG THAT TAKES HOURS TO APPEAR - you cannot
    single-step for six hours

A TRACE RECORDS WHAT HAPPENED AND LETS THE SYSTEM RUN.
You get the SEQUENCE, which is usually the actual
question:

  what happened before the failure?
  in what ORDER did these events occur?
  how LONG did that take?
  how many times did that path execute?
  what did the state look like over TIME?

A DEBUGGER ANSWERS "what is true NOW". A TRACE ANSWERS
"what happened, and in what order". MOST BUGS ARE
SEQUENCE BUGS.

THE OTHER SIDE OF THE TRADE, honestly:
  · a trace only shows what you thought to record
  · you must rebuild and re-run to add a field
  · printing PERTURBS TIMING - the classic heisenbug,
    where adding a printf makes the race disappear
  · and it costs code space and bandwidth

USE BOTH. A debugger to inspect a stopped state
(chapter 03); a trace to understand a sequence.
```

What a good trace line contains

```
/* BAD - and every codebase is full of these: */
    printf("here\n");
    printf("value = %d\n", x);
    printf("error!\n");

/* Useless in a log with a thousand lines from twelve
   modules, and completely useless six months later.

/* GOOD: */
    [00123.456] [INFO ] [i2c    ] i2c.c:214 xfer addr=0x50
                len=32 -> OK (1.2ms)
    [00123.458] [WARN ] [sensor ] sen.c:88  temp=87.5C
                exceeds limit 85.0C
    [00123.461] [ERROR] [net    ] net.c:512 tx failed
                errno=110 (ETIMEDOUT) retry=3/5

/* THE SEVEN FIELDS THAT EARN THEIR SPACE:

   1. TIMESTAMP. Monotonic, high resolution. THE SINGLE
      MOST VALUABLE FIELD - it gives you ordering and
      duration for free. Use a monotonic clock, never
      wall-clock time, which jumps.

   2. LEVEL. So you can filter without rebuilding.

   3. SUBSYSTEM. So you can filter to one module.

   4. LOCATION. File and line, or the function name.
      __FILE__, __LINE__, __func__ cost nothing to add.

   5. THE OPERATION, named in a way you can grep for.

   6. THE VALUES, with UNITS and in a consistent radix.
      "temp=87.5C" not "temp is high". "addr=0x50" not
      "addr=80".

   7. THE OUTCOME, including the ERROR CODE AND ITS NAME.
      "errno=110 (ETIMEDOUT)" saves the reader a lookup.

/* --- THE PATTERN THAT MAKES IT GREPPABLE --- */
    Log KEY=VALUE pairs, consistently. Then:

      grep 'i2c' log.txt | grep 'ERROR'
      awk '/xfer/ {print $NF}' log.txt | sort | uniq -c

    Structured logging (JSON lines) goes further and is
    worth it on Linux-class systems. On an MCU, consistent
    key=value text is the right level.                    */
```

The logging layer

```
/* ------------------------------------------------------
 * log.h - a complete, compile-time-filtered logging layer
 * ------------------------------------------------------ */
#ifndef LOG_H
#define LOG_H

#include <stdint.h>

#define LOG_LEVEL_NONE   0
#define LOG_LEVEL_ERROR  1
#define LOG_LEVEL_WARN   2
#define LOG_LEVEL_INFO   3
#define LOG_LEVEL_DEBUG  4
#define LOG_LEVEL_TRACE  5

/* Per-module override: define LOG_LEVEL before including,
   so one noisy driver can be turned up without drowning in
   everything else. */
#ifndef LOG_LEVEL
#define LOG_LEVEL LOG_LEVEL_INFO
#endif

#ifndef LOG_TAG
#define LOG_TAG "app"
#endif

uint32_t log_time_ms(void);

        for (size_t j = 0; j < 16 && i + j < len; j++) {
            uint8_t c = p[i + j];
            line[n++] = (c >= 32 && c < 127) ? (char)c : '.';
        }
        line[n] = '\0';
        LOG_DEBUG("%s", line);
    }
}
```

NEVER LOG A SECRET

Keys, passwords, tokens, personal data. A UART pad on the board is accessible to anyone with a soldering iron, and a log file gets emailed to support (cryptography chapter 18). Log a *fingerprint* — the first four bytes of a hash — if you need to confirm which key is in use. Add a review check for it; this is one of the most common ways a shipped product leaks its own credentials.

When printing is too slow

```
/* A 115200-BAUD UART CARRIES ~11 KB/S. One 80-character
   line takes 7 MILLISECONDS. In an interrupt handler that
   runs every 100 microseconds, that is not debugging - it
   is a denial of service against your own system.

/* --- 1. RING BUFFER, DEFERRED OUTPUT --- */
    The ISR writes into a RAM buffer and returns. The idle
    loop drains it to the UART.

    static char logbuf[4096];
    static volatile uint32_t head, tail;

    void log_put(const char *s, size_t n) {
        /* single producer here; for multiple producers use
           an atomic head increment (see the OS track) */
        for (size_t i = 0; i < n; i++) {
            uint32_t next = (head + 1) % sizeof logbuf;
            if (next == tail) break;   /* FULL: DROP.
                                          Never block. */
            logbuf[head] = s[i];
            head = next;
        }
    }
    /* AND COUNT THE DROPS. A log that silently discards
       lines will mislead you at the worst moment; print
       "[dropped 412]" when it recovers. */

/* --- 2. BINARY / DEFERRED-FORMAT LOGGING --- */
    Do not format on the device. Log an EVENT ID and raw
    arguments; a host tool formats them using the same
    string table extracted from the ELF.

      · a trace point becomes ~8 bytes instead of 80
      · no snprintf on the target - which is often the
        single largest and slowest function in a small
        firmware image
      · format strings live in the ELF, not in flash

    THIS IS WHAT SEGGER RTT + SystemView, TraceX, Zephyr's
    dictionary logging and the Linux kernel's tracepoints
    all do.

/* --- 3. SEGGER RTT --- */
    Uses the debug probe's memory access to read a RAM ring
    buffer WHILE THE TARGET RUNS. No UART, no pins,
    megabytes per second, and microseconds per call. IF YOU
    HAVE A J-LINK, USE IT - it removes the timing
    perturbation almost entirely.

/* --- 4. ITM / SWO --- */
    ARM Cortex-M's instrumentation trace: write a byte to a
    register, the trace unit streams it out the SWO pin.
    Single-cycle cost.

      ITM_SendChar(c);          /* CMSIS */

    32 stimulus ports, so you can separate channels. Needs
    the SWO pin and a probe that supports it.

/* --- 5. A GPIO PIN AND A SCOPE --- */
```

```
    THE FASTEST INSTRUMENTATION THAT EXISTS, and frequently
    the best:

      GPIOA->BSRR = PIN;      /* one store */
      do_the_thing();
      GPIOA->BSRR = PIN << 16;

    A few nanoseconds. Put a scope or logic analyser on it
    and you get EXACT timing, jitter, and the relationship
    to other signals - things no software trace can give
    you. Toggle a different pin in each ISR and you can SEE
    your system's scheduling.

    THIS IS THE TECHNIQUE THAT SEPARATES EMBEDDED DEBUGGING
    FROM APPLICATION DEBUGGING. Use it.

/* --- 6. TRACE BUFFER IN NON-VOLATILE MEMORY --- */
    For crashes: a small circular buffer in a RAM region
    excluded from initialisation, or in flash. After a
    watchdog reset, dump the last events that preceded it.
    Combined with a reset-reason register, this is how you
    debug field failures you cannot reproduce.          */
```

Tracing on Linux and Windows

```
/* --- LINUX KERNEL --- */
    printk(KERN_INFO "mydrv: probe %s\n", dev_name(dev));
    dev_info(dev, "probe ok\n");        /* PREFERRED -
                                           includes the
                                           device name */
    dev_err(dev, "failed: %d\n", ret);
    dev_dbg(dev, "reg=0x%08x\n", val);  /* dynamic debug */

    /* enable dev_dbg at runtime, no rebuild: */
    # echo 'module mydrv +p' > \
        /sys/kernel/debug/dynamic_debug/control
    # echo 'file mydrv.c line 100-200 +p' > \
        /sys/kernel/debug/dynamic_debug/control

    /* TRACEPOINTS - near-zero cost when disabled */
    # cd /sys/kernel/tracing
    # echo 1 > events/irq/enable
    # cat trace_pipe

    /* trace_printk() for temporary work: goes to the ftrace
       ring buffer instead of the console, so it is
       thousands of times cheaper than printk. Remove it
       before you submit anything. */

    /* AND THE BIG ONES, covered in chapter 04:
       ftrace, perf, eBPF/bpftrace, LTTng. */

/* --- WINDOWS KERNEL --- */
    DbgPrintEx(DPFLTR_IHVDRIVER_ID, DPFLTR_INFO_LEVEL,
               "mydrv: probe\n");

    /* WPP SOFTWARE TRACING is the production answer: */
    DoTraceMessage(TRACE_LEVEL_INFORMATION,
                   "xfer addr=%!HEXDUMP! len=%d", ...);

    · formatted OFF the device by a trace consumer
    · negligible runtime cost
    · always compiled in, enabled at runtime
    · integrated with ETW (Event Tracing for Windows), so
      it correlates with the rest of the system

    Chapter 05 covers the tooling.

/* --- THE COMMON PRINCIPLE ACROSS ALL THREE PLATFORMS --- */
    THE BEST TRACING SYSTEMS ARE ALWAYS COMPILED IN,
    NEGLIGIBLE WHEN DISABLED, AND ENABLED AT RUNTIME.

    A debug build you have to install to diagnose a problem
    is not available when you need it - the problem is
    happening on a production unit, now. Design so that the
    instrumentation is already there and only needs turning
    on.                                                    */
```

How it shows up

Symptom	Cause
Adding a `printf` makes the bug vanish	Timing perturbation — use RTT, ITM or a GPIO

Symptom	Cause
System misses deadlines with logging on	Blocking UART writes — defer to a ring buffer
Log stops partway through a failure	Buffer full and dropping, or the crash beat the drain
Log lines interleaved and corrupted	Multiple producers with no locking or atomic head
Cannot tell what order events occurred in	No timestamps, or wall-clock time that jumped
Flash full after adding logging	Format strings — use deferred-format or dictionary logging
Cannot reproduce in a debug build	The bug is timing-dependent — trace instead
Field unit fails, no information	No persistent trace buffer across reset
Credentials found in a support log	Secrets logged — log a fingerprint instead
Log too noisy to read	No per-module levels or subsystem tags

Check yourself

- ✓ Give six situations where a debugger is the wrong tool.
- ✓ State what a trace answers that a stopped debugger cannot.
- ✓ List the seven fields of a good trace line and what each is for.
- ✓ Explain why `do { } while (0)` wraps a logging macro.
- ✓ Explain compile-time level filtering and why it matters on an MCU.
- ✓ Compute how long an 80-character line takes at 115200 baud.
- ✓ Describe deferred output and why dropped lines must be counted.
- ✓ Explain deferred-format logging and what it saves.
- ✓ Say why a GPIO toggle and a scope is sometimes the best instrument.
- ✓ Enable a Linux `dev_dbg` at runtime without rebuilding.
- ✓ State the principle shared by ftrace, WPP and RTT.

JTAG, SWD and hardware debug

A side channel into the processor that works before any software runs. When the board is dead, the boot loops, or the fault handler fires before a single character reaches the UART, this is the only tool you have.

What the debug port is

```
THE DEBUG PORT IS HARDWARE INSIDE THE CHIP, independent
of the CPU's execution. It can:

  · HALT and RESUME the core
  · READ AND WRITE registers and memory - THROUGH THE
    BUS, so it works even when the CPU is halted or
    stuck
  · SET BREAKPOINTS in flash (hardware comparators)
  · SET WATCHPOINTS on data addresses
  · STEP single instructions
  · RESET the chip, and HALT BEFORE THE FIRST
    INSTRUCTION
  · program flash
  · and stream TRACE

THAT LAST-BUT-ONE POINT IS THE IMPORTANT ONE: "connect
under reset" lets you attach to a chip whose firmware
immediately disables the debug pins, sleeps, or crashes.
It is how you recover a board you have bricked with your
own code.

JTAG (IEEE 1149.1) - the original, 4-5 pins:
  TCK   clock
  TMS   mode select (drives a state machine)
  TDI   data in
  TDO   data out
  TRST  reset (optional)
DAISY-CHAINABLE: several devices on one chain, which is
why it is still used on FPGAs and multi-chip boards. It
also does BOUNDARY SCAN - toggling and reading individual
package pins to test solder joints, independently of the
CPU.

SWD (Serial Wire Debug) - ARM's 2-pin replacement:
  SWDIO  bidirectional data
  SWCLK  clock
  (+ SWO, optional, for trace output)

SAME CAPABILITY, TWO PINS. Universal on Cortex-M, and
what you will use in practice.

THE CONNECTOR, and it matters when the board arrives:
  10-pin 1.27mm Cortex Debug     the modern standard
  20-pin 2.54mm ARM JTAG         older, bulky
  TC2050 "tag-connect"           no connector at all -
                                 spring pins on pads.
                                 COSTS NOTHING IN BOM
                                 AND SAVES YOU EVERY
                                 TIME.

PUT A DEBUG CONNECTOR ON EVERY BOARD YOU DESIGN. Even
production ones - use tag-connect pads, and disable the
port in firmware for shipping units (see below).
```

Probes and the software stack

```
/* --- THE PROBES --- */
    SEGGER J-Link       the reference. Fast flash
                        programming, RTT (chapter 02),
                        excellent target support. The EDU
                        version is inexpensive for
                        non-commercial use.
    ST-LINK             on every Nucleo and Discovery
                        board. Fine for STM32.
    CMSIS-DAP / DAPLink open standard, on many dev boards.
                        Slower, universal.
    Black Magic Probe   runs the GDB SERVER ON THE PROBE -
                        connect GDB directly to a serial
                        port, no OpenOCD needed.
    Vendor probes       Lauterbach TRACE32 and iSYSTEM at
                        the high end: full instruction
                        trace, expensive, and worth it for
                        a team debugging hard timing
                        problems.

/* --- THE SOFTWARE STACK --- */

    GDB  <--TCP:3333-->  OpenOCD / JLinkGDBServer
                              |
                              v  (USB)
                           PROBE
                              |
                              v  (SWD/JTAG)
                           TARGET

    THE GDB SERVER translates GDB's remote protocol into
    probe commands. Understanding that there are three
    separate pieces is most of what makes connection
    failures diagnosable.

/* --- OPENOCD --- */
    $ openocd -f interface/stlink.cfg \
              -f target/stm32f4x.cfg

    Open On-Chip Debugger. Supports hundreds of targets and
    dozens of probes. Its telnet interface (port 4444) is
    useful on its own:

      $ telnet localhost 4444
      > reset halt
      > mdw 0x40021000 4       # read 4 words
      > mww 0x40020014 0x20    # write a word
      > flash write_image erase firmware.elf
      > reg                    # dump all registers

    READING AND WRITING PERIPHERAL REGISTERS BY HAND, with
    the CPU halted, is an extremely direct way to answer
    "is this peripheral configured the way I think?"

/* --- A CONNECTION THAT FAILS --- */
    "Error: init mode failed (unable to connect to the
     target)"

    THE CHECKLIST, in order:
      1. POWER. Is the target powered? Measure it.
      2. GROUND. Is the probe's ground connected? A missing
```

```
   ground is the most common cause.
3. WIRING. SWDIO and SWCLK to the right pins, not
   swapped.
4. RESET. Try "connect under reset" - firmware may be
   disabling the debug pins or entering sleep.
5. PIN REUSE. Did your code reconfigure PA13/PA14 as
   GPIO? That kills SWD. Connect under reset and
   erase.
6. LOW POWER MODE. Deep sleep gates the debug clock.
   Set the DBGMCU standby/stop bits to keep it alive.
7. READOUT PROTECTION. If RDP is set, the port is
   disabled by design. A mass erase may be the only
   way back - and at RDP level 2, there is no way
   back.
8. TARGET SPEED. Drop the adapter clock to 100 kHz
   and retry; long wires and slow crystals both
   matter.
9. CLOCK. Is the target's crystal actually
   oscillating? Scope it.                          */
```

GDB, the parts you need

```
$ arm-none-eabi-gdb firmware.elf
(gdb) target extended-remote localhost:3333
(gdb) monitor reset halt     # "monitor" passes to OpenOCD
(gdb) load                   # flash the image
(gdb) break main
(gdb) continue

# ---- BREAKPOINTS ----
break main                   # by function
break i2c.c:214              # by file:line
break *0x08001234            # by address
break i2c_xfer if addr==0x50 # CONDITIONAL - and note it
                             # is evaluated by GDB, so it
                             # halts EVERY time and is slow
tbreak setup                 # temporary, one shot
info breakpoints
delete 2

# NOTE: A CORTEX-M HAS ONLY 4-8 HARDWARE BREAKPOINTS,
# because code is in flash and cannot be patched with a
# software trap. Exceed the limit and GDB reports a failure
# to set one. Delete the ones you are not using.

# ---- WATCHPOINTS: the most underused feature ----
watch g_state               # break when it is WRITTEN
rwatch g_config             # when READ
awatch g_flag               # either
watch *(uint32_t*)0x20001000

# "SOMETHING IS CORRUPTING THIS VARIABLE AND I CANNOT FIND
# WHAT" IS EXACTLY WHAT A WATCHPOINT IS FOR. Set it, run,
# and the debugger stops at the instruction that did it and
# shows you the backtrace. This turns a two-day bug into a
# two-minute one, and most people never use it.
#
# Hardware watchpoints are also limited (typically 4) and
# they watch an ADDRESS RANGE, so watching a whole struct
# may need several.

# ---- EXECUTION ----
continue / c
next / n           # step over calls
step / s           # step into
finish             # run until the current function returns
until 250          # run until line 250

# ---- STATE ----
print var
print/x reg                 # hex
print *ptr
print arr[0]@16             # ARTIFICIAL ARRAY: 16 elements
                            # from arr[0]. Extremely useful.
print sizeof(struct foo)
x/16xb 0x20000000           # 16 hex bytes
x/8xw 0x40021000            # 8 hex words - a peripheral
x/i $pc                     # the instruction at PC
x/20i $pc                   # disassemble forward
info registers
info locals
info args
```

```
backtrace / bt
bt full                     # with locals at each frame
frame 2                     # switch frames
set var x = 5               # MODIFY state and continue

# ---- WHEN THERE IS NO BACKTRACE ----
# After a hard fault the stack may be unwindable only
# manually. See chapter 06 for reading the fault registers
# and the stacked frame.

# ---- SCRIPTING: put this in .gdbinit ----
define reload
  monitor reset halt
  load
  monitor reset halt
end

define regs
  printf "PC=%08x LR=%08x SP=%08x\n", $pc, $lr, $sp
end

# ---- TUI ----
# Ctrl-X A, or start with `gdb -tui`. Source, registers and
# disassembly in one terminal. layout split, layout regs.
```

THE THREE THINGS A DEBUGGER DOES THAT NOTHING ELSE CAN

```
1. WATCHPOINTS. Catch the instruction that corrupts
   a variable, with a backtrace.
2. CONNECT UNDER RESET. Reach a chip whose firmware
   is hostile to debugging — including your own
   bricked board.
3. READ PERIPHERAL REGISTERS ON A HALTED CORE.
   Answer "is this actually configured?" directly,
   without trusting any code you wrote.
```

Trace, and what it buys

```
/* ARM CoreSight, the units and what each is for: */

    DWT   Data Watchpoint and Trace
            · a CYCLE COUNTER - free, precise timing
            · watchpoints
            · PC sampling for a statistical profile
            · exception tracing
    ITM   Instrumentation Trace Macrocell
            · software-generated messages, single-cycle
              cost (chapter 02)
    ETM   Embedded Trace Macrocell
            · FULL INSTRUCTION TRACE. Every instruction
              executed, reconstructible offline.
    TPIU  Trace Port Interface Unit
            · streams it out, over SWO (1 pin, slow) or a
              4-bit parallel TRACE port (fast, needs a
              proper probe)

/* --- THE CYCLE COUNTER: use this constantly --- */
    /* enable once */
    CoreDebug->DEMCR |= CoreDebug_DEMCR_TRCENA_Msk;
    DWT->CYCCNT = 0;
    DWT->CTRL  |= DWT_CTRL_CYCCNTENA_Msk;

    /* measure anything */
    uint32_t t0 = DWT->CYCCNT;
    function_under_test();
    uint32_t cycles = DWT->CYCCNT - t0;
    /* the subtraction is correct across wraparound,
       for unsigned arithmetic (see the C track) */

    NANOSECOND-RESOLUTION TIMING, no probe required, a few
    lines of setup. IF YOU MEASURE ANYTHING ON A CORTEX-M,
    MEASURE IT WITH THIS.

/* --- FULL INSTRUCTION TRACE (ETM) --- */
    Records every branch, so a host tool can reconstruct the
    exact execution path - thousands of instructions before
    a crash, with no instrumentation and no timing
    perturbation.

    WHAT IT SOLVES THAT NOTHING ELSE DOES:
      · "how did we get to this address?"
      · a corrupted stack with no backtrace
      · a race whose interleaving you cannot otherwise see
      · code coverage on the real target
      · exact cycle-accurate profiling

    THE COST: a probe that supports it (J-Trace,
    Lauterbach, iSYSTEM) and a board that routes the trace
    pins. ROUTE THEM. Adding four pins at schematic time
    costs nothing; adding them after a failure costs a board
    spin.

/* --- ETW/perf EQUIVALENTS --- */
    On Linux and Windows you have perf and ETW instead
    (chapters 04, 05) - same idea, done in software with
    hardware performance counters.                        */
```

Debug ports and security

```
/* A DEBUG PORT IS COMPLETE ACCESS TO THE DEVICE. Read all
   memory, read the keys, modify execution, dump the
   firmware. On a shipped product that is a serious
   vulnerability, and leaving it open is one of the most
   common findings in any hardware teardown (see the
   cryptography track, chapter 21).

/* --- THE LIFECYCLE APPROACH --- */
    DEVELOPMENT   debug open, test keys only
    PRODUCTION    debug DISABLED via a one-way fuse or a
                  protection level, production keys
                  provisioned
    RMA           if debug can be re-enabled at all, THE
                  TRANSITION MUST ERASE ALL SECRETS FIRST

/* --- THE MECHANISMS, by vendor --- */
    STM32          RDP levels 0/1/2. Level 2 is PERMANENT -
                   there is no way back, and no way to
                   debug a returned unit.
    nRF            APPROTECT. Note that early revisions were
                   defeated by a voltage glitch, which is a
                   useful reminder that a protection bit is
                   only as strong as its enforcement
                   (cryptography chapter 19).
    ARMv8-M /
    TrustZone-M    debug authentication with SEPARATE
                   secure and non-secure permissions - you
                   can allow non-secure debug while keeping
                   the secure world closed. This is the
                   right model.
    ADAC           an ARM standard for AUTHENTICATED debug:
                   the port stays physically present but
                   requires a signed challenge-response to
                   unlock, so the vendor can debug a
                   returned unit and an attacker cannot.

/* --- AND THE PRACTICAL ADVICE --- */
      · DO put a debug connector on production boards -
        tag-connect pads cost nothing
      · DO disable the port in the production firmware
        configuration
      · DO verify on an actual production unit that it is
        disabled. "We set the fuse in the build script" is
        not evidence; probing a shipping unit is.
      · DO plan the RMA path before you ship, and make it
        erase
      · and prefer AUTHENTICATED debug over permanent
        lockout if the silicon supports it - a fleet you
        cannot diagnose is its own kind of problem.    */
```

How it shows up

Symptom	Cause
Cannot connect to the target	Work the nine-step checklist — ground and connect-under-reset first
Connects once, then never again	Firmware reconfigured the SWD pins — connect under reset and erase
Connection drops when the device sleeps	Debug clock gated — set the DBGMCU low-power bits

Symptom	Cause
"Cannot set breakpoint"	Hardware breakpoints exhausted — delete unused ones
Watchpoint has no effect	Watching a range larger than the comparator covers
Backtrace is garbage	Stack corrupted, or the frame pointer optimised away — see chapter 06
Variables show `<optimized out>`	Build with `-Og -g3` for debugging
Single-stepping breaks the behaviour	Real-time constraint — use a trace instead (chapter 02)
Flash programming fails intermittently	Adapter speed too high, or a marginal supply
Cannot debug a returned production unit	Permanent readout protection — should have been authenticated debug
Firmware dumped from a shipped product	Debug port left enabled

Check yourself

- ✓ List what the debug port can do independently of the CPU.
- ✓ Compare JTAG and SWD, and say what boundary scan is for.
- ✓ Draw the GDB / server / probe / target stack.
- ✓ Work the nine-step connection checklist from memory.
- ✓ Explain why "connect under reset" recovers a bricked board.
- ✓ Set a conditional breakpoint and say why it is slow.
- ✓ Explain why Cortex-M has only a handful of hardware breakpoints.
- ✓ Explain what a watchpoint solves and why it is underused.
- ✓ Use `print arr[0]@16` and `x/8xw` correctly.
- ✓ Enable and use the DWT cycle counter.
- ✓ Say what full instruction trace gives you that nothing else does.
- ✓ Describe the debug lifecycle and why authenticated debug beats permanent lockout.

The Linux debugging toolkit

A reference for the tools that actually get used, organised by the question you are trying to answer rather than by tool name.

Which tool for which question

Question	Tool
Why did it crash?	`gdb` on the core dump, `dmesg`, `decode_stacktrace.sh`
Is it a memory bug?	ASan, UBSan, Valgrind, KASAN
Where is the time going?	`perf`, flame graphs
What syscalls is it making?	`strace`
What library calls?	`ltrace`
What is the kernel doing?	`ftrace`, `bpftrace`, `/proc`
Why is it stuck?	`gdb` attach, `/proc/PID/stack`, `wchan`
What is on the wire?	`tcpdump`, `wireshark`
What files is it touching?	`lsof`, `fatrace`, `inotifywait`
Is the device present?	`lspci`, `lsusb`, `/sys`, `udevadm`
Where is the memory going?	`/proc/meminfo`, `smem`, `heaptrack`
Is it a race?	TSan, lockdep, `KCSAN`

Crashes

```
# ---- ENABLE CORE DUMPS (they are usually off) ----
$ ulimit -c unlimited
$ cat /proc/sys/kernel/core_pattern
$ sudo sysctl -w kernel.core_pattern=/tmp/core.%e.%p.%t
# systemd systems: coredumpctl list; coredumpctl gdb PID

$ gdb ./myapp /tmp/core.myapp.1234.1699
(gdb) bt full          # backtrace with locals
(gdb) info registers
(gdb) frame 3
(gdb) print *ptr
(gdb) info sharedlibrary
(gdb) thread apply all bt      # ALL threads - and for a
                               # deadlock this is the
                               # first thing to run

# ---- BUILD FOR DEBUGGABILITY ----
CFLAGS += -g3 -Og -fno-omit-frame-pointer
# -g3   includes macro definitions
# -Og   optimised but debuggable. NOT -O0, which changes
#       timing and hides optimiser-dependent bugs, and NOT
#       -O2, which optimises away the variables you want.
# -fno-omit-frame-pointer   makes perf and backtraces work.
#       Costs ~1% and is worth it in production too.

# KEEP THE UNSTRIPPED BINARY for every release you ship.
# A stripped binary plus a core dump is nearly useless, and
# the matching .debug file is the difference between a
# five-minute diagnosis and a week.

# ---- KERNEL OOPS ----
$ dmesg -T | tail -50
$ journalctl -k -b -1        # PREVIOUS boot - after a
                             # crash this is where it is

# decode a raw oops:
$ ./scripts/decode_stacktrace.sh vmlinux < oops.txt

# READING AN OOPS - the fields that matter:
#   "BUG: kernel NULL pointer dereference at 0000000000000018"
#        -> a null struct pointer; 0x18 is the field offset
#   "RIP: 0010:my_driver_probe+0x42/0x120"
#        -> the FUNCTION, the OFFSET INTO IT, and its SIZE

Memory bugs

```
# ---- SANITISERS: use these first, always ----
$ gcc -fsanitize=address,undefined -g -Og prog.c
$ ./a.out
# =================================================
# ERROR: AddressSanitizer: heap-use-after-free
#   READ of size 4 at 0x602000000010 thread T0
#     #0 0x4008f1 in main prog.c:12
#   freed by thread T0 here:
#     #0 0x7f... in free
#     #1 0x4008d5 in main prog.c:10
#   previously allocated by thread T0 here: ...

# ASAN GIVES YOU THREE STACKS: where the bad access
# happened, where it was freed, and where it was allocated.
# That is usually the entire diagnosis.

# WHAT EACH CATCHES:
#   ASan   buffer overflow, use-after-free, double free,
#          use-after-return, leaks. ~2x slowdown, ~3x memory.
#   UBSan  signed overflow, null deref, misaligned access,
#          shifts out of range, bad enum values. Near-free.
#          (see the C track on undefined behaviour)
#   TSan   DATA RACES. ~10x slowdown, and worth every cycle.
#   MSan   reads of UNINITIALISED memory. Needs ALL code
#          instrumented, including libraries.
#
# ASan and TSan CANNOT be combined. Run separately.
# RUN THE SANITISERS IN CI. They find bugs that have not
# manifested yet, which is the only cheap time to find them.

# ---- VALGRIND: no rebuild needed ----
$ valgrind --leak-check=full --show-leak-kinds=all \
           --track-origins=yes ./myapp
# 20-50x slower than ASan but requires no recompilation -
# which matters when you have a binary and no source, or a
# build system you cannot change.
$ valgrind --tool=helgrind ./myapp     # races
$ valgrind --tool=massif ./myapp       # heap profile

# ---- WHERE IS THE MEMORY GOING ----
$ cat /proc/meminfo
$ cat /proc/PID/status | grep -E 'VmRSS|VmSize|Threads'
$ cat /proc/PID/smaps_rollup      # per-process summary
$ smem -tk                        # PSS - the honest
                                  # shared-memory number
$ heaptrack ./myapp && heaptrack_gui heaptrack.myapp.*

# ---- KERNEL-SIDE ----
# CONFIG_KASAN     ASan for the kernel. Use it on any
#                  driver you write.
# CONFIG_KMEMLEAK  kernel leak detector:
$ echo scan > /sys/kernel/debug/kmemleak
$ cat /sys/kernel/debug/kmemleak
# CONFIG_DEBUG_KMEMLEAK, CONFIG_SLUB_DEBUG=FZPU
# CONFIG_KCSAN     kernel race detector
$ cat /proc/slabinfo               # kernel object caches
$ cat /proc/vmallocinfo
```

Performance

```
# ---- THE ONE COMMAND TO KNOW ----
$ perf record -g --call-graph dwarf -F 999 ./myapp
$ perf report --stdio

# -g / --call-graph   capture stacks. dwarf works without
#                     frame pointers; fp is cheaper if you
#                     built with -fno-omit-frame-pointer
# -F 999              999 Hz, deliberately not 1000, to
#                     avoid aliasing with periodic activity

$ perf top                      # live, system-wide
$ perf stat ./myapp             # counters: IPC, cache
                                # misses, branch misses
$ perf stat -e cache-misses,cache-references,\
instructions,cycles ./myapp

# READING perf stat:
#   IPC below ~1.0        stalling - memory or branches
#   high cache-miss ratio poor locality (see the computer
#                         architecture track)
#   high branch-misses    unpredictable control flow

# ---- FLAME GRAPHS: the best way to read a profile ----
$ perf record -F 99 -g -p PID -- sleep 30
$ perf script | stackcollapse-perf.pl | flamegraph.pl \
    > out.svg
# WIDTH = time spent. Look for wide plateaus, not tall
# towers. Height is just stack depth and means nothing.

# ---- WHAT IS IT DOING RIGHT NOW ----
$ strace -f -T -tt -p PID          # syscalls, with timing
$ strace -c ./myapp                # SUMMARY - start here
$ strace -e trace=openat,read ./myapp
$ ltrace ./myapp                   # library calls

# strace -c IS THE FASTEST WAY TO ANSWER "why is this
# slow?" for anything I/O bound. If 90% of the time is in
# one syscall, you are done.

# ---- KERNEL TRACING ----
$ cd /sys/kernel/tracing
# echo function_graph > current_tracer
# echo my_driver_probe > set_graph_function
# echo 1 > tracing_on ; cat trace_pipe

$ trace-cmd record -p function_graph -g my_func ./app
$ kernelshark trace.dat

# ---- bpftrace: the modern answer ----
$ bpftrace -e 'tracepoint:syscalls:sys_enter_openat {
                 printf("%s %s\n", comm, str(args->filename));
               }'
$ bpftrace -e 'kprobe:vfs_read { @[comm] = count(); }'
$ bpftrace -e 'kretprobe:vfs_read /pid == 1234/ {
                 @bytes = hist(retval); }'

# ARBITRARY INSTRUMENTATION OF A RUNNING PRODUCTION KERNEL,
# safely, with no rebuild and no reboot. This is the single
# biggest advance in Linux debugging in fifteen years, and
# the bcc tools (execsnoop, opensnoop, biolatency,
```

```
# runqlat, tcpconnect) are ready-made scripts worth
# knowing.

# ---- LATENCY AND SCHEDULING ----
$ cyclictest -t4 -p 80 -n -i 200 -l 100000   # RT latency
$ perf sched record -- sleep 5 ; perf sched latency
$ chrt -f 80 ./myapp                          # run at RT
                                              # priority
$ taskset -c 2 ./myapp                        # pin to a
                                              # CPU
```

THE ORDER TO REACH FOR THESE

1. dmesg / journalctl — did the kernel already tell you?
2. strace -c — is it syscall bound?
3. perf stat — is it compute or memory bound?
4. perf record + flame graph — where exactly?
5. sanitisers — is it a latent memory or race bug?
6. bpftrace — a question none of the above answered.

Most investigations end at step 1 or 2. Reaching for a profiler before checking whether the kernel logged the answer is the most common wasted hour.

Devices, drivers and the system

```
# ---- IS THE DEVICE THERE ----
$ lspci -nnk                  # -k shows the bound DRIVER
$ lsusb -t                    # tree view, with drivers
$ ls /sys/bus/i2c/devices/
$ ls /sys/bus/platform/drivers/mydriver/
$ udevadm info -a -n /dev/ttyUSB0   # full attribute chain
$ udevadm monitor --property        # live hotplug events
$ cat /proc/device-tree/soc/i2c@40005400/status  # DT
$ dtc -I fs -O dts /proc/device-tree | less      # decompile
                                                 # the live
                                                 # DT

# "THE DRIVER DOESN'T LOAD" - THE CHECKLIST:
#   1. is the module present?        lsmod | grep mydrv
#   2. does the ID table match?      modinfo mydrv | grep alias
#   3. did probe run?                dmesg | grep mydrv
#   4. is the device in the DT/ACPI, and status = "okay"?
#   5. is its clock enabled?         /sys/kernel/debug/clk/clk_summary
#   6. is its regulator on?          /sys/kernel/debug/regulator/
#   7. did another driver claim it?  lspci -k, /proc/iomem
#   8. what did probe return?        dev_err messages, or
#                                    -EPROBE_DEFER (which is
#                                    normal - it will retry)

# ---- INTERRUPTS AND RESOURCES ----
$ cat /proc/interrupts             # WATCH THE COUNT CHANGE.
                                   # Not incrementing means
                                   # the IRQ never fires.
$ cat /proc/iomem
$ cat /proc/ioports
$ cat /proc/dma

# ---- LOCKING AND DEADLOCK ----
# CONFIG_PROVE_LOCKING (lockdep) - reports a potential
# deadlock the FIRST TIME an inconsistent lock order is
# observed, even if it never actually deadlocks. Enable it
# in any kernel you are developing against.
$ cat /proc/lockdep_stats
$ cat /proc/PID/stack             # kernel stack of a stuck
                                  # task
$ cat /proc/PID/wchan             # what it is waiting on

# ---- NETWORK ----
$ tcpdump -i eth0 -w cap.pcap 'port 443'
$ ss -tulpn                       # sockets and owning
                                  # processes
$ ip -s link ; ethtool -S eth0    # error counters

# ---- FILES AND I/O ----
$ lsof -p PID
$ ls -l /proc/PID/fd/
$ iostat -x 1 ; iotop
$ fatrace                         # every file access,
                                  # system-wide

# ---- USEFUL /proc AND /sys ENTRIES ----
/proc/PID/maps       memory map - find which library an
                     address is in
/proc/PID/smaps      per-mapping detail
/proc/PID/limits     the limits actually in effect
```

```
/proc/PID/environ    the environment it actually got
/proc/cmdline        kernel boot arguments
/proc/config.gz      the running kernel's config
/sys/kernel/debug/   debugfs - drivers expose their state
                     here, and yours should too
```

How it shows up

Symptom	Cause / tool
No core dump after a crash	`ulimit -c` is 0, or `core_pattern` pipes elsewhere
Backtrace shows only `??`	Stripped binary — keep the unstripped one
Variables `<optimized out>`	Rebuild with `-Og -g3`
perf shows no call graph	Frame pointers omitted — use `--call-graph dwarf`
Crash only in release builds	Undefined behaviour — run UBSan
Intermittent corruption under load	Data race — run TSan or enable KCSAN
Driver never probes	Work the eight-step checklist; often an ID or device-tree mismatch
`-EPROBE_DEFER` in dmesg	Normal — a dependency is not ready; it will retry
IRQ count never increments	Wrong IRQ number, wrong trigger type, or the pin is not muxed
Peripheral registers read as zero	Clock or regulator not enabled — check the debugfs summaries
Task stuck forever	`/proc/PID/stack` and SysRq-w
Memory grows without bound	`heaptrack`, or kmemleak for kernel allocations

Check yourself

- ✓ Match each of the twelve questions to its tool.
- ✓ Enable core dumps and open one in GDB.
- ✓ Explain why `-Og` is preferred over both `-O0` and `-O2`.
- ✓ Read a kernel oops and identify the function, offset and cause.
- ✓ Say what each of ASan, UBSan, TSan and MSan catches, and which cannot be combined.
- ✓ Explain what Valgrind offers that ASan does not.
- ✓ Record a profile and read a flame graph correctly.
- ✓ Interpret `perf stat`'s IPC and cache-miss figures.
- ✓ Write a `bpftrace` one-liner and say why it is safe on production.
- ✓ Work the eight-step "driver does not load" checklist.
- ✓ Explain what lockdep detects that a deadlock test would not.
- ✓ Give the six-step escalation order and say where most investigations end.

The Windows debugging toolkit

WinDbg is the most capable debugger in common use and the one with the steepest learning curve. This is the subset that does the work, plus the driver-specific tools that have no Linux equivalent.

Setting up

```
REM ---- INSTALL ----
REM Windows SDK "Debugging Tools for Windows", or:
winget install Microsoft.WinDbg

REM ---- SYMBOLS: DO THIS FIRST OR NOTHING WORKS ----
setx _NT_SYMBOL_PATH srv*C:\symbols*https://msdl.microsoft.com/download/symbols

REM add your own build output IN FRONT:
setx _NT_SYMBOL_PATH
"C:\myproject\out;srv*C:\symbols*https://msdl.microsoft.com/download/symbols"

REM and source, so you get source-level stepping:
.srcpath C:\myproject\src

REM ---- WITHOUT SYMBOLS, EVERY STACK IS HEXADECIMAL AND
REM      USELESS. If a stack looks like nonsense, run
REM      !sym noisy and .reload /f and read what it says
REM      it could not find.

REM ---- KERNEL DEBUGGING: two machines, or a VM ----
REM On the TARGET (an admin prompt), for a network
REM connection:
bcdedit /debug on
bcdedit /dbgsettings net hostip:192.168.1.10 port:50000 key:1.2.3.4
REM ^ it prints a KEY. Save it - the host needs it.

REM Then on the HOST:
windbg -k net:port=50000,key=1.2.3.4

REM Other transports:
bcdedit /dbgsettings serial debugport:1 baudrate:115200
bcdedit /dbgsettings usb targetname:mytarget

REM ---- TEST SIGNING, for driver development ----
bcdedit /set testsigning on
REM reboot. Without this an unsigned driver will not load,
REM and the failure message is not always obvious.

REM ---- CRASH DUMP CONFIGURATION ----
REM System Properties -> Advanced -> Startup and Recovery
REM   Kernel memory dump   the usual choice
REM   Complete memory dump needs a page file at least RAM
REM                        size; use it when you need user
REM                        memory too
REM Dumps land in C:\Windows\MEMORY.DMP

REM ---- FORCE A CRASH, to test the dump path ----
REM Enable the keyboard crash: HKLM\SYSTEM\CurrentControlSet\
REM   Services\kbdhid\Parameters\CrashOnCtrlScroll = 1
REM then Ctrl + ScrollLock + ScrollLock.
REM TEST THIS BEFORE YOU NEED IT.
```

The commands that matter

```
* ---- THE THREE-COMMAND CRASH ANALYSIS ----
!analyze -v          * START HERE, ALWAYS. Identifies the
                     * bugcheck, the faulting module, the
                     * probable cause and the stack.
                     * It is right most of the time.

Reading a bugcheck

```
* !analyze -v output, and what to actually read:

  DRIVER_IRQL_NOT_LESS_OR_EQUAL (d1)
  Arguments:
    Arg1: ffffb00000000000   memory referenced
    Arg2: 0000000000000002   IRQL at the time
    Arg3: 0000000000000001   0 = read, 1 = WRITE
    Arg4: fffff80512345678   address that referenced it

  READ THE FOUR ARGUMENTS. They usually contain the whole
  answer: what was touched, at what IRQL, read or write,
  and from where.

* ---- THE BUGCHECKS YOU WILL ACTUALLY MEET ----

  0x0A  IRQL_NOT_LESS_OR_EQUAL
        Touched pageable memory, or a bad pointer, at
        DISPATCH_LEVEL or above.
  0xD1  DRIVER_IRQL_NOT_LESS_OR_EQUAL
        The same thing, and it was a driver. THE MOST
        COMMON DRIVER BUGCHECK BY A LARGE MARGIN.
        Cause: paged memory accessed at raised IRQL, or a
        freed pointer.
  0x1E  KMODE_EXCEPTION_NOT_HANDLED
  0x50  PAGE_FAULT_IN_NONPAGED_AREA
        Freed memory, or a wild pointer.
  0x7E  SYSTEM_THREAD_EXCEPTION_NOT_HANDLED
  0x9F  DRIVER_POWER_STATE_FAILURE
        A driver did not complete a power IRP. Arg1 = 3
        means a device object blocked the transition.
  0xC4  DRIVER_VERIFIER_DETECTED_VIOLATION
        Driver Verifier caught you. The subcode says
        exactly what.
  0xC9  DRIVER_VERIFIER_IOMANAGER_VIOLATION
  0xC5  DRIVER_CORRUPTED_EXPOOL
        Pool corruption - you wrote past an allocation.
  0x139 KERNEL_SECURITY_CHECK_FAILURE
        A stack cookie or list-entry corruption check.
  0x133 DPC_WATCHDOG_VIOLATION
        A DPC ran too long, or IRQL stayed high. Usually a
        loop that should have been in a work item.

* ---- THE IRQL RULE THAT CAUSES MOST OF THESE ----
    PASSIVE_LEVEL (0)   may touch paged memory, may block
    APC_LEVEL (1)
    DISPATCH_LEVEL (2)  NO PAGED MEMORY. NO BLOCKING. NO
                        WAITING.
    DIRQL (3+)          device interrupt level

    At DISPATCH_LEVEL or above, touching pageable memory
    faults, and a page fault cannot be serviced because
    the page-fault handler needs to wait. THAT IS BUGCHECK
    0xD1, and it is why the rule exists.

    !irql               * check where you are
    KeGetCurrentIrql()  * from code

* ---- A HANG RATHER THAN A CRASH ----
    !analyze -v -hang
    !process 0 7        * every thread stack
```

```
!locks              * held resources and waiters
!stacks 2           * all kernel stacks, filtered
Look for a cycle: A waits on a lock held by B, which
waits on a lock held by A.
```

DRIVER VERIFIER IS NOT OPTIONAL

```
verifier /standard /driver mydrv.sys
shutdown /r /t 0

It injects allocation failures, checks IRQL rules,
detects pool corruption immediately rather than
later, catches leaked resources at unload, and forces
DMA and IRP misuse to fail loudly at the point of the
mistake.

verifier /flags 0x209BB /driver mydrv.sys   (more)
verifier /volatile /flags 0x8 /adddriver mydrv.sys
verifier /querysettings
verifier /reset                             (turn off)
```

It will crash your driver on bugs that would otherwise corrupt memory silently and fail a week later in someone else's code. **Run every driver under Verifier before shipping it** — and expect the first run to find something.

The rest of the toolkit

```
REM ---- SYSINTERNALS: download the whole suite ----
Process Explorer   handles, DLLs, threads, stacks. The
                   better Task Manager.
Process Monitor    EVERY file, registry, network and
                   process event, with a stack for each.
                   THE FIRST TOOL for "why can't it find
                   this file" and "why is this failing with
                   access denied".
                   FILTER HARD or you will drown - by
                   process name first.
WinObj             the kernel object namespace: device
                   objects, symbolic links, sections
DebugView          captures DbgPrint output from user AND
                   kernel mode, without a debugger
                   attached. Enable kernel capture in the
                   menu.
Autoruns           what starts, and from where
RAMMap / VMMap     physical and virtual memory breakdown
Handle             which process has that file open
LiveKD             kernel debugging on a LIVE system with
                   no second machine - read-only, but
                   frequently enough

REM ---- ETW: the platform's tracing infrastructure ----
wpr -start GeneralProfile -filemode
REM ... reproduce ...
wpr -stop trace.etl
wpa trace.etl                REM Windows Performance
                             REM Analyzer

logman query providers       REM everything that can be
                             REM traced
tracelog -start mytrace -guid #GUID -f out.etl -flag 0xff
tracefmt out.etl -o out.txt  REM decode WPP (chapter 02)

REM ETW IS THE SAME IDEA AS ftrace/eBPF: always compiled
REM in, negligible when off, enabled at runtime. It covers
REM the kernel, drivers, .NET and applications in ONE
REM correlated timeline, which is genuinely better than
REM anything on Linux for whole-system analysis.

REM ---- DEVICE AND DRIVER STATE ----
pnputil /enum-devices /connected
pnputil /enum-drivers
devcon status *              REM from the WDK
devmgmt.msc                  REM and turn on
                             REM View -> Devices by
                             REM connection

REM ---- INSTALLATION FAILURES ----
REM C:\Windows\INF\setupapi.dev.log
REM IT LOGS EXACTLY WHY AN INSTALL FAILED - signature,
REM ranking, a missing file, a hardware ID mismatch. Search
REM it before guessing.

REM ---- DRIVER TESTING ----
REM HLK (Hardware Lab Kit) - required for WHQL
REM certification
REM Static Driver Verifier, at build time:
msbuild /p:RunCodeAnalysis=true
```

```
REM SDV does formal verification of DDI usage rules and
REM finds real bugs on paths your tests never reach.
REM Code Analysis with driver-specific rules:
REM   /analyze plus the WDK ruleset

REM ---- USER-MODE CRASHES ----
REM Configure Windows Error Reporting local dumps:
REM HKLM\SOFTWARE\Microsoft\Windows\
REM   Windows Error Reporting\LocalDumps
REM     DumpFolder  = C:\dumps
REM     DumpType    = 2   (full)
windbg -z C:\dumps\myapp.exe.1234.dmp
!analyze -v
```

How it shows up

Symptom	Cause
Stacks are all hex addresses	Symbols not configured — set `_NT_SYMBOL_PATH`, run `!sym noisy`
Bugcheck 0xD1	Paged memory or a bad pointer at raised IRQL
Bugcheck 0x133	A DPC ran too long — move the work to a work item
Bugcheck 0xC4	Driver Verifier caught a rule violation — read the subcode
Bugcheck 0x9F	A power IRP was never completed
Pool corruption reported far from the cause	Run under Verifier — it catches it at the point of the write
Driver will not load, no error	`setupapi.dev.log` has the reason; check test signing
Breakpoint on `DriverEntry` never hits	Use `bu`, not `bp` — the module is not loaded yet
Cannot find why a file open fails	Process Monitor, filtered by process name
System hangs, no crash	`!process 0 7` and `!locks` — look for a wait cycle
KMDF request handled by the wrong queue	`!wdflogdump` and `!wdfqueue`
Leak with no obvious owner	`!poolused 2` — needs unique pool tags

Check yourself

- ✓ Configure a symbol path and explain why it must come first.
- ✓ Set up kernel debugging over the network, including the key.
- ✓ Name the three commands you run first on any crash dump.
- ✓ Use `dt` to dump a typed structure, recursively.
- ✓ Explain what `!drvobj`, `!devstack` and `!irp` each tell you.
- ✓ Say why `!wdflogdump` comes first for a KMDF driver.
- ✓ Read the four arguments of a 0xD1 bugcheck.
- ✓ State the IRQL rule and explain why violating it causes 0xD1.
- ✓ Explain the difference between `bp` and `bu`.
- ✓ Say what Driver Verifier injects and checks, and why you run it before shipping.
- ✓ Describe what ETW has in common with ftrace and WPP.
- ✓ Say where to look when a driver installation fails.

Bug patterns and their signatures

Most bugs are one of about twenty recurring shapes. Recognising the shape from the symptom takes you from "something is wrong" to a short list of causes in seconds, which is most of what experience buys.

Memory bugs

```
BUFFER OVERFLOW
  SIGNATURE   corruption of a variable ADJACENT to the
              one you wrote; a smashed stack canary;
              crash in free() far from the real bug;
              works until a struct layout changes
  CAUSES      off-by-one on a bound, strcpy, sprintf,
              a length in elements used as bytes
  FIND IT     ASan, Driver Verifier, a canary pattern
              around buffers

USE AFTER FREE
  SIGNATURE   works most of the time, then garbage; the
              data is plausible but WRONG; often
              timing-dependent
  CAUSES      a second pointer to freed memory; a
              callback firing after teardown; refcount
              dropped early
  FIND IT     ASan; set pointers to NULL after free; use
              a poison pattern

DOUBLE FREE
  SIGNATURE   heap corruption, a crash in the allocator,
              an abort from glibc
  CAUSES      two error paths both freeing; ownership
              unclear

MEMORY LEAK
  SIGNATURE   RSS grows monotonically; fails after hours
              or days; degrades then dies
  CAUSES      an error path that returns without
              freeing; a missing put() on a refcounted
              object
  FIND IT     heaptrack, Valgrind, kmemleak,
              !poolused

UNINITIALISED READ
  SIGNATURE   works in debug, fails in release; the
              value is different every run; adding a
              printf changes it
  CAUSES      a missing initialiser; a struct field
              added and not set in one construction site
  FIND IT     MSan, Valgrind, and simply initialising
              everything

STACK OVERFLOW
  SIGNATURE   corruption with no obvious writer;
              hard fault; crash on entering a function;
              only under deep recursion or a large local
  CAUSES      a large local array, deep recursion, an
              ISR stack too small, alloca
  FIND IT     paint the stack with a pattern at boot and
              measure the high-water mark. DO THIS ON
              EVERY EMBEDDED PROJECT.

THE UNIFYING CHARACTERISTIC OF ALL SIX: THE SYMPTOM
APPEARS FAR FROM THE CAUSE, in space and in time. That
is exactly why the sanitisers are worth their slowdown -
they move the report back to the moment of the mistake.
```

Concurrency bugs

```
/* --- DATA RACE --- */
    SIGNATURE   rare, load-dependent, disappears under a
                debugger, differs between machines, worse
                or better on more cores
    THE CLASSIC:
        if (!ptr)              /* thread A checks */
            ptr = alloc();     /* thread B also checks,
                                  both allocate */
    ALSO:  count++ is READ, MODIFY, WRITE - three
           operations, interruptible between any two.
    FIND IT     TSan, KCSAN, helgrind
    FIX IT      a lock, or an ATOMIC operation - not a
                volatile, which orders nothing (see the C
                track)

/* --- DEADLOCK --- */
    SIGNATURE   total hang, no CPU usage, threads blocked
                on locks
    CAUSE       inconsistent lock ORDER. A takes L1 then
                L2; B takes L2 then L1.
    FIND IT     lockdep, !locks, all-thread backtraces
    FIX IT      A GLOBAL LOCK ORDERING, documented, and
                enforced. Never acquire a lock while
                holding one you did not plan for.

/* --- LOST WAKEUP --- */
    SIGNATURE   a thread waits forever even though the
                condition became true
    CAUSE       the condition was signalled between the
                check and the wait
    FIX         the condition-variable pattern, ALWAYS with
                a loop:
                    while (!condition)
                        wait(cv, lock);
                The `while` also handles SPURIOUS WAKEUPS,
                which are permitted by the specification and
                do occur.

/* --- PRIORITY INVERSION --- */
    SIGNATURE   a high-priority task misses its deadline
                for no visible reason; intermittent and
                load-dependent
    CAUSE       high waits on a lock held by low, and
                MEDIUM preempts low so it never releases
    FIX         priority inheritance, or a priority
                ceiling. (This is the Mars Pathfinder bug,
                and it is worth knowing the story.)

/* --- ABA --- */
    SIGNATURE   a lock-free structure corrupts under load
    CAUSE       a value read as A, changed to B and back to
                A; the compare-and-swap succeeds but the
                world moved
    FIX         a tagged pointer with a version counter, or
                hazard pointers. And seriously consider not
                writing lock-free code.

/* --- TORN READ/WRITE --- */
    SIGNATURE   a 64-bit value observed half-updated on a
                32-bit machine
```

```
    FIX         atomics of the right width, or a lock

/* --- MISSING MEMORY BARRIER --- */
    SIGNATURE   works on x86, fails on ARM. Reordering
                visible only on weakly-ordered
                architectures.
    CAUSE       the compiler or the CPU reordered stores;
                a peripheral write was buffered
    FIX         the right barrier, or the right atomic
                ordering (see the ARM track on memory
                ordering)
    AND NOTE: THIS IS WHY x86 EXPERIENCE MISLEADS ON ARM.
    x86's strong ordering hides bugs that ARM exposes
    immediately.

/* --- REENTRANCY --- */
    SIGNATURE   corruption when an ISR fires during a
                function that the main loop also calls
    CAUSE       shared state, a static local, a non-atomic
                read-modify-write on a peripheral register
    FIX         critical sections, or lock-free by design  */
```

C and arithmetic

```
/* --- INTEGER OVERFLOW --- */
    SIGNATURE   a negative length; an enormous allocation;
                a loop that never terminates; a bounds
                check that passes when it should not
        if (offset + len > size)    /* OVERFLOWS -> passes */
        if (len > size - offset)    /* correct, given
                                       offset <= size    */
    AND SIGNED OVERFLOW IS UNDEFINED BEHAVIOUR, so the
    optimiser may delete the check entirely (see the C and
    compilers tracks).

/* --- IMPLICIT CONVERSION --- */
    SIGNATURE   a comparison that is always true or always
                false
        if (strlen(s) - 1 >= 0)    /* size_t: ALWAYS TRUE */
        int c = getchar();
        if (c == EOF)              /* correct - and `char c`
                                      would be a bug */
    FIND IT     -Wconversion, -Wsign-compare

/* --- SIZEOF ON A POINTER --- */
        void f(int arr[]) { sizeof(arr); }   /* = 8, not
                                                the array */
    Arrays DECAY to pointers when passed. Pass the length.

/* --- UNINITIALISED STRUCT PADDING --- */
    memcmp on structs compares PADDING, which is
    indeterminate. Two logically equal structs compare
    unequal.
    FIX: compare fields, or memset the struct first.

/* --- STRICT ALIASING --- */
        float f = *(float*)&i;     /* UB */
    The optimiser assumes an int* and a float* cannot alias
    and reorders accordingly. Use memcpy - it compiles to
    the same instruction and is defined.

/* --- MISSING volatile --- */
    SIGNATURE   a loop reading a hardware register or an
                ISR-modified flag never exits; works at -O0
                and hangs at -O2
    FIX         volatile on the variable. And note that
                volatile provides NO atomicity and NO
                ordering between different objects.

/* --- FORMAT STRING MISMATCH --- */
        printf("%d", (long)x);      /* UB */
        printf("%d", size_t_value); /* wrong on 64-bit */
    Use the macros: %zu for size_t, PRIu32 from inttypes.h.
    FIND IT     -Wformat=2, which catches all of these.

/* --- THE ERROR PATH NOBODY TESTED --- */
    SIGNATURE   fine until something fails, then a leak, a
                double free, or a crash
    CAUSE       cleanup paths that are never exercised
    FIND IT     FAULT INJECTION. Make every allocation fail
                once. Driver Verifier does this for you on
                Windows; on Linux, failslab and
```

```
                fail_page_alloc do the same. THIS FINDS
                REAL BUGS EVERY TIME IT IS RUN.           */
```

> **THE DEBUG/RELEASE DIVIDE**
> "Works in debug, fails in release" is almost always one of five things: **uninitialised memory** (debug builds often zero it), **a missing `volatile`**, **undefined behaviour** the optimiser exploited, **a timing-dependent race** that the slower debug build hid, or **an assertion that had a side effect** and was compiled out. Check those five before anything else.

Hardware and embedded

```
/* --- CLOCK NOT ENABLED --- */
    SIGNATURE   the peripheral reads back all zeros or
                reset values; writes have no effect; no
                error reported
    THE SINGLE MOST COMMON EMBEDDED BRING-UP BUG. Enable
    the peripheral clock before touching any of its
    registers.

/* --- PIN NOT MUXED --- */
    SIGNATURE   the peripheral looks correctly configured
                and nothing appears on the pin
    A pin has one function at a time. Check the alternate
    function register, and check with a scope.

/* --- READ-MODIFY-WRITE ON A REGISTER --- */
        REG |= BIT;      /* three operations */
    An interrupt between them loses the other write. And
    some registers are WRITE-1-TO-CLEAR, where |= clears
    every pending flag, not just yours. READ THE REGISTER
    DESCRIPTION.

/* --- ALIGNMENT FAULT --- */
    SIGNATURE   hard fault on a cast from a byte buffer;
                works on x86, faults on Cortex-M0
    FIX         memcpy into a properly aligned object

/* --- ENDIANNESS --- */
    SIGNATURE   values byte-swapped over a network or a bus
    FIX         explicit conversion at every boundary;
                never cast a buffer to a struct

/* --- DMA AND CACHE COHERENCY --- */
    SIGNATURE   DMA'd data is stale or partially correct;
                works with the cache off
    CAUSE       the CPU wrote to a cached buffer the device
                then read, or the device wrote to memory the
                CPU has cached
    FIX         clean before the device reads, invalidate
                after it writes - or use the DMA API and
                let it do this (Linux track), or a
                non-cacheable buffer.
    AND WATCH THE CACHE LINE: an invalidate affects a whole
    line, so an adjacent variable sharing the line gets
    discarded too. Align and pad DMA buffers to a cache
    line.

/* --- BUFFER NOT IN DMA-CAPABLE MEMORY --- */
    A stack buffer, or memory the device's address space
    cannot reach. Silently transfers garbage.

/* --- ISR TOO LONG --- */
    SIGNATURE   missed interrupts, jitter, a watchdog
                reset, a DPC watchdog bugcheck
    FIX         do the minimum in the ISR; defer the rest

/* --- MISSING FLAG CLEAR --- */
    SIGNATURE   the ISR fires continuously and the system
                appears hung
    FIX         clear the interrupt source, and re-read the
                register afterwards to ensure the write has
```

```
                landed before returning.

/* --- FLOATING INPUT --- */
    SIGNATURE   a GPIO reads randomly, and touching the
                board changes it
    FIX         enable a pull-up or pull-down

/* --- POWER AND DECOUPLING --- */
    SIGNATURE   resets under load, corruption during radio
                transmission or motor start, only on some
                units
    FIX         scope the rail WITH THE LOAD APPLIED, at a
                fast timebase. A brownout of a few
                microseconds does not show on a multimeter.

/* --- SILICON ERRATA --- */
    SIGNATURE   the hardware does not do what the reference
                manual says
    THE FIX     READ THE ERRATA SHEET. Vendors publish
                them. Some of them are extraordinary, and
                the workaround is usually documented.    */
```

Symptom to cause

Symptom	Look at first
Works in debug, fails in release	Uninitialised memory, `volatile`, UB, a race, an assertion with a side effect
Works on x86, fails on ARM	Memory ordering, alignment, signedness of `char`
Fails only under load	A race, a resource limit, or a timing margin
Fails after hours or days	A leak, a counter wrap, fragmentation
Fails on one unit only	Hardware, calibration data, or a per-unit configuration
A `printf` makes it go away	A race, or a timing-dependent bug
Crash in `free` or the allocator	Heap corruption from an earlier overflow
Corrupted value with no writer	Buffer overflow, stack overflow, or DMA
Total hang, no CPU use	Deadlock — get all thread stacks
Total hang, 100% CPU	Infinite loop, or an interrupt flag never cleared
Peripheral reads all zeros	Clock not enabled
Data byte-swapped	Endianness at a boundary
Stale DMA data	Cache maintenance missing
Fails only when cold or hot	Timing margin, crystal drift, marginal supply
Bounds check passes wrongly	Integer overflow or an implicit conversion

Check yourself

- ✓ Name six memory bug patterns and the signature of each.
- ✓ Say what all memory bugs have in common and why sanitisers help.
- ✓ Describe the check-then-act race and why `volatile` does not fix it.
- ✓ Explain deadlock's cause and the one discipline that prevents it.
- ✓ Write the correct condition-variable wait and give two reasons for the loop.

- ✓ Explain priority inversion and its fix.
- ✓ Rewrite `offset + len > size` safely and say why the original fails.
- ✓ Give the five causes of "works in debug, fails in release".
- ✓ Say why x86 experience misleads about memory ordering on ARM.
- ✓ Explain the DMA cache-coherency failure in both directions, and the cache-line trap.
- ✓ Say what a peripheral reading all zeros almost always means.
- ✓ Describe fault injection and why it finds bugs every time.

The board bring-up checklist

A new board arrives and nothing works. This is the order to attack it in — strictly bottom up, verifying each layer before trusting anything above it.

The principle

```
BRING UP IN LAYERS. VERIFY EACH ONE BEFORE MOVING UP.

  7  APPLICATION
  6  DRIVERS AND PERIPHERALS
  5  CONSOLE / STDIO
  4  RAM AND THE C RUNTIME
  3  CLOCKS
  2  DEBUG CONNECTION
  1  POWER
  0  THE PHYSICAL BOARD

THE MISTAKE EVERYONE MAKES: flashing the full application
onto a brand-new board and wondering why nothing happens.
You have just introduced seven layers of possible failure
at once, with no way to distinguish them.

START AT LAYER 0. GET A BLINKING LED BEFORE ANYTHING
ELSE.

A BLINKING LED PROVES A REMARKABLE AMOUNT:
  · power is present and stable enough
  · the clock configuration works
  · reset released correctly
  · the vector table is where the CPU expects it
  · the C runtime initialised
  · main() was reached
  · GPIO configuration works
  · your build and flash toolchain are correct

That is layers 0 through 4 in one test, and it takes ten
minutes. NEVER SKIP IT.

AND THE SECOND PRINCIPLE: ON A NEW BOARD, DO NOT TRUST
THE SCHEMATIC OR THE ASSEMBLY. Both contain mistakes.
Measure.
```

Layers 0-2: power and access

```
/* --- 0. BEFORE APPLYING POWER --- */
  [ ] VISUAL INSPECTION under magnification: solder
      bridges, tombstoned parts, missing components,
      COMPONENTS FITTED THE WRONG WAY AROUND (check pin 1
      on every polarised part)
  [ ] CHECK FOR SHORTS with a meter: every supply rail to
      ground, and rail to rail. A short here saves the
      board.
  [ ] verify the assembly matches the BOM - wrong-value
      resistors in a divider are common and invisible
  [ ] confirm the input polarity and voltage before
      connecting anything

/* --- 1. POWER --- */
  [ ] apply power through a CURRENT-LIMITED SUPPLY. Set the
      limit to a little above the expected draw. If it
      immediately limits, power down and find the short.
  [ ] MEASURE EVERY RAIL with a meter. Tolerance, typically
      +-5%.
  [ ] check the POWER SEQUENCING if the datasheet requires
      an order - many SoCs do, and violating it can damage
      the part or leave it wedged
  [ ] SCOPE EVERY RAIL, AC-coupled, at a fast timebase.
      Ripple, and any dip at start-up. A multimeter will
      not show a 2 microsecond brownout that resets your
      MCU.
  [ ] check the current draw against expectation. Far too
      high means a short or a mis-stuffed part; far too low
      means something is not powered at all.
  [ ] check thermals - anything unusually hot after a
      minute is wrong

/* --- 2. THE DEBUG CONNECTION --- */
  [ ] RESET pin: is it released? Scope it at power-up. A
      held reset is a very common cause of "the board is
      dead".
  [ ] BOOT MODE pins: strapped correctly for the boot
      source you intend?
  [ ] connect the probe. Ground first (chapter 03).
  [ ] read the CHIP ID register. This proves SWD/JTAG
      works, the core is alive, and the part is what you
      think it is.
        > mdw 0xE0042000       # DBGMCU_IDCODE on STM32
  [ ] if it will not connect, work the nine-step checklist
      in chapter 03. Try "connect under reset" early.
  [ ] MASS ERASE the part. Factory-programmed content and
      leftover test firmware both cause confusing
      behaviour.

/* AT THIS POINT YOU HAVE A CONNECTION TO A LIVE CHIP. Every
   remaining problem is now diagnosable, which is a
   qualitatively different situation from ten minutes
   ago.                                                  */
```

Layers 3-5: clocks, RAM, console

```
/* --- 3. CLOCKS --- */
  [ ] FIRST, RUN FROM THE INTERNAL OSCILLATOR. It always
      works. Do not configure the PLL yet.
  [ ] blink an LED with a crude delay loop. THE FIRST
      MILESTONE.
  [ ] now switch to the external crystal, ONE STEP AT A
      TIME:
        · is the crystal oscillating? Scope it with a 10x
          probe - a 1x probe's capacitance can stop a
          crystal, which is a genuinely confusing failure
        · are the load capacitors the value the crystal
          datasheet specifies?
        · does the ready flag set? DO NOT SPIN FOREVER
          WAITING:
              uint32_t to = 100000;
              while (!(RCC->CR & RCC_CR_HSERDY) && --to)
                      ;
              if (!to) fall_back_to_internal_osc();
          A firmware that hangs in a clock wait loop looks
          exactly like a dead board.
  [ ] configure the PLL. CHECK THE FLASH WAIT STATES FIRST
      - at a higher core clock the flash needs more wait
      states, and setting the clock before the wait states
      is an instant hard fault.
  [ ] VERIFY THE ACTUAL FREQUENCY. Output the system clock
      on the MCO pin and measure it, or time a known delay
      loop against a stopwatch. DO NOT ASSUME THE
      CONFIGURATION WORKED - a wrong clock makes every
      subsequent baud rate and timer wrong, and the symptom
      is "the UART outputs garbage".

/* --- 4. RAM AND THE C RUNTIME --- */
  [ ] internal RAM: the startup code has already used it if
      you reached main()
  [ ] EXTERNAL RAM (SDRAM/DDR), if fitted, needs its
      controller configured, and then TESTED:
        · walking ones and walking zeros - catches stuck
          and shorted data lines
        · an address test (write the address to itself) -
          catches ADDRESS line faults, which present as
          aliasing rather than corruption
        · a pattern test over the full range
        · AND TEST AT TEMPERATURE. Marginal timing passes
          at 25C and fails at 70C.
  [ ] check the LINKER SCRIPT regions match the actual
      memory map
  [ ] check .data was copied and .bss was zeroed - a global
      that is unexpectedly nonzero means the startup code
      is wrong
  [ ] SET UP STACK PAINTING NOW, while it is easy:
        fill the stack with 0xA5 at boot; a later
        high-water-mark check tells you the real usage
        (chapter 06)

/* --- 5. THE CONSOLE --- */
  [ ] configure the UART and print something
  [ ] IF IT IS GARBAGE, THE CLOCK IS WRONG. Garbled output
      at a consistent wrong rate is almost always a system
      clock that is not what you configured. Go back to
      step 3.
```

```
  [ ] if there is nothing at all: check the pin mux, check
      TX and RX are not swapped, check the peripheral clock
      is enabled, and scope the TX pin to see whether
      anything is coming out at all.
  [ ] print the clock frequencies, the reset reason, and
      the build ID at boot. YOU WILL WANT ALL THREE
      CONSTANTLY.
  [ ] install a fault handler that prints the fault
      registers (chapter 06) - do this before you have
      faults, not after

/* NOW YOU HAVE A CONSOLE. Everything from here is ordinary
   debugging.                                              */
```

THE THREE MILESTONES

```
1. THE CHIP ID READS BACK.
   Power, reset and debug access all work.

2. AN LED BLINKS.
   Clocks, reset, vector table, C runtime, GPIO and
   your entire toolchain work.

3. THE CONSOLE PRINTS.
   You now have observability, and every remaining
   problem is a normal debugging problem.

Do not attempt anything else until all three pass. Every
hour spent trying to debug an application on a board that
has not reached milestone 2 is wasted.
```

Layer 6: peripherals

```
/* ONE AT A TIME. Never bring up two peripherals at once -
   you will not know which one is failing.               */

/* --- THE UNIVERSAL SEQUENCE FOR ANY PERIPHERAL --- */
  1. ENABLE ITS CLOCK. Then read a register back. If it
     reads zero or the reset value and writes do not stick,
     the clock is off. (chapter 06 - the most common bug in
     this whole chapter.)
  2. CONFIGURE THE PINS: mux, direction, speed, pull,
     open-drain where required.
  3. CONFIGURE THE PERIPHERAL, in the ORDER THE REFERENCE
     MANUAL SPECIFIES. Some registers can only be written
     while the peripheral is disabled.
  4. READ BACK EVERY CONFIGURATION REGISTER and compare it
     to what you wrote. Reserved bits, write-protected
     registers and clock-gated writes all silently discard.
  5. THE SIMPLEST POSSIBLE TRANSACTION. One byte. Polled,
     not interrupt-driven, not DMA.
  6. SCOPE IT. Confirm the signal is physically present and
     correct.
  7. ONLY THEN add interrupts.
  8. ONLY THEN add DMA.

/* --- GPIO --- */
  [ ] output: set a pin, measure it. Toggle it, scope it.
  [ ] input: tie the pin high and low, read it. CHECK THE
      PULL CONFIGURATION - a floating input reads randomly.

/* --- I2C --- */
  [ ] pull-ups fitted? Value appropriate for the bus
      capacitance? (2.2k-10k typically; too weak gives
      slow rising edges and a bus that half-works)
  [ ] SCAN THE BUS - address every device from 0x08 to
      0x77 and see who ACKs. This immediately proves
      wiring, pull-ups and addressing.
  [ ] SCOPE SDA AND SCL. Look at the RISE TIME - a slow
      rise is the classic weak-pull-up signature. Look for
      the ACK bit.
  [ ] check the address: 7-bit versus 8-bit conventions
      differ between datasheets and APIs, and a factor-of-
      two address error is the most common I2C mistake.
  [ ] a stuck bus (SDA held low by a confused slave)
      recovers by clocking SCL manually nine times

/* --- SPI --- */
  [ ] MODE: CPOL and CPHA must match the slave. Four
      combinations, and the wrong one gives plausible
      garbage rather than nothing.
  [ ] chip select polarity and timing
  [ ] MOSI/MISO not swapped
  [ ] read a known register - most devices have an ID
      register, and that is your test
  [ ] scope all four signals together

/* --- UART --- */
  [ ] baud rate, and therefore the clock (step 3)
  [ ] TX/RX crossed correctly
  [ ] voltage levels - 3.3V versus 5V versus RS-232, which
      is inverted and bipolar
  [ ] flow control configuration matching both ends
```

```
/* --- ADC --- */
  [ ] reference voltage present and correct
  [ ] measure a known voltage; check the reading matches
  [ ] sampling time long enough for the source impedance -
      too short reads low and the error scales with
      impedance

/* --- FLASH / STORAGE --- */
  [ ] read the JEDEC ID first
  [ ] write and read back a page
  [ ] erase and confirm it reads all 0xFF
  [ ] check timing at the temperature extremes

/* --- USB / ETHERNET --- */
  [ ] clock accuracy - USB needs 0.25%, so the internal RC
      oscillator is usually not good enough
  [ ] termination, and the magnetics for Ethernet
  [ ] enumerate; check the descriptors with a host tool
  [ ] and a PROTOCOL ANALYSER is worth its cost here - USB
      problems are almost undiagnosable without one     */
```

Record what you find

```
/* A BRING-UP LOG IS A DELIVERABLE, NOT A PERSONAL NOTE.

   FOR EACH BOARD REVISION, RECORD:
     · every measured rail voltage and current
     · the actual clock frequencies measured
     · every deviation from the schematic - blue wires,
       lifted pins, changed resistor values, DNF parts
     · which peripherals were verified and how
     · every errata that applied and the workaround used
     · every mistake found in the schematic or layout, with
       enough detail for the next revision to fix it
     · photographs of any rework

   WHY IT MATTERS:
     · the next revision's fixes come from this list
     · when board #7 behaves differently from board #1, the
       log tells you what is different
     · a colleague debugging at 2am can read it
     · and PRODUCTION NEEDS TO KNOW which reworks are
       required on which units

/* --- AND THE THINGS TO BUILD INTO THE FIRMWARE NOW --- */
     · a BOOT BANNER printing the build ID, the git hash,
       the measured clock frequencies and the reset reason
     · a RESET REASON DECODER - power-on, watchdog,
       software, brownout, pin. When a unit reboots in the
       field this is the first thing you will want.
     · a FAULT HANDLER that prints the fault registers and
       the stacked frame (chapter 06)
     · STACK PAINTING and a high-water-mark report
     · a SELF-TEST command that exercises every peripheral
       and prints pass/fail - which then doubles as the
       production test
     · a persistent TRACE BUFFER surviving reset
       (chapter 02)

   ALL OF THIS COSTS A DAY DURING BRING-UP AND SAVES WEEKS
   OVER THE PRODUCT'S LIFE. It is also far harder to
   retrofit later, because by then the board is "working"
   and nobody wants to touch the startup code.          */
```

How it shows up

Symptom	Cause
Board completely dead	Reset held, no power, or a short — measure before assuming
Supply limits immediately	Short — power down and find it
Debugger will not connect	Chapter 03's checklist; try connect-under-reset
LED blinks at the wrong rate	Clock is not what you configured
Hangs before `main`	Spinning in a clock-ready loop, or flash wait states wrong
UART prints garbage	Clock wrong — go back to layer 3
UART prints nothing	Pin mux, TX/RX swapped, or peripheral clock off
Peripheral registers read zero	Clock not enabled

Symptom	Cause
Configuration register reads back different	Write-protected, reserved bits, or written while enabled
I2C never ACKs	Pull-ups, address convention, or wiring — scan the bus
SPI returns plausible garbage	Wrong CPOL/CPHA mode
External RAM fails only when warm	Marginal timing — test at temperature
Works on board 1, not board 7	Rework difference — read the bring-up log
Crystal will not start	Wrong load capacitors, or a 1× scope probe stopping it

Check yourself

- ✓ List the eight layers and explain why bring-up is strictly bottom up.
- ✓ Say what a blinking LED proves — all eight things.
- ✓ Give the pre-power checks, in order.
- ✓ Explain why a rail must be scoped as well as measured.
- ✓ Say why reading the chip ID is the right first debug step.
- ✓ Explain why you start on the internal oscillator.
- ✓ Write a clock-ready wait with a timeout and say why the timeout matters.
- ✓ Explain why flash wait states must be set before raising the clock.
- ✓ Describe how to verify the actual clock frequency.
- ✓ Give the three memory tests for external RAM and what each catches.
- ✓ Give the eight-step universal peripheral bring-up sequence.
- ✓ Say why garbled UART output points at the clock.
- ✓ List the six things to build into the firmware during bring-up.

Glossary

The terms and acronyms used across this site, with the chapter that explains each one properly. Definitions here are short on purpose — they are for recognition, not for learning from.

A – C

Term	Meaning
AArch64	The 64-bit ARM execution state. The instruction set is A64.
ABI	Application Binary Interface — register usage, stack layout, struct layout and calling convention. What lets separately compiled code link.
AEAD	Authenticated Encryption with Associated Data. Confidentiality and integrity in one primitive. cr-09
APIC	x86 interrupt controller. ARM's equivalent is the GIC.
ASan	AddressSanitizer — compile-time instrumentation catching memory errors. ref-04
Atomic	An operation that completes indivisibly with respect to other observers.
Attention	Weighted averaging of values, with weights from query–key similarity. ai-19
Barrier	An instruction constraining the ordering of memory operations. `DMB`, `DSB`, `ISB` on ARM.
BSP	Board Support Package — the vendor's port of an OS or RTOS to a board.
Bugcheck	A Windows kernel panic. The blue screen. ref-05
Cache coherency	Keeping multiple caches consistent. A DMA device outside the coherency domain requires explicit maintenance.
CFI	Control Flow Integrity — restricting indirect branches to valid targets.
Chinchilla	The scaling result: about 20 training tokens per parameter is compute-optimal. ai-23
Constant time	Execution whose timing does not depend on secret data. cr-19
Context switch	Saving one execution context and restoring another.
CoreSight	ARM's debug and trace architecture: DWT, ITM, ETM, TPIU. ref-03
Cross-entropy	The loss function of essentially every model here; equals negative log likelihood. ai-10

D – H

Term	Meaning
DMA	Direct Memory Access — a device reading or writing memory without the CPU. The reason SMMUs exist.
DPC	Deferred Procedure Call — Windows' deferred interrupt work, at DISPATCH_LEVEL. Linux's equivalent is a softirq or tasklet.
DPA	Differential Power Analysis — key recovery from many power traces. Constant-time code does not stop it. cr-19
DTB / Device tree	A data structure describing non-discoverable hardware to the kernel.
ECDH / ECDSA	Elliptic-curve key exchange and signatures. cr-14, cr-15
EL0–EL3	ARM Exception Levels: application, OS, hypervisor, firmware.
Embedding	A learned dense vector representing a token. ai-17
Errata	Documented silicon bugs. Read the sheet. ref-06

Term	Meaning
ETW	Event Tracing for Windows — always-compiled-in, runtime-enabled tracing. ref-05
Flash Attention	Tiled attention that never materialises the n×n matrix. Exact, not approximate. ai-19
Forward secrecy	Past sessions stay secret after a long-term key is stolen. Requires ephemeral keys. cr-13
ftrace	The Linux kernel's built-in function tracer. ref-04
GIC	Generic Interrupt Controller — ARM's interrupt distribution and prioritisation.
GQA	Grouped-Query Attention — query heads share key/value heads, shrinking the KV cache. ai-19
Hard fault	Cortex-M's catch-all exception for memory, bus and usage faults.
HKDF	The standard key derivation function: extract then expand, with a context string. cr-10
HMAC	The standard hash-based MAC. Its nesting defeats length extension. cr-08
HSM	Hardware Security Module — where signing keys belong. cr-18
Hypervisor	Software running at EL2 that virtualises the machine for guest operating systems.

I – M

Term	Meaning
IOMMU / SMMU	Address translation and access control for device DMA. The MMU for peripherals.
IRP	I/O Request Packet — the unit of I/O in the Windows kernel. `!irp` decodes one.
IRQL	Windows' interrupt request level. At DISPATCH_LEVEL and above you may not touch paged memory or block. ref-05
ISR	Interrupt Service Routine. Keep it short; defer the rest.
ITM / SWO	Cortex-M instrumentation trace and its output pin. Single-cycle logging. ref-02
KASAN	AddressSanitizer for the Linux kernel.
KMDF / UMDF	Windows Driver Framework, kernel and user mode. Preferred over raw WDM.
KV cache	Cached keys and values, making generation linear instead of quadratic. Often larger than the model. ai-25
LayerNorm / RMSNorm	Per-sample feature normalisation; RMSNorm drops the mean subtraction. ai-22
Lockdep	Linux's lock-order validator — reports potential deadlocks before they happen.
LoRA	Low-Rank Adaptation — fine-tuning via a small low-rank weight update. ai-24
MAC	Either Message Authentication Code (cr-08) or Multiply-Accumulate (ai-04). Context disambiguates.
Memory-bound	Limited by bandwidth rather than arithmetic. Token generation is memory-bound. ai-04
MFU	Model FLOPs Utilisation — achieved over peak. 40–55% is good. ai-23
MMIO	Memory-Mapped I/O — device registers in the address space. Always `volatile`.
MMU	Memory Management Unit — virtual to physical translation and permissions.
MoE	Mixture of Experts — many FFNs, a router picks a few per token. Saves compute, not memory. ai-22
MPU	Memory Protection Unit — region-based permissions without translation. Cortex-M.

N – R

Term	Meaning
NEON / SVE / Helium	ARM SIMD: Cortex-A, scalable vector, and Cortex-M (MVE) respectively.
Nonce	A number used once. Reuse breaks GCM catastrophically. cr-09
NPU	Neural Processing Unit — a fixed-function accelerator, usually int8 matmul. ai-27
NVIC	Cortex-M's nested vectored interrupt controller.
OTP / eFuse	One-time programmable bits. Where root key hashes and anti-rollback counters live. cr-18
Paged attention	Block-allocated KV cache with a per-request block table. Virtual memory, for attention. ai-25
Perplexity	exp of the cross-entropy — the effective number of options the model is choosing between. Not comparable across tokenisers. ai-10
PKI	Public Key Infrastructure — certificates chaining to a trusted root. cr-16
Pre-norm	Normalisation inside the residual branch. What makes deep transformers trainable. ai-22
Priority inversion	A high-priority task blocked by a low-priority lock holder that a medium-priority task preempts. ref-06
PSA Crypto	ARM's crypto API abstracting hardware and software implementations. cr-21
PUF	Physically Unclonable Function — a key derived from manufacturing variation, never stored.
Quantisation	Representing weights in fewer bits, with a scale factor. ai-26
RAII	Resource Acquisition Is Initialisation — C++ ownership tied to object lifetime.
Residual stream	The un-transformed path through a transformer; a shared bus every layer reads and adds to. ai-22
RLHF / DPO	Preference-based post-training, with and without a reward model. ai-24
RoPE	Rotary position embedding — rotate Q and K by angle ∝ position, giving relative position for free. ai-21
RTT	SEGGER Real-Time Transfer — logging via a RAM buffer read by the probe while running. ref-02

S – Z

Term	Meaning
Scaling laws	Loss falls as a power law in parameters, data and compute. Lets you predict a large run from small ones. ai-23
Secure boot	Each stage verifies the next before transferring control, rooted in immutable ROM. cr-15
Secure element	A separate certified chip holding keys that never leave it. cr-18
SFT	Supervised Fine-Tuning — instruction pairs, with the prompt masked out of the loss. ai-24
SMC	Secure Monitor Call — the instruction that enters EL3 / the secure world.
Softmax	Turns scores into a distribution. Always subtract the maximum first. ai-06
Speculative decoding	A small model drafts, the big model verifies in one pass. Identical output distribution. ai-25
Straight-through estimator	Passing the gradient through a non-differentiable step such as rounding. ai-26
SWD	Serial Wire Debug — ARM's two-pin debug port. ref-03
SwiGLU	The gated FFN used by most recent models; `d_ff` becomes 8/3·d. ai-22
TEE	Trusted Execution Environment — an isolated world, typically TrustZone plus a trusted OS.
Tokeniser	Text to integers, usually by BPE. Matched permanently to its model. ai-16

Term	Meaning
TPM	Trusted Platform Module — PCRs, sealing, attestation, monotonic counters.
Transformer	Attention plus FFN, each wrapped in a norm and a residual, stacked. ai-20
TrustZone	ARM's secure/non-secure partitioning, propagated across the interconnect by the NS bit.
TSan	ThreadSanitizer — data race detection. ~10× slowdown, worth it.
UB	Undefined Behaviour — the optimiser may assume it never happens, and does. ref-06
volatile	Prevents the compiler caching a value in a register. Provides *no* atomicity and *no* ordering between objects.
WCET	Worst-Case Execution Time — the number that matters in a real-time system, not the average.
WDM	Windows Driver Model — the raw IRP-based interface beneath KMDF.
WPP	Windows software tracing: formatted off-device, negligible cost, runtime-enabled. ref-02
Watchpoint	A breakpoint on *data* access. The fastest way to find what corrupts a variable. ref-03
X25519	Curve25519 key exchange. 32-byte keys, constant time, no validation to get wrong. cr-13
XPU	Access-control hardware gating which masters may reach which address ranges.
XTS	The disk-encryption mode. Confidentiality only — *no* integrity. cr-18
ZeRO / FSDP	Sharding optimiser state, gradients and parameters across devices. ai-23

TERMS THAT MEAN DIFFERENT THINGS IN DIFFERENT TRACKS

```
MAC       Message Authentication Code / Multiply-Accumulate
          / Media Access Control
KEY       a cryptographic key / an attention key vector
BLOCK     a cipher block / a storage block / a transformer
          block / a scheduling state
CACHE     CPU cache / KV cache / page cache
TENSOR    an n-dimensional array (the physics meaning is
          not implied)
TRACE     execution trace / matrix trace
DECODE    instruction decode / token generation
PAGE      a memory page / a flash page
ATTENTION the mechanism / what you should pay to the
          errata sheet
```

Check yourself

- ✓ Define IRQL and state the rule that causes most Windows driver bugchecks.
- ✓ Explain what a nonce is and what its reuse costs in GCM.
- ✓ Say what the KV cache is and why it can exceed the model.
- ✓ Explain what `volatile` does and the two things it does not.
- ✓ Distinguish MMU, MPU and SMMU.
- ✓ Say what forward secrecy requires.
- ✓ Explain why perplexity is not comparable across tokenisers.
- ✓ Give three meanings of "MAC" and say how context disambiguates.
- ✓ Say what XTS provides and what it conspicuously does not.
- ✓ Explain what a watchpoint does and why it is underused.

Books, manuals and practice environments

Where to go after this site. The primary sources, the books worth owning, and — more importantly — the hardware and exercises that turn reading into competence.

Primary sources

```
READ THE SPECIFICATION. Not a blog post about the
specification.

This is the single habit that separates engineers who
can solve novel problems from those who can only apply
remembered patterns. Secondary sources are for
orientation; the primary source is where the answer
actually is, and it is usually free.

ARM
  ARM Architecture Reference Manual (ARM ARM) for
    Armv8-A / Armv9-A - the definitive text. Enormous.
    Use it for lookup, never linearly.
  Armv8-M Architecture Reference Manual
  Cortex-M Technical Reference Manuals - per-core
  Procedure Call Standard (AAPCS) - the ABI
  ARM Cortex-M Generic User Guide - the practical
    subset, and the right place to start
  TrustZone, SMMU and GIC architecture specifications
  -> developer.arm.com/documentation

YOUR SILICON VENDOR
  The REFERENCE MANUAL - every register, every bit
  The DATASHEET - electrical, timing, pinout
  The ERRATA SHEET - READ THIS ONE. It explains
    behaviour the reference manual does not.
  Application notes - often excellent and overlooked

LINUX
  The kernel source itself. Documentation/ is
    substantial and current.
  Documentation/process/ - how to contribute
  lore.kernel.org - mailing list archives, where the
    reasoning lives
  elixir.bootlin.com - the best kernel source browser
    there is
  LWN.net - the best technical journalism in the field.
    Subscribe; it funds the writing.

WINDOWS
  learn.microsoft.com/windows-hardware/drivers
  The WDK samples on GitHub - genuinely good starting
    points
  The Windows Internals books (below)

STANDARDS
  ISO C (N3220 for C23 drafts; the drafts are free)
  ISO C++ (eel.is/c++draft, and cppreference.com for
    daily use)
  RFCs - rfc-editor.org. TLS is RFC 8446; ChaCha20-
    Poly1305 is RFC 8439.
  NIST FIPS and SP 800 series for cryptography
```

Books worth owning

Area	Book
Architecture	Hennessy & Patterson, *Computer Architecture: A Quantitative Approach* — the reference. Patterson & Hennessy, *Computer Organization and Design* — the accessible one, start here.
Architecture	Bryant & O'Hallaron, *Computer Systems: A Programmer's Perspective* — **if you buy one book on this list, buy this one.**
C	Kernighan & Ritchie, *The C Programming Language* — dated, still the clearest. Klemens, *21st Century C* for modern practice.
C	Seacord, *Effective C* — current, careful about undefined behaviour.
C++	Meyers, *Effective Modern C++*. Stroustrup, *A Tour of C++* for a fast survey.
Rust	*The Rust Programming Language* (free online). *The Rustonomicon* for unsafe. *The Embedded Rust Book*.
Operating systems	Arpaci-Dusseau, *Operating Systems: Three Easy Pieces* — free, and better than most paid textbooks.
Linux kernel	Love, *Linux Kernel Development* (dated but clear). Corbet et al., *Linux Device Drivers* (dated; read alongside current source). Kaiwan Billimoria, *Linux Kernel Programming* — current.
Windows	Russinovich et al., *Windows Internals* parts 1 and 2. Orwick & Smith, *Developing Drivers with the WDF*.
Embedded	White, *Making Embedded Systems* — the best book on the discipline rather than a chip. Yiu, *The Definitive Guide to ARM Cortex-M*.
Real-time	Liu, *Real-Time Systems*. Buttazzo, *Hard Real-Time Computing Systems*.
Compilers	Aho et al., *Compilers* (the dragon book). Cooper & Torczon, *Engineering a Compiler* — more practical. Nystrom, *Crafting Interpreters* — free, and the most enjoyable.
Cryptography	Aumasson, *Serious Cryptography* — **the right book for an engineer.** Ferguson, Schneier & Kohno, *Cryptography Engineering*. Boneh & Shoup, *A Graduate Course in Applied Cryptography* (free) for the theory.
Security	Dowd et al., *The Art of Software Security Assessment*. Huang, *The Hardware Hacker*.
ML foundations	Bishop, *Pattern Recognition and Machine Learning*. Goodfellow et al., *Deep Learning* (free online). Prince, *Understanding Deep Learning* (free) — the most current.
ML practice	Géron, *Hands-On Machine Learning*. Warden & Situnayake, *TinyML* — directly relevant to ai-27.
Mathematics	Strang, *Introduction to Linear Algebra* (and his MIT lectures). Deisenroth et al., *Mathematics for Machine Learning* (free).
Debugging	Agans, *Debugging: The Nine Indispensable Rules* — short, and it will change how you work. Zeller, *Why Programs Fail*.
Craft	Hunt & Thomas, *The Pragmatic Programmer*. Ousterhout, *A Philosophy of Software Design* — short and unusually good on complexity.

Hardware to learn on

```
/* YOU CANNOT LEARN EMBEDDED SYSTEMS WITHOUT HARDWARE. Buy
   something. The total cost of a genuinely capable bench is
   under three hundred dollars.                          */

/* --- BOARDS, roughly in order of what to get first --- */
    RASPBERRY PI PICO / PICO 2       ~$5
      Dual Cortex-M0+/M33, and the RP2040/RP2350's PIO is a
      genuinely novel and instructive peripheral. Excellent
      documentation. START HERE if you have nothing.

    ST NUCLEO or DISCOVERY           ~$15-30
      Cortex-M0 to M7, ON-BOARD ST-LINK, huge community.
      The most practical general-purpose learning platform.

    NORDIC nRF52840-DK               ~$50
      Bluetooth, TrustZone-M on the nRF5340/nRF54, and
      Zephyr support. For wireless and security work.

    ESP32-S3                         ~$10
      Wi-Fi, Bluetooth, an NPU-ish vector unit, and a
      completely different ecosystem worth seeing.

    RASPBERRY PI 4 or 5              ~$60
      A full Cortex-A Linux machine you can compile kernels
      for and reflash without fear. THE RIGHT PLATFORM FOR
      THE LINUX DRIVER TRACK.

    BEAGLEBONE BLACK / AI-64
      Excellent for device tree, PRU real-time cores, and
      mainline kernel work.

    QEMU                             free
      Boot a kernel, attach GDB, and never brick anything.
      -M virt with a Cortex-A53 runs the Linux track's
      examples, and it is what the PL031 driver project
      targets.

    AN OLD PC or a VM                free
      For the Windows driver track: a second machine or a
      Hyper-V guest for kernel debugging (ref-05).

/* --- INSTRUMENTS, in order of value per dollar --- */
    LOGIC ANALYSER                   $10-400
      A cheap 8-channel clone with sigrok/PulseView is
      $10 and will transform your debugging. A Saleae is
      $400 and better. GET ONE BEFORE YOU GET AN
      OSCILLOSCOPE - most embedded problems are digital
      timing, and a logic analyser decodes I2C, SPI and
      UART for you.

    OSCILLOSCOPE                     $150-400
      Rigol DHO800 or similar. For analogue questions:
      supply ripple, rise times, crystal oscillation
      (ref-07).

    MULTIMETER                       $30
      Continuity, voltage, current. The most-used
      instrument on any bench.

    BENCH SUPPLY WITH CURRENT LIMIT  $60
```

```
      The current limit is the feature. It has saved more
      boards than any other tool.

    USB-SERIAL ADAPTER (3.3V)        $5
      Buy several. You will lose them.

    J-LINK EDU                       $60
      For RTT (ref-02) and reliable flashing across
      vendors.

    USB PROTOCOL ANALYSER            $100+
      Only if you do USB work - and if you do, essential.

/* --- AND THE THING PEOPLE SKIP --- */
    A SOLDERING IRON AND SOME FLUX. Being able to fit a
    tag-connect header, tack a wire onto a test point, or
    lift a pin is a genuine debugging capability
    (ref-07).                                          */
```

> **THE SINGLE MOST VALUABLE PURCHASE**
>
> A cheap logic analyser. Ten dollars, and it converts "the driver doesn't work" into "the bytes are going out but the ACK never comes back". Almost every embedded problem is a question about what is actually happening on a wire, and until you can see the wire you are guessing.

Projects that teach

```
/* READING IS NOT LEARNING. Build these, in roughly this
   order. Each one forces a specific set of chapters to
   become concrete.                                      */

  1. BLINK AN LED WITH NO LIBRARIES.
     Registers only, from the reference manual. Then write
     the startup code and linker script yourself.
     -> the C track, computer architecture, ref-07

  2. A UART DRIVER, polled, then interrupt-driven, then
     with a ring buffer, then DMA.
     -> interrupts, concurrency, ref-02

  3. A BOOTLOADER that verifies and jumps to an
     application image.
     -> linkers, memory maps, and then signatures
        (cr-15)

  4. PORT AN RTOS, or write a cooperative scheduler with a
     context switch in assembly. Writing the context switch
     yourself teaches more than a term of reading.
     -> the OS track

  5. A LINUX CHARACTER DRIVER, then a platform driver with
     device tree, then one with interrupts and DMA.
     -> the Linux track; lx-28 and lx-29 are exactly this

  6. A WINDOWS KMDF DRIVER and its user-mode client.
     -> the Windows track; win-23 and win-24

  7. IMPLEMENT AES AND SHA-256 FROM THE SPECIFICATION.
     Then make them constant time. Then check with dudect.
     -> the cryptography track, cr-19

  8. A TLS CLIENT on an MCU, with a pinned root and a
     device certificate.
     -> cr-16, cr-17, cr-21

  9. A COMPILER for a small language, following Crafting
     Interpreters. Then emit real machine code.
     -> the compilers track

 10. THE TINY TRANSFORMER (ai-28), then shrink it, quantise
     it, and run it on the Pico.
     -> the AI track, end to end

 11. REVERSE-ENGINEER SOMETHING YOU OWN. Dump the firmware
     from a cheap device, find the UART, identify the
     architecture, disassemble it. Legally, on your own
     hardware. This teaches more about how real products
     are built - and how badly - than any number of
     tutorials.

 12. FIX A BUG IN AN OPEN-SOURCE PROJECT, and get the patch
     merged. The review is the education.
     -> lx-30 covers the kernel process specifically

/* --- HOW TO PRACTISE, not just what --- */
    · BUILD SOMETHING YOU WANT. Motivation carries you
      through the tedious parts, and there are many.
```

```
    · FINISH THINGS. A finished small project teaches more
      than three abandoned ambitious ones, because the last
      20% is where the real problems live.
    · READ OTHER PEOPLE'S CODE. The kernel, FreeRTOS,
      Zephyr, mbedTLS, llama.cpp. Pick a subsystem and read
      it properly.
    · EXPLAIN IT. Write it down, or teach someone. You will
      discover what you do not actually understand.
    · AND KEEP A LOG. Of bugs you found, and how. It
      compounds.                                          */
```

Staying current

```
/* --- WORTH FOLLOWING --- */
    LWN.net                  Linux and systems. Subscribe.
    lore.kernel.org          the mailing lists themselves
    Hacker News, lobste.rs   noisy, occasionally excellent
    Interrupt (Memfault)     one of the few genuinely good
                             embedded engineering blogs
    Embedded.fm              podcast, long-running
    The Amp Hour             hardware
    /r/embedded, /r/rust_embedded
    Zephyr and Rust-embedded matrix/discord channels

/* --- CONFERENCES, most with free recorded talks --- */
    Embedded Linux Conference, Linux Plumbers, FOSDEM,
    Embedded World, CppCon, RustConf, Chaos Communication
    Congress (excellent hardware security work), Black Hat
    and DEF CON, NeurIPS and ICML for machine learning.

    WATCH THE TALKS. Many are better than the equivalent
    book chapter and are forty minutes long.

/* --- CERTIFICATIONS, honestly --- */
    Largely not valued in this field. A portfolio of things
    you have built, and contributions people can read, are
    worth considerably more. The exceptions are
    domain-specific safety certifications (IEC 61508,
    ISO 26262, DO-178C) where the process qualification
    genuinely matters to employers in those industries.

/* --- AND A CLOSING NOTE ON THIS SITE --- */

    281 chapters is a great deal of reading and none of it
    is a substitute for the work. The tracks were written
    to be a MAP - to tell you what exists, what it is for,
    what the failure modes look like, and where the primary
    source is.

    THE ACTUAL LEARNING HAPPENS WHEN YOU BUILD SOMETHING
    THAT DOES NOT WORK AND YOU FIND OUT WHY.

    Everything in ref-01 through ref-07 exists to make that
    process faster. Everything else exists so you know what
    you are looking at when you get there.

    Go and build something.                               */
```

Check yourself

- ✓ Name the primary source you would consult for an ARM exception-level question.
- ✓ Say which vendor document explains behaviour the reference manual does not.
- ✓ Name one book per track you intend to read.
- ✓ List the minimum hardware bench and its total cost.
- ✓ Say why a logic analyser comes before an oscilloscope.
- ✓ Explain why a current-limited bench supply matters.
- ✓ Pick three projects from the list and say which chapters each exercises.
- ✓ Give the four rules for how to practise, not just what to build.
- ✓ Say what this site is for, and what it is not a substitute for.
